Calcium signalling has been shown to have a role in the activation of epithelial cells in response to nanoparticles [51] and in TNF- α gene expression in macrophages [52].

Taken together, these data imply that transition metals, organics and ultrafine particles are active constituents of particulate air pollution that stimulate intracellular signalling pathways leading to calcium changes, MAPK signalling, NF- κ B activation and histone acetylation which combine to cause enhanced transcription of cytokines and other proinflammatory genes through oxidant-mediated mechanisms (see Fig. 34.1).

Chronic PM exposure and changes in airways morphology

In cigarette smokers, COPD is associated with distal airspace enlargement characteristic of emphysema and/or small airway remodelling ('small airways disease') [53]. There are no studies demonstrating PM-induced emphysema, but several studies have looked at pathologic changes in the small airways in individuals chronically exposed to high levels of PM.

Souza *et al.* [54] evaluated autopsy lungs from forensic (violent death) cases of 34 residents of low PM regions of Brazil, and 50 residents of São Paulo, a region with a mean annual PM₁₀ of approximately 80–100 $\mu\text{g}/\text{m}^3$, 1991–95. The vast majority of the subjects (90%) were males and the mean age at death was approximately 28 years. Approximately 60% were smokers, but the average amount of smoking, 7 pack-years, was low. Souza *et al.* graded changes in

the small airways in histologic sections and also determined the gland : wall ratio in the large airways. Regardless of smoking status, no differences were seen for gland : wall ratio between high PM and low PM subjects, but anthracosis, inflammation, wall thickness and mucus hypersecretion were generally greater in smokers and somewhat greater in high PM compared with low PM subjects in both the smoking and non-smoking groups. The authors used the anthracosis score as a surrogate of PM exposure, and found that this correlated with airway wall inflammation and airway wall thickness.

The findings of Souza *et al.* [54] imply that long-term residence in high PM regions leads to the type of small airway remodelling that has been shown to correlate with clinical airflow obstruction in cigarette smokers [53]. However, this study was confounded both by smoking (more than half of the subjects were smokers) and probable occupational dust exposure (again, more than half had occupational dust exposures). Nonetheless, the statistical analysis indicated an effect of PM level after adjustment for these confounders.

Pinkerton *et al.* [55] also examined forensic death autopsy lungs, in this instance from 42 Hispanic males from the Fresno County Coroner's Office. During the time the samples were collected, mean PM₁₀ levels in Fresno were 43.5 $\mu\text{g}/\text{m}^3$ and mean PM_{2.5} levels were 22 $\mu\text{g}/\text{m}^3$. The subjects were again relatively young (median age 33 years) and approximately 50% were smokers. Pinkerton *et al.* found histologic evidence of cigarette smoke injury in the form of chronic bronchitis and more proximal small airway remodelling in about half of the subjects. The larger airways showed few abnormalities, but the distal small airways contained considerable carbonaceous dust and birefringent particles with the highest particle loads in the walls of generation 1 respiratory bronchioles and in membranous bronchioles. Of particular note, the amount of dust (i.e. visible pigment graded on a semi-quantitative scale) correlated with the degree of fibrosis in these airways.

As in the study by Souza *et al.* [54], occupational dust exposure was a problem because most of these men had worked in local farming operations or in blue collar occupations and farming is known to be a very dusty process in this region. Additionally, smoking produces lesions that are similar in location and appearance to those caused by dusts, and synergistic interactions between smoke and dust may amplify dust effects. Nonetheless, this study lends support to the idea that chronic high level PM can produce small airways abnormalities.

In an attempt to overcome these problems, we (Churg *et al.* [56]) examined autopsy lungs from a group of women from another high PM region, Mexico City (3-year mean PM₁₀ = 66 $\mu\text{g}/\text{m}^3$) and compared them with lungs of subjects from Vancouver, a city with low PM (1984–93 average

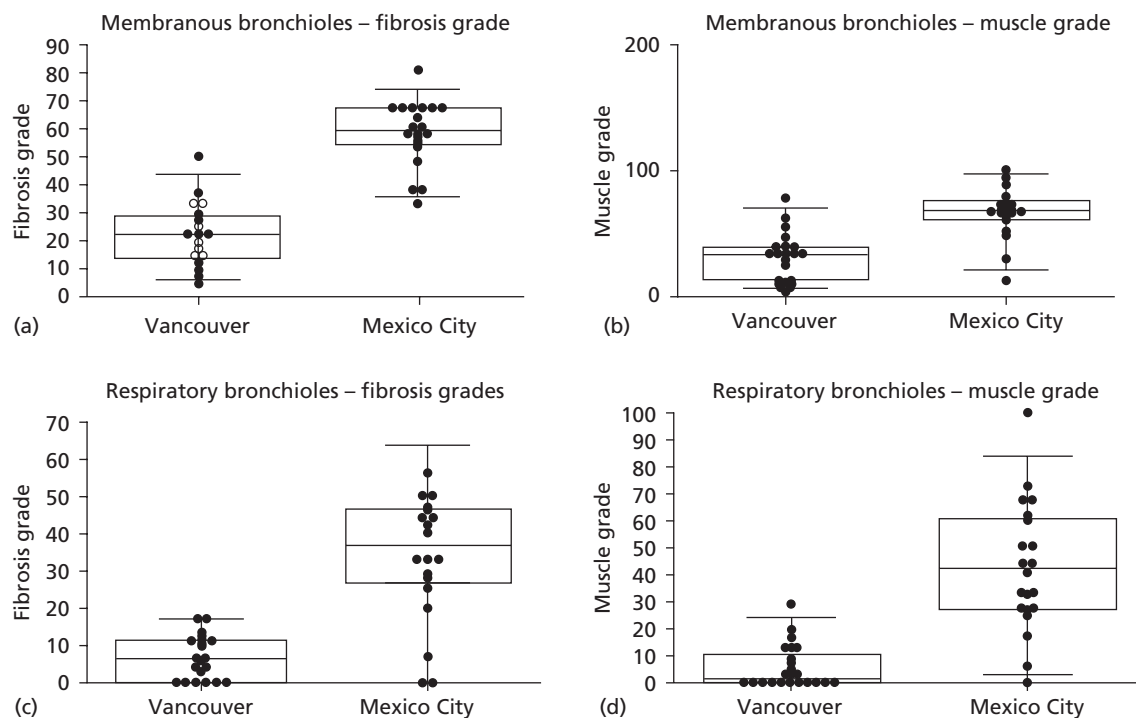

Figure 34.2 (a–d) Box plots showing histologic grades for airway fibrous tissue (a,b) and wall muscle (c,d) in membranous and respiratory bronchioles of autopsy lungs from subjects from Mexico City (high particulate material [PM] area) and Vancouver (low PM area). The bar in the middle of the box is the median and whiskers indicate the 95th and 5th percentiles. For each comparison the measured parameters are significantly greater in the Mexico City lungs.

= 25 $\mu\text{g PM}_{10}$ and 15 $\mu\text{g PM}_{2.5}$) [57]. All subjects were never-smokers, did not have a history of occupational dust exposure and, for the subjects from Mexico City, did not cook with biomass fuels, a process that, as noted above, has been associated with chronic airflow obstruction [13,14]. We carried out a formal grading procedure for amount of muscle and fibrous tissue in the walls of the small airways, and found that the lungs from Mexico City had considerably greater fibrosis and muscle in both the membranous and respiratory bronchioles (Fig. 34.2 and see also Plate 34.1; colour plate section falls between pp. 354 and 355). There was also greater luminal distortion in the Mexico City lungs. Of particular interest, when we used a microdissection procedure to evaluate particulate content of the airway walls by analytical electron microscopy, we found chained aggregates of carbonaceous spheres with the morphology of DEP.

Thus, our study suggests that, even in the absence of smoking and occupational dust exposure, chronic exposure to high levels of PM leads to small airway remodelling, probably caused by PM particles that enter and are retained in the airway walls. One could argue that our results might also reflect the presence of other types of air pollution, because there are considerably greater concentrations of ozone, NO_2 , SO_2 and CO in Mexico City compared with

Vancouver. While synergistic interactions are possible, the lesions that we observed are essentially identical to the small airway lesions found in workers occupationally exposed to mineral dusts in the absence of other pollutants [53] and thus we believe that PM are the primary pollutant responsible for these effects.

Taken in aggregate, our data, and the results of Souza *et al.* [54] and Pinkerton *et al.* [55], suggest that chronic exposure to high levels of PM produces distinctly visible small airway lesions, in particular increases in fibrous tissue, muscle and, in the respiratory bronchioles, pigmented dust. These findings thus provide an anatomic basis for the functional abnormalities detected in persons with chronic exposures to elevated PM concentrations.

Experimental studies on PM and airway wall remodelling

Despite the large number of experimental studies demonstrating acute proinflammatory effects of PM outlined in the previous section, relatively little is known about chronic effects.

We have established a tracheal explant system which can be used to examine fibrogenic events in the airway wall.

The model employs small segments of rat trachea which are exposed to dust or PM and then maintained in air organ culture for extended periods, during which time surface particles are taken up by the epithelial cells and eventually transported to the underlying interstitial tissues. Using this system, we showed that amosite asbestos fibres, known fibrogenic agents *in vivo*, produce airway wall remodelling in the form of increased procollagen and hydroxyproline, a measure of collagen content [58]. This process appeared to be driven by active oxygen species (AOS), probably through redox cycling of surface iron on the fibre, because it could be inhibited by deferoxamine and AOS scavengers.

To examine the effects of PM, we employed two different approaches. First, 0.12 μm TiO_2 particles were used as a model of relatively inert fine PM particles [59]. By themselves the TiO_2 particles had no effect in the tracheal explants, but if the particles were first loaded with cationic iron by incubation in an Fe(II)/Fe(III) chloride solution, they caused increased pro-collagen gene expression and increased hydroxyproline in a fashion analogous to asbestos. The hydroxyl radical scavenger tetramethylthiourea (TMTU) and deferoxamine prevented these effects. Fibrogenesis was mediated through NF- κB activation with an unusual pattern of I $\kappa\text{B}\alpha$ phosphorylation, because increased levels of both phosphoserine-32/36 and phosphotyrosine were found. These findings suggested that otherwise inert particles that contain bioavailable iron can cause generation of AOS and subsequent fibrogenesis through an NF- κB mediated mechanism involving I $\kappa\text{B}\alpha$ degradation, possibly via two different mechanisms in the epithelial and mesenchymal compartments. Of interest, iron loading also lead to an NF- κB dependent increase in gene expression of prolyl-4-hydroxylase, an enzyme crucial to collagen formation, thus providing one mechanism by which AOS may control tissue collagen levels.

To determine whether actual PM could induce airway wall remodelling, explants were exposed to Ottawa Urban Air Particles (EHC93, closely corresponding to PM_{10}) or DEP [60]. After 7 days in air organ culture, both types of PM produced increased procollagen gene expression and increased tissue hydroxyproline, and these effects could be completely blocked by antioxidants and NF- κB inhibitors. Both types of PM also produced increases in gene expression of TGF- β_1 , a powerful pro-fibrogenic cytokine. With the Ottawa urban air particles EHC93, TGF- β gene expression operated through an AOS-driven pathway, but for DEP, TGF- β gene expression proceeded through a MAPK pathway. These findings therefore show that PM particles can produce airway wall fibrosis and that a variety of different pathways are involved.

Iron is an important component of many types of PM, and the findings just described correspond in a general way to a considerable number of observations that link PM

toxicity to the presence of transition metals, mostly iron, but also vanadium [33,47,61–63]. To further investigate the role of iron, we treated iron-loaded TiO_2 with citrate and then applied the citrate extract to tracheal explants [59]. The extract proved to be an even more powerful inducer of pro-collagen gene expression than was the dust itself. Thus, these results imply that leaching of redox-active iron from PM may be one mechanism behind PM-induced airway wall remodelling, although other mechanisms probably apply to DEP.

Air pollution, COPD and cardiovascular disease

There is now convincing evidence of a link between air pollution, especially particles, and deaths and hospitalizations for cardiovascular disease. In humans, this has been demonstrated epidemiologically as increased cardiovascular deaths [17,64] and hospitalization [65] in relation to increases in PM_{10} . In addition, panel studies have shown increases in PM to be associated with triggering of myocardial infarction [66] and increased dysrhythmia [67]. These effects could be driven by a number of mechanisms including local inflammation in the lungs causing systemic inflammatory effects (reviewed in [68]) that could impact on atherosclerotic plaque stability [69]. Irritative or inflammatory effects of particles could also affect the autonomic nervous system to cause effects on heart rhythm [70].

In COPD there is a two- to threefold increased risk of cardiovascular disease, and ischemic cardiac injury is found in COPD in association with increased acute phase proteins [71]. Systemic inflammation is well-documented in COPD [72] and increases in C-reactive protein [73] and fibrinogen [74] have been reported. Increases in these components of the acute phase response are also related to increases in PM in normal elderly people and are an independent risk factor for acute cardiovascular mortality [75]. Hypertension is also a risk factor for acute cardiovascular death and hypertension is common in COPD [76].

Atheromatous plaques, the inflammatory lesions of coronary artery disease, form in the walls of arteries and typically contain leucocytes, smooth-muscle cells, foam cells and a lipid-rich core capped by a fibrous layer of connective tissue and fibroblasts [77]. The lipid core of the plaque is highly thrombogenic, containing lipid-rich macrophage foam cells. When a plaque ruptures, thrombogenesis can result, leading to an ischemic episode. It is notable that plaque rupture and small areas of denudation and thrombus deposition are a common subclinical finding on the surface of atheromatous plaques at autopsy [78]. These findings suggest that the balance between fibrinogenesis and fibrinolysis is the factor that modifies plaque rupture

and dictates whether a thrombus forms or not. Any effect of particle deposition in the lungs that favours clotting would increase the likelihood of thrombus formation in a susceptible individual when a plaque ruptures. Known risk factors include increased plasma fibrinogen, factor VII coagulant activity (factor VIIc), as well as impaired endogenous fibrinolysis. It is the relative balance between the acute local release of tissue plasminogen activator (tPA) and its subsequent inhibition through the formation of complexes with plasminogen activator inhibitor type 1 (PAI-1), which determines the level of endogenous fibrinolytic activity and hence the risk of propagation of subclinical microthrombi on atheromatous plaques, that ultimately lead to coronary arterial occlusion and myocardial ischaemia [29].

In a human *in vivo* model to assess the acute fibrinolytic capacity, the endothelium-dependent vasodilator, substance P can be used to stimulate tPA release in the forearm blood vessels [79]. Acute cigarette smoking has been shown to cause a marked inhibition of both peripheral arterial and coronary arterial substance P-induced tPA release [79,80].

Many of the mechanisms of cigarette smoke induced proinflammatory events are mediated by oxidative stress [81] and similar mechanisms have been invoked for environmental particles [31]. Thus, oxidative stress could be a mechanism for particle-induced changes in fibrinolysis, which may be relevant to thrombosis propagation and coronary artery occlusion in susceptible individuals in response to increased particulate air pollution levels. In COPD, many of the risk factors for sudden cardiovascular death are present: hypertension, acute phase response, oxidative stress, cigarette smoke induced fibrinolytic deficit and all of these are potentially subject to modification by air pollution. Thus, COPD patients can be seen as a particularly susceptible group for the adverse cardiovascular effects of PM.

Conclusions

Epidemiological studies show a clear relationship between increases in air pollution levels and both mortality and morbidity in patients with established COPD. Such studies also suggest that, even in non-smokers, long-term exposure to high levels of ambient pollutants can by itself cause COPD. It is not easy, given the complex nature of air pollution, to ascribe these effects to a single entity, and all of the main gaseous pollution components have proinflammatory effects. However, particles appear to be especially harmful. An accumulating body of experimental evidence suggests that oxidative stress induced by particles, especially those containing transition metals, along with the inflammatory reaction to such particles, are the underlying mechanisms. Chronic inflammatory and fibrogenic responses to the background particle pollution cloud could

cause long-term remodelling of airways, while short-term increases in PM₁₀ might elicit an additional inflammatory burden on the airways, causing exacerbations. COPD patients are a susceptible group for cardiovascular disease and PM-mediated oxidative stress and inflammation can impact on important coagulation and atherogenic pathways which may explain the increased cardiovascular mortality and morbidity associated with increases in particulate air pollution.

CHAPTER 35

Viruses in COPD

Sam Hibbitts and Colin Gelder

Viruses are comprised of a limited number of proteins and nucleic acid, either in the form of RNA or DNA. They lack the enzymes required for efficient nucleic acid replication and therefore have to subvert the host cell in order to propagate. Viruses vary in complexity from small single-stranded RNA viruses with less than a dozen open reading frames (ORF) (viral equivalent of genes) to large double-stranded DNA viruses containing hundreds of ORF.

The nucleic acid in viruses can be either single or double stranded. Single-stranded RNA viruses can either have their genetic information on one strand or on several short segments of RNA and this nucleic acid can either be the same sense as messenger RNA (positive strand viruses) or as the complementary sense (negative strand). In order to produce mRNA negative strand, viruses have to produce a positive strand template (cRNA).

Viruses are classified as 'lytic' or 'non-lytic' according to whether they destroy the host cell in the process of replication. Much of the pathology seen during a non-lytic viral infection is caused by the host response rather than the virus itself. Some viruses are able to persist after the acute infection either by lying dormant or by integrating part of their genetic information into the host genome. There is currently interest in the possibility that latent adenovirus infection may contribute to the pathogenesis of COPD (see below).

Respiratory viruses typically target the mucosal membrane of the respiratory tract epithelium and cause a localized infection with a short incubation period of 1–3 days. The lung parenchyma may also be targeted as part of a generalized infection. While most respiratory virus infections are self-limiting, the consequences of this acute infection can have longer term complications, and these are discussed below. Electron microscope (EM) images of the different respiratory viruses are illustrated in Plate 35.1 (colour plate section falls between pp. 354 and 355).

Major respiratory viruses

Negative strand RNA viruses

Influenza A and B

Influenza viruses are members of the *Orthomyxoviridae* and are responsible for local outbreaks, epidemics and pandemics of acute respiratory illness. Although influenza infection usually produces a short-lived self-limiting illness, it is associated with complications, including primary viral pneumonia and secondary bacterial infection, and considerable excess morbidity and mortality. Such complications and death are more likely to occur in individuals with chronic respiratory, cardiac or metabolic disease, the immunocompromised and those over the age of 65 years: the high-risk groups.

Influenza viruses are lytic and possess a negative sense segmented single-stranded (ss) RNA genome approximately 10 kb in size. There are three genera (A, B and C), with influenza A and B being the most significant. The viral genome consists of eight fragments that complex with viral proteins to form a helical ribonucleoprotein (RNP). The virions are typically 100–200 nm in size and spherical with spikes projecting from the outer lipid envelope. The surface spike glycoproteins of influenza A are haemagglutinin (HA) and neuraminidase (NA), influenza B has a combined surface coat protein [1,2]. These glycoproteins exhibit regular limited changes in their antigenic structure, termed antigenic drift. This leads to the emergence of new influenza A and B strains and winter outbreaks and epidemics of influenza.

In influenza A, antigenic drift is interspersed by less frequent large changes in structure termed antigenic shift, with different combinations of HA and NA (new subtypes) and these usually cause pandemics of influenza. Such pandemics have occurred in 1890, 1918, 1957, 1968 and 1977. The 1918 pandemic is believed to have killed

at least 40 million people [3]. To date, 15 subtypes of haemagglutinin and nine subtypes of neuraminidase have been described. While only one or two subtypes are found in most mammalian species, all are present in aquatic birds, which are thought to be the original source of the haemagglutinin and neuraminidase genes found in pandemic influenza A viruses [4] (for further information visit www.cdc.gov/ncidod/diseases/flu/fluivirus.htm).

Respiratory syncytial virus

Respiratory syncytial virus (RSV) is responsible for a range of respiratory illnesses including bronchiolitis in infants, and coryzal illness and tracheobronchitis in adults. In addition, RSV is increasingly recognized to be an important pathogen in COPD (see below). In temperate climates, annual outbreaks of RSV infection occur during the winter season, whereas its incidence in the tropics is during the summer and rainy months. The virus is transmitted through respiratory secretions. During an epidemic, nosocomial infections are common, particularly in hospitals and nurseries, with virus shedding apparent up to 3 weeks after the acute infection.

RSV is a member of the *Paramyxoviridae* family in the *Pneumovirus* genus with a negative sense ssRNA genome and is non-lytic. RSV virions are 120–300 nm in size with a lipid envelope and glycoprotein spikes on their surface. It encodes 10 viral proteins, eight of which are structural and two are non-structural [5]. There are two serological groups, RSV A and RSV B; however, the significance of this strain variation in terms of clinical outcome and epidemiology remains unclear (for further information visit <http://www.cdc.gov/ncidod/dvrd/revb/respiratory/rsvfeat.htm>).

Metapneumovirus

Human metapneumovirus (hMPV) was first described by van den Hoogen *et al.* [6] who were able to isolate the virus from young children with respiratory tract disease, and demonstrated, by studying old sera, that hMPV has been present in the European community for more than 50 years. The virus causes symptoms that are similar to human RSV and the majority of children appear to have been infected with hMPV by 5 years of age. The virus also impacts upon the elderly and the immunocompromised. Genetically, it is most closely related to type C avian pneumoviruses (APV; previously termed turkey rhinotracheitis virus, TRTV). The majority of currently published studies have not looked for this virus.

Positive-strand RNA viruses

Picornoviruses

Rhinoviruses are Picornoviruses and are the most common causative agent associated with the common cold. There

are at least 100 different serotypes of this virus, which is transmitted through aerosols, infected surfaces and hand-to-hand contact. Rhinoviruses target cells of the upper respiratory tract causing inflammation. Infections occur throughout the year and although the associated illness is mild in healthy individuals, this virus is associated with exacerbations of asthma and COPD (see below).

Rhinoviruses are non-lytic and have a linear positive sense ssRNA genome approximately 8 kb in size with a 5' protein primer and 3' poly (A) tail that in itself is infectious. Picornavirus virions are icosahedral, approximately 18–30 nm in diameter, non-enveloped with a protein capsid. The virus particles enter the cell through attachment to intercellular adhesion molecule type 1 (ICAM-1). The viral genome functions as a mRNA for direct translation into a large polyprotein that undergoes a series of cleavages to form the structural and non-structural viral proteins. Cellular mRNA translation is inhibited and virus release involves destruction of the host cell [7].

Rhinoviruses differ from other members of the *Picornaviridae* family in that they can not withstand acidic environments and have an optimal growth temperature of 33°C. A number of antivirals including interferons have been tested as treatment for the common cold with limited effectivity results and generation of a vaccine has proved difficult because of the numerous rhinovirus serotypes [8].

Coronaviruses

'Usual' coronaviruses

Coronaviruses are the second most common pathogen associated with the common cold (2–10% of cases). There are two known human serotypes (229E and OC43). Replication of these viruses is restricted to the epithelium cells of the upper respiratory tract and in typically healthy individuals only the nasal passages are affected with no fever or sore throat. However, in patients with underlying respiratory disorders including COPD, coronaviruses can exacerbate clinical symptoms (see below).

Coronaviruses have a large RNA genome of approximately 30 kb that is positive sense ssRNA 5' capped and 3' polyadenylated and, as with rhinoviruses, the 5' cap is infectious in its own right. The virions are pleomorphic, ranging in size from 60 to 220 nm, with heavily glycosylated glycoprotein surface spikes. Entry into cells is thought to involve endocytosis and viral RNA translation produces two large polyproteins that, when cleaved, produce an RNA polymerase. This proceeds to transcribe a negative copy of the RNA genome which serves as a template for transcription of a positive copy and subgenomic mRNAs which each encode one of the viral proteins. A lipid envelope is acquired from the host cell and virus release is through fusion of vesicles containing progeny virions with the plasma membrane of the host cell [9,10].

Severe acute respiratory syndrome

The first cases of severe acute respiratory syndrome (SARS) were reported in November 2002 in Guangdong Province, China, with an outbreak of atypical pneumonia affecting 305 people with five deaths. Epidemiological studies identified spread along recognized international air travel routes with reports of cases in Asia, North America and Europe. Health-care workers proved to be at 'high-risk' with potential exposure to a new and readily transmissible disease. By early May 2003 the cumulative number of reported cases exceeded 7000 in 30 countries over six continents with 623 attributable deaths [11].

General symptoms include fever, headache, discomfort and body ache, with some mild respiratory symptoms. Two to seven days following infection air passages may feel blocked and a dry cough can develop. Transmission is via close contact with an infected individual through aerosols and direct contact with infectious material [12].

A previously unrecognized coronavirus has been isolated from patients with SARS and this is thought to be the causative agent [13]. At the time of writing, the initial diagnostic tests for suspected SARS cases include a coronavirus antibody test and reverse transcriptase polymerase chain reaction (RT-PCR). With no vaccine or treatment yet available, control has been via isolation and quarantine with standard, airborne and contact precautions recommended (www.who.int/csr/sars/en/).

DNA viruses

Adenovirus

Adenovirus is a lytic double-stranded DNA virus with more than 40 known serotypes, responsible for a range of human and animal diseases that affect the upper and lower respiratory tract, the eye and the gastrointestinal tract. Adenoviruses are estimated to contribute to 5–10% of respiratory tract infections in children. The replication cycle of adenovirus is initiated when the virus adheres to the host cell receptor followed by internalization via endocytosis. The viral genome is then translocated into the cell nucleus and transcription of both DNA strands occurs using the cellular RNA polymerase II that forms early and late mRNAs encoding the 'early' and 'late' proteins, respectively. The first early gene expressed is E1A which operates in *trans* to activate the host cell transcription machinery. This gene encodes nuclear phosphoproteins that regulate the expression of certain viral and cellular genes. The E1A protein has a number of functions including initiation of cell division, transformation, immunosuppression and influencing cellular transcription by interacting with nuclear regulatory proteins and thus affecting transcription factor DNA binding. There is an overall activation of the cell and the virus in essence takes over its machinery so that the host cell becomes a manufacturer of virus particles [14,15] (for

further information visit www.cdc.gov/ncidod/dvrd/revb/respiratory/eadfeat.htm).

Viral detection techniques

Culture

Virus isolation utilizing cell culture remains one of the predominant methods used by clinical laboratories to investigate clinical specimens for potential viral infection. With appropriate samples and cell-lines, this technique remains sensitive and specific for the detection of a range of viruses when there is a visible cytopathic effect (CPE). A positive viral identification indicates viable virus within a sample which can also be used for further investigations. Virus isolation via culture, however, is a slow process which can take up to 7–14 days before a result is obtained, which is often inadequate for appropriate patient management. Primary cell-lines from primates are often required for an accurate result (best yields for influenza and parainfluenza viruses) and their use is becoming increasingly difficult to justify. In addition, culture has been found to be less sensitive than the emerging viral molecular detection methods and inefficient at detecting viruses with limited CPE.

Serology

The humoral response triggered by viral infection forms the basis of serology testing. Typically, during the acute stage of infection an immunoglobulin M (IgM) and IgG antibody response is observed; however, the functional response is variable. Early serology testing did not differentiate between an IgM and IgG response, with diagnosis determined by seroconversion or rise in Ab titre after acute infection. Insensitivity and cross-reactivity with different antigens plus a positive identification only after an acute infection limited its use in a clinical setting. The latest serological tests are based on solid phase linked immunoassays and include:

- 1 *Indirect assays*: viral Ag fixed onto a solid phase, patient serum added and presence of specific Ab to this Ag detected, with differentiation between IgM and IgG;
- 2 *Competitive assays*: compete labelled Ab with Ab present in a clinical specimen for binding to a fixed target Ag;
- 3 *Capture assays*: capture of IgM or IgG species present in a clinical sample to a solid phase followed by addition of target Ag and labelled Ab.

IgM assays give indication of a recent infection and IgG assays indicate prior infection. More recent serology assays are automated and therefore require limited hands-on time. The main drawbacks to serology testing is still possible cross-reactivity and its dependence on an individual mounting an immune response, therefore it is inappropriate for use on immunocompromised patients.

Immunofluorescence

Direct or indirect immunofluorescence (IF) is an effective rapid diagnostic technique. Monoclonal antibodies to a specific pathogen are utilized and this procedure is used routinely for respiratory viral screening of clinical specimens for RSV, parainfluenza, influenza and adenovirus. A range of specimens can be investigated using IF including nasopharyngeal aspirates (NPA), throat and nasal swabs, with results available in a short time frame. The main drawback of the procedure is its requirement for a quality specimen with enough of the viral target cells for a positive identification. Sensitivity of the assay can also vary with virus variants that may possess altered amino acid sequences, envelope or outer capsid proteins and new emerging viral strains would be missed when suitable antibody preparations are not yet available for their detection.

Polymerase chain reaction

To date, molecular amplification procedures mainly use polymerase chain reaction (PCR) amplification for detection and analysis of DNA viral targets and RT-PCR for RNA viruses. PCR requires a pair of primers that each hybridize to one strand of a double-stranded DNA (dsDNA) target across a defined region that becomes exponentially amplified. The hybridized primer acts as a substrate for a DNA polymerase (*Taq*) that creates a complementary strand through addition of deoxynucleotides. The PCR process can be summarized in three steps:

- 1 dsDNA separation (> 90°C);
- 2 primer annealing (50–75°C); and
- 3 polymerization (72–78°C).

The incubation length for each step and the cycling parameters are optimized for each target and require a thermal cycler. Traditional detection of PCR products uses electrophoresis in the presence of ethidium bromide with visualization by illumination with short wave (254 nm) ultraviolet light. 'Nested PCR' is a variant of standard PCR in which a second round of amplification takes place using the product of the first round as the DNA template and a second set of primers specific for regions within this first round amplicon. This technique is extremely sensitive but prone to false-positive reactions unless great care is taken to prevent cross-contamination. The advent of 'real-time' PCR technology reduces the need for post-PCR analysis with fluorogenic labels incorporated onto the probes generating a signal in proportion to the amount of amplification product produced [16].

RT-PCR incorporates the standard PCR technique with an additional pre-PCR-RT step required to produce a DNA copy of an RNA target. This method utilizes random or specific primers to the RNA target and a reverse transcriptase that creates the first strand complementary DNA

(cDNA) via addition of deoxynucleotides. Alternative procedures use thermostable polymerases with RT activity or *Taq*/RT mixes for single-tube reverse transcription and amplification.

Nucleic acid sequence based amplification (NASBA)

Nucleic acid sequence based amplification (NASBA) is an alternative procedure for amplification of RNA targets. It amplifies RNA in a manner analogous to the replication of retroviruses (Fig. 35.1) [17,18]. The NASBA reaction contains oligonucleotide primers and three enzymes: avian myeloblastosis virus-reverse transcriptase (AMV-RT), RNase H and T7 RNA polymerase for target specific amplification [19,20]. The reaction occurs at 41°C and results in the exponential amplification of products within 90 min, producing antisense single-stranded RNA as the major amplification product. Detection of NASBA products has been reported using probe-capture hybridization and electrochemiluminescence (ECL) [17,20] and 'real-time' detection using molecular beacons has been described [21,22]. Molecular beacons are hairpin-shaped oligonucleotides with a loop region containing a probe sequence complementary to the target amplicon and a stem with complementary arm sequences located on either end of the probe sequence [23]. A fluorophore is covalently linked to one arm and a quencher to the other, so in the absence of its target amplicon fluorescence is quenched by energy transfer. When the probe hybridizes to its target to form a rigid double helix, a conformational change occurs that separates the quencher from the fluorophore enabling fluorescence to occur.

New molecular technologies (PCR, RT-PCR, NASBA) may give a more accurate reflection of the contribution of respiratory viruses with their increased sensitivity and specificity, plus their ability to identify new emerging

Figure 35.1 Schematic of nucleic acid sequence based amplification (NASBA).

Table 35.1 Comparison of different techniques utilized for viral detection.

Technique	Culture	Serology	Immunofluorescence	PCR	NASBA
Time to result	7–14 days	Variable < 1 day	< 1 day	2–6 h	2–4 h
Cost(s)	Low	Medium	Low–medium	High	High
Assay sensitivity/ assay specificity	Medium–high if there is a visible viral CPE	Medium–high although in some cases cross-reactivity and interference	Variable: high if appropriate Abs available	High	High
Advantages	Viable virus isolated for further study	Speed, numerous sample types can be analysed	Speed, high sensitivity for certain viruses	Speed, possible application to new emerging viruses	Speed, possible application to new emerging viruses
Limitations	Slow and multiple cell- lines required	Some spurious results, inappropriate for immunocompromised patients	High-quality samples for testing required	Cost	Cost
Ease of use	Labour intensive, cell-culture trained staff	Rapid, can be automated	Skilled staff needed	Trained staff required	Trained staff required

CPE, cytopathic effect; NASBA, nucleic acid sequence based amplification; PCR, polymerase chain reaction.

respiratory viruses (e.g. hMPV and SARS) or viruses that grow inadequately in culture and may be missed by traditional procedures. Additional benefits of molecular techniques include fast turn around time for results and use of a range of specimen types even when cell/target copy number is low (e.g. samples from children).

There is a wide variation between the different techniques that have been used to detect respiratory viruses in COPD patients, ranging from traditional culture through to PCR. To elucidate accurately the significance and contribution respiratory viruses have on the pathogenesis of COPD, optimized sensitive and specific viral detection assays should be utilized. Work on this field relying exclusively on culture and/or serology is likely to have underestimated the potential role of viruses. Table 35.1 compares the different techniques currently utilized for viral diagnostics.

Viruses and the development of COPD

Role of childhood infections in later development of COPD

Individuals who develop lower respiratory viral infections in early childhood go on as a group to have reduced lung volume in adulthood [24,25]. The most likely interpretation of these data is that infection of the developing lung in infancy and childhood leads to a reduction in lung growth, although it is possible that individuals with small lungs

as infants who are genetically programmed to have small lungs as adults are more susceptible to lower respiratory tract infection. Viruses are isolated in 20–30% of all cases of respiratory infections in the paediatric setting, and RSV infection is the major cause of bronchiolitis in the first few years of life [26], and has therefore attracted much interest. Indeed, almost 100% of infants are infected with RSV during their early years and of these 66% of infections occur within their first year. Nine studies between 1978 and 2000 studied long-term prognosis of RSV infection with only one studying the control group simultaneously as the RSV-infected hospitalized children [26,27] (study design and results are discussed in more detail later). Study designs varied but all found the post-bronchiolitis group to have increased airway obstructions with diminished lung function that persists for several years (reviewed in [28]). The mechanism by which RSV initiates and induces these changes remains unclear and is likely to involve a number of genetic and environmental factors. However, RSV stimulation of host Th2 immune cells is thought to be a contributing factor.

Strannegard *et al.* [26] studied children hospitalized for RSV-induced bronchiolitis and controls. These children were monitored at 1, 3 and 7 years of age [26,27]. At 1 year, bronchiolitic illness was associated with higher RSV Ab (immune) response and by 3 years allergic sensitization and onset of asthma was more frequent in children with a history of bronchiolitis. Allergic sensitization was elevated in children with higher levels of IgA Ab at 1 year, supporting

previous findings that the Th2 response (involved in IgA Ab production) maybe activated by RSV and contribute to subsequent developmental problems in the lung. By 7.5 years of age, bronchial obstructive disease and allergic sensitization (any wheezing) were increased in RSV children, with a higher prevalence of asthma compared with controls. Hereditary and environmental risk factors were also evaluated but RSV bronchiolitis remained the most statistically significant.

A number of studies have investigated potential mechanisms in which RSV can cause dysfunction in the airways. Recent findings suggest that RSV infection may cause changes in both airway and immune function. Kao *et al.* [29] focused on RSV infection of the airway epithelium investigating both *in vitro* and *in vivo* models. Many cell types are thought to be involved in airway injury but the epithelium remains a major target. RSV was found to increase the release of nitric oxide (NO) from epithelial cells and this was dependent upon virus replication and involved Th2 cytokines. NO has numerous functions within the lung and in view of the observed complications associated with RSV infection, may serve as an important signalling molecule for immune cells.

Other groups have shown RSV-induced changes in the autonomic regulation of airway smooth muscle (ASM) and airway hyperresponsiveness (AHR) and sensitization to aeroallergens. Interestingly, early ribavirin treatment of children with RSV bronchiolitis in healthy infants reduced both the incidence and severity of reactive airway disease and hospital admissions for respiratory-related illness [30].

Although many children with RSV-associated wheeze appear to stop wheezing in later childhood, it is not yet known what happens to these individuals in adulthood, and it has been suggested that they might be predisposed to COPD in later life [31].

Adenoviruses and COPD

While cigarette smoking is clearly the major risk factor for the development of COPD, only 10–20% of heavy smokers actually develop significant emphysema and airway obstruction [32]. Thus, other factors including either host genetics and/or environmental exposure must contribute to the pathogenesis of COPD. Latent adenoviral infection has been proposed to contribute to COPD as the production of adenoviral proteins in the absence of viral replication has been demonstrated in an elegant series of studies by Professor J. Hogg *et al.* (see below). Such latent infections are thought to amplify cigarette-induced lung inflammation and contributing to COPD development.

Evidence of persistent adenoviral infection has been reported in the tonsils of children [33], and from PBMCs [34] and lungs [35] of asymptomatic adults [35]. Expression of the E1A protein of adenovirus has been detected in

the lung epithelial cells even after the virus has stopped replicating and clinical symptoms have cleared [36]. Studies have reported that the copy number of the E1A gene is found in higher numbers in the lungs of patients with COPD than in matched controls [35].

Animal models with latent adenoviral infection develop an exaggerated inflammatory response and excess emphysema when challenged with cigarette smoke. These studies have supported the hypothesis that cigarette smoke alone results in lung inflammation that is more pronounced when the E1A gene of adenovirus is present. Thus, an excess response to cigarette smoking appears to be linked to latent adenoviral infection.

This has led to the hypothesis that the E1A DNA persists after a childhood infection of adenovirus and its gene products contribute to the inflammation process in the lungs of smokers which accounts for why although all smokers display airway inflammation, airway obstruction only occurs in a minority.

A number of groups have attempted to determine the mechanism by which this process of accelerated inflammation in the lung may occur. Keicho *et al.* [32] investigated epithelial lung cells stably transfected with E1A. The inflammatory stimuli lipopolysaccharide (LPS) induced an increase in the surface expression of ICAM-1 and this was mediated by E1A up-regulating IL-8 production (demonstrated at the mRNA and protein level), which was not observed in control cells. The levels of interleukin 1 β (IL-1 β), IL-6, granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) were not affected or different between control and transfected cells. Keicho *et al.* [32] speculate that this may be an important mechanism by which amplification of inflammation of the lungs occurs, thereby enhancing its susceptibility to other irritants.

The numbers of neutrophils found in the airways of smokers is proportional to the amount smoked and, interestingly, increased numbers of neutrophils are present in lavage fluid of patients with chronic bronchitis. The role and contribution of neutrophils to airway obstruction is not fully elucidated but is thought to be related to the proteases that they release. However, their presence in the airway would require some form of chemotaxis to enable the observed migration of neutrophils to occur. IL-8 is a potent chemoattractant and activator of neutrophils. In addition, IL-8 levels have been found to be elevated in COPD patients. Taken together, this would suggest that the E1A protein of adenovirus could have a key role in recruiting neutrophils to the airways, thus enhancing the inflammatory response in the lungs that can lead to emphysema.

A study of patients with severe emphysema found the number of different inflammatory cell types to be elevated in the lungs with the exception of B cells [37]. However, there was no significant difference in the smoking history of

the patients and control subjects. Interestingly, a fivefold increase in the number of epithelial cells expressing the E1A protein in patients with mild emphysema was observed, which increased to 41-fold in severe cases. The increased levels of E1A were found to be directly proportional to an increased number of inflammatory cells in the tissue and airspaces of the lung. The alveolar type II cells targeted by adenovirus cover 7% of the surface of the lung. Polymorphonuclear cells of the immune system have been found to enter the alveolar space through junctions of type I and II alveolar cells, which would make these cells ideal sites for amplification of inflammatory cell migration. The up-regulation of ICAM-1 and IL-8 by E1A protein that appears to reside in these type II cells long after acute adenovirus infection would increase the number of cells entering the airspace of the lung.

The expression of viral proteins in lung epithelial cells augments the lung inflammatory response via adaptive immune mechanisms. This was demonstrated by a study with transgenic mice expressing influenza viral protein in alveolar epithelial cells. When challenged with CD8⁺ T cells sensitized to the same viral protein there was an observed epithelial-driven MHC restricted inflammatory response. Thus, there was a specific immune response to the presence of the viral protein in the absence of a lytic infection and this may represent what occurs during a latent infection.

Thus, a number of social, genetic and developmental factors may be required to develop severe infection.

HIV infection and COPD

HIV-1 infects the pulmonary macrophages and lymphocytes of the lung and decreases the numbers of CD4⁺ T cells. HIV in the lung may also be responsible for the infiltration of cells ('lymphocytic alveolitis') into the alveolar spaces that is observed in all HIV-positive patients [38]. A number of reports have identified a connection between HIV infection and airways disease and emphysema, with an increase in acute bronchitis in HIV-positive patients compared with controls [39]. In addition, HIV is thought to increase susceptibility to smoking-induced emphysema that correlates with increased numbers of CD8⁺ T-cells as shown in a study comparing lung lymphocyte numbers and physiology between infected and uninfected groups matched by age and smoking history [40].

Viruses and COPD exacerbations

An exacerbation of COPD has been defined as 'a sustained worsening of the patient's condition from the stable state, beyond normal day to day variations, that is acute in onset and necessitates a change in regular medication' [41]. In

individuals with mild or moderate disease, an exacerbation may be the first occasion at which they seek medical attention, and is an opportunity for medical intervention and health education [42]. As an individual's lung function slowly declines, the chance that medical care and hospitalization will be required during an exacerbation increases [43,44] and if inpatient care is required it is associated with high treatment cost and considerable mortality (reviewed in [45]).

Individuals with COPD vary considerably in the number of exacerbations they experience. Population-based studies have also established that individuals with chronic lung diseases experience more acute lower respiratory symptoms in association with an upper respiratory tract infection than healthy controls [46,47] and there is evidence that the patients who have the most frequent exacerbations also have the lowest health status [48], and that exacerbation frequency may predict accelerated decline in lung function [49,50], although this is controversial [43,51] and may only relate to current smokers [50]. In addition, while symptoms during an acute exacerbation may be short lived, in a minority of individuals its effects can last for several months [52] possibly because of negative conditioning of skeletal muscles.

Influenza and COPD

Influenza causes regular seasonal outbreaks of acute respiratory illness interspersed by less frequent epidemics and pandemics. During an influenza outbreak there are increases in all cause mortality. Several large epidemiological studies have demonstrated that individuals with chronic illnesses including COPD have an increased risk for respiratory illness-related hospitalization during influenza outbreaks independent of age, and morbidity and mortality in excess of the already high underlying rates associated with old age [53–57].

Influenza vaccines are 70–90% effective in preventing 'flu-like' illness in young fit adults, and approximately 40–60% effective in preventing the symptoms of influenza in individuals over 65 years of age, and have been shown to reduce mortality, hospital admissions and be highly cost effective. These findings lead to the current recommendation that patients with COPD should receive annual influenza vaccinations (ACIP as above). However, while influenza vaccination increases 'herd immunity' it must be emphasized that individuals who have been vaccinated can and do still develop influenza and its complications.

The evidence that viruses have a role in acute exacerbations of COPD

For many years bacterial infection was regarded as the primary cause of acute exacerbations of COPD. However,

careful studies have demonstrated that there is no bacteriological evidence of infection in approximately 50% of exacerbations, and that the frequency of isolation of bacteria does not increase during an exacerbation [58,59].

Investigations into the possible role of viruses in exacerbations of COPD can be divided into those employing 'traditional methods' of viral detection including serology and culture, and those using molecular techniques. The advantages and disadvantages of these techniques have already been discussed, the key points being that several viruses, including Rhinoviruses, are difficult to detect by traditional methods, and that the sensitivity of molecular techniques is greater than traditional methods (with the possible exception of immunofluorescence).

Examples of studies using 'traditional methods' include work by Smith *et al.* [47], who detected viruses or *Mycoplasma pneumoniae* infection in 18% of COPD exacerbations and 6% of illness-free periods; Buscho *et al.* [60], who reported viral or *M. pneumoniae* infection in 25% of 166 acute episodes of exacerbation and 14% of 138 remission periods; and Gump *et al.* [61] who reported that one-third of the 116 exacerbations observed could be related to viral infection.

A more detailed study was carried out by Greenberg *et al.* [62] who investigated viral contribution to acute exacerbations of COPD in a longitudinal cohort study, in which they compared patients with COPD with age-matched controls with no previous chronic respiratory disease. Approximately 90% of subjects had received an influenza vaccination. Viral culture and serology were used to provide evidence for viral infection, and exacerbations were considered to be virus-associated if a virus was isolated within 7 days of the onset of symptoms, or if serological evidence of infection was found in consecutive paired samples. There were 221 episodes of respiratory illness in the control group (1.4 per year) compared with 323 in the individuals with COPD (2.4 per year). Within the COPD group, respiratory illness occurred more frequently in individuals with a forced expiratory volume in 1 s (FEV_1) of more than 50% predicted than those with an FEV_1 of less than 50% predicted (3.0 vs 1.8 acute respiratory illnesses per year, respectively). The duration of respiratory illness did not vary significantly between the patients and controls. Viral infections were associated with respiratory symptoms in 39% of the control group and 19% of COPD group, and a similar pattern of viral infection was seen in both groups. In the COPD group, Parainfluenza virus accounted for 29% of exacerbations where a virus was detected, Picornaviruses and Coronaviruses both accounted for 23% (three-quarters of Picornaviruses were Rhinoviruses), influenza A and B viruses (11%), RSV (11%), Adenovirus (1%) and cytomegalovirus (CMV) (1%). No specific viral agent was associated with either mild or severe exacerbations of COPD,

nor was any association found between specific viral pathogens and illness duration.

Walsh *et al.* [63] investigated the impact of respiratory viruses in 134 individuals with COPD or chronic heart disease during two winters. Ninety per cent of these subjects had received influenza vaccination. Nasopharyngeal swabs were taken for viral culture and paired serum samples were examined for serological evidence of viral infection. One hundred and fifty-five illnesses were observed and 36 were probably related to viral infection and five possibly related. The following viruses were associated with exacerbations: influenza A and B (39%), RSV (20%), Rhinovirus (17%), Coronavirus (20%) and Parainfluenza (5%). The clinical symptoms associated with RSV and influenza were the most severe, causing both upper and lower respiratory symptoms, although only the later was associated with fever.

The first study on the role of viruses in acute exacerbations of COPD to use RT-PCR was that of Seemungal *et al.* [48], who investigated a cohort of 83 patients. Respiratory viruses and atypical bacteria were detected by PCR, viral culture and serology. PCR has advantages over traditional culture-based methods for the detection of several respiratory viruses, most notably Rhinovirus. In this study, 64% of exacerbations were associated with a cold up to 18 days before exacerbation. Viruses were detected in 66 of 168 exacerbations (39%). Rhinoviruses accounted for 58% of the viral-associated exacerbations and 16.4% were caused by influenza. Virally associated exacerbations lasted for a longer length of time and occurred more frequently than other exacerbations. Interestingly, in this study, RSV and non-respiratory RSV were detected in 23.5 and 16% of samples taken from patients when stable. This observation needs to be re-examined in future studies, but might indicate a role for RSV in disease pathogenesis, or alternatively that this molecular assay was oversensitive.

The second published study was by Rohde *et al.* [64], who investigated the role of viruses in acute exacerbations of COPD in a case-control study comparing acute exacerbations with stable patients with COPD. Samples from both upper and lower respiratory tract were examined (nasal lavage and induced sputum). Viruses were detected by nested RT-PCR. Respiratory viruses were found more often in respiratory and nasal samples of acute exacerbations of COPD than in stable patients (56 vs 19%), and when the two sets of samples were analysed separately this difference between stable and unwell patients was only seen in the induced sputum samples. The most common viruses detected in this study were Picornaviruses (36%), influenza A (25%) and RSV (22%).

This is a rapidly advancing field: it is important that further studies are conducted, in different populations and with a variety of new molecular techniques including 'real

time PCR' and NASBA. Further information is also required on the relative sensitivity and specificity of the molecular assays employed in these studies. In addition, the possibility that the recently discovered metapneumovirus may have a role in COPD exacerbations needs to be examined.

Implications for therapy

The data presented above indicate that viruses can be associated with 30–60% of acute exacerbations of COPD. Current therapy for acute exacerbations relies on bronchodilators, antibiotics and oral corticosteroids. In terms of preventative therapy, all patients with COPD should be advised to have an annual influenza vaccination. To date, attempts to produce a vaccine for RSV and other respiratory viruses have been unsuccessful. Patients should be advised to avoid children (including their own grandchildren) if they are unwell as they are a main source of transmission for many respiratory viruses in the community. In addition, it may not be advisable to bring patients with stable COPD to a general practitioner (GP) or hospital outpatient clinics for review while respiratory viruses are circulating. Staff with acute respiratory symptoms should also avoid contact with individuals with COPD.

Drug therapy for influenza is available in the form of amantadine, and the neuraminidase inhibitors oseltamivir and zanamivir. Studies are required to test the efficacy of these drugs in COPD exacerbations when these viruses are circulating. New therapies for RSV and Rhinovirus infections are coming close to the market and these will need to be rigorously tested in acute exacerbations of COPD.

Overall, there may be a role for the testing of novel antiviral agents in the treatment of COPD exacerbations, through clinical trials supported by viral diagnostics.

CHAPTER 36

Bacteria

Sanjay Sethi

Bacterial infection potentially contributes in several ways to the aetiology, pathogenesis and the clinical course of chronic obstructive pulmonary disease (COPD) [1]. However, the precise role of bacterial infection in COPD has been a matter of controversy and debate for several decades [2–5]. Opinion has ranged from a pre-eminent role (along with mucus hypersecretion), as embodied in the British hypothesis, to bacterial infection being regarded as a mere epiphenomenon [2–5]. The last decade has seen a resurgence of interest in this area, with the application of modern research techniques which have significantly increased our understanding of the contribution of bacterial infection to this disease.

Five potential pathways by which bacteria could contribute to the aetiopathogenesis of COPD can be identified:

- 1 Bacteria cause up to 50% of acute exacerbations of COPD with consequent morbidity and mortality.
- 2 Chronic colonization of the tracheobronchial tree by bacterial pathogens amplifies the chronic airway inflammation present in COPD and accelerates progressive airway obstruction (vicious circle hypothesis).
- 3 Invasion and persistence of bacterial pathogens in respiratory tissues alters the host response to noxious stimuli such as tobacco smoke and/or induces a chronic inflammatory response and thus contributes to the pathogenesis of COPD.
- 4 Patients with COPD develop hypersensitivity to bacterial antigens which enhances airway hyperreactivity and induces eosinophilic inflammation.
- 5 Acute severe childhood lower respiratory tract bacterial infection damages the immature lung, impairs lung growth resulting in smaller lung volumes in adulthood, thereby predisposing an individual to the development of COPD.

These pathways are used as framework to discuss the potential roles of bacteria in COPD, with an emphasis on typical bacterial pathogens and on information gained from newer research techniques in the last decade. Chronic

infection with an atypical bacterial pathogen, *Chlamydia pneumoniae*, which has been a recent focus of investigation in COPD, is also discussed.

Bacterial pathogens as a cause of acute exacerbations of COPD

Both primary bacterial infection of the lower airway and secondary bacterial infection following an antecedent viral infection could cause acute exacerbation [6]. Investigation of bacterial causation of exacerbations in the past relied on sputum culture, serological studies and placebo-controlled antibiotic trials [1]. Because of limitations of the available techniques and study design, the results of these studies have been confusing and contradictory. An understanding of these limitations is important to recognize how more recent investigations with improved methods and design have had different results than these earlier studies.

Sputum cultures

Bacteria are isolated from sputum in 40–60% of acute exacerbations of COPD. Table 36.1 summarizes the sputum bacteriology obtained in 14 recent antibiotic comparison trials in acute exacerbation that enrolled more than 9600 patients [7–20]. Variation in the relative incidence of specific pathogens likely relate to patient inclusion criteria and sputum culture techniques. The three predominant bacterial species isolated are non-typeable *Haemophilus influenzae* (NTHI), *Moraxella catarrhalis* and *Streptococcus pneumoniae*. Other, less frequently isolated, potential pathogens are *Haemophilus parainfluenzae*, *Staphylococcus aureus*, *Pseudomonas aeruginosa* and *Enterobacteriaceae*.

The isolation of a bacterial pathogen from a body site that is normally sterile is strong evidence for a causative role of that pathogen. However, this does not apply to isolation of

Table 36.1 Bacterial pathogens isolated from sputum in recent studies of acute exacerbation of chronic bronchitis. Data is from [7–20]. (From Sethi [114] with permission.)

	No. of patients	% culture +for PPB	Percentage of total bacterial isolates

PPB, potentially pathogenic bacteria.

bacterial pathogens from sputum in acute exacerbations of COPD. Several longitudinal cohort studies have consistently demonstrated that the incidence of bacterial isolation from sputum was not greater during exacerbations of COPD than during stable disease [21,22].

With increased understanding of bacterial pathogenesis in the past several decades has come the realization that sputum culture, when used alone as a research tool to delineate the cause of exacerbations of COPD, has major limitations. Sputum is invariably contaminated by variable amounts of upper airway secretions that often contain potential pathogens as transient normal flora. This limitation can be overcome when uncontaminated lower respiratory secretions are obtained by bronchoscopy and cultures performed quantitatively, as discussed subsequently. Identification of pathogens as species by sputum culture, in the absence of strain differentiation, does not distinguish between pre-existing colonization and acquisition of a new infecting strain. This limitation can be overcome by strain differentiation with molecular typing of the pathogens recovered from sputum. These new approaches to respiratory sampling and sputum bacteriology, although extremely useful in research settings, because of their complexity are not applicable to everyday clinical practice.

Another important limitation of sputum cultures is sampling error, both within a sputum sample and between sputum samples. Bacterial flora is non-uniformly distributed within a sputum sample, leading to sampling error within a single sample [23]. This error can be reduced by homogenization of sputum and semi-quantitative cultures. Another potential source of error that has not been systematically explored is the sampling error between samples. All studies to date of bacterial causation of exacerbations have utilized a single culture of sputum at the time of presentation. It is quite possible that obtaining multiple sputum cultures during the course of an exacerbation may reveal a larger proportion of possible bacterial aetiology.

Serological studies to bacterial antigens

Development of a host immune response to a microbial pathogen supports a causative role. In the past, this approach was mainly applied to the study of NTHI in exacerbations of COPD, with confusing and contradictory results [1]. A critical analysis of eight of these studies based on current knowledge of bacterial pathogenesis demonstrates their limitations [24–31]. Four of the eight studies compared antibodies in single sera obtained from patients, with sera obtained from healthy controls. Because of wide variability between individuals in such single titres, this approach is not sensitive and could fail to detect significant immune responses [24–27]. In the other four studies with paired sera, the acute sera were obtained at the time of presentation, rather than prior to onset of infection [25–31]. Exacerbations can manifest over days to weeks, therefore a substantial immune response could be present in acute sera obtained at clinical presentation of the exacerbation, which can confound the results. Seven of the eight studies utilized a single or a small panel of laboratory strains of NTHI as an antigen, instead of the strains recovered from sputum during the exacerbations [24–29,31]. Considerable variation exists in the surface antigenic structure among NTHI strains. Therefore, such methodology fails to detect strain-specific immune responses [1]. Furthermore, immunoassays utilized in these seven studies were not specific for antibodies to epitopes exposed on the bacterial surface [24–29,31]. Such potentially protective antibodies often develop against a background of abundant antibodies to non-surface exposed or cross-reactive epitopes, and therefore could easily be missed in such immunoassays.

Recent studies have attempted to address the limitations of previous work and provide a more accurate picture of the immune response to bacterial pathogens following exacerbations. These studies have used the infecting strain as antigen, immunoassays specific for antibodies to

surface-exposed epitopes and paired patient serum samples, with the pre-infection samples obtained prior to the exacerbation.

Antibiotic trials

A dramatic benefit of antibiotics over placebo in randomized double blind trials would support the importance of bacteria in acute exacerbations of COPD. However, most placebo-controlled antibiotic trials in acute exacerbations have demonstrated either a small or no benefit with antibiotic therapy [32]. This lack of efficacy of antibiotics has been interpreted as absence of bacterial causation of exacerbations [4]. There are several alternative explanations for trials showing no benefit with antibiotics in acute exacerbations. The expected benefits of antibiotics in a mucosal infection such as exacerbations of COPD primarily are a more rapid resolution of symptoms and prevention of complications. Unfortunately, the speed of resolution of symptoms has not been carefully measured in studies of antibiotics in acute exacerbations. Instead, the primary endpoint in these studies has been resolution or improvement of symptoms 2–3 weeks after the onset of the exacerbation. The systemic immune inflammatory response resolves a large proportion of bacterial exacerbations in this time period, disguising any potential effect of antibiotics. Many of these studies did not enrol sufficient numbers of subjects and are therefore underpowered (type 2 error). This limitation is compounded in studies that included patients with mild impairment of lung function, who are likely to have a low rate of complications. Exacerbations are non-bacterial in 50% of patients, with no expected benefit from antibiotics, again predisposing these studies to a type 2 error. Several of these studies used antibiotics that are not very efficacious against the major respiratory pathogens and may not penetrate well into bronchial tissues and fluids. These factors are likely to diminish the effect of antibiotics in exacerbations and make their effectiveness difficult to discern from placebo.

A meta-analysis of nine trials published in 1995 demonstrated a small but significant beneficial effect of antibiotics over placebo in acute exacerbation [32]. Two more trials have been published since the publication of this meta-analysis. In addition, a trial that was published in Italian in 1991 has been subject to additional analysis and published in English [33–35]. These three trials illustrate the difficulties in interpretation of placebo-controlled antibiotic studies in acute exacerbation. These three trials differ in patient population, antibiotics used, concomitant treatment and endpoints and not surprisingly show different results. Sachs *et al.* [33] enrolled 71 patients with relatively mild COPD, included patients with asthma and had an 11% incidence of bacterial exacerbations. All

subjects received steroids and were randomized to amoxicillin, co-trimoxazole or placebo. The rate of treatment success in this study was 91.5% and no benefit was seen with antibiotics. Considering the size of the study, the patient population, the aetiology of exacerbation and choice of antibiotics, it would have been surprising to see a benefit with antibiotics.

Nouira *et al.* [34] enrolled 93 patients with exacerbations of severe underlying COPD requiring ventilatory support in an intensive care unit (ICU) and randomized them to ofloxacin or placebo. No corticosteroids were administered. The tracheobronchial aspirates revealed bacterial pathogens in 61% of the exacerbations. Antibiotics had a dramatic benefit in this study, reducing the risk of mortality and need for additional antibiotics by 17.5-fold and 28.4-fold, respectively.

Allegra *et al.* [35] compared amoxicillin/clavulanate with placebo in 414 exacerbations in 369 patients with varying severity of underlying COPD. A unique feature of this study was the measurement of primary outcome at 5 days, instead of the traditional 2–3 weeks. Clinical success or improvement was seen with amoxicillin/clavulanate in 86.4% of patients compared with 50.6% of patients with placebo. The difference between antibiotics and placebo was greater with increasing severity of underlying airway obstruction.

Placebo-controlled antibiotic trials demonstrate benefit with antibiotics, especially if patients are enrolled in adequate numbers, have moderate to severe underlying COPD or if the primary endpoint is determined early in the course of the exacerbation [33–35]. Systemic corticosteroids also are of benefit in exacerbations of COPD [36]. Whether the benefit with antibiotics and corticosteroids are independent of each other and therefore additive is an important research question not yet addressed in well-designed and conducted trials. Another important question that needs to be addressed in future antibiotic trials in exacerbations of COPD is whether an antibiotic with greater microbiological efficacy *in vitro* results in better outcome than an antibiotic with limited microbiological efficacy *in vitro*.

Taken together, results of sputum culture studies, serological studies and antibiotic trials do not provide conclusive proof for the role of bacteria in exacerbations of COPD. In fact, one interpretation of these observations is that isolation of bacteria from sputum during exacerbations represents chronic colonization: an ‘innocent bystander’ role [3,4,37,38]. In the last decade, several investigators have revisited the issue of whether bacteria cause acute exacerbations of COPD with either new diagnostic modalities or research techniques, in an attempt to overcome the limitations of previous studies. These investigations provide a more rigorous evaluation of bacteria as a cause of exacerbations.

Table 36.2 Bronchoscopic studies in acute exacerbations of COPD. (From Sethi [114] with permission.)

Bronchoscopic sampling of lower respiratory tract in exacerbations of COPD

Bronchoscopic samples of tracheobronchial secretions obtained by protected specimen brush (PSB) or by bronchoalveolar lavage (BAL) are uncontaminated by upper respiratory tract secretions and have the additional advantage that bacterial concentrations in these samples above certain thresholds correlate with tissue infection [39]. Studies that have used this methodology in acute exacerbations have consistently shown significant bacterial infection of the distal airways in approximately 50% of patients [40–43]. The bacterial species isolated in these studies are the same spectrum of pathogens usually isolated from sputum during acute exacerbation (Table 36.2).

Chronic colonization of the lower airway remains a potential confounder in these studies. Monso *et al.* [40] addressed this by including a control group of 29 patients with stable COPD for comparison with the patients with exacerbations. Although 25% of patients with stable COPD had bacteria in the lower airways at concentrations of $\geq 10^3$ colony-forming units/mL, exacerbation was associated twice as often with these bacterial concentrations. A higher threshold of $\geq 10^4$ colony-forming units/mL of pathogenic bacteria was seen in 25% with exacerbations and only 5% in stable COPD [40]. Bandi *et al.* [44] utilized bronchoscopy to study infection of the lower airways with NTHI in COPD. Besides sampling the tracheobronchial lumen, bronchial mucosal biopsies were also examined for intracellular NTHI by immunostaining with a monoclonal antibody. Intracellular NTHI was found in 33% of stable subjects and in 87% of exacerbations [44]. The patients with exacerbations were all severely ill, requiring intubation and mechanical ventilatory support.

Bronchoscopic sampling of the tracheobronchial tree provides substantial support for the pathogenic role of bacteria in a proportion of acute exacerbations, in view of the consistent results obtained by different investigators and the increased rate of isolation of pathogenic bacteria in exacerbations than in stable COPD.

Molecular epidemiology of bacterial pathogens

A major controversy in understanding the role of bacteria in exacerbations has been the results of sputum culture studies in cohorts of patients with COPD that included only species identification of the bacterial pathogens isolated. These studies consistently found no difference in the isolation rate of bacterial pathogens during exacerbation and stable COPD [21,22]. An alternative explanation offered for these findings was the 'bacterial load' model of infection in COPD, where an increase in titre of a bacterial species in the airway is responsible for the transition from stable

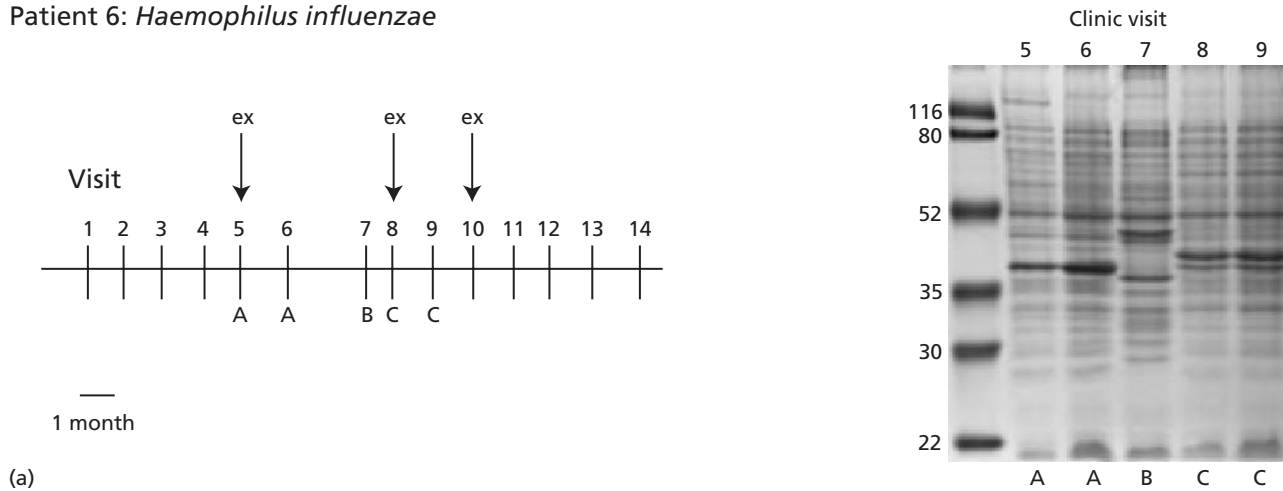

to exacerbation state [45]. Early studies of bacterial titres in the sputum of patients with COPD did not support this model [21]. However, more recent studies [46,47] have provided evidence that bacterial numbers are increased during acute (purulent) exacerbations compared with the stable clinical state. Recent advances in bacterial pathogenesis have demonstrated considerable genetic diversity between the individual strains of a bacterial species, including alterations in their surface antigenic structure. Such variation in the surface antigenic structure of bacterial pathogens allows bacterial strains to evade pre-existing host immunity and cause recurrent infection. Because the previous cohort studies did not differentiate between the strains of the pathogens isolated from sputum over time in their cohorts, they did not address the possibility that such a mechanism of strain variation could underlie recurrent bacterial exacerbations in COPD.

A recent longitudinal cohort study in COPD combined clinical information, sputum culture and molecular typing of the pathogens isolated from sputum in order to determine whether acquisition of a strain of a pathogen that was new to the patient was associated with the development of an exacerbation [48]. Indeed, the acquisition of a strain that the patient had not been infected with earlier was associated with a 2.15-fold increase in the risk of exacerbation. This increased risk of exacerbation was seen with three of the four major pathogens implicated in acute exacerbation: NTHI, *S. pneumoniae* and *M. catarrhalis* (Table 36.3; Fig. 36.1). *P. aeruginosa* did not demonstrate such an association. These results provide further evidence of the role of bacteria in causing a substantial proportion of exacerbations. Furthermore, they suggest that the mechanism of recurrent exacerbations in these patients is not a periodic increase in bacterial load, but rather infection with a bacterial strain with an antigenic structure new to the host. Such an infection leads to an immune and inflammatory response that presents clinically as an acute exacerbation. Once the

Figure 36.1 Time lines of patients 6 and 39. Each line with a number on the time lines indicates a clinic visit. The arrows marked 'ex' indicate exacerbations. Isolates of each bacterial species were assigned types based on banding patterns in gels. The first isolate from each patient was assigned the letter A. All subsequent isolates with the identical banding pattern were also assigned the letter A. Subsequent isolates with different banding patterns were assigned consecutive letters B, C, etc. The lettering system is applicable to the individual patient. Therefore, an isolate labelled A in one patient, for example, is not the same strain as an isolate labelled A from another patient. (a) Each letter under the time line represents a positive sputum culture for *Haemophilus influenzae*. Culture results for *H. influenzae* exclusively are shown. The gel on the right is a sodium dodecyl sulphate polyacrylamide gel stained with Coomassie blue showing whole bacterial cell lysates of isolates recovered at visits 5-9. The letters A, B and C indicate the molecular types based on banding patterns. Molecular mass standards are noted on the left of the gel in kilodaltons (kDa). (b) Each letter under the time line represents a positive culture for *Moraxella catarrhalis*. Culture results for *M. catarrhalis* exclusively are shown. The gel below the timeline is a pulsed field gel stained with ethidium bromide showing *Sma*I digested DNA from isolates recovered at clinic visits as noted. The letters A-E represent molecular types based on banding patterns. Molecular mass standards are noted on the left of the gel in kilobases. (From Sethi *et al.* [48] with permission.)

exacerbation is resolved, the strain may be eliminated or may persist in the airways without causing increased symptoms.

In this study, a one-to-one relationship between strain acquisition and development of exacerbation was not demonstrated (i.e. not every exacerbation was associated with acquisition of a new strain and neither was every new strain acquisition associated with an exacerbation) [48]. This is not surprising if one considers the complex biology of the host–pathogen interaction that determines the clinical consequences of a new strain acquisition in a patient with COPD. Strains of bacterial pathogens differ in virulence. Therefore, it is possible that less virulent new strains do not induce enough of a host inflammatory response and therefore symptoms to reach the threshold of a clinical exacerbation. Even when infected with new bacterial strains of comparable virulence, the intensity of the inflammatory response and the threshold of respiratory symptoms at which they perceive the need to be treated may differ among patients with COPD. Adding to the complexity of the situation, strains that were pre-existing in the patient may undergo antigenic variation and the new variant that emerges may evade the host immune response, proliferate and cause increased symptoms [49,50].

Immune responses to bacterial pathogens in acute exacerbations of COPD

Recent investigations have explored the immune response in serum to bacterial pathogens in acute exacerbations of COPD with methods that avoid the pitfalls of earlier studies and are closer to an optimal design. In addition, investigators have started examining other aspects of the immune response to pathogens, such as cell-mediated and mucosal immunity with novel observations. The ability to manipulate bacterial DNA to clone and express recombinant individual bacterial antigens and create bacterial mutants that lack specific antigens has opened up another avenue to investigate the immune response following exacerbations.

Bakri *et al.* [51] have shown that following exacerbations associated with *M. catarrhalis*, new serum immunoglobulin G (IgG) antibodies and/or new sputum IgA antibodies directed at the infecting strain developed in two-thirds of exacerbations. The mucosal and serosal immune response occurred concurrently as well as independently of each other. Outer membrane protein (OMP) CD is a 45-kDa protein, which is a highly conserved surface antigen of *M. catarrhalis* and is a potential vaccine antigen. Approximately 20% of patients with COPD who experience either exacerbation or colonization with *M. catarrhalis* develop new serum IgG to this protein [52].

Several new and exciting observations regarding the immune response to NTHI have also been made recently.

A recent study that characterized the serum antibody response from two adults with exacerbations of COPD resulting from NTHI illustrates that novel findings can be obtained with new investigative techniques [53]. Both patients developed new bactericidal antibodies to their infecting strain. Immunoblot assays with homologous strains revealed antibodies to many antigens, with minimal differences between pre- and postexacerbation sera in spite of development of new bactericidal antibodies (Fig. 36.2).

Immunoblot assays detect antibodies to many epitopes on bacterial OMPs, including those buried within the outer membrane and not available for binding on the intact bacterium. Antibodies to epitopes that are not on the bacterial surface are not likely to be protective. OMPs of NTHI share cross-reactive epitopes with OMPs of many Gram-negative bacteria. Most of the cross-reactive epitopes are buried in the membrane and not on the bacterial surface. In order to detect the meaningful and potentially protective immune response, immunoassays that specifically detect antibodies to epitopes on the bacterial surface should be used. Such assays include whole cell radioimmunoprecipitation assays, flow cytometry and functional assays such as bactericidal and opsonophagocytosis assays. Subjecting the serum in Figure 36.2 to whole cell radioimmunoprecipitation revealed that the patient developed new antibodies to OMP P2 and to higher molecular mass proteins, an observation that was missed by immunoblot assay. Adsorption studies further established that new bactericidal antibodies were directed at strain-specific epitopes on the P2 protein [53]. OMP P2 is strongly immunogenic in experimental animals and humans [54–57]. The surface-exposed loops of the P2 protein are under intense immune selective pressure and show considerable variability among strains of NTHI. The expression of strain-specific immunodominant epitopes represents a mechanism by which the bacterium induces antibodies that will protect against recurrent infection by the homologous strain but will not protect against infection by heterologous strains.

Although most studies of immune response to respiratory pathogens have focused on antibody production, cellular immune responses to these pathogens are also likely to be important. P6 is a highly conserved 16-kDa OMP of NTHI that is immunogenic in animals and humans and is a potential vaccine candidate. Abe *et al.* [58] recently compared blood lymphocyte proliferative response to OMP P6 of NTHI in patients with COPD who had experienced a NTHI exacerbation in the preceding 12 months with patients who had not experienced such an exacerbation and with healthy controls. They demonstrated that susceptibility to NTHI exacerbation was associated with a specific decrease in blood lymphocyte proliferation with OMP P6 (Fig. 36.3). This suggests that failure to recognize OMP P6

Figure 36.2 Immunoblot assay (a) and whole cell radioimmunoprecipitation assay (b) with pre-exacerbation serum (lanes A) and postexacerbation serum (lanes B) from an adult with COPD who experienced an exacerbation resulting from non-typeable *Haemophilus influenzae*. Assays were performed with the homologous infecting strain. Molecular mass standards are noted in kDa to the left of each panel. Note that immunoblot assays detect antibodies to many bands with minimal difference between pre- and postexacerbation sera. By contrast, whole cell radioimmunoprecipitation assays with the same sera show the development of new antibodies to P2 (arrow) and higher molecular weight proteins following the exacerbation. IgA, immunoglobulin A; IgG, immunoglobulin G; IgM, immunoglobulin M. (From Yi *et al.* [53] with permission.)

as an important antigen may confer susceptibility to NTHI exacerbations in patients with COPD.

King *et al.* [59] compared adaptive immune responses to NTHI in patients with bronchiectasis with chronic NTHI infection with healthy controls and found that while normal controls had a Th1 response, patients with bronchiectasis had a Th2 response. NTHI has the ability to invade cells and persist intracellularly. Therefore, a predominant Th2 response, as seen in patients with bronchiectasis, would not be effective in clearing the NTHI infection. Whether a similar phenomenon is seen in patients with COPD with chronic NTHI infection needs to be investigated.

These studies have demonstrated the development of specific immune responses to infecting strains of NTHI and of *M. catarrhalis* and support the role of bacterial infection in acute exacerbations of COPD. Similar evidence with other bacterial species would help to define their role in acute exacerbations.

Airway inflammation measurement and correlation with bacteriology

An exciting development in airways disease research has been the recognition that sputum measurements of cells and mediators accurately reflect the milieu of the lower airways. Interleukin-8 (IL-8) is the most potent neutrophil chemokine in the lower airways, tumour necrosis factor

α (TNF- α) is important in neutrophil migration in to the airway lumen and neutrophil elastase is released from activated neutrophils and causes matrix degradation. Neutrophilic inflammation is the usual host response to a bacterial infection, therefore bacterial exacerbations should be associated with significantly greater neutrophilic inflammation than non-bacterial exacerbations. Several studies in exacerbations of COPD have systematically examined the effect of bacterial infection on airway inflammation [60–62]. In one such study, bacterial exacerbations were associated with significantly greater IL-8, TNF- α and neutrophil elastase levels in expectorated sputum than non-bacterial exacerbations in the same patients (Fig. 36.4) [60]. Gompertz *et al.* [61] measured markers of neutrophilic inflammation in serial sputum samples obtained from patients experiencing acute exacerbations over 8 weeks and demonstrated that in exacerbations associated with purulent sputum, there is a significant decline in neutrophilic airway inflammation over time. This decline is especially significant in the first 5 days. Contrary to the above studies, Aaron *et al.* [62] were not able to demonstrate a difference in granulocyte inflammatory markers in sputum in bacterial and non-bacterial exacerbations. However, their study was hampered by a small sample size of one bacterial, two viral and 11 exacerbations of unknown aetiology.

This association between pathogen presence and

Figure 36.3 Lymphocyte proliferative assays to outer membrane protein P6 of *Haemophilus influenzae*. The three groups of subjects are H, healthy control subjects; C, COPD patients with no exacerbation resulting from *H. influenzae* in the prior year; N, COPD patients with exacerbation resulting from *H. influenzae* in the prior year. The log stimulation index is a measure of lymphocyte proliferation in response to the antigenic stimulus which was either outer membrane protein P6 (P6) or tetanus toxoid (TT). Values shown are log transformed means with standard error bars. (From Abe *et al.* [58] with permission.)

neutrophilic inflammation in the airways strongly supports a bacterial causation of exacerbations. In addition, as neutrophil elastase is a major driver of lung injury, elevated levels of this enzyme seen in bacterial exacerbations could contribute significantly to the loss of lung function seen in COPD.

One can conclude that current evidence indicates that bacterial infection causes approximately 40–50% of acute exacerbations of COPD. The complexity of the host–pathogen interaction that determines the outcome of each encounter between a potential respiratory pathogen and a patient with COPD is being increasingly appreciated.

Vicious circle hypothesis

Because of the wide variety of defence mechanisms, in a healthy lung the tracheobronchial tree is sterile. In patients with COPD, the tracheobronchial tree may be chronically ‘colonized’ with potential respiratory pathogens, predominantly NTHI, *S. pneumoniae* and *M. catarrhalis* [40,63–66].

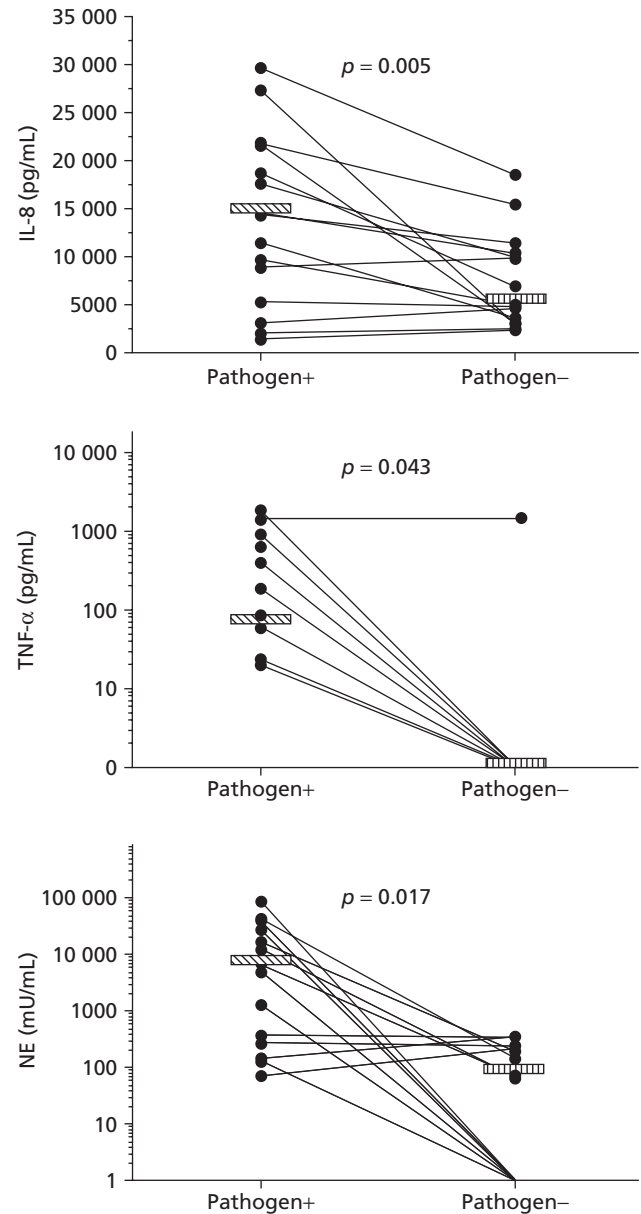

Figure 36.4 Paired comparison of airway inflammation in pathogen-positive exacerbations with pathogen-negative exacerbations. Lines connect the measured values from individual patients. Horizontal bars represent median values. The p values obtained with the Wilcoxon signed-rank test are shown. IL-8, interleukin 8; NE, neutrophil elastase; TNF- α , tumour necrosis factor α . (From Sethi *et al.* [60] with permission.)

Although this chronic colonization was recognized several decades ago by bronchoscopic sampling of the respiratory tract, several recent studies have extended those observations [44,65,67–69]. These studies have shown that the incidence of colonization increases with increasing severity

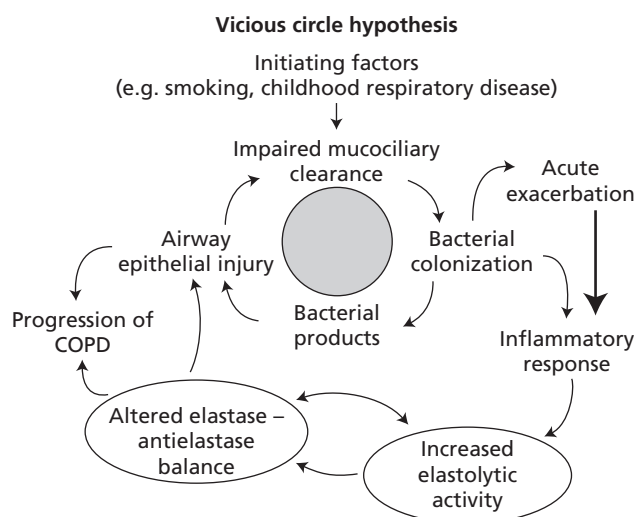

Figure 36.5 Diagrammatic representation of the vicious circle hypothesis. (From Sethi *et al.* [113] with permission.)

of obstructive disease and is more common in current smokers. In one such study, Zalacain *et al.* [65] were able to document colonization by potential respiratory pathogens in 23.1% of mild, 41.7% of moderate and 57.7% of severe cases of COPD. A ‘vicious circle hypothesis’ explains how chronic bacterial ‘colonization’ of the lower airways in patients with COPD can perpetuate inflammation and contribute to progression of the disease (Fig. 36.5) [1,70]. There are several reasons to suspect that cofactors besides tobacco smoke contribute to the pathogenesis of COPD. Only approximately 15% of smokers go on to develop COPD. Chronic inflammation persists in the airways and parenchyma in spite of smoking cessation and COPD does develop in non-smokers. The vicious circle hypothesis has been proposed as one such cofactor in the development and the course of COPD. *In vitro* and *in vivo* evidence supporting this hypothesis is discussed below.

Three interlinked components are contained in the vicious circle:

- 1 Bacteria persist in the lower respiratory tract by impairing mucociliary clearance.
- 2 Bacterial colonization of the lower respiratory tract is an independent stimulus to airway inflammation with consequent lung damage.
- 3 Bacterial exacerbations of COPD intermittently further increase airway inflammation and contribute to lung damage and progression of airway obstruction.

Bacterial infection and mucociliary clearance

Excessive or altered mucus production, disruption of normal ciliary activity and airway epithelial injury can contribute to impaired mucociliary clearance. Respiratory tract

pathogens implicated in COPD and their products can cause all of these effects *in vitro*. Cell-free filtrates of broth cultures of some strains of NTHI, *S. pneumoniae* and *P. aeruginosa* stimulate secretion of mucous glycoproteins by explanted guinea pig airway tissue [71]. This stimulation is a true secretory effect and not passive release of preformed intracellular macromolecules resulting from cellular damage. The *Pseudomonas* stimulatory products are 60–100 kDa proteases. The NTHI and pneumococcal stimulatory exoproducts are 50–300 kDa in size and do not possess proteolytic activity. Wang *et al.* [72] have demonstrated that NTHI is a potent stimulator of the mucin gene *MUC5AC* in respiratory epithelial cell lines. Furthermore, cytoplasmic proteins of NTHI were more potent stimulators of *MUC5AC* than whole bacteria and membrane proteins. All 10 clinical isolates tested in this study were capable of *MUC5AC* induction but did differ quantitatively in their mucin inducing capability.

Cell-free supernatants of NTHI and *P. aeruginosa* rapidly inhibit ciliary beat frequency (CBF) of strips of human nasal ciliary epithelium, by inducing ciliary dyskinesia and ciliostasis [73]. Bacterial products may be a potent stimulus for neutrophil migration into the airways, and human neutrophil elastase inhibits ciliary activity and damages respiratory epithelium [74,75]. Therefore, neutrophil elastase released in the airways could act synergistically with bacterial products and cause further inhibition of tracheobronchial ciliary function. NTHI causes airway epithelial injury in an *in vitro* tissue culture model of nasal turbinate epithelium [76]. At 14 h, patchy injury developed to the airway epithelium, with bacterial cells now associating with these damaged epithelial cells but not with intact epithelium. At 24 h, detached epithelial cells with adherent bacteria were seen.

In conclusion, bacteria that colonize and infect the lower respiratory tract in COPD, especially NTHI, are capable of impairing mucociliary clearance by several different mechanisms, which in turn fosters a tracheobronchial milieu in which they can persist, supporting the central tenet of the vicious circle hypothesis (see Fig. 36.5).

Bacterial colonization and airway inflammation

The presence of bacteria in the lower airways in stable COPD has been labelled ‘colonization’, implying it to be innocuous to the host. Bacteria in the airways are in a constant state of turnover, releasing extracellular products, as well as undergoing lysis with release of a variety of proteins, lipo-oligosaccharide (LOS) and peptidoglycan [77]. LOS is a potent inflammatory stimulus; in fact, repeated instillation of LOS can lead to development of emphysema in hamsters [78]. It is therefore quite likely that this ‘colonization’ actually is a low-grade smouldering infection that induces chronic airway inflammation. In the large airways,

such inflammation would contribute to mucus production and in the small airways it could contribute to respiratory bronchiolitis and progressive airway obstruction [79,80]. Both *in vitro* and *in vivo* studies provide support for these concepts.

Exposure of explant cultures of human bronchial epithelium to LOS from NTHI significantly increases IL-6, IL-8 and TNF- α secretion and intercellular adhesion molecule 1 (ICAM-1) expression in the explanted tissue [81]. The levels of inflammatory mediators attained in the culture medium are adequate to increase neutrophil chemotaxis and adherence *in vitro*. Increased secretion of IL-6, IL-8, TNF- α and monocyte chemoattractant protein-1 (MCP-1) with exposure of a human tracheal epithelial cell-line to whole bacterial cells of NTHI was demonstrated in another recent study [82]. Furthermore, the expression of these pro-inflammatory molecules was only partially accounted for by LOS in the bacterial cell, suggesting that other bacterial components of NTHI also have proinflammatory activity.

An association between bacterial colonization and tracheobronchial inflammation among patients with stable COPD has also been demonstrated in recent studies with both sputum and bronchoscopic samples [83–85]. In the study by Hill *et al.* [83], sputum IL-8, leukotriene B₄ (LTB₄), neutrophil elastase and myeloperoxidase activity and albumin leakage from serum to sputum correlated with the bacterial load in the airways determined by quantitative culture of sputum. Soler *et al.* [84] found that isolation of potentially pathogenic bacteria was associated with significantly more polymorphonuclear cells and TNF- α and a trend to higher IL-8 levels in BAL in asymptomatic smokers and patients with COPD. Furthermore, bacterial colonization of the lower respiratory tract occurred not only in 32% of the patients with established COPD, but was also seen in 42% of smokers with normal lung function. Therefore, bacterial colonization of the lower airways appears to be an early phenomenon in the course of COPD. Furthermore, bacterial colonization is an independent stimulus for inflammation in the distal airways and therefore may contribute to the progression of COPD.

Bacterial exacerbations and airway inflammation

Airway inflammation in bacterial exacerbations of COPD is characterized by abundant free neutrophil elastase in the sputum, suggesting that these exacerbations increase the airway elastase burden and could contribute to progressive airway obstruction [60,61]. However, previous epidemiological studies had failed to show a relationship between the number of exacerbations and decline of lung function, which may have been related to limitations of study design [60,86–88]. Two recent longitudinal cohort studies, the

Lung Health study in early COPD and the East London study with more advanced COPD, have shown that exacerbations are associated with progressive loss of lung function [89,90]. As the aetiology of exacerbations was not assessed systematically in either of these studies, it is not clear if bacterial and non-bacterial exacerbations contribute equally to progressive airway obstruction.

In conclusion, it is becoming increasingly apparent that the presence of bacteria in the lower airways in patients with COPD, even when they are clinically stable, is not innocuous. Additional airway inflammation secondary to bacterial ‘colonization’ and infection could contribute to symptoms and progression of airway obstruction in COPD. However, it is possible that this infection-associated inflammation is confined to the larger airways and does not extend to the small airways, which is the predominant site of obstruction in COPD. Thus, this additional inflammation may only contribute to the bronchitic component of COPD with no impact on the more significant obstructive component. Therefore, the vicious circle appears to exist; however, its importance in the natural history of COPD is as yet unknown.

Chronic bacterial infection by respiratory tissues

New, very sensitive and specific detection techniques for determining the presence of bacterial organisms in tissue have produced interesting and somewhat surprising observations regarding the site of NTHI infection in respiratory tissues. *Chlamydia pneumoniae* is an obligate intracellular pathogen that may have a role in the pathogenesis of COPD.

Intracellular and intercellular invasion of non-typeable *H. influenzae*

NTHI has been long regarded as an extracellular pathogen in the respiratory tract. Recent data from several investigators have shown that the organism’s niche in the human respiratory tract is not limited to the surface of epithelial cells. Studies utilizing cultures of human lung epithelial cells have revealed that a small percentage of adherent NTHI enter epithelial cells in a process that involves actin filaments and microtubules [91]. In addition, NTHI is capable of paracytosis or passage between cells [92]. NTHI that penetrate the epithelial cell layer are protected from the bactericidal activity of several antibiotics and antibodies [93]. In assays employing primary human airway cultures, NTHI adheres to and enters exclusively non-ciliated cells in the population by the process of macropinocytosis [94]. NTHI has also shown the capability to survive after being

phagocytosed by mouse macrophages [95]. In this study, 84% of clinical isolates were able to survive at least 24 h in the mouse macrophages.

In addition to these elegant *in vitro* studies, *in vivo* studies confirm intracellular and intercellular invasion by NTHI of the mucosal surface of the human respiratory tract. Examination of adenoids of children removed at adenoidectomy with *in situ* hybridization and selective cultures for NTHI revealed viable bacteria in macrophage-like cells [96]. In lung explants obtained from patients undergoing lung transplant, NTHI was diffusely present in the epithelium, the submucosa of the bronchi, the bronchioles, the interstitium and the alveolar epithelium as determined by *in situ* hybridization and polymerase chain reaction for OMP P6 [97]. Additional mechanisms that could allow persistence of NTHI in the lower respiratory tract of patients with COPD include the formation of biofilm and the change of host immune response to a Th1 predominance [59,98].

Bacteria in tissues are protected from antibiotics and bactericidal antibodies and may act as reservoirs of infection [93]. Tissue infection by NTHI could also contribute directly or indirectly to the pathogenesis of COPD. Chronic low-grade infection could directly induce a chronic inflammatory response in the lung parenchyma and the airways that could be additive or synergistic to the inflammatory effects of tobacco smoke. Indirectly, such an infection could enhance the damaging effects of tobacco smoke on respiratory tissues. On the other hand, it is possible that this tissue infection is simply a marker of compromised local immunity. The significance of this tissue infection by NTHI in the course of COPD needs to be further investigated.

Chronic *Chlamydia pneumoniae* infection in COPD

Acute *C. pneumoniae* infection can cause bronchitis, pneumonia and acute exacerbations of COPD. Chronic infection with *C. pneumoniae* is being actively investigated as a cause of several systemic diseases, especially coronary artery disease [99]. In a recent study, the incidence of chronic *C. pneumoniae* infection was 71% in patients with severe COPD, 46% in mild–moderate COPD and 0% in the control group [100]. Blasi *et al.* [101] compared COPD patients with and without evidence of chronic infection with *C. pneumoniae* and found more frequent bacterial colonization and more frequent exacerbations in the *C. pneumoniae* positive group. However, the *C. pneumoniae* positive patients had more severe airway obstruction, which confounds the findings ascribed to *C. pneumoniae* infection. A 6-week course of azithromycin in a subset of the *C. pneumoniae* positive patients resulted in a temporary clearance of the infection. Whether chronic infection with *C. pneumoniae* contributes to the pathogenesis of COPD or is a reflection of compromised local immunity warrants further investigation.

Hypersensitivity to bacterial antigens in COPD

Allergic bronchopulmonary aspergillosis is an infectious disease with predominantly allergic manifestations mediated by a Th2 type immune response and characterized by IgE and eosinophil predominance [102]. Persistent infection of the tracheobronchial tree with bacteria is characteristic of COPD, resulting in prolonged contact between the airway lymphoid tissue and bacterial antigens. This could lead to the emergence of IgE antibodies to bacterial antigens, which could induce eosinophil infiltration and mast cell degranulation on repeated exposures to the bacterial antigens. An increased number of eosinophils is a component of airway inflammation in patients with COPD, and tissue and airway lumen eosinophilia becomes more prominent during exacerbations [103].

The ability of bacterial pathogens to induce histamine release, hypersensitivity and IgE-mediated inflammation has been investigated sporadically. Formalin killed suspensions of NTHI and *S. aureus* induced non-IgE-mediated and enhanced IgE-mediated histamine release from human airway mast cells [104]. The enhancement of IgE-mediated histamine release appears to be mediated by the LOS of NTHI [105]. Ahren *et al.* [106] have shown that NTHI interacts with eosinophils through β -glucan receptors and induces an innate inflammatory response.

Patients with acute exacerbations of chronic bronchitis have basophil bound IgE and serum IgE to homologous strains of NTHI and *S. pneumoniae* isolated from sputum with the acute exacerbation [107]. In another study in asthmatics, 29% of patients had serum IgE antibodies to NTHI and/or *S. pneumoniae* [108]. This sensitization to bacterial antigens may contribute to the bronchoconstriction and airway inflammation seen with acute exacerbations of COPD.

These observations regarding histamine release, eosinophil activation and IgE to bacterial antigens suggest that bacterial pathogens, either directly or indirectly via a Th2 type immune response, could contribute to the eosinophilia, airway hyperreactivity and bronchoconstriction seen in patients with COPD.

Childhood lower respiratory tract infection and adult lung function

An association between childhood lower respiratory tract infection and impaired lung function in adulthood was investigated in four studies that reported spirometric lung function in cohorts of adult patients for whom reliable information was available regarding the incidence of lower

Table 36.4 Association of childhood lower respiratory tract infection with lung function in adults. (From Sethi [114] with permission.)

Study	<i>n</i>	Childhood lower respiratory tract infection	Age at follow-up (years)	Effect on FEV ₁
Barker <i>et al.</i> [109]	639 (all male)	Bronchitis or pneumonia in first year	59–67	↓ 200 mL
Shaheen <i>et al.</i> [111]	618	Pneumonia in first 2 years Bronchitis in first 2 years	67–74	↓ 650 mL (in men with pneumonia)

Shaheen <i>et al.</i> [112]	239	Pneumonia in first 14 years Bronchitis in first 14 years	57.6 ± 4.3	↓ 390 mL (with pneumonia in first 2 years) ↓ 130 mL (with bronchitis in first 2 years)

FEV₁, forced expiratory volume in 1 s.

respiratory tract infection (bronchitis, pneumonia, whooping cough) in childhood (less than 14 years of age) (Table 36.4) [109–112]. All four studies have consistently shown a lower forced expiratory volume in 1 s (FEV₁) and often a lower forced vital capacity (FVC) in association with a history of childhood lower respiratory tract infection, after controlling for confounding factors such as tobacco exposure [109–112]. The magnitude of this defect in FEV₁ tends to be greater in older cohorts but is not large enough to cause symptomatic pulmonary disease on its own. However, this defect in FEV₁ could make the individual susceptible to the effects of additional injurious agents that cause COPD. The defect in lung function is not obstructive but is consistent with ‘smaller lungs’, suggesting impaired lung growth.

The association between childhood lower respiratory tract infection and impaired lung function in adulthood could stem from damage to a vulnerable lung undergoing rapid postnatal growth and maturation by the infectious process. If this was the case, then the effect of infection on lung function should be seen only in the first 2 years of life, the major period of postnatal lung growth, and not in later childhood (3–14 years). However, this has not been a consistent observation in the studies to date [109–112]. An alternative explanation for the observed association is that an undetermined genetic factor predisposes these individuals to lower respiratory tract infections in childhood as well as a lower FEV₁ in adulthood. This explanation implies that impaired lung growth antedates the respiratory tract infection, with the infectious episode being a marker of the vulnerability of smaller lungs to infection in childhood.

Although a substantial proportion of childhood respira-

tory infections are viral, bacterial infections, especially with *Streptococcus pneumoniae* and *Haemophilus influenzae*, are common causes of severe pneumonia in children [113]. The aetiology of childhood lower respiratory tract infection was not established in the cohort studies, therefore whether the impact of viral infection differs from bacterial infection is not known. The impact of childhood bacterial lower respiratory tract infection on lung growth and therefore on the development of COPD is likely to be greater in developing countries where such infections are common and often inadequately treated.

Future directions

Substantial new information has emerged regarding the potential pathways by which bacterial infection can contribute to the course of COPD; however, several important questions remain to be answered. The complexity of the host–pathogen interaction that determines the outcome of each encounter between a potential respiratory pathogen and a patient with COPD is being increasingly appreciated. Further studies should try to better understand this interaction. Specifically, the virulence determinants of pathogens that induce host inflammatory responses need to be better understood. There is a large variability in the incidence of exacerbations among patients with COPD. We need to elucidate the host defence factors that protect some of these patients from bacterial exacerbations. In addition, protective host immune response that develops following exacerbations needs to be characterized to facilitate vaccine development. The interplay between different aetiological

factors including the environment, viruses, atypical pathogens and bacteria needs to be better understood in order to improve treatment of exacerbations and develop novel preventive strategies.

Whether the vicious circle of bacterial infection leads to progressive airway obstruction or contributes to the symptoms of COPD has not been determined. Whether tissue infection by pathogens such as NTHI and *C. pneumoniae* contributes to progression of disease or is simply a marker of compromised bacterial clearance and local immunity needs investigation.

COPD is a heterogeneous disease and the role of bacteria and the pathways by which infection contributes to its pathogenesis is likely to vary among subsets of patients with COPD. Regarding bacterial infection as the central mechanism of development of all COPD or dismissing it as an epiphenomenon are unlikely to be correct viewpoints. Most likely, in a subset of patients with COPD, bacterial infection contributes substantially to progression of their disease. Identification of this subset of patients could lead to therapeutic interventions to alter the natural history of their disease.

CHAPTER 37

Genetic factors

Craig P. Hersh and Edwin K. Silverman

In the early 19th century, the American physician James Jackson, Jr. observed that patients with pulmonary emphysema were more likely than healthy individuals to have parents affected with the disease, marking the first description of the hereditary nature of chronic obstructive pulmonary disease (COPD) [1]. Over a century would pass before Laurell and Eriksson discovered α_1 -antitrypsin (AAT) deficiency as a cause of hereditary emphysema [2]. To date, severe AAT deficiency remains the only proven genetic risk factor, yet it accounts for less than 1% of COPD cases worldwide [3]. This chapter details the approaches that have been used to study the genetics of COPD in the vast majority of patients who do not have severe AAT deficiency.

COPD is considered a genetically complex disease; disease inheritance does not follow a simple mendelian pattern. As in other complex diseases, like hypertension and diabetes, family studies have been used to demonstrate familial aggregation of COPD, as well as familial correlations in lung function measures, which are important associated phenotypes. Families have also been used to perform genome-wide linkage analyses, searching for chromosomal regions contributing to COPD and related traits. Finally, case-control studies have examined the association between disease and specific variants in candidate genes.

Similar to other complex human diseases, environmental risk factors have an important role in the development of COPD; these factors are described in Chapters 33 and 34. The critical importance of cigarette smoking as a determinant of COPD requires that any genetic study must consider smoking as a possible modifier of the effects of the genes of interest. The paradigm of gene-environment interaction in COPD, using smoking as a clear and readily quantifiable risk factor, can serve as a model for the study of other complex human diseases, where the environmental exposures may be more difficult to measure.

α_1 -Antitrypsin deficiency

Severe AAT deficiency is the only proven genetic risk factor for COPD and is reviewed in detail in Chapter 38. Severe AAT deficiency is usually brought about by homozygosity for the mutant Z allele (protease inhibitor [PI] ZZ), and the development of lung and liver disease appears to follow an autosomal recessive inheritance pattern. There are estimated to be 70 000–100 000 severely AAT-deficient individuals in the USA and a similar number in Europe [4]. Although an important cause of COPD in affected individuals, severe AAT deficiency accounts for only a small fraction of COPD cases worldwide. The risk of COPD in the carriers of a Z allele (e.g. PI MZ) or other variants of the AAT gene is discussed below.

Severe AAT deficiency is classically associated with early-onset COPD, yet many individuals with severe AAT deficiency have normal lung function; the method of subject ascertainment and the history of cigarette smoking can modify the likelihood of COPD development [5]. Severe AAT deficiency provides an instructive model of gene-environment interaction that can be applied to the study of other COPD candidate genes [6]. In addition, other genes are likely to contribute to the development of airflow obstruction in individuals with severe AAT deficiency. Discovery of these modifier genes may lead to insight into the genetics of COPD in the majority of individuals who do not have severe AAT deficiency.

Familial aggregation

The hallmark of any inherited disease is clustering within families, and demonstration of familial aggregation is the necessary first step in the genetic analysis of a complex trait. However, familial similarities may be the result of genetics

or shared environmental exposures, or both. Twin studies can be used to separate these two types of effects. If a trait is more correlated within pairs of monozygotic twins, who share all of their genes, than within pairs of dizygotic twins, who usually share a similar environment but only half of their genes, then a genetic influence is likely. Such twin studies have been used to demonstrate a genetic contribution to pulmonary function measures [7,8]. Genetic effects on pulmonary function measures have also been shown in a study of monozygotic twins raised apart, thereby eliminating the shared environment, and in studies of first-degree relatives (nuclear families or sib-pairs); statistical models must be used to estimate familial correlations and to adjust for common environmental exposures in the latter design [9–12].

Familial correlation has been examined for the rate of lung function decline, a different phenotype than the cross-sectional lung function measures, such as forced expiratory volume at 1 s (FEV_1) or forced vital capacity (FVC), that were analysed in previous studies [13]. Gottlieb *et al.* [13] used baseline and follow-up spirometry data from both the original Framingham Heart Study cohort as well as their offspring. They demonstrated significant heritability of the rate of decline in lung function. Genetic factors accounted for 5, 18 and 13% of the population variation in decline in FEV_1 , FVC and $FEV_1:FVC$ ratio, respectively. These heritability estimates were higher in smokers (18, 39 and 14%) suggesting a gene–environment interaction effect.

In the early 1960s, several case reports were published that described families with multiple members affected by COPD [14–16]. Case reports of COPD in twins have been published, but formal twin studies have not been performed [17]. Family studies have shown that both airflow obstruction and chronic bronchitis are more common in first-degree relatives of individuals with COPD than in the general population, even after adjustment for smoking status [18–23].

In the Boston Early-Onset COPD Study, Silverman *et al.* [24] collected data on families ascertained through a proband with severe early-onset COPD, based on the hypothesis that severe early-onset disease is more likely to have genetic influences than later-onset disease. Proband had an FEV_1 less than 40% of predicted, were younger than 53 years old and did not have severe AAT deficiency (e.g. PI Z, PI null–null). All available first-degree relatives, older second-degree relatives (aunts, uncles and grandparents) and spouses were invited to enrol. Participants completed a protocol that included a respiratory questionnaire, spirometry (pre- and postbronchodilator) and a blood draw. Compared with community controls, first-degree relatives of early-onset COPD probands had significantly increased risks of reduced FEV_1 and chronic bronchitis. This was especially prominent in current or ex-smoking first-degree

relatives, with odds ratios (OR) of 4.5 (95% confidence interval [CI], 1.8–11.5) for an FEV_1 of less than 80% predicted and 3.6 (95% CI, 1.1–11.5) for chronic bronchitis [24]. Greater bronchodilator responsiveness was also found in current and ex-smoking first-degree relatives of early-onset COPD probands, compared with current and ex-smoking controls [25]. Further analysis has shown that female first-degree relatives (current and ex-smokers) have an increased risk for reduced FEV_1 and greater bronchodilator responsiveness compared with male first-degree relatives [26].

In a study conducted in the UK, McCloskey *et al.* [27] examined siblings of probands that had been selected with airflow obstruction and a low gas transfer factor, indicative of emphysema. The probands had severe COPD, although the FEV_1 thresholds for inclusion varied by age, from an FEV_1 of less than 60% of predicted for subjects 55 years of age or younger to an FEV_1 of less than 20% of predicted for subjects 61–65 years of age. They found an increased risk of COPD in current or ex-smoking siblings of probands compared with matched controls (OR = 4.7; 95% CI, 2.6–8.4); the odds ratio was even higher in current or ex-smoking siblings with less than a 30 pack-year smoking history. Non-smoking siblings were found to have normal spirometry. The probands recruited by McCloskey *et al.* did not show the female predominance that was seen by Silverman *et al.* [26].

Linkage analysis

In addition to determining familial aggregation of a trait, family studies can be used for linkage analysis. In this method, a panel of DNA-based polymorphic markers, usually consisting of short tandem repeat (STR) markers, is genotyped across the genome in order to determine which chromosomal locations co-segregate with the trait of interest. These markers are usually in non-coding regions, so they do not typically identify specific genes for the disease; rather they mark areas of the genome that are linked to the disease trait. Statistically, this is expressed as a LOD score, which represents the logarithm (\log_{10}) of the odds of linkage. Investigators can then focus their search using association studies of biologically plausible genes located in the region of linkage (positional candidate genes) or systematically genotype markers for association at narrow intervals across the linked region (fine mapping).

Using the Boston Early-Onset COPD Study families, Silverman *et al.* [28,29] performed linkage analyses for both qualitative and quantitative COPD-related phenotypes. Using prebronchodilator spirometry, modest evidence for linkage was found on chromosomes 12 and 19 for moderate airflow obstruction (defined as FEV_1 less than 60%

Phenotype	Chromosome	Maximum LOD score*	
		Prebronchodilator	Postbronchodilator
FEV_1	1	1.24	2.24
	8	1.58	3.30
	12	1.66	1.33
	19	1.80	1.94
FEV_1/FVC	1	1.89	2.52
	2	4.05	4.42
	17	2.35	2.44

FEV₁, forced expiratory volume in 1 s; *FVC*, forced vital capacity; LOD, logarithm of the odds.
* In extended pedigrees, LOD scores ≥ 1.9 provide evidence of suggestive linkage, and LOD scores ≥ 3.3 provide evidence of significant linkage [30].

Table 37.1 Results of linkage analyses of pre- and postbronchodilator spirometry in severe early-onset COPD families [31].

predicted with $FEV_1 : FVC$ less than 90% predicted), on chromosomes 8 and 19 for mild airflow obstruction (defined as FEV_1 less than 80% predicted with $FEV_1 : FVC$ less than 90% predicted) and on chromosomes 19 and 22 for chronic bronchitis. Restricting the analysis to smokers only increased the strength of the linkage evidence in several genomic regions. Using quantitative prebronchodilator spirometric phenotypes, more impressive evidence for linkage was demonstrated. Significant evidence for linkage to $FEV_1 : FVC$ was found on chromosome 2q; suggestive evidence for linkage to $FEV_1 : FVC$ on chromosomes 1 and 17 and to *FVC* on chromosome 1 was also demonstrated [30]. Additional markers were genotyped on chromosome 12p, providing suggestive evidence for linkage of FEV_1 to this region.

In addition, postbronchodilator spirometric measures and bronchodilator responsiveness phenotypes were assessed for linkage [31]. Significant evidence of linkage for postbronchodilator FEV_1 was found on chromosome 8p, with a LOD score of 3.30, which represented a doubling of the LOD score for prebronchodilator FEV_1 (Table 37.1). Significant linkage for postbronchodilator $FEV_1 : FVC$ was found on chromosome 2q (LOD score = 4.42). Regions on chromosomes 3 and 4 showed modest evidence for linkage to measures of bronchodilator responsiveness.

Several linkage studies of pulmonary function measures in non-diseased subjects have been reported. Using families from the Framingham Study, Joost *et al.* [32] found suggestive evidence for linkage of FEV_1 on chromosome 6 and of *FVC* on chromosome 21. In a genome scan of families in the National Heart, Lung and Blood Institute Family Heart Study, Wilk *et al.* [33] found suggestive evidence for linkage of $FEV_1 : FVC$ ratio on chromosome 4 and of both FEV_1 and *FVC* on two distinct regions on chromosome 18. This study was unable to replicate the findings of Joost *et al.*, but a region of linkage to $FEV_1 : FVC$ ratio on chromosome 1 was

found that was similar to the results in the Boston Early-Onset COPD Study families, although the LOD scores were modest in both studies.

Malhotra *et al.* [34] analysed 264 members of 26 families in Utah, which had been collected as part of the Centre d'Etude du Polymorphisme Humain (CEPH) genetic mapping project. They found suggestive evidence of linkage for $FEV_1 : FVC$ on chromosome 2 (LOD score = 2.36), which corresponded to the region of significant linkage found by Silverman *et al.* [29]. Suggestive linkage for $FEV_1 : FVC$ ratio was also seen on chromosome 5 (LOD = 2.23), replicating a result from a previous study by Ober *et al.* [35] conducted in the isolated population of Hutterites in South Dakota. The validation of previous results in another population by Malhotra *et al.* marks an important step in the study of the genetics of COPD. However, the varying results of the other previous studies do not necessarily make their results less important. The differences in linkage results could relate to differences in study design and subject ascertainment; Silverman *et al.* analysed linkage for disease phenotypes, while the other groups examined linkage for lung function in families from the general population.

Association studies

Most studies of the genetic epidemiology of COPD have been association studies. As is the case for many other complex diseases, the majority of association studies in COPD genetics have utilized the case-control design. To perform an association study, a plausible candidate gene is identified, using prior knowledge of the biology of the disease. Genetic variants, usually single nucleotide polymorphisms (SNPs), are genotyped in the candidate gene, and frequencies of these variants are compared with individuals affected by the disease (cases) and unaffected

controls. A positive association does not necessarily imply that the variant is functional (i.e. disease-causing); it may be in close genetic proximity (linkage disequilibrium) to the functional variant. Spurious association may also be found because of confounding by ethnic differences between cases and controls, known as population stratification.

Some of the candidate genes that have been associated with COPD in case–control studies are listed in Table 37.2. These candidate genes can be divided into groups, based on pathophysiological mechanisms implicated in COPD [3]. Important pathways include: proteases and protease inhibitors, genes involved in oxidant–antioxidant balance and xenobiotic metabolism, and inflammatory mediators. Association studies of genes in each of these pathways are discussed.

Proteases and antiproteases

α_1 -Antitrypsin

Since the discovery of severe AAT deficiency as a rare cause of COPD, many studies have examined the risk associated with the more common heterozygous types. Three different

methodologies have been used to assess the risk of COPD in PI MZ heterozygotes, and the results have been inconsistent. Case–control studies have tended to find a moderately increased risk for COPD in PI MZ subjects [21,36–40]. Other investigators have used a population-based design, measuring lung function and AAT type in a community sample. Two large studies of 500 subjects in Rochester, New York and of 2944 subjects in Tucson, Arizona have shown no difference in lung function between PI MZ heterozygotes and normal individuals [41,42].

Several studies have used a longitudinal design to test whether the rate of lung function decline varies across PI phenotypes. In a population-based cohort of over 9000 adults in Copenhagen, Dahl *et al.* [43] found a slightly increased rate of decline in FEV_1 in PI MZ heterozygotes compared with PI MM individuals (25 vs. 21 mL/year; $P = 0.048$).

Sandford *et al.* [44] examined PI MZ heterozygotes in the National Heart, Lung and Blood Institute sponsored Lung Health Study (LHS) population. The LHS recruited 5887 smokers, aged 35–60 years, with mild airflow obstruction on spirometry. They were followed over 5 years to examine the effects of smoking cessation intervention and ipratropium bromide on decline in lung function [45]. From this cohort, Sandford *et al.* [44] identified 283 individuals with rapid decline in lung function ($\Delta FEV_1 = -154 \pm 3$ mL/year) and 308 individuals with no decline ($\Delta FEV_1 = +15 \pm 2$ mL/year); these two groups were used as cases and controls, respectively. Using this approach, they found PI MZ heterozygosity to be more common among the rapid decliners than the non-decliners; the association was stronger in the subjects with a family history of COPD.

Silva *et al.* [46] analysed the relationship between PI phenotype and decline in lung function in a community sample in Tucson. The study included over 2000 randomly sampled white individuals who were followed for an average of 15 years; more than half of the participants were current or former smokers. They found no differences in the rate of decline in FEV_1 between the PI phenotypes. In addition, PI MZ heterozygotes were not found to be more common among individuals with a rapid rate of FEV_1 decline compared with those with a slow decline, categories similar to those used in the Sandford *et al.* [44] paper. The inconsistent results across different studies of PI MZ heterozygotes, which have been performed in different populations and which have employed different study designs, may indicate that only a subgroup of PI MZ individuals are at an increased risk of developing COPD.

A polymorphism in the 3' region of the PI gene has also been identified; this variant does not appear to affect serum AAT levels. Some studies have found this SNP to be associated with COPD [47,48]; studies in other populations have found no evidence of association [44,49,50].

α_1 -Antichymotrypsin

α_1 -Antichymotrypsin (AACT) is another serine protease inhibitor, located in close proximity to the AAT gene. Poller *et al.* [51] described one mutation associated with decreased AACT levels (Pro229Ala) and another that caused a dysfunctional protein (Leu55Pro); both of these mutations were associated with COPD. However, these findings could not be replicated in other populations [49,52,53]. Ishii *et al.* [53] found a polymorphism in the signal peptide (Ala15Thr) to be associated with COPD. As AACT levels were not affected, this is unlikely to be the causative mutation; it may be in linkage disequilibrium with a functional variant. Another study did not find evidence of this association [49].

Matrix metalloproteinases

Mouse models and human experiments have pointed to a role for the matrix metalloproteinases (MMPs) and tissue inhibitors of metalloproteinases (TIMPs) in the development of emphysema [54–56]. A functional polymorphism has been identified in the promoter of MMP-9 (C-1562T) [57]. Among 110 Japanese smokers, the –1562T allele was associated with the presence of emphysema on computed tomography (CT) scan (OR = 2.69; $P = 0.02$) [57]. Joos *et al.* [58] examined MMP polymorphisms in the subjects in the LHS with the fastest and slowest rates of decline in FEV_1 . They found the MMP-1 G-1607GG polymorphism to be associated with a fast rate of decline ($P = 0.02$). In addition, haplotypes consisting of the MMP-1 G-1607GG and the MMP-12 Asn357Ser alleles were strongly predictive of rapid decline ($P = 0.0007$). An additional SNP in MMP12 and two MMP-9 polymorphisms were not associated with pulmonary function decline.

Two variants were discovered in tissue inhibitor of metalloproteinases-2 (TIMP-2) in 88 Japanese COPD patients and 40 smoking controls [59]. The allele frequency of a silent variant in exon 3 was significantly higher in COPD cases ($P < 0.0001$). A variant in the promoter region showed a borderline association ($P = 0.049$).

Antioxidants and xenobiotic metabolizing enzymes

Heme oxygenase-1

Cigarette smoke contains reactive oxygen species (ROS) that may contribute to COPD through direct injury to lung tissues, oxidation of antiproteases or up-regulation of inflammatory genes [60]. Heme oxygenase-1 (HMOX1), which degrades heme to biliverdin, is important for pro-

tection against heme- and non-heme-mediated oxidant stress in the lung [61]. Yamada *et al.* [62] genotyped a dinucleotide (GT)_n repeat in the promoter region and found a greater number of long repeat alleles in smokers with emphysema compared with smokers without emphysema (OR = 2.4). *In vitro* studies revealed that increased size of the (GT)_n repeat might reduce HMOX1 inducibility by ROS, suggesting a functional mechanism for this polymorphism. However, no association between the number of HMOX1 (GT)_n repeats and rate of decline in lung function was found in the LHS population [63].

Microsomal epoxide hydrolase

Microsomal epoxide hydrolase (EPHX1) is involved in the first-pass metabolism of highly reactive epoxide intermediates, such as those found in cigarette smoke. Polymorphisms in exon 3 (Tyr113His) and exon 4 (His139Arg) have been suggested to decrease (slow allele) or increase (fast allele) enzyme activity, respectively [64]. Smith and Harrison [65] found increased proportions of homozygous slow individuals in groups of patients with clinically diagnosed COPD or pathologically confirmed emphysema compared with control blood donors; however, they also found the fast allele to be more frequent among COPD cases than controls. Sandford *et al.* [44] found a higher frequency of homozygous slow individuals among the rapid decliners compared with the non-decliners in the LHS (OR = 2.4). The effect was stronger in those with a family history of COPD.

In a study of 180 former workers in a Japanese poison gas factory, Yoshikawa *et al.* [66] found no difference in either slow or fast allele EPHX1 frequencies between individuals with and without COPD. However, the slow allele appeared to be associated with the severity of COPD. Studies in two other populations failed to find associations between either EPHX1 polymorphism and the risk of COPD [67,68].

Glutathione S-transferases (M1, P1, T1)

The glutathione S-transferases (GST) are a family of enzymes that are important in the detoxification of hydrophobic and electrophilic compounds, including polycyclic aromatic hydrocarbons found in cigarette smoke. Homozygous deletion of the GST M1 gene can be found in up to 50% of some populations [69]. In a French population, homozygous GST M1 deficiency was more common in individuals with chronic bronchitic with either moderate or severe obstructive lung disease, compared with control smokers [70]. In 168 British patients undergoing surgery for lung cancer, the frequency of GST M1 deletion was higher in those with pathological evidence of emphysema compared with blood

donor controls; there was no difference in frequency of the deletion in those with lung cancer only, compared with controls [71]. No association between GST M1 deletion and COPD was found in a Korean population [67].

The GST P1 gene has been found to have greater expression in alveoli, alveolar macrophages and respiratory bronchioles, compared with GST M genes [72]. An exon 5 polymorphism (Ile105Val) in GST P1 has been shown to confer increased activity towards certain substrates [73]. In a study of Japanese men, homozygosity for the wild type GST P1 allele was found more frequently in COPD cases than in smoking controls (OR = 3.5) [74]. This result could not be replicated in a Korean population [75]. In addition, no association was seen between deletion of the GST T1 gene and COPD in the same Korean population [67]. In the LHS subjects, the polymorphisms in GST M1, P1 and T1 were not associated with the rate of lung function decline, when each variant was analysed individually [63]. When all three GST polymorphisms were present, there was a borderline association ($P = 0.03$); the authors

note that this may represent type 1 error resulting from the multiple comparisons performed.

Inflammatory cytokines

Tumour necrosis factor α (TNF) is a proinflammatory cytokine that is found in high concentrations in the sputum of COPD patients [76]. A polymorphism at position -308 in the promoter region (TNF1/2) has been described, with increased gene expression *in vitro* resulting from the TNF*2 minor allele [77]. Multiple COPD association studies have been reported, with conflicting results (Table 37.3). Huang *et al.* [78] found a higher frequency of the TNF*2 allele in 42 Taiwanese men with chronic bronchitis compared with matched controls (OR = 11.1) and compared with a second control group that included a population sample of schoolchildren. In a Japanese study, the TNF*2 allele was more frequent in 106 COPD patients than in smoking controls or blood donors [79]. The same authors found a

Table 37.3 Case definitions used in association studies of the tumour necrosis factor α (TNF) -308 polymorphism and COPD [44,78-81,83-86].

Study	Country	Diagnosis	Spirometry	Other criteria

trend towards association between the TNF*2 allele and low attenuation areas on high-resolution computed tomography (HRCT) scans of COPD patients [80]. Other studies in Caucasian [81–85] and Japanese [86] populations have failed to observe an association between this TNF promoter polymorphism and COPD. This polymorphism was not associated with lung function decline in the LHS [44]. However, one group did find that COPD patients homozygous for the TNF*2 allele had less reversible airflow obstruction and greater mortality over 2-year follow-up [82]. No associations have been found between a polymorphism in the lymphotoxin- α gene (also known as TNF- β) and COPD or lung function decline [44,83,84].

In a mouse model, inducible overexpression of the cytokine interleukin 13 caused emphysema, mucus metaplasia and inflammation; this phenotype is similar to changes seen in human COPD [87]. Two polymorphisms in IL-13 have been associated with asthma in prior studies [88]. In the LHS population, these two polymorphisms (Arg130Gln, C-1112T) were not associated with rate of lung function decline [89]. However, the IL-13 promoter polymorphism C-1055T (referred to as C-1112T in the previous reference) was found more frequently in COPD patients compared with both smoking ($P = 0.01$) and healthy population ($P = 0.002$) controls in a Dutch study [90].

Other candidate genes

Vitamin D binding protein, also known as group-specific component (GC), has three major serum isotypes (1F, 1S, 2), based on two separate point mutations. It has long been considered a candidate gene for COPD, based on its role in C5a-mediated neutrophil chemotaxis. In 114 matched pairs of COPD patients and controls, Kueppers *et al.* [21] found that homozygosity for Gc-2 allele was protective against COPD ($P = 0.049$). Horne *et al.* [91] observed that even a single Gc-2 allele was protective, and that homozygous Gc-1F individuals were at increased risk of COPD (OR = 7.1). In a study of patients referred for lung cancer surgery, Schellenberg *et al.* [92] found Gc-2 homozygous individuals to be more common among those without airflow obstruction compared with those with obstruction. There was no difference in neutrophil chemotaxis by genotype, suggesting that the protective effect was mediated through a different mechanism. A Japanese study could not replicate the protective effect of the Gc-2 allele, but found the risk of COPD to be increased in Gc-1F homozygotes [93]. However, two other studies failed to find an association between GC variants and lung function [44,94].

Other candidate genes have been shown to be associated with COPD or related phenotypes in single case-control

studies (see Table 37.2). It remains to be seen whether these results can be replicated in other populations.

Interpretation of association studies

For most of the candidate gene variants that have been associated with COPD, subsequent studies have often been unable to replicate the positive associations found in the initial study. This lack of consistency is not unique to the study of COPD; it is a problem throughout the field of genetic epidemiology [95,96]. The reasons for this are multiple. One problem is the varied case definitions used in studies of COPD, an inherently heterogeneous disorder. Table 37.3 highlights the different phenotypes used in studies of the TNF -308 polymorphism, as an example. Different authors included or excluded cases with chronic bronchitis or with asthma-related phenotypes, such as bronchodilator responsiveness. If a gene were important in one particular phenotype, such as chronic bronchitis, then this association might be easily missed. In addition, varying thresholds for defining airflow obstruction in COPD cases have been used, which could also contribute to the inconsistent results.

Many of the reported case-control association studies suffer from small sample sizes. High-throughput genotyping technologies have served to reduce costs and should allow for increasingly larger studies [97]. Publication bias is common throughout biomedical research, and it may be even more pronounced in genetic studies [95]. Failure to replicate findings in different studies may also represent true differences in the genetic determinants of disease in different populations, referred to as genetic heterogeneity.

Case-control association studies can be subject to false-positive results because of differences in ethnicity – whether obvious or not – between cases and controls; this is known as population stratification. Statistical techniques are available to test for population stratification in association studies [98], although few authors have performed these tests on a routine basis. Using family-based methods for association studies avoids the potential problem of spurious results brought about by population stratification [99]. Use of this design is increasing in the study of COPD genetics. The potential problems with case-control association studies, as well as a strategy for evaluating these studies, have been reviewed by Silverman and Palmer [100].

Conclusions and future directions

Multiple studies have demonstrated that hereditary factors are important in the development of COPD, but severe AAT deficiency remains the only proven genetic risk factor.

Several interesting associations to biologically plausible candidate genes have been found, but these results have not been consistently replicated in other populations. Family-based linkage studies have identified chromosomal regions where susceptibility genes for COPD are likely to reside, but further work will be necessary to identify the relevant genes, as well as the functional variants within those genes.

Mouse models have been used to identify genes potentially involved in the development of human emphysema, and future animal studies will continue to further our understanding of COPD pathogenesis and uncover candidate genes that can then be studied in human populations. Gene expression profiling using microarray technology is another promising tool in the identification of genetic risk factors for COPD [101]. Clearly, further research is necessary to identify the genetic variants that lead to an increased risk of COPD in the majority of individuals without severe AAT deficiency.

CHAPTER 38

α_1 -Antitrypsin deficiency

Loutfi S. Aboussouan and James K. Stoller

α_1 -Antitrypsin (AAT) deficiency is a common but under-recognized condition. In this chapter, we first review the history of AAT deficiency, and then discuss the epidemiology, clinical features and treatment, including augmentation therapy and emerging therapies.

History

AAT deficiency was first described in 1963 when Laurell and Eriksson found that the electrophoretic patterns of stored serum specimens of some patients with emphysema were lacking α_1 bands [1]. Eriksson [2] subsequently described the heritability of emphysema in such individuals in 1964 and some salient clinical features, including bibilar distribution and premature onset [3].

Significant progress ensued in elucidating the pathogenetic mechanisms of this disease. Experimental emphysema was produced in rats using the plant protease papain [4,5] and Kueppers and Bearn [6] demonstrated the ability of AAT to inhibit proteases. These findings provided an experimental basis for the association between AAT deficiency and the development of emphysema [6], and laid the groundwork for the protease-antiprotease hypothesis of emphysema [7].

The subsequent discovery of neutrophil elastase by Aaron Janoff in 1968 [8] and recognition of the high affinity of neutrophil elastase for AAT [9] established neutrophil elastase rather than trypsin as the natural substrate of AAT. Nevertheless, the original name of AAT deficiency has persisted. Studies by Senior *et al.* [10] in 1977 found that neutrophil elastase could likewise induce emphysema, albeit of a milder form compared with that produced by pancreatic elastase [10,11].

Progress in molecular biology led to key advances, including the sequencing of the AAT protein in 1984 [12], identification of the gene on chromosome 14 [13] and

recognition of several clinically relevant variants [13]. While AAT deficiency was recognized in 1969 as a cause of liver storage disease and cirrhosis [14], understanding the mechanism of impaired secretion of the Z-type protein and intrahepatocyte accumulation awaited the elucidation of loop-sheet polymerization by Lomas *et al.* [15] in 1992.

Clinical advances have included the use of purified AAT derived from pooled human plasma for exogenous administration [16], the establishment of important registries, including the National Heart, Lung and Blood Institute (NHLBI) sponsored Registry for Individuals with Severe AAT Deficiency from 1988 to 1996 [17], the patientsponsored Alpha-1 Foundation Research Registry in 1997 [18], and the Alpha-One International Registry (AIR) in 1996.

Epidemiology of AAT deficiency

A review of the epidemiology of AAT deficiency provides two major insights:

- 1 AAT deficiency is common; and
- 2 AAT deficiency is under-recognized by clinicians, causing significant adverse effects.

With regard to the frequency of AAT deficiency, estimates have been undertaken in several ways: an indirect epidemiological approach based on estimates of emphysema prevalence, an indirect analysis of genetic epidemiological surveys and a direct population-based screening approach.

To assess the frequency of AAT deficiency in the USA using indirect means, the National Health Information Survey estimates that 3.2 million Americans have emphysema [19]. Results of a study by Lieberman *et al.* [20] in which 965 patients in the COPD clinic of the Sepulveda Veterans Administration Hospital show that 1.9% had emphysema on the basis of severe deficiency of AAT. Applying this prevalence estimate to the estimated number

Table 38.1 Prevalence estimates of severe α_1 -antitrypsin (AAT) deficiency (PI*ZZ and/or PI*Znull) in selected population screening studies.

First author [Ref.]	Years	Location of study	Subject population	Number with severe AAT deficiency/number screened	Prevalence of severe AAT deficiency (%)
Sveger [26]	1972–74	Sweden	Newborns	122/200 000	1/1639 (0.061)
O'Brien [23]	1971–74	Oregon	Newborns	21/107 038	1/5097 (0.0196)
Silverman [24]	1987	St. Louis	Blood donors	7/20 000	1/2857 (0.035)
Spence [25]	1993	New York state	Newborns	3/11 081	1/3694 (0.0271)

of Americans with emphysema suggests that approximately 61 000 Americans have symptomatic COPD on the basis of severe AAT deficiency.

Another approach uses published genetic epidemiological surveys to estimate the PI*Z mean gene frequency in a given population, and then extrapolates to the population at risk for the PI*ZZ allele combination. For the USA, this approach estimates the population at risk for PI*ZZ to be 47 321 [21], although weighed estimates adjusting for the different ethnic subgroups of the US population suggest a higher number of 59 047 [22].

Although derived differently, these estimates agree closely with prevalence estimates that come from direct population-based screening studies. Of the several population-based screening studies performed (Table 38.1) [23–26], the two largest have involved the screening of 200 000 newborns in Sweden [26] and 107 038 newborns in Oregon [23]. In the Swedish screening study, the frequency of PI*Z individuals was found to be 122/200 000, or 1 in 1639. In the Oregon screening experience, the frequency of PI*ZZ individuals was approximately threefold lower at 1 in 5097. Combining the three US studies [23–25] yields a frequency of 1 in 4455. Applying this estimate to the 2000 US population of 281 000 000 [27] suggests that the number of PI*ZZ individuals in the USA today is 63 000, of whom most can be expected to develop emphysema [28–30]. In this regard, the prevalence of severe AAT deficiency approximates that of another common genetic pulmonary condition, cystic fibrosis, the frequency of which has been estimated to be 1 in 11 000 [31].

In the context that AAT deficiency is common, the question naturally arises as to why so few AAT deficient patients are known to the medical community. Indeed, recent estimates of the number of AAT deficient individuals currently receiving intravenous augmentation therapy with pooled human plasma AAT are fewer than 10 000 and large central laboratories for testing for AAT deficiency suggest a ceiling estimate of 14 000 severely deficient individuals (E. Campbell, personal communication).

Studies addressing the frequency of AAT deficient individuals show that individuals with severe AAT deficiency

often escape medical detection. For example, in a study of the frequency of severe deficiency of AAT in St. Louis, Silverman *et al.* [24] sampled 20 000 blood specimens donated to the St. Louis blood bank, among which seven individuals with PI*ZZ AAT deficiency were found. Reasoning that blood donation neither selected for nor against having severe AAT deficiency, these investigators suggested that this prevalence among blood donors predicted 700 PI*ZZ individuals in St. Louis with a population of 2 million at the time of the study. Yet, when these investigators attempted to identify all known PI*ZZ individuals by contacting pulmonary physicians in St. Louis, only 28 PI*ZZ patients could be detected (4% of the expected population of 700), suggesting that the majority of AAT deficient individuals in St. Louis at that time were unrecognized by the medical community. Similar findings regarding frequent under-recognition were reported by Tobin *et al.* [30] in a British Thoracic Association survey of all PI*Z samples at two specialized laboratories in England, suggesting that only 4.5% of British PI*Z subjects had been detected by 1980.

Finally, that under-recognition occurs frequently and confers adverse psychological effects has been demonstrated by Stoller *et al.* [32] in a 1992 survey of 300 self-reported PI*ZZ individuals. When given a questionnaire addressing the number of physicians seen for attributable symptoms and the mean interval between the first AAT deficiency-related symptom, the group reported an average delay between first symptom and initial diagnosis of AAT deficiency of 7.2 (\pm 8.3) years. Furthermore, 44% of these respondents reported having to see at least three physicians with attributable symptoms before the initial diagnosis of severe AAT deficiency was made [32]. More recent estimates confirm this long diagnostic delay and under-recognition. In a survey of 974 individuals mostly receiving augmentation therapy at home, Campos, Sandhaus and Wanner (R.A. Sandhaus, personal communication) observed that the mean interval between first symptom and initial diagnosis was 7.8 \pm 9.2 years and that 34.6% reported seeing at least three physicians before the diagnosis of AAT deficiency was made.

That adverse events result from the delayed diagnosis of AAT deficiency has been suggested by Stoller *et al.* [32]. For example, the mean number of adverse psychosocial effects correlated weakly but significantly with the number of doctors seen before initial diagnosis (Spearman's $\rho = 0.20$; $P = 0.005$), although no correlation of adverse effects was observed with the interval between the first attributable symptom and initial diagnosis (Spearman's $\rho = 0.05$; $P = 0.43$) [32].

Pathophysiology and genetics of AAT deficiency

Loop-sheet polymerization

AAT is the prototypic member of the *serine protease inhibitor* (serpin) superfamily of proteins that have a major role in diverse biological pathways [33]. The characterization of loop-sheet polymerization as the molecular defect underlying AAT deficiency has not only helped clarify the pathogenesis of the associated liver disease, but has also allowed expansion of this model to the pathobiology of other serpinopathies. For instance, mutations and loop-sheet polymerization of other serpins such as antithrombin, C1 inhibitor, and neuroserpins cause thrombosis, angioedema, and inclusion body dementia, respectively [33–35]. This model has been further applied to elucidate other mechanisms of diseases such as Alzheimer's disease, amyloidosis, Huntington's disease and the prion encephalopathies, thereby spanning the gamut of acquired, genetic and 'infectious' diseases [36].

Underlying this susceptibility of serpins to mutations and polymerization is instability of their β -sheet structure

(Fig. 38.1) [37]. In the most common allele associated with severe deficiency, PI*ZZ AAT deficiency, a single substitution of lysine for glutamic acid at position 342 widens the β -sheet and allows partial insertion of the reactive site loop into the gap to create an intermediate and unstable monomeric form (see Fig. 38.1) [38]. The β -sheet can then either accept its own loop and form a latent form, or the loop of an adjacent molecule and form a dimer (see Fig. 38.1) [38]. The dimer stabilizes, increases its β -sheet and proceeds to polymerization in an irreversible process (see Fig. 38.1) [39]. This process is in equilibrium, with approximately 15% of Z antitrypsin secreted into the plasma as monomers [15,33]. Although the Z molecule may polymerize spontaneously, factors that increase the likelihood of polymerization include increase in temperature and in Z antitrypsin concentration [15], and possibly a decrease in pH [39].

Mechanism for the development of emphysema

Neutrophils are present in the lower respiratory tract and provide a chronic low-level burden of neutrophil elastase [40]. Despite its name, AAT reacts with neutrophil elastase much more avidly than with trypsin in a mutually suicidal interaction [41,42]. AAT is produced in the liver and reaches the lungs by diffusion from the circulation and by local production in macrophages and bronchial epithelial cells [33,43]. In the normal state, there is an excess of AAT in the lung, thereby providing an adequate protective screen against the elastolytic effect of neutrophil elastase [28].

In PI*ZZ individuals, the protease–antiprotease concept posits an imbalance between the AAT protective screen and the neutrophil elastase burden, with consequent unchecked proteolytic activity leading to emphysema [7].

Figure 38.1 Structure of α_1 -antitrypsin and mechanism of polymerization. A substitution of lysine for glutamic acid at position 342 (arrow) widens the β -sheet A (circle) and results in the formation of an unstable intermediate monomer (M^*). The gap in the β -sheet A can either accept its own loop to form a latent conformation (L), or form a dimer by accepting the loop of another α_1 -antitrypsin molecule (D). The dimer proceeds to polymerization in an irreversible process (P). (From Lomas and Mahadeva [33] with permission.)

This imbalance results in large part from low serum levels of AAT because of retention of polymers in the endoplasmic reticulum of liver cells [15]. Also, the Z-type antitrypsin is about five times less effective than normal antitrypsin as an inhibitor of neutrophil elastase [44]. Lastly, Z-type antitrypsin has been identified in the lung as loop-sheet polymers that are not only functionally inactive against neutrophil elastase [45], but also chemoattractants for human neutrophils [46].

Indirectly, unchecked neutrophil elastase in AAT deficiency may promote a positive feedback loop by stimulating macrophages to release leukotriene B₄, itself a potential mediator of neutrophil chemotaxis [47,48]. AAT can also act as modulator of the inflammatory response by inhibiting other chemotactic factors such as C3a and C5a [49].

Mechanism of liver disease

Based on the link between temperature and polymerization, febrile episodes were initially proposed as the explanation for the phenotypic variability of liver disease in PI*ZZ individuals [15], although clinical considerations make this is an unlikely mechanism [50]. Rather, a lag in intracellular degradation of Z-type protein correlates with the expression of liver disease in PI*ZZ individuals [51]. Polymers of Z-type protein have been identified on electron microscopy as inclusions within the endoplasmic reticulum of the liver [15], and account for the periodic acid–Schiff stain positivity and diastase-resistant material on liver biopsies of affected individuals. Retention of the mutant Z molecules in the endoplasmic reticulum appears to have a key role in the development of liver disease and may be caused by an impaired interaction between Z-type protein and its molecular chaperone, calnexin [52]. The precise mechanism by which the intrahepatocyte accumulation of unsecreted AAT causes liver disease remains elusive.

Clinical features and diagnosis of AAT deficiency

Lung disease

Emphysema

Although the precise degree of risk is unknown, individuals homozygous for the Z allele are considered to be at high risk for developing emphysema. Differentiating features of this type of emphysema include a more likely occurrence at an early age (i.e. less than 50 years), a panacinar pathology and basilar distribution [53,54]. Studies may be biased towards overestimating the risk of emphysema in AAT deficiency because most patients are ascertained on the basis of pulmonary symptoms. In a survey from the British

Thoracic Association, Tobin *et al.* [30] sought to determine the risk of developing emphysema by identifying PI*ZZ in siblings of their index cases, thereby partially removing the bias of selection based on attendance at a chest clinic. Radiographically confirmed emphysema was present in 87% of all PI*ZZ subjects, 91% of the index cases and 73% of the non-index cases [30]. Ninety per cent of PI*ZZ smokers had emphysema, compared with 65% of non-smokers [30]. Additionally, abnormalities of lung function were reported in the majority of individuals without radiographical changes [30]. These data closely agree with those of the Swedish National Registry, in which only 29% of the participants were identified because of lung disease, indicating that in adult PIZ homozygotes, 29% of never-smokers and 10% of ever-smokers were healthy, with the majority of the remainder identified as having lung disease [28]. Lastly, postmortem series from Malmö General Hospital in Sweden suggest that only 20% of PIZ homozygotes had no chronic obstructive lung disease [28].

Several studies have attempted to further define susceptibility genes for the development of emphysema. Sandford *et al.* [55] have shown that 6% of COPD individuals were heterozygous for the Z allele (PI*MZ) compared with none of the controls, while the S allele was not associated with emphysema. These authors concluded that the Z allele but not the S allele was a risk factor for COPD in the heterozygous state [55]. These observations were supported in other studies by Turino *et al.* [56] and Alvarez-Granda *et al.* [57], who noted that the PI*SZ phenotype confers little or no added risk of developing COPD except in smokers. In a population-based cohort study by Dahl *et al.*, individuals with the MZ genotype had a slightly greater rate of decline of forced expiratory volume in 1 s (FEV_1) were more likely to have airway obstruction, and had a trend towards a higher incidence of hospitalization and mortality from COPD, compared to individuals with the MM genotype [58]. On the other hand, a population study of PI*MZ heterozygotes from the Tucson Epidemiologic Study of Airways Obstructive Diseases failed to show any increased risk of developing airflow obstruction in MZ individuals [59].

Asthma

Several studies have shown a 15–30% prevalence of asthma in patients with AAT deficiency. In 1041 patients from the NHLBI Alpha-One Registry, a self-report of asthma diagnosed by a physician was found in 38% [60]. When asthma was also defined by bronchodilator responsiveness and recurrent wheezing attacks, asthma was diagnosed in 21% and in 12.5% of those with a normal FEV_1 [60]. In another study of 97 young adults (approximately 22 years of age) from an original cohort of 129 PIZ homozygotes identified by neonatal screening, 29% reported recurrent wheezing and 15% carried a diagnosis of asthma despite normal

spirometry [61]. The frequency of wheezing in ever-smokers was much higher at 56% [61]. In a study from the Italian Registry, the prevalence of methacholine hyper-responsiveness in 86 individuals with different phenotypes (including MZ, MS, SZ, ZZ) was similar in subjects vs controls (16 vs 11%, respectively; $P = 0.66$), but hyperresponsive subjects demonstrated a positive correlation between AAT blood levels and PD20 FEV_1 values ($r = 0.71$; $P < 0.01$) [62]. In one study of 90 asthmatic patients, plasma elastase inhibitory capacity was markedly reduced in asthmatic subjects compared with controls despite higher plasma α_1 -protease inhibitor levels, raising the possibility of a functional AAT deficiency as a component of the inflammatory process of asthma [63].

Recognizing the importance of preventive measures, the World Health Organization has recommended that all patients with COPD and adults and adolescents with asthma be screened for AAT deficiency [64]. Also, a recent international standards document from the American Thoracic Society, European Respiratory Society, American College of Chest Physicians, American Respiratory Care Foundation, and the Alpha-1 Foundation has endorsed diagnostic testing in all symptomatic adults with fixed airflow obstruction [65].

Bronchiectasis

Whether bronchiectasis is associated with severe deficiency of AAT has been the subject of controversy. For example, a computed tomography (CT) study of 117 non-smoking PI*ZZ individuals showed a 26% frequency of bronchiectasis [66], with smaller studies indicating a prevalence as high as 43% [67,68]. However, the distribution of AAT alleles in individuals with bronchiectasis is similar to that of control subjects, suggesting that bronchiectasis develops alongside the emphysema or associated chronic bronchitis rather than as a direct effect of AAT deficiency [69,70]. Moreover, the self-reported prevalence of bronchiectasis from subjects in the NHLBI Registry of Individuals with AAT deficiency was only 2%. This suggests that the high prevalence of bronchiectasis on computed tomography (CT) studies may not carry significant clinical import or that self-reported prevalence represents underdiagnosis [71].

Bronchitis

Chronic sputum expectoration has been found in up to 59% of smokers and 29% of never-smokers with AAT deficiency [30]. Similarly, bronchitis has been found in 33% of individuals enrolled in a patient-organized registry of 712 participants [18]. Also, the odds ratio for developing chronic bronchitis has been reported as 9.6 in PI*ZZ compared with PI*MM individuals [58]. Passive smoking has been proposed as one risk factor associated with the development of chronic bronchitis in AAT deficiency [72]. While

a clinical presentation consistent with chronic bronchitis may simply reflect the underlying pathology of AAT deficiency, a study of non-smoking patients with AAT deficiency suggests that chronic sputum production confers an adverse prognosis with greater impairment in spirometric variables, lower arterial oxygen tension, increased air trapping, inferior health status and an increased number of exacerbations [66].

Liver disease

AAT deficiency is considered the most common genetic cause of liver disease [50]. Although liver dysfunction predominates in the first two decades of life among individuals with the Z allele (and only a few others, e.g. M_{malton}) there is a life-long risk for developing liver disease. For instance, in one large screening study, 22 out of 120 PI Z infants (18%) had some evidence of liver disease, including obstructive jaundice in 14 (12%) and minor abnormalities in eight (7%) [26]. Cirrhosis may develop in 50% of affected children, 25% may die in the first decade of life and 2% present with cirrhosis in later childhood [73]. In a large-scale postmortem study predominantly involving adults, there was a strong link between AAT deficiency in males and the development of cirrhosis (odds ratio 7.8 vs matched controls) and hepatocellular carcinoma (odds ratio 20 vs matched controls) [74].

Panniculitis

Panniculitis is a skin disorder characterized by spontaneous ulceration with clear or serosanguineous drainage and an occasional angioedema-type of presentation [75,76]. It is found in association with several disease entities including lupus, pancreatic fat necrosis, Weber–Christian syndrome, lymphoproliferative disease, erythema nodosum and AAT deficiency [77]. Panniculitis in the setting of AAT deficiency was first described in by Warter *et al.* [78] in 1972, is uncommon and is associated with a variety of phenotypes, including PI*ZZ [79], PI*SZ [80], PI*SS [81] and, in one report, a PI*MS individual with normal plasma levels [82]. The treatment of choice is augmentation therapy, although dapson [83] and tetracycline agents have also been used [80,83,84], the latter perhaps because tetracyclines inhibit collagenase activity [84]. The dramatic response of panniculitis to AAT augmentation therapy [85,86] and to liver transplantation [85] suggests that panniculitis, like emphysema, is caused by unopposed proteolytic activity [87].

Other disorders

Several other disorders with common features of either collagen tissue destruction or inflammation have been

reported less commonly to be associated with AAT deficiency. Some of these disorders involve impairment of vascular integrity such as dissection of carotid [88], coronary [89] and intracranial [90] arteries, splenic [91], intracranial or abdominal aneurysms [92] and fibromuscular dysplasia [93]. These aneurysms do not appear to develop as a result of a protease–antiprotease imbalance [94], and in one report there was no increased frequency of PI*ZZ AAT deficiency among patients with abdominal aortic aneurysms [95]. Other associations include systemic vasculitis (especially C-ANCA-positive vasculitis) [96], peripheral neuropathy [97], colon cancer [98] and inflammatory bowel disease [99].

Treatment and prevention

Preventive measures

Preventive measures are particularly important because AAT augmentation therapy is not universally available to all the individuals for whom it may be indicated [64]. Reasons for this unavailability include variation between countries on conclusions about whether augmentation therapy is effective and hence approval by regulatory agencies, the cost of augmentation therapy, drug supply constraints and insurance issues.

As with COPD in general, smoking cessation remains the most important initial intervention. For instance, in a long-term follow-up report of PI*ZZ individuals identified in a mass screening programme of newborns in Sweden, although parental rates of smoking were higher than those of a control group when the children were 5–7 years old, the smoking rate of PI*ZZ children at 18–20 years of age was lower than that of age-matched peers [100].

Other preventive measures advocated by the World Health Organization include occupational, environmental, genetic counselling and immunization against influenza and *Pneumococcus* infections [64]. Regarding environmental exposures, kerosene heater use at home and agricultural occupations have been associated with decreased lung function in non-smoking PI*ZZ individuals [72].

Exogenous augmentation therapy

Evidence of biochemical efficacy

Augmentation therapy is the regular administration of purified AAT with the intent of replenishing the patient's antielastase capacity. Criteria used to evaluate the efficacy of augmentation therapy have been both biochemical and clinical; the biochemical efficacy criterion is restoring levels of AAT in relevant components (e.g. blood, interstitium) above a so-called 'protective' threshold value, which is the lowest value necessary to eliminate the emphysema risk.

In defining an endpoint for augmentation therapy, a protective serum AAT threshold level of 11 μmol (normal 20–53 μmol) has been established based on the levels separating PI*SZ individuals (levels 8–19 μmol), who have a minimal risk of developing emphysema except in smokers [56], from PI*ZZ individuals (levels 2.5–7 μmol), who have a 65–90% risk of developing emphysema [29,30,101]. Using different preparations of pooled human plasma AAT, Wewers *et al.* [102] and Stoller *et al.* [103] demonstrated that intravenous infusion of AAT at a weekly dose of 60 mg/kg produced serum levels generally exceeding the protective threshold between dosing intervals. Similar results were obtained by Stockley *et al.* [104], who demonstrated a progressively increasing nadir from 10.7 μmol before the second infusion, to 14.4 μmol by the end of the 4th week. Biweekly (120 mg/kg every 14 days) [105] and monthly (250 mg/kg every 28 days) [106,107] schedules for infusion were found to be safe but, in keeping with the 4–5 day serum half-life of exogenous AAT, did not consistently maintain levels above 11 μmol . For instance, serum levels were maintained above this protective threshold for 7–8 days of the biweekly infusion interval [105], and for 23–25 days out of a 28-day infusion interval [106,107]. Currently, the US Food and Drug Administration (FDA) has approved AAT augmentation for weekly administration alone.

A threshold of 1.3 μmol was also suggested for epithelial lining fluid (ELF) levels based on the linear relationship between serum and epithelial lining fluid AAT and by extrapolating from the empirical 11 μmol serum threshold [102]. Studies have shown that weekly administration yielded ELF AAT levels that exceeded the ELF threshold 83% of the time [102]. In the monthly administration regimens, ELF AAT levels averaged 2.35 μmol at day 28 [106]. Moreover, most studies have shown that intravenous augmentation enhances the ability of the lung ELF to inhibit neutrophil elastase [102,103,106].

Overall, the available evidence establishes the biochemical efficacy of augmentation therapy, which was the basis upon which purified pooled human plasma antiprotease was approved by the US FDA in 1988.

Evidence of clinical efficacy

Several studies have addressed the clinical efficacy of augmentation therapy (Table 38.2) [104,107–112] using diverse endpoints of success, including mortality [108], rate of FEV_1 decline [107,108,111,112], rate of elastin degradation based on urinary desmosine [109], loss of lung tissue as assessed by CT scan [107], frequency of lung infections [110] and sputum inflammatory markers [104] (see Table 38.2).

Two observational studies, one comparing treated German patients with untreated Danish patients [111], and one

Table 38.2 Available studies on clinical efficacy of augmentation therapy.

Author(s) [Ref.]	Date	Design	Infusion interval	Outcome measures	Main results
Seersholm <i>et al.</i> [111]	1997	Observational cohort, concurrent controls	Weekly	FEV ₁ decline	In patients with FEV ₁ 31–65% predicted, augmentation slowed the decline of FEV ₁ by 21 mL/year (<i>P</i> = 0.04)
NHLBI Registry [17]	1998	Observational cohort, concurrent controls	51.3% weekly 25.3% biweekly 21.8% monthly	FEV ₁ decline, Survival	In patients with FEV ₁ 35–49% predicted, augmentation slowed the decline of FEV ₁ by 27 mL/year (<i>P</i> = 0.03). In the whole group, the risk ratio of death with augmentation was 0.64 compared with non-recipients (<i>P</i> = 0.02)
Dirksen <i>et al.</i> [107]	1999	Randomized controlled trial	Every 28 days	FEV ₁ decline Lung density (CT)	Loss of lung tissue was 2.6 g/L/year with placebo and 1.5 g/L/year with augmentation (<i>P</i> = 0.07). FEV ₁ decline was 59 mL/year in the augmentation group and 79 mL/year in the placebo group (<i>P</i> = 0.25)
Gottlieb <i>et al.</i> [109]	2000	Descriptive	Weekly	Urinary desmosine	Augmentation did not reduce the rate of elastin degradation
Lieberman [110]	2000	Observational (Web-based survey)	56% weekly 36% biweekly 7% monthly	Frequency of lung infections	The number of lung infections per year decreased from 3–5 pre-augmentation to 0–1 post-augmentation
Wencker <i>et al.</i> [112]	2001	Observational (before–after)	Weekly	FEV ₁ decline	Rates of FEV ₁ decline pre- and post-augmentation were 49.2 vs 34.2 mL/year, respectively (<i>P</i> = 0.019)
Stockley <i>et al.</i> [104]	2002	Descriptive	Weekly	Sputum markers of inflammation	Augmentation reduced sputum leukotriene B ₄

CT, computed tomography; FEV₁, forced expiratory volume in 1 s; NHLBI, National Heart, Lung and Blood Institute.

study from the NHLBI Registry [108] comparing treated with untreated patients, both showed that receipt of augmentation therapy was associated with a slowed rate of FEV₁ decline (by more than 20 mL/year in the subset of patient with moderately to severely reduced FEV₁) (see Table 38.2) [108,111]. Similarly, in an observational study by Wencker *et al.* [112] comparing the rate of decline of FEV₁ before and after weekly augmentation therapy in patients with moderately reduced FEV₁ (mean 41% predicted), the rate of decline was 49 mL/year before augmentation and 34 mL/year after augmentation [112]. In contrast to these observational studies, the single available randomized controlled trial of intravenous augmentation therapy showed no significant difference in the rate of decline of FEV₁ between recipients of placebo and active drug (25.2 vs 26.6 mL/year, respectively) [107]. It is noteworthy that the patients in this randomized trial received monthly instead of weekly augmentation, and that the AAT levels were maintained above the protective threshold for

23–24 days out of the 28-day infusion schedule [107]. At the same time, this trial showed a trend toward a slower loss of lung density among augmentation therapy recipients. Specifically, using CT densitometry as a measure of lung density, augmentation therapy recipients showed a yearly rate of loss of 1.5 vs 2.6 g/L/year in placebo recipients (*P* = 0.07) [107]. This finding has increased enthusiasm to consider CT densitometry as an outcome for assessing emphysema progression in future randomized trials of augmentation therapy [107].

Observational studies have addressed other clinical endpoints of augmentation therapy in patients with AAT deficiency. In a Web-based questionnaire sent to users of an international Internet support group for individuals with AAT deficiency, Lieberman [110] found that the percentage of individuals experiencing two or more lung infections per year was 18% in those receiving augmentation therapy compared with 65% before initiating augmentation (*P* < 0.001) and 55% in those who never received

augmentation ($P < 0.001$) compared with augmentation recipients [110].

Finally, Stockley *et al.* [104] treated 12 patients with intravenous augmentation therapy at a dosage of 60 mg/kg weekly for four doses and repeatedly analysed the sputum and serum samples over 8 weeks. The sputum AAT levels were associated with an increase in the ability of secretions to inhibit porcine pancreatic elastase and a significant decrease in sputum leukotriene B₄ [104]. This finding is of particular significance in that leukotriene B₄ may be the major mediator of neutrophil chemotaxis in AAT deficiency [47,48] and of consequent accelerated lung destruction by neutrophil elastase.

Emerging approaches

In the context that intravenous augmentation poses significant difficulties, there is enthusiasm to develop alternative treatment approaches. Specific examples of the disadvantages of intravenous augmentation therapy are the required frequency of use, the need for intravenous infusion, drug inefficiency and cost [113]. Regarding the efficiency of therapy, only 2–3% of intravenously administered AAT is delivered to the deep lung [114]. Also, in a recent analysis, augmentation therapy with AAT was found to have less cost-effectiveness than other conventional health interventions, with an incremental cost-effectiveness ratio of up to \$312 511 per quality-adjusted life-year, indicating a need for more clinically and cost-effective therapy for AAT deficiency [115].

Given these shortcomings of intravenous augmentation therapy, attention has turned to new approaches, including aerosolized AAT with both pooled human plasma antiprotease and recombinant-produced proteins.

Aerosolized AAT

Advantages of replenishing AAT by the aerosol route include enhanced convenience, direct delivery to the target organ and decrease in the amount of drug required. Still, several issues remain to be resolved before this modality becomes available, including bioengineering of the therapeutic aerosol, resolution of patient-dependent variability in delivery technique, documentation of effective alveolar deposition, and demonstration of clinical and biochemical efficacy.

Several clinical studies have addressed the biochemical efficacy of aerosolized AAT. In one study, 29 normal volunteers who inhaled 200 mg of AAT experienced an increase in AAT concentration and antineutrophil activity in bronchoalveolar lavage samples, with a half-time in the lungs for AAT and antineutrophil elastase activity of 69.2 and 53.2 h, respectively [116]. In another study, administering aerosolized recombinant AAT to deficient individuals at

single doses ranging from 10 to 200 mg augmented ELF antineutrophil elastase defences in proportion to the dose administered, and was detected in serum, suggesting the protein had crossed the epithelial layer into the interstitium [117]. In one study by Hubbard *et al.* [118], 100 mg of pooled human AAT administered by aerosol every 12 h to 12 patients with AAT deficiency augmented ELF levels to a mean of 5.86 μmol , well above proposed protective levels.

Other studies address factors that affect the alveolar deposition of aerosolized AAT. Kropp *et al.* [114] studied the patterns of deposition of ¹²³I-labelled AAT administered by aerosol to 18 patients with severe AAT deficiency, and found that peripheral deposition was significantly improved in individuals with FEV₁ of more than 40% predicted compared with those with more severe disease. In a study by Brand *et al.* [119], controlled slow and deep inhalation allowed as much as 50% alveolar deposition in 12 patients with moderate to severe AAT deficiency. Other studies suggest that high-intensity nebulization associated with low ventilation enhances drug delivery to the lungs [120].

Gene therapy

Several characteristics of AAT deficiency make it a theoretically attractive target for gene therapy, including the single gene defect, a well-defined molecular biology and encoding by the gene of a secreted product [43]. Additionally, only partial expression of normal AAT may be necessary to address the lung disease, despite persistence of the genetic defect [121]. Studies have usually targeted the lung rather than the liver for transfection with AAT encoded genes for several reasons:

- 1 the unique susceptibility of the lung to the disease;
- 2 the alveolo-capillary membrane barrier;
- 3 the resultant large gradient between serum and ELF AAT levels; and
- 4 technical limitations in the amount of gene material that can be effectively transferred.

The vectors used to transfect the lung have included recombinant viruses, liposomes and receptor-mediated gene transfer [43,122].

In the one human study to date, plasmid–liposome complexes were used to transfect the nasal epithelium of five AAT deficient individuals with a normal AAT gene, and demonstrated an increase in the concentration of AAT in nasal lavage compared with the control nostril [43]. This study also showed that while nasal lavage AAT levels were much lower than with intravenous augmentation, nasal interleukin 8 concentrations were reduced while the subjects were on gene therapy and not while receiving augmentation. Thus, local expression of AAT, even at subtherapeutic levels, may confer advantages such as the ability to interdict proteolytic activity and reduce markers

of inflammation in areas not usually exposed to circulating AAT [43]. Adenoviral vectors have also been shown to be effective in animal models [123].

Disadvantages of these vectors include the paucity of specific cell receptors on the surface of human respiratory epithelium, and their ability to cause an inflammatory response and trigger an immune response [43]. While there are techniques to diminish the side-effects associated with adenoviral vectors, alternatives such as adeno-associated virus vectors have been explored. Nevertheless, use of adeno-associated virus has disadvantages, including impaired transduction to the lungs because of existing airway inflammation and the lack of specific receptors on the apical surface of airway epithelial cells [124].

In another study, transfection of pulmonary macrophages in rats was achieved by targeting mannose receptors to internalize plasmid DNA complexed with a mannose-terminal molecular conjugate [122], suggesting this may be an alternative strategy.

Other emerging approaches

Characterization of AAT deficiency as a conformational disease and better understanding of the mechanisms of its associated liver and lung disease have suggested other new approaches to treatment.

Inhibition of intrahepatic polymerization has been one such approach. In one study, a small peptide homologous to the reactive centre loop was found to selectively bind to the β -sheet of Z AAT and to inhibit polymerization *in vitro* [125]. While this approach may increase secretion, it also inactivates AAT and therefore supplementation may still be necessary for prevention of lung disease. However, it clearly holds promise for treating liver disease [125].

Another study capitalizes on the putative mechanism of retention of polymerized AAT in the endoplasmic reticulum by providing cellular chaperones to reverse the process. Specifically, oral 4-phenylbutyric acid (PBA) administered to mice transgenic for the human AAT gene increased their blood levels of human AAT to 20–50% of normal mouse and human levels [126]. This approach is promising in that PBA has been safely used in children with urea cycle disorders and, if successful, could prevent or treat both liver and lung manifestations of the disease. A pilot study of PBA is currently underway [127].

Recognizing the important role of neutrophil elastase in the pathogenesis of lung disease in AAT deficiency, other inhibitors of this enzyme also have promise. Some of these agents include endogenous low molecular weight inhibitors of neutrophil elastase (such as eglin C) and manufactured compounds such as sivelestat (which has been predominantly studied in acute lung injury) [128] and ONO-6818 [129]. The latter agent was found to inhibit the development of neutrophil elastase-induced emphysema in rats

[129], but human phase II studies in subjects with AAT deficiency were discontinued because of elevation of liver enzymes.

Overall, such emerging approaches offer promise for new and better therapies for severe AAT deficiency.

Body weight and systemic effects

Emile F. M. Wouters

Chronic obstructive pulmonary disease (COPD) is characterized by the progressive development of airflow limitation that is not fully reversible. The clinical syndrome of COPD encompasses different disease conditions varying from chronic obstructive bronchitis with obstruction of small airways to emphysema characterized by enlargement of airspaces and destruction of lung parenchyma, loss of lung elasticity and closure of small airways. The association of an abnormal inflammatory response of the lungs to noxious particles or gases with airflow limitation in COPD indicates the critical role of the inflammatory process in the pathogenesis of COPD [1].

Besides these primary effects of COPD in the lungs, there is growing evidence in the literature that the clinical syndrome of COPD is often associated with significant extrapulmonary manifestations or systemic effects [2,3]. Weight loss is a phenomenon that has long been recognized in the clinical course of COPD patients. Fowler and Godlee [4] first described this association in patients with emphysema in the late 19th century. Attempts to describe different COPD classifications retained body weight as an important discriminator [5,6]. In the 1960s, several studies reported that low body weight and weight loss are negative predictive factors of survival in COPD [7]. At that time, weight loss was considered to be an integral part of the clinical picture of chronic bronchitis, without adequate analysis of the underlying mechanisms or related functional consequences. Nutritional depletion was considered as an inevitable and irreversible terminal event related to the severity of airflow obstruction. It was even hypothesized that weight loss was an adaptive mechanism to decrease oxygen consumption in these disabled patients.

Based on the emerging public health concern for COPD, there is growing interest in defining treatment and treatment strategies that make a difference in the outcomes of patients. Goals of effective COPD management are widely accepted and are largely related to the experienced symp-

tomatology of patients: relief of symptoms, improvement in exercise capacity, improvement in health status, prevention of exacerbations and complications, prevention of disease progression and reduction of mortality [1]. In a heterogeneous disease condition such as COPD, selection of appropriate outcome measures depends on the aspect of the disease being addressed. This is particularly relevant for COPD, as a variety of non-pharmacological treatment procedures are considered as evidence-based management strategies despite any effect on specific measures such as forced expiratory volume in 1 s (FEV_1). In this paper, body weight will be discussed as part of the multicomponent pathology in COPD patients.

Prevalence of depletion in COPD

If the human body is considered as a single compartment, the measurement of weight and height provides a simple assessment of nutritional status. Generally, the subject's weight is compared with a reference parameter. Actual body weight can be related to the 'ideal body weight' (IBW) as derived from height, sex and frame size, based on the Metropolitan Life insurances tables [8]. Low body weight is generally and arbitrarily defined as body weight less than 90% IBW. Another approach is the use of indices of relative weight such as the body mass index (BMI) or Quetelet index, which is the ratio of body weight divided by height squared.

The US Department of Agriculture and the US Department of Health and Human Services in their 2000 report on '*Nutrition and Your Health*' proposed a BMI between 18.5 and 24.9 kg/m² as a target for a healthy weight [9]. A BMI lower than 18.5 kg/m² is considered underweight, greater than 25 kg/m² connotes overweight and a BMI greater than 30 kg/m² indicates obesity. However, it was stated in the same report that weights above or below the healthy weight range may actually be healthy and that weights

inside the healthy weight range may not be healthy, stressing the assessment of body composition even in normal persons [9]. This is particularly important in clinical conditions where standardization in the nomenclature of body composition in weight loss is important [10]. Roubenoff *et al.* [10] suggested specific definitions for cachexia, wasting and sarcopenia. In cachexia, the loss of body cell mass, the total actively metabolizing and contracting tissue, is greater than the loss of weight. In wasting, the decrease in body cell mass and weight are parallel. Cachexia is always accompanied by wasting, but wasting does not always lead to cachexia. Sarcopenia refers to an involuntary generalized loss of skeletal muscle mass and strength [10].

In the absence of two-compartment analysis of body composition, dividing body weight into a fat and a fat-free compartment, depletion in fat-free mass (FFM) can be masked by an increase in fat mass resulting in a normal body weight, or a low body weight can be present with preservation of FFM [11,12]. Therefore, especially in patients with low body weight, further assessment of body compositional changes has to be advocated.

Presence of low body weight is a frequent finding in COPD patients. Hunter *et al.* [13] reported nutritional depletion in 50% of hospitalized patients with a clinical diagnosis of COPD. Among 779 men included in the National Institutes of Health clinical trial of intermittent positive-pressure breathing, 25% weighed less than 90% IBW: 51% of the more obstructed group ($FEV_1 < 35\%$ predicted) and 20% in the less obstructive patients ($FEV_1 > 47\%$ predicted) [14].

Schols *et al.* [11] reported data of body weight and body composition in a group of 255 patients with moderate to severe COPD, consecutively admitted to a pulmonary rehabilitation programme. An IBW of less than 90% predicted was found in 27% of patients with a 35% predicted $FEV_1 \leq 50\%$ predicted, 41% of patients with a FEV_1 less than 35% predicted and even 46% of patients with hypoxaemia ($Pao_2 \leq 7.3$ kPa). This study indicates that low body weight commonly occurs in COPD patients eligible for pulmonary rehabilitation and that nutritional depletion significantly contributes to the experienced functional impairment in these patients [11]. Engelen *et al.* [12], studying body composition in relation to respiratory and peripheral skeletal muscle function in a group of COPD outpatients, reported weight loss in 17% of the study group.

Prevalence of malnutrition was studied in a cohort of more than 4000 patients with COPD treated with long-term oxygen therapy [15]. The prevalence of malnutrition, as defined by a BMI of less than 20, was 23% in men and 30% in women. The prevalence of low body weight was reported to be very high in patients with acute respiratory failure and in patients accepted for lung transplantation, with values up to 60% and 72%, respectively [16,17].

Besides measurement of body weight or BMI, nutritional status can be defined by unintentional weight loss. Unintentional weight loss of more than 10% during the past 6 months is categorized as severe malnutrition [18]. A recent prevalence study conducted in the Netherlands of 501 patients admitted to the pulmonary ward for non-oncological illnesses reported more than 10% weight loss in 13% of patients and a 5–10% weight loss in 14% of patients. A weight loss of 5–10% over a 6-month period is considered as a risk for malnutrition. Remarkably, a significant number of patients had manifested unintentional weight loss with BMI values within the normal range [19].

It can be concluded that low body weight and muscle wasting is a common problem in COPD patients. Further studies are needed to illustrate changes in body weight as part of the natural history of the disease.

BMI and the risk for development of COPD

Different studies reported a relationship between low BMI and the risk of COPD. In the Tecumseh Community Health Study it was found that the incidence rate of obstructive airways disease, defined as FEV_1 less than 65% predicted, was highest in lean men and lowest in overweight men [20]. The possibility that subjects who are susceptible to COPD may be leaner than subjects who are not susceptible was also raised by other authors [21]. Chen *et al.* [22] reported that a BMI less than 20 among male subjects and a BMI greater than or equal to 28 among female subjects were associated with an increased prevalence of COPD. In this cross-sectional study, no distinction was made between emphysema and chronic bronchitis. Harik-Khan *et al.* [23], using the Baltimore Longitudinal Study of Aging database, examined if asymptomatic subjects with lower initial body mass were at greater risk of developing COPD during subsequent follow-up. COPD was considered to be present if the participants received any of the following diagnoses during follow-up: emphysema, chronic bronchitis or chronic airway obstruction, or if $FEV_1 : FVC$ was less than 0.7 during follow-up. These authors reported that middle-aged and older men with low body weight, as measured by BMI, were at a substantially higher risk of developing COPD even after adjusting for other potential risk factors, including cigarette smoking, age, FEV_1 percentage of predicted, abdominal obesity and educational status. This inverse association of baseline BMI and subsequent COPD was significant. Guerra *et al.* [24], using a nested case-control study from the longitudinal cohort of the Tucson Epidemiological Study of Airways Obstructive Diseases reported that the association between BMI and COPD is largely affected by the type of diagnosis: emphysema was more associated with low BMI

categories and chronic bronchitis with high BMI categories. By combining patients with chronic bronchitis and patients with emphysema in a single COPD category, these authors reported a U-shaped risk trend, meaning that low and high BMIs increase the risk for the disease [24].

The effects of food deprivation on normal lung structure and function have not been well studied in any systematic and detailed manner. One of the earliest pathological studies of human lungs was carried out by Stein and Fenigstein [25] who reported 13.5% of emphysema cases in Warsaw ghetto residents and that these emphysematous lesions were found in all age groups from childhood to senility. Keys *et al.* [26] described changes in physiology in normal adult men after 24 weeks of semi-starvation. In this study, the vital capacity was progressively diminished, most likely the result of respiratory muscle weakness [26]. Reductions in vital capacity are also described in female patients with anorexia nervosa [27].

Significance of body weight as outcome measure

BMI and disease characterization

In the 1960s, Filley *et al.* [6] described two contrasting types of patients with chronic airway obstruction based on clinical criteria and body weight: the 'pink puffer' and the 'blue bloater'. The 'pink puffer', the emphysematous patient, was more breathless with marked hyperinflation, thin in appearance with major weight loss. The 'blue bloater' had more severe central cyanosis and was frequently obese; this blue bloating type has often been considered as the chronic bronchitis subtype of COPD [6].

Several authors have attempted to correlate the degree of weight loss with the presence and severity of emphysema. A relationship between the ratio of residual volume to total lung capacity and weight loss had already been reported in the early 1960s [28]. Sukumalchantra and Williams [29] reported that the disease progression in a 5-year follow-up study of patients with severe COPD, as manifested by reduction in maximum mid-expiratory flow rate and increased airway resistance, occurred only in patients who had lost more than 10% of their initial weight; furthermore, the reduction in diffusing capacity was also more severe in patients who had suffered weight loss during the study period. The relationship between nutritional status and COPD subtypes was further evidenced in the paper of Openbrier *et al.* [30], who demonstrated that patients with emphysema were somatically depleted in comparison with patients with chronic bronchitis. They found that in patients with emphysema a good correlation was present with the degree of airflow limitation as well as with the single-breath

diffusing capacity. Others reported that transfer coefficient of diffusing capacity (K_{CO}) was significantly lower in those COPD patients with FFM depletion vs patients without FFM depletion. Furthermore, 38% of the patients with a K_{CO} less than 60% predicted compared with 5% of the patients with a K_{CO} greater than or equal to 80% were considered depleted [12]. These data indicate that weight loss and nutritional depletion is a particular problem in those patients with impaired diffusing capacity. High-resolution computed tomography (HRCT) is an imaging procedure that allows direct assessment of the presence, extent and severity of emphysema [31]. Engelen *et al.* [32] analysed body weight and body composition in COPD patients, subdivided into an emphysematous group and a bronchitis group based on HRCT. Body weight and BMI as well as FFM and fat mass were significantly lower in emphysematous patients compared with the bronchitis group.

Remarkably, these data were confirmed by studies focusing on fibre type redistribution in skeletal muscles. Emphysematous patients have a more marked type I–IIIX fibre type redistribution in the vastus lateralis than non-emphysematous patients and controls [33]. Further studies are needed to unravel these muscular abnormalities especially in the emphysematous subgroup. At least, these data support evidence for a relationship between COPD subtypes and particular changes in body composition.

Functional performance and health status

Dyspnoea and exercise intolerance are prominent symptoms in COPD patients. In addition to airflow limitation and impaired diffusing capacity, it became evident during last decade that respiratory and skeletal muscle weakness are important determinants of these symptoms [34,35]. Although muscle dysfunction is highly related to muscle wasting [36,37], much of the literature demonstrates that BMI can be considered as an indicator of functional disability. In underweight COPD patients, impaired respiratory muscle strength has been demonstrated [11,38–41]. These data are supported by autopsy data, which demonstrate that body weight and muscularity profoundly affect diaphragm muscle mass [42]. Changes in BMI associated with muscle tissue depletion significantly impairs skeletal muscle strength in COPD patients [37,43].

A close relationship between poor muscle condition, reflected by reduction in percentage ideal body weight or BMI, and maximal aerobic capacity has been observed in several studies [36,44–46]. Furthermore, reduced body mass has an independent negative effect on muscle aerobic capacity in COPD patients, as manifested by a decrease in maximal oxygen consumption, reduction in the lactate threshold and slowing of oxygen consumption kinetics [47]. Data regarding the relationship between walking

distance and BMI are rather conflicting. While some authors have reported that in malnourished patients with stable advanced disease the degree of weight loss bears no relation to the work capacity at submaximal levels [44,48], others have demonstrated a significant association between walking distance and body weight [45]. Positive outcomes on peak exercise parameters as well as on walking distance have been reported by nutritional intervention in depleted COPD patients [49].

The functional consequences of being underweight and particularly of FFM depletion have also been reflected as a decreased health status as measured by the St. George Respiratory Questionnaire (SGRQ) [50]. In another study, depletion of FFM had a greater impairment in the activity and impact scores of the SGRQ, irrespective of body weight [51]. Others reported that underweight COPD patients are more dyspnoeic than normal-weight patients, partly as a consequence of decreased respiratory muscle strength [41].

Health care utilization

There is growing evidence in the literature that nutritional depletion in COPD is related to higher health care utilization, especially of inpatient services. In a small group of chronic hypercapnic patients, Vitacca *et al.* [51] reported that basal body weight, the decline in FEV_1 and the rate of deterioration of arterial blood gases were related to the necessity of intensive care unit (ICU) admission. Some years later, the same group reported that underlying general conditions such as malnutrition and a high physiology score (APACHE II) were unfavourable indices of outcome for acute exacerbation of COPD (AECOPD) treated with medical therapy and that flow limitation as assessed by forced expiratory manoeuvres provides additional information. The discriminant analysis showed, in decreasing order of power, that nutritional prognostic index, APACHE II score, FEV_1 : FVC ratio, vital capacity (VC) (% predicted) and FVC (% predicted) provided a significant distinction between patients requiring mechanical ventilation and those who could be treated with medical therapy only [52]. Kessler *et al.* [53] reported that besides gas exchange impairment and pulmonary haemodynamic worsening, the risk of being hospitalized for COPD was significantly increased in patients with a low BMI and patients with a limited 6-minute walking distance [53]. Nutritional depletion also increased the risk of early non-elective readmission in patients previously admitted for an exacerbation [54]. A prospective cohort study of 1016 patients admitted to hospital for AECOPD described that survival time after AECOPD was independently related to severity of illness, BMI, age, prior functional status, Pao_2 , Fio_2 , congestive heart failure, serum albumin and the presence of cor pulmonale [55].

In patients with emphysema undergoing lung volume

reduction surgery, a deficient nutritional status identifiable by BMI was found in approximately 50% of patients. This impaired nutritional status was associated with increasing morbidity following lung volume reduction surgery (LVRS), manifested by prolonged ventilatory support and increased length of hospital stay [56]. Similar data were reported in lung transplant candidates: duration of mechanical ventilation and time spent in the ICU was significantly related to initial body composition [17]. Furthermore, it was demonstrated that lung transplant recipients with BMIs lower than the 25th percentile, or less than 80% of the predicted weight for a certain height, and/or those patients with lean body mass depletion have a worse survival rate following lung transplantation [17,57,58]. These findings are confirmed by analysis of the impact of BMI on outcomes in critically ill patients based on a large multi-institutional ICU database. It was found that low BMI was associated with increased mortality and worsened hospital discharge functional status [59]. In patients with severe COPD treated with home long-term oxygen therapy (LTOT), Chailleux *et al.* [15] recently reported that low BMI was the most powerful predictor of duration and rate of hospitalization, independently of blood gas levels and respiratory function. The lowest hospitalization rates were observed in the obese patients in this study.

BMI and COPD-related mortality

The relationship between weight loss and being underweight with mortality has been the subject of investigation since the 1960s. Vandenberg *et al.* [7] reported a significant association between weight loss and survival in patients with COPD: 5-year mortality was 50% in those losing weight, compared with only 20% in weight-stable patients with COPD. Several retrospective studies using different COPD populations also provided evidence for a relationship between low BMI and mortality, independent of FEV_1 [14,60,61]. Remarkably, a decreased mortality risk was observed in overweight patients with COPD compared with underweight patients and with subjects of normal weight [14,61]. In COPD patients randomly allocated to LTOT or medical treatment, Gorecka *et al.* [62] found that BMI was a significant predictor of survival, independent of FEV_1 . In a cohort of more than 4000 patients treated with LTOT, Chailleux *et al.* [15] reported that low body weight was an independent risk factor for mortality: the 5-year survival rates were 24%, 34%, 44% and 59%, respectively, for patients with BMIs of less than 20, 20–24, 25–29 and greater than or equal to 30. The best prognosis again was observed in overweight and obese COPD patients on LTOT. In one study, weight gain after nutritional supplementation was also related to decreased mortality independent of FEV_1 , resting arterial blood gases, smoking, age and gender

[61]. Studies describing factors associated with COPD deaths also reported that being underweight is one of the determinants of those patients who died with COPD [63,64]. A Danish population study, including more than 2000 subjects and a 17-year follow-up, confirmed these noted associations between body weight and mortality risk [65]. Using normal-weight subjects (BMI 20.0–24.9 kg/m²) as reference, the relative risk of death, adjusted for smoking, chronic mucus hypersecretion, FEV₁ and gender was significantly increased in underweight subjects but decreased in overweight and even obese subjects with airflow obstruction. A similar but weaker association was observed in subjects with mild and moderate disease. The specific relationship between FFM and mortality was reported by Marquis *et al.* [66], demonstrating that midhigh muscle cross-sectional area obtained by CT scan and FEV₁ were found to be the only significant predictors of mortality.

Therefore, it can be concluded that from the point of view that improvement of prognosis is one of the management goals in COPD, assessment of BMI is a good predictor of mortality and outcome in these patients.

Pathogenesis of weight loss

Weight loss, particularly loss of fat mass, occurs if energy expenditure exceeds dietary intake. Muscle wasting is a consequence of an imbalance between synthesis and breakdown of protein. Impairments in total energy balance can occur simultaneously, but these processes can also be dissociated because of altered regulation of substrate metabolism [67]. Several studies have provided evidence for involvement of systemic inflammation in the pathogenesis of tissue depletion in patients with COPD [68–71]. Systemic inflammation could modify energy homeostasis partly by interaction between cytokines and leptin metabolism. Leptin is synthesized by adipose tissue and is the afferent hormonal signal to the brain regulating fat mass [72,73]. Disturbances in the tightly regulated equilibrium between protein synthesis and breakdown can also be induced by systemic inflammation, at least by activation of the adenosine triphosphate (ATP) dependent ubiquitin–proteasome pathway [74,75]. Direct effects of tumour necrosis factor on differentiated skeletal muscles have been reported. Treatment with this factor reduces the total protein and myosin heavy-chain content in a manner dependent on time and concentration [76]. Muscle wasting might also be the result of a decreased number of fibres, resulting from changes in the regulation of skeletal muscle regeneration or activation of apoptotic pathways [77,78]. New insights into the regulation of the processes of atrophy and hypertrophy could provide opportunities for modulation of these processes in the future [79].

CHAPTER 40

Lung connective tissue

Sarah E. Dunsmore and Geoffrey J. Laurent

Key concept

The structural integrity of the lung and the biological activity of its resident cells are dependent on a diverse group of connective tissue glycoproteins and proteoglycans.

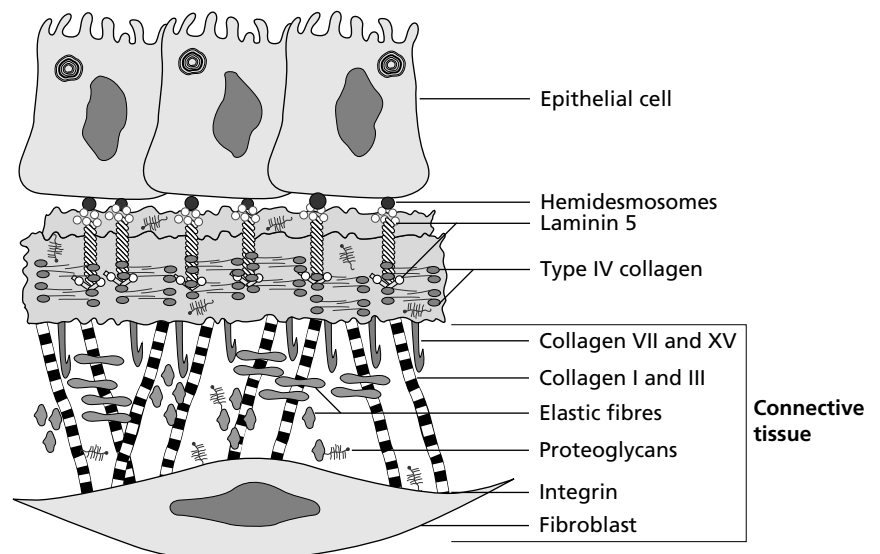

Fundamental physical properties, such as the intrinsic recoil of the lung, are governed by connective tissue, which consists of cells and extracellular matrix and has the general function of supporting and filling space between organs. In the lung, fibrous connective tissue is found throughout the pulmonary interstitium and large airways. In addition, cartilage, a specialized form of connective tissue, encircles the trachea and large bronchi preventing collapse of these structures. In this chapter, the individual components that confer structure and function to lung connective tissue are described.

Figure 40.1 Matrix protein structure and organization. Epithelial cells are linked to connective tissue via a network of matrix proteins. Laminin 5 connects hemidesmosomes on the basal surface of epithelial cells to the type IV collagen network in the lamina densa of the basement membrane. Anchoring fibrils composed of type VII and type XV collagen link the basement membrane to the interstitial matrix where type I collagen, type III collagen and elastic fibres are found. Integrins located on the fibroblast cell surface interact with many matrix proteins including type I collagen. (Reprinted from Gibson *et al.* [225], p. 83, with permission from Elsevier.)

Each type of connective tissue is uniquely organized to play a distinct part in normal lung function. Matrix components of lung connective tissue also regulate cell phenotype, gene expression and motility via interactions with integrins and other cell surface receptors (Fig. 40.1). Following a brief discussion of cartilage, this chapter focuses on the cells and matrix proteins found in the pulmonary interstitium. The final section of this chapter provides an introduction to the matrix-related pathology of COPD.

Cartilage

Hyaline cartilage lines the walls of the trachea and large bronchi and is responsible for keeping these airways open despite changes in intrathoracic pressure during breathing.

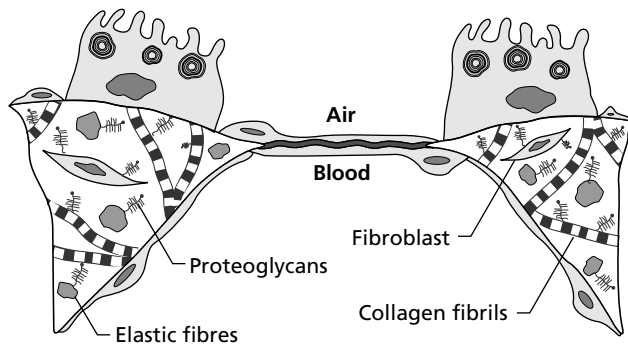

Figure 40.2 Pulmonary interstitium. At the gas exchange interface alveolar capillaries and alveolar type I epithelial cells share a basement membrane. In other portions of the alveolar wall, collagen fibrils and elastic fibres are the major components of the pulmonary interstitium which also contains fibroblasts and proteoglycans (not to scale). (Reprinted from Gibson *et al.* [225], p. 83, with permission from Elsevier.)

Chondroblasts produce the components of the cartilage extracellular matrix: hyaluronan, collagen types II, VI, IX, X, XI and XII, and aggrecan. Mature cartilage consists of chondrocytes embedded in lacunae surrounded by a matrix of proteoglycan aggregates and type II collagen fibres. In one model of cartilage function, collagen fibres in the outer layers oppose tensile forces and proteoglycans in the central zone resist compression forces [1].

The pulmonary interstitium

The connective tissue components of the pulmonary interstitium are key determinants of lung function providing the mechanical scaffold that maintains structural integrity during ventilation. Fibres of the matrix proteins, collagen and elastin, form this scaffold [2–5] (Fig. 40.2). It has long been recognized that devastating consequences result from disruption of pulmonary interstitial matrix homeostasis [6]. Pulmonary fibrosis is a consequence of increased interstitial matrix deposition, particularly of types I and III collagen. In this disease, gas exchange is adversely affected by the loss of capillary beds and decreased regional compliance resulting from the thickening of the pulmonary interstitium. Conversely, degradation of elastin is a characteristic of pulmonary emphysema [7,8]. The reduction in elastin content of the pulmonary interstitium adversely affects ventilation by decreasing the intrinsic recoil of the lung [9–12].

Cells of the pulmonary interstitium

Fibroblasts are omnipresent in lung connective tissue and are responsible for production of the pulmonary interstitial

matrix. Under normal conditions, macrophages are the only other cell type present to an appreciable extent in the pulmonary interstitium. In the inflamed lung, however, leucocytes, lymphocytes and mononuclear cells infiltrate the pulmonary interstitium. In COPD, the normal inflammatory response to cigarette smoke appears to be amplified by oxidative stress [13,14] and/or other mechanisms [15–19] resulting in irreversible elastolysis in the pulmonary interstitium. Much effort is being devoted to the development of novel anti-inflammatory therapies for COPD.

Structure and function of interstitial matrix proteins

Matrix proteins have characteristic structures and functions. Collagens and proteoglycans are ubiquitous components of the extracellular matrix. Elastic fibres, on the other hand, are specialized structures found only in tissues subject to mechanical stress. General aspects of the biology of the major classes of matrix proteins are briefly reviewed in this section.

Collagens

In simple terms, collagens may be thought of as the ‘struts’ of the lung – rod-like structures that limit lung deformation. Information contained within the collagen amino acid sequence dictates formation of these precisely ordered, rod-like structures. Collagens consist of three polypeptide chains containing the amino acid sequence (Gly-x-y). Gly-x-y sequences associate to form triple helices and, by definition, all collagens contain at least one triple helical region [20]. Although x and y may be any amino acid, proline and hydroxyproline predominate in these positions such that approximately every third x is proline and every third y is hydroxyproline. Hydroxyproline is not unique to collagen; however, concentrations in collagen are much higher than those in other proteins so hydroxyproline can be used as a specific index of collagen synthesis and concentration.

Collagen gene structure and organization

Genetic diversity arose during the metazoan radiation largely as a result of the mechanisms of exon shuffling and gene duplication. Human collagen gene structure reflects these events [21]. A 54 base pair unit that encodes the characteristic Gly-x-y repeat is thought to represent the ancestral collagen gene [22]. Evolution of collagens occurred by deletion, duplication and shuffling of Gly-x-y repeats (i.e. in nine base pair units). Thus, many collagen genes contain exons of 36, 45, 54, 63 and 108 base pairs [23]. Most collagen genes are composed of many exons, with 14 genes consisting of 50 or more exons [23–25]. Five collagen genes contain alternative transcription start sites; 16 are alternatively spliced [23,24,26,27].

The 43 collagen genes are located on 17 different chromosomes [23–27]. Several are found in close proximity on the same chromosome. The genes encoding the six polypeptide chains that are constituents of type IV collagen are clustered head-to-head [28–30] on chromosomes 13 (COL4A1 and COL4A2; 13q34), 2 (COL4A3 and COL4A4; 2q35-q37) and X (COL4A5 and COL4A6; Xq22). Collagen genes are oriented tail-to-tail [31] on chromosomes 2 (COL3A1 and COL5A2; 2q14-q32) and 6 (COL9A1 and COL19A1; 6q12-q14). COL12A1 is also positioned on chromosome 6 [32] slightly over four mega base pairs from COL9A1. Three collagen genes (COL6A1, COL6A2 and COL18A1) map to the same cytogenetic location [33] on chromosome 21 (21q22.3).

Transcription of collagen genes

Binding of a variety of transcription factors [34] to defined motifs in the promoter region of collagen genes [35–53] is the primary determinant of spatial and temporal collagen expression [24,25,27,54–73]. Expression of some collagen genes is also influenced by transcriptional regulatory elements located in introns [74–97] and in 3′ untranslated regions of the genes [98]. Epigenetic mechanisms such as DNA methylation restrict collagen expression to particular cell types [99,100] and to precise developmental stages [101,102]. In the event of tissue injury, cytokines such as transforming growth factor β (TGF- β) and tumour necrosis factor α (TNF- α) can affect collagen transcription by activating signalling pathways that lead to nuclear translocation of DNA binding factors [103–112].

Posttranscriptional regulation of collagen gene expression occurs during the processes of translation initiation and mRNA degradation. An evolutionarily conserved 5′ stem-loop structure which encompasses the AUG start codon inhibits translation of collagen $\alpha 1(I)$, $\alpha 2(I)$ and $\alpha 1(III)$ mRNA transcripts [113]. Interactions of RNA binding proteins with this 5′ stem-loop structure [114,115] and with a 3′ polypyrimidine rich region [116,117] protect collagen $\alpha 1(I)$ mRNA from deadenylation-dependent decay. Inhibition of translation initiation which facilitates binding of cytokine-regulated transcription factors [113] and delay of procollagen mRNA degradation may be important mechanisms in the pathogenesis of fibrotic disorders [116].

Procollagen translational modifications

A series of co and posttranslational modifications of collagen polypeptide chains begins with cotranslational cleavage of the signal sequence from preprocollagen. Hydroxylation of proline and lysine residues is required for formation of stable triple helical regions in mature collagen [118–121]. Hydroxylation begins as a cotranslational process and continues posttranslation until triple helix formation is complete. Biochemical reactions are accomplished by three enzymes: procollagenproline dioxy-

genase (EC 1.14.11.2), procollagenproline 3-dioxygenase (EC 1.14.11.7) and procollagen-lysine 5-dioxygenase (EC 1.14.11.4) which recognize specific sequences (X-Pro-Gly, Pro-4Hyp-Gly and X-Lys-Gly, respectively) in procollagen. These enzymes require ferrous iron, 2-oxoglutarate, molecular oxygen and ascorbate for activity.

Collagen triple helical structures are stabilized by glycosylation [122]. Glycosylation of procollagen is a cotranslational event. Two enzymes located on the inner endoplasmic reticulum membrane, procollagen galactosyltransferase (EC 2.4.1.50) and procollagen glucosyltransferase (EC 2.4.1.66), link sugar residues to procollagen hydroxylysines. A lysyl hydrolase isoform (lysyl hydrolase 3) possesses low levels of glucosyltransferase activity [123,124] that appear to be necessary for type IV collagen assembly [125]. Collagen propeptides also contain N-linked oligosaccharides [126–131].

Trimerization of α chains and triple helix propagation

Collagen triple helix formation takes place in the endoplasmic reticulum. Sequences in the C propeptide region of secreted collagens mediate assembly of the appropriate triad of procollagen chains [132,133]. Triple helix assembly is more efficient when inter- [134] and intrachain disulphide bonds [135] are present. Protein disulphide-isomerase (EC 5.3.4.1), one of the most abundant enzymes in the endoplasmic reticulum, catalyses the formation of disulphide bonds in secretory proteins and maintains disulphide isomerase activity [136] when it functions as the β subunit of prolyl 4-hydroxylase [136,137]. Protein disulphide-isomerase also acts as a molecular chaperone by binding to the C propeptide region of monomeric collagen [138] in order to prevent the secretion of unassembled collagen chains [139,140]. Triple helix propagation of secreted collagens proceeds from the C- to the N-terminal [133,141,142]. For transmembrane collagens, triple helix folding appears to be in the more typical N- to C-terminal direction [143,144]. The *cis-trans* isomerization of peptide bonds, which is catalysed by peptidylprolyl isomerase (EC 5.2.1.8), is the rate limiting step in collagen triple helix assembly [141,145–147].

Fibrillogenesis and supramolecular structure assembly

Correctly folded procollagen traffics from the endoplasmic reticulum to the Golgi stacks [148]. A collagen-specific molecular chaperone, HSP47 [149,150], is involved in this process. HSP47 binds to Gly-X-Arg repeats [151–154] in triple helical collagen [154–156] and is necessary for collagen secretion [157] which occurs via cisternal maturation of the Golgi stacks [158]. Collagen function is dependent upon the post-Golgi assembly of procollagen molecules into fibrils and other supramolecular structures (Fig. 40.3).

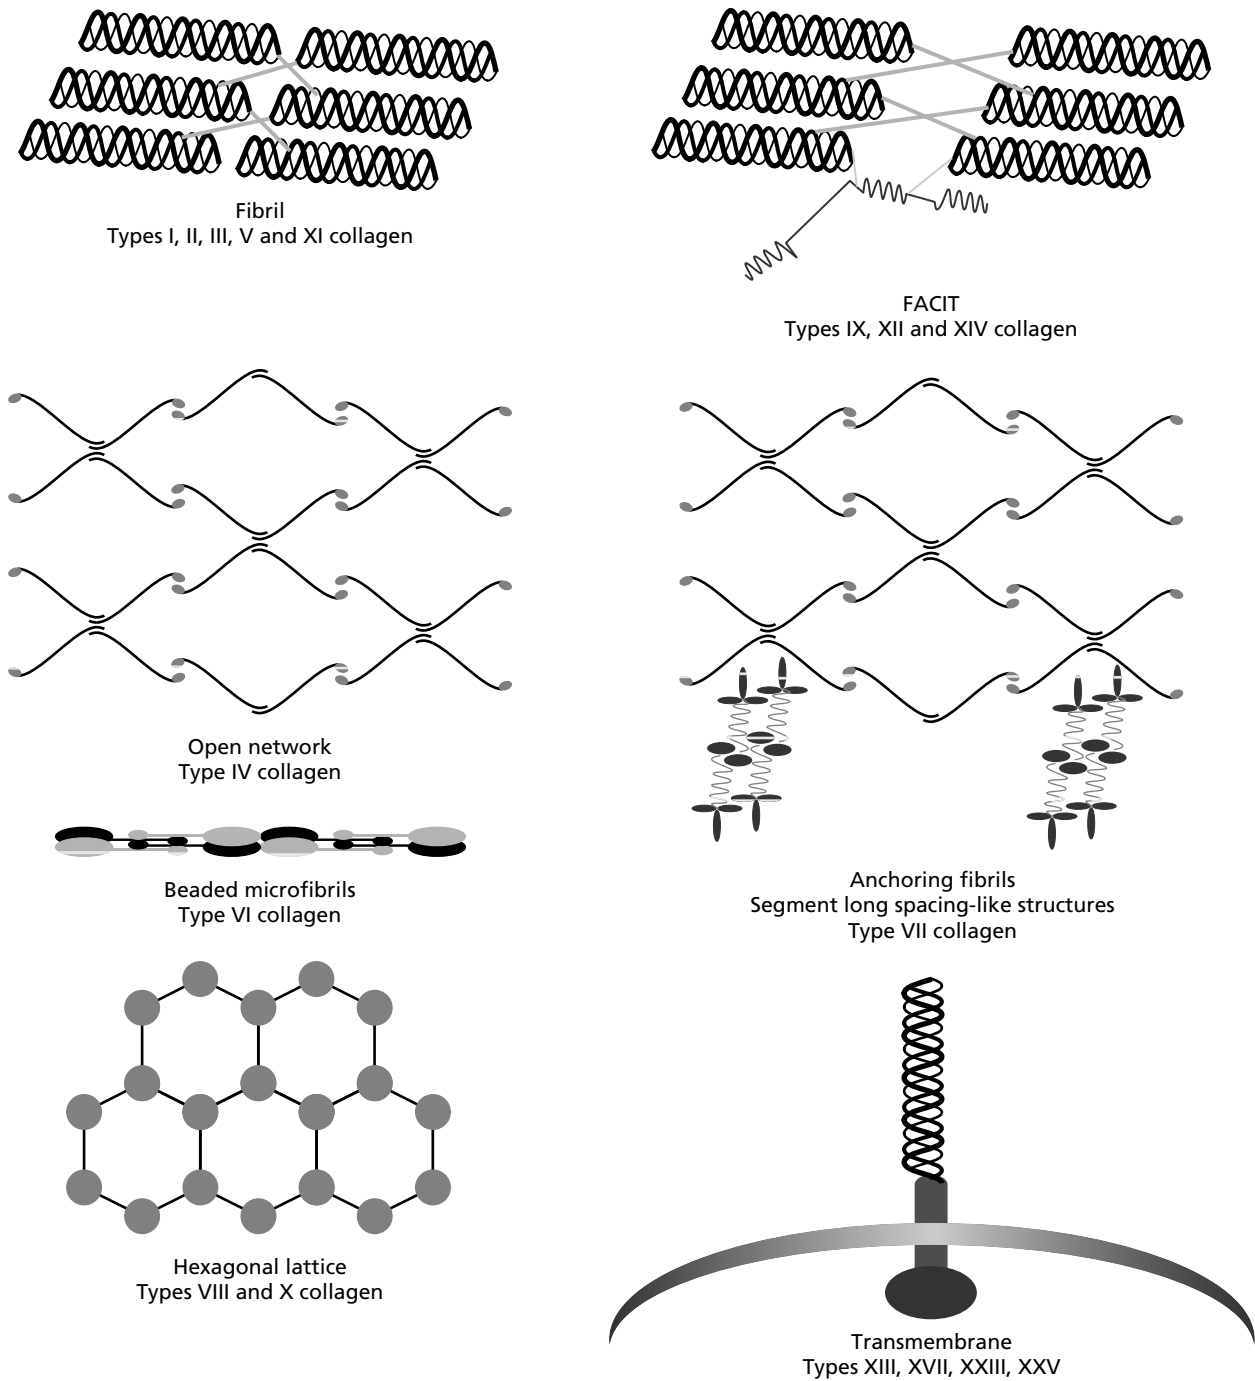

Figure 40.3 Collagen supramolecular structures. (Reprinted from Laurent and Shapiro [226], p. 173, with permission from Elsevier.)

Fibril formation has been well characterized [148,159–163]. Removal of N-terminal telopeptides by procollagen N-endopeptidase (EC 3.4.24.14) and cleavage of C-terminal telopeptide sequences by procollagen C-endopeptidase (EC 3.4.24.19) initiates fibrillogenesis [164–166]. Protein-lysine 6-oxidase (EC 1.4.3.13) cross-links exposed telopep-

tide sequences to stabilize fibril structure. FACIT collagens [167] form bridges between interstitial collagen fibrils.

The macromolecular assembly of the open network structure of type IV collagen, the principal non-fibrillar collagen, has been extensively studied [168]. Anchoring

fibrils composed of type VII collagen associate with the type IV collagen network in the cutaneous basement membrane to stabilize the dermal–epidermal boundary [169]. Details of the molecular assembly of other non-fibrillar collagens into beaded microfibrils [170] and hexagonal lattices [168] have been reported. Transmembrane collagens [171] form homotrimers with the collagenous domain extracellularly oriented.

Collagens in the lung

Fibrillar collagens (types I, II, III, V and XI) are the most abundant proteins in the lung accounting for approximately 15–20% of the dry weight of the tissue [172]. Their primary function is to confer tensile strength to all distensible components of the lung such as the large airways, blood vessels and alveolar interstitium. Types I and III collagen (in a ratio of 2 : 1) represent approximately 90% of the collagens in the adult human lung. These collagens are located throughout the alveolar interstitium, in pulmonary blood vessels, the visceral pleura and in the connective tissue sheaths that surround the tracheobronchial tree. Type I collagen confers tensile strength and rigidity to tissues; whereas type III, which forms a more reticular network of fibres, is more important in bestowing compliance. Tensile strength of bronchial and tracheal cartilage is largely determined by types II and XI collagen. Small amounts of type V collagen are present in basement membranes. It is also found in association with type I collagen in the interstitium, alveolar walls and blood vessels.

Type IV collagen is the most abundant non-fibrillar collagen found in the lung, constituting approximately 5% of parenchymal collagen. Instead of forming fibrils, the amino and carboxy terminal regions of the type IV collagen molecule laterally associate to form open network structures which are thought to have a role in the structural and barrier functions of the basement membrane. Type IV collagen is responsible for the tensile strength of the blood–gas barrier and plays a large part in preventing stress failure of the pulmonary capillaries under normal conditions [173].

Many other non-fibrillar collagens are present in the lung. Type VI collagen is found in the pulmonary interstitium and vasculature, as fine filaments associated with types I and III collagen. Pulmonary arterioles and venules contain type VIII collagen. Although information on localization is lacking, expression of types IX and XII collagen in the lung has been documented. Collagen types XV and XVIII, which are also proteoglycans, are components of the lung basement membrane. Although it has been speculated that these other non-fibrillar collagens may have a role in determining tensile strength or in facilitating collagen fibril assembly, their specific functions in the lung are not known.

Elastic fibres

Simplistically, elastic fibres are the springs that snap the lung back to resting volume following inflation. Elastic fibres [174], assembled from fibrillin-rich microfibrils and tropoelastin, are very stable structures; some may last for the life span of the organism [175]. The relative proportion of microfibrils to elastin, however, declines with increasing age. Thus, the scaffold for elastic fibre assembly is only present for a limited period of time, and degradation of elastin in the adult has been believed to lead to irreversible pathology.

In the lung, elastic fibres are predominately found in the parenchyma where, together with collagen fibrils, an integral fibre network that comprises the architectural skeleton of the lung is formed. This fibre network is a key determinant of the mechanical properties of the lung. Elastic fibres encircle respiratory bronchioles and alveolar ducts in a helical fashion and appear as a fine mesh in alveolar walls. In the walls of the pulmonary artery and arterioles, elastic fibres are organized into concentric sheets or lamellae.

Elastin

Elastin is a unique matrix protein that is capable of being stretched several times its resting length under tension with a rapid recovery to its original size when the force is released [176]. It is an insoluble protein composed mainly of hydrophobic amino acids (44%), glycine (33%) and proline (10–13%). Two pentapeptides, Val-Pro-Gly-Val-Gly and Pro-Gly-Val-Gly-Val, repeat frequently in the molecule and are thought to form large spiral regions that contribute to the distensibility of the protein [177]. Phylogenetic analysis indicates that the appearance of elastin in vertebrate species coincides with the development of pulsatile blood flow and closed circulatory systems [178].

Elastin is formed by cross-linking of lysine residues on its soluble precursor, tropoelastin [179]. Tropoelastin is transcribed from a single gene located on chromosome 7 [180,181]. The gene consists of 34 small exons (30–225 base pairs) interspersed between large introns [182,183]. Tropoelastin gene transcription is initiated from three major and four minor sites [182]. Transcripts are subject to alternative splicing particularly in the region encoded by exon 33 [184,185]. Pre and posttranscriptional regulatory mechanisms of tropoelastin gene expression have been described [186–188]. Posttranslational modification of tropoelastin is minimal. Although proline hydroxylation may occur, it is not necessary for tropoelastin secretion [189]. Two molecular chaperones, BiP and FKBP65, are important in the trafficking of tropoelastin from the endoplasmic reticulum to the Golgi apparatus [190]. It has been proposed that a 67-kDa elastin-binding protein functions as

an intracellular chaperone to prevent tropoelastin aggregation and degradation [191]. Newly secreted tropoelastin forms globules on the cell surface [192]. These globules then interact with microfibrils via regions in the carboxy terminal of tropoelastin [193]. The process of cross-linking of tropoelastin lysine residues [194], which is catalysed by protein-lysine 6-oxidase (EC 1.4.3.13), begins in the cell surface globules and continues on the elastic fibre [195]. Cross-linking of tropoelastin to fibrillin-1 by protein-glutamine gamma-glutamyltransferase (EC 2.3.2.13) further stabilizes elastic fibre structure [196]. Molecules such as fibulin-5 [197,198], which are found at the interface of cell surface elastin globules and extracellular matrix elastic fibres, are essential for elastogenesis. Impaired elastic fibre assembly may contribute to the pathogenesis of COPD [199].

Proteoglycans

The simplistic analogy for proteoglycans is 'goo'. In the lung and other organs, proteoglycans are the primary 'space-fillers' of connective tissue. Proteoglycans are a diverse family of large molecules in which a core protein is covalently linked to sulphated polysaccharides or glycosaminoglycans (GAGs). GAGs may be divided into three classes: chondroitin sulphate/dermatan sulphate, heparan sulphate/heparin and keratan sulphate; a proteoglycan may be comprised of GAGs from more than one class. Hyaluronan, a non-sulphated GAG, is not a true proteoglycan because of its lack of a core protein. Proteoglycans are synthesized by a variety of cell types and are multifunctional components of most extracellular matrices and plasma membranes. Because of their large hydrodynamic volumes and charge characteristics, hyaluronan and proteoglycans exert a profound influence on lung compliance and fluid balance.

Early studies used cationic dyes, which react with negatively charged regions of carbohydrates and GAGs, to demonstrate the presence of proteoglycans in the lung. More recent studies have utilized antibodies and cDNA probes obtained from molecular cloning of various proteoglycans. These studies have demonstrated that the matrix proteoglycans [200]: versican, perlecan, agrin, decorin, biglycan, PRELP, lumican and fibromodulin are components of the lung extracellular matrix. Versican is a member of the hyalectan gene family which contains proteoglycans that interact with hyaluronan and lectins. In pulmonary fibrotic disorders, versican, a chondroitin/dermatan sulphate proteoglycan, appears to form a provisional matrix in which myofibroblasts synthesize type I collagen [201]. Perlecan and agrin are referred to as basement membrane proteoglycans and are predicted to function in determining the filtration properties of the alveolar basement mem-

brane [202,203]. Both are heparan sulphate proteoglycans and are also likely to function in sequestering growth factors. Agrin, because of its structural similarity to Kazal-type serine protease inhibitors, may have a role in protecting proteins from degradation [204].

Decorin, biglycan, PRELP, lumican and fibromodulin are part of the family of small leucine-rich proteoglycans. This family is divided into three distinct subclasses based on genomic and protein organization. Decorin and biglycan, which contain chondroitin sulphate/dermatan sulphate GAGs, form one subclass. Both are primarily found in the pulmonary interstitium. Levels of decorin and biglycan are increased in pulmonary fibrosis and decreased in pulmonary emphysema [205]. Decorin and biglycan are hypothesized to function by sequestering growth factors and by facilitating collagen fibril assembly. Exogenously administered decorin is antifibrotic. This antifibrotic effect is attributed to binding and inactivation of TGF- β .

PRELP, lumican and fibromodulin, which contain keratan sulphate GAGs, are part of another subclass of the small leucine-rich proteoglycan family. In the lung, PRELP has only been detected at the mRNA level. The walls of the pulmonary vasculature contain lumican. Expression of fibromodulin is observed in animal models of lung injury. Lumican and fibromodulin appear to be important in collagen fibril assembly [206,207]. However, specific functions of these proteoglycans in the lung are not known.

Matrix-related pathology of COPD

Although destruction of elastic fibres in the lung interstitium is regarded as the pathological hallmark of emphysema, it is clear that excess matrix protein deposition or fibrosis often occurs in the airways of the COPD patient. Thus, the response of lung connective tissue to intrinsic and extrinsic factors associated with COPD is not uniform, and this should be taken into account in the design of therapeutic strategies for treatment of this disease.

Airway fibrosis

Deposition of collagenous and non-collagenous matrix proteins in the airways is part of a larger remodelling process that also includes changes in smooth muscle and mucus glands. Persistent inflammation in the small airways leads to subepithelial deposition of fibronectin and tenascin followed by fibroblast activation and production of collagen types I and III. Although the functional consequences of matrix protein deposition in the airways are not completely understood [208], excessive deposition of collagens and other molecules will have profound effects on mechanical properties, metabolism, cell function and transport

properties of airways. It is possible that matrix protein deposition in the airways is a teleological response to prevent airway collapse. However, excess matrix protein deposition may contribute to narrowing of the airway lumen and thus, in the long term, limit ventilation.

Emphysema

There are two major forms of emphysema: panacinar and centrilobular. Panacinar emphysema predominates in the lower lung zones and occurs in people deficient in α_1 -proteinase inhibitor, the serpin that blocks the activity of neutrophil elastase. Uniform destruction of the alveolar walls and permanent enlargement of the alveoli are observed. As the disease progresses, all respiratory airspaces distal to a terminal bronchiole are affected. Centrilobular emphysema predominates in the upper lung zones and begins with inflammation in the terminal and respiratory bronchioles with subsequent enlargement of the alveoli and more distal respiratory airspaces. It is thought to result as a consequence of prolonged exposure to cigarette smoke.

Treatment of COPD – a matrix perspective

Lung connective tissue is a dynamic structure. Fibroblasts, in particular, are active in synthesis, organization and degradation of extracellular matrix. Some matrix components, such as recently synthesized collagens and proteoglycans, are turned over quite rapidly while other components, such as elastic fibres, are very stable. Initial attempts to understand the role of connective tissue in COPD focused on regulation of matrix turnover and on identification of the enzymes responsible for elastic fibre destruction. Recently, more research effort has been devoted to understanding the process of alveolar regeneration. Thus, from a matrix perspective, emphysema treatment may be viewed as limiting elastic fibre destruction and/or restoring function to damaged alveolar units. Airway fibrosis also is frequently present in COPD patients and may be a major cause of airflow limitation. It remains unclear if specific treatments for airway fibrosis, which remain to be developed, will improve COPD outcome.

Protease inhibition

Since the first association of α_1 -antitrypsin deficiency with emphysematous lung disease [209,210], much effort has been focused on the design of neutrophil elastase inhibitors for COPD treatment. Indeed, the elastase–anti-elastase hypothesis has dominated COPD research for the past 40 years. Although clinical use of neutrophil elastase inhibitors is not common, many compounds have been tested in animal models and in clinical trials [211]. A broad

spectrum of extracellular and intracellular proteases, many with elastolytic capacity, is present in the COPD patient [212]. Furthermore, data from animal models [213,214] indicate that other proteases may be important in elastic fibre destruction and COPD pathogenesis. Although it appears that the protease–antiprotease hypothesis may be more extensive than originally envisioned, effective inhibition of elastolytic proteases will continue to be an attractive strategy for attenuating COPD progression.

Alveolar regeneration

To completely restore normal lung function to the COPD patient, repair and regeneration of damaged alveolar units is necessary. Although clinical implementation of regenerative medicine remains a revolutionary and futuristic goal, data from animal studies are providing evidence of some critical components of this process. The complexity of alveolar development is exemplified by the reports of defective alveogenesis in at least eight distinct ‘knock-out’ mice [215]. Alveolar enlargement in mice deficient in TIMP-3 [216], surfactant protein D [217] and the β_c -integrin subunit [218] underscores the importance of these molecules in regulating alveolar homeostasis. Models in which emphysema is induced by apoptosis of alveolar endothelial [219] or epithelial cells [220] highlight the role of parenchymal cell turnover in the maintenance of alveolar structure. Perhaps the most promising finding from animal studies is that in elastase-damaged lungs, alveolar function and architecture can be restored by retinoic acid treatment [221]. Translation of these animal studies to clinical practice represents one of the most promising and challenging areas of COPD research.

Conclusions

It has long been recognized that the fundamental physical properties of the lung are determined by connective tissue. More recently, it has been appreciated that matrix proteins interact directly with receptors on the cell surface to initiate signalling cascades with the capacity to regulate the majority of cellular functions including proliferation, migration and differentiation. Despite this knowledge, none of the present clinical strategies for treating COPD directly target matrix proteins. A better understanding of matrix protein biology and new approaches for treating connective tissue disorders are still needed.

One long-term goal is the development of strategies that will enable regeneration of normal lung in damaged areas. The restoration of alveolar architecture in elastase-treated rats by retinoic acid treatment [221] provides evidence that extensive matrix damage can be repaired. Derivation of

lung epithelium from embryonic [222] and bone marrow derived stem cells [223,224] implies that various types of precursor cells may be potentially useful in repopulating damaged areas of the lung. Continual application of cutting edge science to current issues in pulmonary medicine is our best hope for development of better treatments for lung disease and eventual realization of the goal of lung regeneration.

Acknowledgement

The authors would like to thank Huw D. Jones, UCL Media Resources, for his help in the preparation of Figures 40.1 and 40.2.

SECTION 5

Clinical considerations
and complications

CHAPTER 41

Aerosols and delivery systems

Stephen P. Newman

The inhaled drug delivery route is recognized as having a number of advantages over oral and parenteral routes, and these are highly relevant for drug delivery in patients with COPD. These advantages derive from the drug being delivered directly to the site in the body where it is required: the airways of the lungs [1]. Because the drug is targeted direct to the lungs, without having to undergo hepatic first-pass metabolism, it is possible to use a lower dose of inhaled bronchodilator than would be required by the oral route. The onset of drug action is generally relatively rapid, and the incidence of side-effects relatively low.

When drugs are given by inhalation, whether for therapeutic purposes, for bronchial provocation testing or for medical diagnosis, they are delivered as aerosols [2–4]. An aerosol is defined as a stable dispersion or suspension of solid particles or liquid droplets in a gaseous medium [5]. Aerosols vary in size from very small particles such as those in tobacco smoke (sometimes less than 0.1 μm diameter) to fog droplets and pollens exceeding 50 μm diameter, but those aerosols used in the treatment and diagnosis of pulmonary diseases are generally confined to the 0.5–10.0 μm size range.

Aerosol properties

Particle size distributions

Particle or droplet size is the single most important aerosol characteristic, because it is key to determining how much aerosol can enter the patient's lungs, and where within the lungs deposition takes place [6,7]. Two additional properties are also important: density and shape. A particle or droplet with greater than unit density behaves aerodynamically as though it is larger than its physical size, while a particle or droplet with less than unit density behaves aerodynamically as though it is smaller than its physical size [8].

Aerosol particles are seldom perfect spheres; for instance, drug particles delivered from inhaler devices are often micronized crystals of highly irregular shape.

Density and shape are taken into account by defining an aerodynamic diameter (D_a) as

$$D_a = D_p \times \sqrt{\rho},$$

where D_a is the diameter of a spherical unit density (1 g/cm^3) particle or droplet, having the same settling velocity in air as the particle or droplet in question; D_p is the physical diameter of the particle or droplet; and ρ is the specific gravity, i.e. its density relative to that of water.

Aerosol particle or droplet distributions may be termed either monodisperse or heterodisperse. In a monodisperse aerosol, all the particles or droplets are approximately the same size, while in a heterodisperse aerosol, the particles or droplets cover a spectrum of sizes [9]. Virtually all aerosols delivered for the purposes of medical treatment or diagnosis are heterodisperse in character. When considering heterodisperse size distributions, it is important to recognize that the size distribution by number and the size distribution by mass are very different, and that the latter will be more important. Relatively little drug mass is carried by a large number of small particles; for instance, 1000 1- μm particles carry the same amount of drug as a single 10- μm particle.

The particle size spectra of medical aerosols are generally complex, but can often be approximated as log-normal distributions [9]. If the size distribution is plotted cumulatively, then two commonly used parameters may be determined:

- 1 the mass median aerodynamic diameter (MMAD), which is the size distribution such that half the aerosol mass is contained in smaller droplets and half in larger droplets; and
- 2 the geometric standard deviation (GSD).

The GSD is dimensionless, one definition being as the ratio of the 84% point on the cumulative distribution to the 50% point (Fig. 41.1). In practice, medical aerosols often have GSDs in the region of 2–3, while a size distribution that is

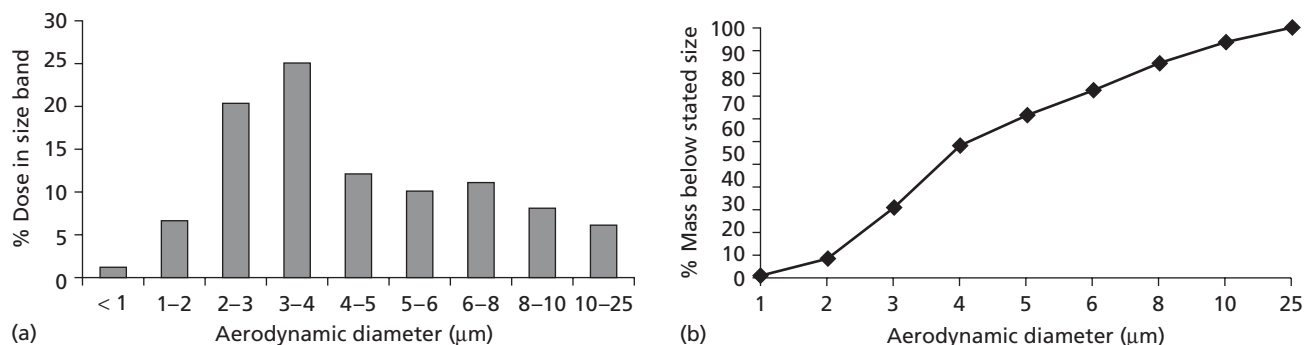

Figure 41.1 Particle size spectrum of a heterodisperse aerosol. (a) Percentage of drug mass plotted versus aerodynamic diameter; and (b) cumulative plot showing percentage of drug mass contained in particles smaller than the stated size. From the cumulative plot, it is possible to determine mass median aerodynamic diameter (MMAD) as the 50% point (3.9 μm), and geometric standard deviation (GSD) as the ratio of 84% to 50% points (7.8 : 3.9 μm , i.e. 2.0).

‘acceptably’ monodisperse has a GSD less than 1.22 [10]. Monodisperse aerosols can be produced by devices such as the spinning disc generator or condensation aerosol generator [11]. While MMAD is a useful measure of the ‘average’ particle size, its relevance probably diminishes as the GSD increases [12].

Measuring particle size

The regulatory authorities place great importance upon the particle size distributions of aerosols delivered from inhaler devices, and companies developing new inhaled drug products devote much time and effort to these measurements. Most particle size data are obtained from cascade impactors such as the Andersen Sampler and Multistage Liquid Impinger, in which aerosol particles are collected on a series of stages, according to their aerodynamic sizes [13,14]. In these devices, each stage may be washed with a suitable solvent, so that the mass of drug associated with each size band may be quantified by an appropriate analytical method. The use of simulated breathing patterns [15], or the use of inlets based on models of the human upper airways [16], may improve the precision of impactor measurements. Various optical methods, generally using laser light, may also be used to determine aerosol size distributions [13,17]. While these optical methods may be quick and simple, they measure aerosol particles and droplets irrespective of whether they contain drug, and hence cannot distinguish between drug and carrier particles, or between droplets containing drug and those only containing diluent.

Effects of humidity

Aerosol particles and droplets may be influenced by hygroscopic effects [18]. Some drug and carrier materials are highly water-soluble, and when particles enter the humid

environment of the lungs they may absorb moisture and grow rapidly in size [19]. These effects are not confined to solid particles. Liquid aerosols comprising hypertonic droplets may absorb water in the lungs and increase in size, in order to bring the droplets to the same tonicity as the respiratory tract, while hypotonic droplets may shed water and hence reduce in size [20].

Deposition mechanisms

Deposition of aerosols in the human respiratory tract takes place by three main mechanisms: (i) inertial impaction; (ii) gravitational sedimentation; and (iii) Brownian diffusion.

Inertial impaction

Inertial impaction occurs in the upper airways (mouth and pharynx), and at the bifurcations between the larger, more central, airways in the lungs [6]. This process may occur when the airway changes direction; if the aerosol particle has too much inertia, then it may be unable to follow the air-stream and may strike the airway wall where it becomes deposited. The probability of inertial impaction is proportional to the product of $D_a^2 \times Q$, where D_a is the aerodynamic diameter and Q is the linear velocity of air. The product $D_a^2 \times Q$ is sometimes termed the ‘impaction parameter’ [6]. Experimental studies show upper airway deposition increases in proportion to this parameter [21].

Within the lungs, inertial impaction is confined mostly to the large central airways, because the total airway cross-section increases rapidly after the first few airway generations [22]. Hence, the linear velocity of air (Q in the impaction parameter) is much lower in the more peripheral airways of the lungs. Impaction can occur both during inhalation and exhalation. The effects of impaction may be

augmented by the creation of turbulent airflows within the airways; for instance, the passage of air through the larynx creates turbulence and an unstable airflow, which may enhance deposition within the trachea [23].

Gravitational sedimentation

Gravitational sedimentation takes place in the small airways and alveoli, when aerosol particles or droplets fall under gravity onto the airway wall, either during breath-holding, or during slow steady breathing. A particle settling under gravity accelerates to a steady terminal settling velocity, at which the gravitational force is balanced by the resistance of the air through which the particle falls. The terminal settling velocity is directly proportional to the square of the aerodynamic diameter (D_a^2). The product $D_a^2 \times T$, where T is the residence time in the respiratory tract, is sometimes called the 'sedimentation parameter' [6]. In the peripheral regions of the lungs, the linear velocity of air is low and residence times are relatively long. Also, as the lung periphery is approached, diameters of individual airways become narrower, so that particles settling under gravity have a relatively small distance to fall. To give an example, a 5- μm diameter unit density particle sediments at a rate of 0.74 mm/s [24], so that in a 3-s breath-hold pause, the distance fallen is 2 mm; this guarantees that particles of this size will deposit completely in small conducting airways of diameter 2 mm, assuming they are able to penetrate this deeply into the lungs.

Brownian diffusion

Brownian diffusion is a very important deposition mechanism for submicronic particles, especially those less than 0.5 μm diameter, and is confined mostly to the alveoli, although it can occur in other parts of the respiratory tract [24]. Most of the mass of therapeutic aerosols is usually contained in particles more than 1 μm diameter, so that for therapeutic aerosols, Brownian diffusion is generally less important than inertial impaction and gravitational sedimentation.

Electrostatic charge effects

Most aerosol particles and droplets become electrically charged to some degree during their formation process, and may be attracted towards airway surfaces, leading to greater deposition than would be observed for an electrically neutral aerosol [25]. Generally, however, the electrical charging of aerosols appears to have a minor role in determining the probability of aerosol deposition compared with the more probable processes of inertial impaction and gravitational sedimentation. Electrical charges accumulating on inhaler

devices may be important, as they may attract aerosol particles onto the walls of the device, reducing the quantity of drug available for inhalation, as will be described subsequently.

Factors determining deposition patterns

The quantity of aerosol deposited in the lungs, and site within the lungs at which deposition occurs, depends on three basic factors: (i) aerodynamic particle size; (ii) inhalation mode; and (iii) airway anatomy.

Effect of particle size

The effect of particle size on deposition in the tracheobronchial and alveolar regions of the lungs, and in the upper airways, has been examined [26] using monodisperse sebacate oil droplets (Fig. 41.2). These data show that as particle size increases, the likelihood of deposition by inertial impaction in the upper airways also increases, which explains why the size band below 5 μm is termed the 'fine particle fraction', or sometimes the 'respirable fraction'. The optimal size for alveolar deposition is smaller than that for tracheobronchial deposition. Total deposition in the airways decreases to reach a minimum around 0.5 μm , but increases below this size as a result of Brownian diffusion. The effect of particle size on distribution of aerosols within the lungs has been shown in calculations [27] of the amount of deposition taking place in different generations of the Weibel model of the lungs [22]. Aerosol particles of 7 μm diameter have their major deposition site in the first few airway generations (by inertial impaction), but particles of 3 μm diameter have their major deposition site in the small conducting airways and alveoli (by gravitational sedimentation).

Figure 41.2 Mean percentage deposition in oropharynx, conducting airways of the lungs and alveolated regions of the lungs, of monodisperse particles in healthy subjects, inhaling at 1.5 L tidal volume and a 4-s breathing cycle. (Data from Heyder *et al.* [26].)

Effect of inhalation mode

The inhalation mode is also critically important. Because the nose is a very efficient 'filter' for aerosol particles and droplets, upper airway deposition is higher and lung deposition correspondingly lower, for nose breathing compared with mouth breathing [28]. Hence, inhaled drugs targeted to the lungs should be inhaled via the mouth and not via the nose.

The inhaled flow rate is generally the single most important inhalation parameter, because this determines the likelihood of deposition by inertial impaction in the oropharynx and large central pulmonary airways. Slow inhalation is usually the preferred inhalation technique for therapeutic aerosols in the treatment of COPD patients, because this tends to reduce oropharyngeal deposition and to increase penetration into the lungs [7]. However, inhalation from dry powder inhalers is a major exception to this rule, as is described later. Deep inhalation allows aerosol particles and droplets to penetrate more peripherally into the lungs, where they may undergo gravitational sedimentation. For this reason, a period of breath-holding is generally recommended after inhaling a medical aerosol, and is incorporated into the patient instruction leaflet for many inhaled drug products [29].

Effect of airway anatomy

The airways of the subject inhaling an aerosol are also a critical determinant of the deposition pattern. Even in healthy subjects, there is wide intersubject variability in aerosol deposition patterns, which represents the effect of random variations in airway anatomy [30]. Upper airway anatomy is especially variable, and can be altered at will, for instance by changing the position of the tongue. In addition, there is a more systematic effect in patients with COPD and other obstructive pulmonary conditions, in whom the airways may be narrowed by the presence of oedema, mucus hypersecretion and bronchospasm. Thus, the intrapulmonary deposition pattern is likely to be more 'central' than in healthy subjects [31]. Deposition in large central airways of the lungs results in part from a turbulent airflow, but turbulence can be minimized, and a more peripheral deposition pattern produced, by inhaling drug particles in a helium-oxygen mixture rather than in air [32]. Patients with asthma and COPD may show greater total lung deposition than healthy subjects, because a smaller fraction of the aerosol may be exhaled [33]. Deposition patterns in adolescents broadly resemble those of adults, but younger children would be expected to show lower total lung deposition and a more central deposition pattern within the lungs [34]. These changes result primarily from the airways in children being relatively narrow, but also from differences in breathing patterns between children and adults.

Measuring aerosol deposition

Deposition of medical aerosols can be measured in humans using either radionuclide imaging techniques, or certain pharmacokinetic methods [35,36]. Radionuclide imaging techniques [37,38] consist of the two-dimensional imaging method of gamma scintigraphy, or the three-dimensional methods of single photon emission computed tomography (SPECT) and positron emission tomography (PET). Either the drug formulation, or occasionally the drug molecule itself, is radiolabelled by a gamma-ray-emitting or positron-emitting radionuclide, and the deposition pattern imaged *in vivo* [39–41]. Pharmacokinetic methods are based upon either plasma concentrations or urinary excretion of drug; for instance, utilizing the assumption that drug appearing in the systemic circulation in the first few minutes after inhalation has been absorbed only via the lungs [42–44]. Alternatively, oral charcoal may be used to eliminate drug absorption from the gastrointestinal tract [45]. Pharmacokinetic methods have been made easier by the development of analytical methods capable of quantifying very low concentrations of drug in biological fluids. Taken as a whole, these deposition methods have been used extensively to improve our fundamental understanding of the factors upon which the delivery of medical aerosols depend, and to quantify the deposition of drugs delivered from novel inhaler devices relative to already marketed products. Aerosol deposition patterns have also been predicted in a variety of studies involving mathematical modelling [28,46–48], often showing good agreement with experimental data.

While particle size distributions of medical aerosols are considered excellent laboratory measures of product performance, *in vitro* parameters such as fine particle fraction are not reliable indicators of lung deposition *in vivo* [49]. Fine particle fraction systematically overestimates lung deposition, and may fail to predict accurately the relative performance of two products in clinical practice [50]. Hence, both *in vitro* particle size data and *in vivo* deposition data have important roles in documenting the delivery characteristics of new inhaled drug products. Lung deposition data have been shown to correlate with the clinical effects of drugs used in the treatment of asthma and COPD [51,52].

Aerosol delivery systems

Drugs given by inhalation are delivered as aerosol particles or droplets. If inhalation therapies are to be effective, then the right amount of drug must be delivered to the airways, and inhalation devices that are efficient, reliable and effective are thus required. Pressurized metered dose inhalers

(pMDIs) and nebulizers have traditionally been the devices of choice for delivering inhaled drugs to patients with COPD, but these are now being augmented by novel dry powder inhalers (DPIs), and by new 'soft mist inhalers' containing aqueous or ethanolic liquid formulations. The remaining sections of this chapter review the range of inhaler technologies either available now, or likely to be available in the near future. Each type of device has advantages and disadvantages, as set out in Table 41.1.

Pressurized metered dose inhalers

Contents of pressurized metered dose inhalers

The first pMDI was introduced in 1956 by 3M Riker Laboratories [53], initially to deliver non-selective β -agonists such as adrenaline and isoprenaline. Subsequently, they have been used for a range of bronchodilators including

Table 41.1 Advantages and disadvantages of different types of inhaler device.

Device	Advantages	Disadvantages
pMDI	Quick to use Convenient Compact Portable Multidose Cannot contaminate contents Relatively inexpensive	Difficult to use correctly Propellants needed to generate aerosol Delivery of large doses inconvenient Usually low lung deposition/high oropharyngeal deposition Only formulated for limited drug range
pMDI + Spacer	Quick to use Relatively inexpensive Easier to use than pMDI alone Multidose Can be used with facemask by infants Large doses more convenient than by pMDI alone Better lung targeting than for pMDI alone May reduce local and systemic effects for inhaled steroids	More bulky/less convenient than pMDI Propellants needed to generate aerosol Static charge may reduce drug delivery
Nebulizer	Easy to use (relaxed breathing) Suitable for all age groups Suitable in severe COPD Large doses can be given Unusual drugs can be given Oropharyngeal deposition low No propellants needed	Unit-dose Treatments slow Equipment bulky and inconvenient Compressors may be expensive Electricity supply may be needed Easy to contaminate contents Big variations between models
SMIs	Quick to use Generally very high lung deposition Generally compact and portable Multidose No propellants needed	Little experience in clinical practice May be more expensive than pMDI
DPIs	Quick to use Most are breath-actuated No propellants or electricity needed Compact Portable Difficult to contaminate contents	Not all devices are multidose Usually more expensive than pMDI Maximum inspiratory effort usually needed Only formulated for limited drug range Capsule handling problems for elderly

salbutamol, terbutaline, salmeterol, formoterol and ipratropium bromide, together with corticosteroids such as beclometasone dipropionate, budesonide and fluticasone propionate, for use by patients with obstructive airways disease. The drug substance is either a micronized suspension or a solution in propellants, and may be mixed with a surfactant or other excipients [54]. Until recently, all pMDIs contained a mixture of two or three chlorofluorocarbon (CFC) propellants (CFC 12 with CFC 11 and/or CFC 114), often known better by one of their tradenames (Freon). Many pMDIs have now been reformulated with either hydrofluoroalkane (HFA) 134a or HFA 227 (Table 41.2), which do not contain chlorine and hence do not deplete stratospheric ozone [55].

The key component of the pMDI is the metering valve, which allows small quantities (25–100 μL) of the formulation to be dispensed accurately as required. The vapour pressure inside the canister varies from product to product, but is typically 3–4 atmospheres. When the device is fired (actuated), spray formation is a two-step process, consisting of an initial rapid ‘flashing’ of some of the propellants in the dose, followed by slower evaporation of the remainder [56]. The initial velocity at the actuator nozzle may exceed 30 m/s, and the initial propellant droplet MMAD may exceed 20 μm [57], although rapid decreases in both velocity and particle size occur as the propellants evaporate.

Drug delivery from pressurized metered dose inhalers

The pMDI has many positive features, being compact, portable, convenient and multidose, and these features explain why it has been so successful over almost half a century, despite having changed relatively little (at least prior to the introduction of HFA propellant formulations) during that period [58]. However, the pMDI also has some significant negative features. Most pMDIs are inherently inefficient at delivering drug to the lungs, because the rapid velocity and large size of the propellant droplets will cause most of the dose to deposit by inertial impaction in the oropharynx [59]. No more than approximately 10–20% of the dose actually deposits in the lungs from most pMDIs [60], and this percentage may be further reduced by poor inhaler technique. Some patients cannot co-ordinate actuation with their inhalation [61], and this may result in a reduced amount of drug being deposited in the lungs (or even no drug at all) compared with correct technique. Other patients may exhibit the so-called ‘cold Freon’ effect, which makes them stop inhaling as the evaporating propellant droplets hit the back of the mouth [62]. If inhalation is resumed quickly, then drug should reach the lungs, but some patients stop inhaling entirely or inhale through the nose [63].

In order to derive optimal benefit from drugs delivered by pMDIs, patients need to use them correctly, and good

inhaler technique involves a number of components. Coordination and avoiding ‘cold Freon’ problems are not the only issues. The dose should be actuated during the course of a slow deep inhalation, and this should be followed by several seconds’ breath-holding [64]. This inhalation mode makes sense, because slow deep inhalation allows aerosol particles and droplets the maximum chance of avoiding impaction in the oropharynx, while breath-holding allows particles and droplets to deposit by gravitational sedimentation at their furthest point of penetration into the lungs. Some experts recommend an ‘open mouth’ inhalation technique, in which the pMDI is held several inches away from the mouth to reduce impaction [60], but placing the mouthpiece of the actuator between closed lips is the method generally adopted. Priming the device (firing doses to waste before use if the pMDI has not been used recently) and shaking the can may also be required in order to assure reproducible dosing. The canister should be held upright with the valve downwards during use, or else the metering chamber will not refill under gravity.

Reformulation with hydrofluoroalkane propellants

Reformulation of drugs for asthma and COPD in HFA propellants is a complex and time-consuming undertaking. HFA 134a has similar thermodynamic properties to CFC 12, but it has not been possible to find direct replacements for CFC 11 or CFC 114 [65], which have higher boiling points and lower vapour pressures (see Table 41.2). Reformulation has required the development of novel surfactants, novel valve components and new filling methods [66], together with conducting clinical studies to demonstrate that these products are safe for administration to humans. To reflect these issues, and in recognition of the importance of pMDIs to the welfare of society, CFCs were granted an exemption under the Montreal Protocol [67], allowing their use in pMDIs to continue temporarily even after other uses had been banned. The introduction of HFA products is proceeding, but is not yet complete, and seems to be most rapid in Europe. It is likely that CFC-based pMDIs will linger on for several more years in some parts of the world. While HFA propellants do not deplete stratospheric ozone, they do have a significant greenhouse warming potential (see Table 41.2).

Some companies have chosen to develop HFA products that directly replace CFC products in equal doses, making a ‘seamless transition’ [68]. However, other companies have recognized that it is possible, by manipulation of formulation, metering valve and actuator nozzle, to make ‘better’ pMDIs, which deposit drugs in the more efficiently in the lungs [69], and which are effective in smaller doses [70]. These activities have largely involved reformulation of corticosteroid products in which the drug is in solution, with ethanol as a co-solvent, rather than taking the more

Table 41.2 Properties of propellants used in pressurized metered dose inhalers. (Thermodynamic data from Pischtiak [65].)

Propellant	Structure	ODP	GWP	BP (°C)	VP (bars at 20°C)
CFC 11	CCl ₃ F	1	1	23.7	0.89
CFC 12	CCl ₂ F ₂	1	3	-29.8	5.66
CFC 114	C ₂ Cl ₂ F ₄	0.7	3.9	3.6	1.82
HFA 134a	C ₂ H ₂ F ₄	0	0.3	-26.1	5.72
HFA 227	C ₃ HF ₇	0	0.7	-15.6	3.90

common form of micronized particles. A formulation of beclometasone dipropionate (Qvar[®], 3M Healthcare) was the first of these products, and others are under development. They are intended to improve pulmonary targeting of inhaled corticosteroids and to reduce systemic exposure. Irrespective of whether or not their daily drug dose has changed, patients must be educated appropriately when being switched to HFA-based products, and made aware that the spray will probably taste different and may well feel different on the back of the throat [71].

Novel pressurized metered dose inhaler devices

Some recent developments in actuator technology can also help to ensure efficient drug delivery. Breath-actuated pMDIs such as Autohaler [72] and Easi-Breathe [73] fire the spray automatically by a spring mechanism as the patient breathes in, making them potentially very useful for poor coordinators. Another device (Spacehaler) slows down the spray before it leaves the actuator [74]. As well as reducing oropharyngeal deposition and increasing lung deposition, devices like the Spacehaler (now known as Neo-Haler) could also help to ensure drug delivery in patients who experience 'cold Freon' problems.

Pressurized metered dose inhalers with spacer devices

Types of spacer

Spacer devices are attachments or extensions to the mouthpiece of a pMDI, aimed at placing some separation between the pMDI itself and the patient's mouth, so that the likelihood of the spray impacting in the mouth is reduced [75]. The earliest spacer was an elongated mouthpiece on one

model of the original 3M pMDI product [53], followed almost two decades later by much larger homemade spacers or holding chambers constructed from empty plastic bottles [76]. Spacers have been available commercially since the late 1970s, and are essentially of three types:

- 1 simple tube spacers, which have a volume of 50–200 mL;
- 2 holding chambers, which also vary in size, often being as large as 750 mL, and generally incorporating a one-way valve in the mouthpiece; and
- 3 'reverse-flow' devices.

In the last type of device, the pMDI is actuated into the spacer but in the opposite direction to the patient's mouth; on inhalation either the spacer collapses, or vents open so that room air can be entrained via the device.

Drug delivery from spacer devices

The design of spacers (also known as add-on devices, extension devices, chambers, etc.) varies considerably, and hence the drug delivery characteristics of each spacer are probably unique [77]. Nevertheless, they have some common effects on the drug delivery process. Oropharyngeal deposition from pMDIs is always reduced by spacer devices, because the 'ballistic' component of the spray impacts in the device and not in the patient's oropharynx. This may reduce both the systemic side-effects [78] and the local side-effects [79] of inhaled corticosteroids. Lung deposition is often increased, although this is not always the case. The clinical effects of drugs delivered by spacers are likely to be enhanced in patients with poor inhaler technique, but this may not occur in patients with good technique [80], who may already be receiving adequate drug from a pMDI alone. Spacers make pMDIs easier to use, because both coordination and 'cold Freon' problems are reduced. This is especially true for large volume holding chambers such as the Nebuhaler and Volumatic, where the spray may be fired into the spacer, and then inhaled subsequently, but it has also been shown that coordination is less critical when a simple tube spacer is used [81]. Spacer devices appear to be a viable alternative to nebulizers for delivering large doses of inhaled bronchodilators, both to patients with severe acute asthma and to patients with chronic obstructive pulmonary disease [82]. It is possible to use spacers with facemasks, which may be especially valuable in small children [83,84].

Correct use of spacers

While spacers reduce some of the problems of using pMDIs correctly, it is still important that they should be used in the right way. The manufacturer's instructions often recommend inhaling each dose from a spacer in a single deep breath, but a satisfactory clinical response may often be obtained by breathing tidally [85,86]. However, while it

Figure 41.3 Mean (SD) lung deposition (percentage ex-valve dose) from two plastic spacers (Volumatic and Nebuhaler) which were tested both with and without ‘priming’ to reduce static charge accumulation. The data are compared with those for a metal spacer (Nebuchamber) which had undergone similar treatment. Priming was required to optimize drug delivery from the two plastic spacers, but not from the metal spacer. (Data from Kenyon *et al.* [89].)

is possible to fire multiple doses into spacers and inhale them in a single breath, this will reduce delivery efficiency compared with inhaling the same number of single doses in single breaths [87]. Increasing the delay time between actuation and inhalation also reduces the delivered dose [87]. Perhaps most critically of all, plastic spacers may accumulate static charge during handling, which causes aerosol to be attracted to the walls of the spacer and deposit there prematurely. This may lead to reductions in respirable dose [88], lung deposition [89] and clinical response [90]. In order to reduce static charge build-up, washing a plastic spacer in household detergent and allowing it to air-dry has been recommended [91,92]. A lightweight metal spacer (Nebuchamber) was recently introduced, and drug delivery from this device is not susceptible to static charge effects [89], as shown in Figure 41.3. Plastic spacers that do not require static charge are now available [93].

Nebulizers

Types of nebulizer

Nebulizers convert a drug solution or suspension into a spray. The term ‘nebulizer’ is usually reserved for unit-dose devices containing liquid volumes between 1 and 5 mL. Novel multidose devices using the same or similar formulations (‘soft mist inhalers’) are described in the following section of this chapter. Most nebulizers use compressed gas, which passes through a narrow Venturi, to form the spray, and these are known as ‘jet’ nebulizers [94]. Owing to evaporation, the temperature of the nebulizer solution

decreases, and its concentration increases, during the nebulization process. Ultrasonic nebulizers, in which liquid is atomized as it falls onto a piezoelectric crystal, are now probably less common than a decade ago, partly because sonification has been shown to damage some drug molecules [95]. Some new models of nebulizer are based upon the use of a vibrating mesh of micron-sized holes [96,97]. An aerosol is formed when drug solution passes through the mesh. These devices may overcome some of the limitations of conventional nebulizers, and could replace them in clinical practice in due course.

Advantages and disadvantages of nebulizers

Compared with the pMDI, nebulizers have both advantages and disadvantages. It is easy to use a nebulizer, because the dose can be inhaled by normal relaxed breathing, via either a mouthpiece or a facemask [98], without the need for co-ordination or any specific inhalation manoeuvre. It is possible to deliver very large drug doses if required, for instance up to 1 g of some antibiotics [99]. Nebulizers seem popular with patients, and are often used at home with many hospitals offering a nebulizer service [100]. Because solutions of histamine or methacholine can easily be nebulized, they are the devices of choice in bronchial challenge tests [4].

However, nebulizers have some significant disadvantages or limitations [101]. Only a single dose may be placed in the nebulizer chamber, and treatment times are relatively long, with 10–15 min being needed typically to nebulize several millilitres of solution. Nebulizer apparatus is bulky and inconvenient, because an air compressor or power unit is required, in addition to the nebulizer itself. A range of additives may be included in nebulizer formulations in order to maintain sterility, and the potential of these additives to cause bronchoconstriction should be borne in mind [102]. Nebulizers cannot compete with pMDIs and DPIs in the portable inhaler market, but have their own niche uses, for instance to deliver large doses of inhaled bronchodilators to patients with acute asthma or severe COPD, who might find difficulty using a pMDI successfully, or to deliver less usual drugs such as inhaled antibiotics or inhaled α_1 -antitrypsin. However, as has already been described, a pMDI plus spacer device may offer a viable alternative to a nebulizer in some situations [82].

Drug delivery from nebulizers

There are likely to be major differences between nebulizer systems in their output characteristics [103,104] and efficiency of delivery into the lungs [105,106], which should be taken into account when selecting nebulizer equipment. Factors affecting drug delivery from nebulizers include the design and brand of nebulizer, volume fill,

Figure 41.4 Breath-enhanced output jet nebulizer device. (From Knoch and Sommer [107] with permission.)

compressed gas flow rate and whether a solution or suspension is used (solutions are generally easier to nebulize than suspensions). Droplet size of nebulized aerosol decreases as the compressed gas flow rate through the nebulizer is increased. Even when used under optimal conditions, nebulizers are relatively inefficient. The majority of the dose may be retained in the nebulizer as a 'dead volume', lost on connecting tubing or vented during exhalation [106]. The use of 'active Venturi' or 'breath-enhanced output' devices (Fig. 41.4), in which a system of valves is used to control air flow and hence to increase aerosol output during the inhalation phase of breathing, helps to maximize delivery efficiency [107]. Spacer devices attached to nebulizers can be used to store aerosol generated during the exhalation phase of breathing [108], but increase the bulk and complexity of the system. Nebulizers can be placed in ventilator circuits to treat intubated patients [109], but very little of the dose is actually delivered to the lungs [110]. Standards for testing nebulizers in the laboratory [111] have recently been set, and guidelines issued for best nebulizer practice [112].

Novel nebulizer systems

Two recently introduced nebulizer systems have aimed to exert greater control over the particle size and/or patients' breathing patterns. In Adaptive Aerosol Delivery (AAD) devices, a jet nebulizer is equipped with an inhalation monitoring unit, so that the aerosol delivery is continuously adjusted to coincide with the first half of each individual patient's inhalation [113]. This provides a means of controlling more accurately the dose each patient receives, and provides extremely reproducible deposition of drug in the lungs, as well as enhancing patient compliance [114]. In the AKITA system [115], both particle size and breathing pattern are controlled, in order to target drugs as efficiently

as possible to specific lung regions. In one study involving COPD patients, inhaled volume was adjusted for each individual patient, and inhaled flow rate was carefully controlled [116]. AKITA-based devices provided the highest and most reproducible deposition in the peripheral lung, and minimized the time required to deposit a given drug dose. The AKITA system was proposed for delivering inhaled α_1 -antitrypsin to patients with emphysema, bearing in mind that it is inherently difficult to achieve high peripheral lung deposition in COPD, owing to the presence of airways obstruction.

Soft mist inhalers

Novel technologies

Multidose inhalers using liquid formulations are a relatively new development in inhaler technology. These devices use formulations similar to those in nebulizers, and yet can compete in the portable inhaler market. They are not true nebulizers, but should be considered as a new category of inhaler device [117,118]. These so-called 'soft mist inhalers' have a variety of operating principles, including forcing liquid through a narrow nozzle or nozzles under pressure [119,120], ultrasonics [121], vibrating meshes [122,123], electrohydrodynamics [124] and thermal inkjet technology [125]. Soft mist inhalers have proved to be amongst the most efficient of inhaler devices [126,127]. They may have their most important roles in the delivery of expensive drug substances [128], targeting drugs intended for systemic delivery via the lungs (such as insulin), and to achieve a reduction in potential systemic side-effects for inhaled corticosteroids.

Respimat® device

One soft mist inhaler (SMI) has particular relevance in the treatment of COPD. Respimat® SMI (Boehringer Ingelheim) is capable of containing more than 100 doses of an aqueous or ethanolic-based formulation, each of which is delivered via a metering valve with a volume as low as 15 μL [129]. The device is actuated by the energy contained in a coiled spring, and the spray is formed by a sophisticated nozzle system (Fig. 41.5). Boehringer have used the opportunity provided by the phasing out of CFC propellants to develop an entirely novel way of delivering inhaled bronchodilators. Compared with a pMDI, the spray velocity from Respimat® SMI is much reduced (hence the term 'soft mist inhaler'), so that less oropharyngeal deposition occurs. The time taken to generate the spray is more than 1 s (compared with approximately 0.2–0.4 s in a pMDI), and it is considered that this combination of factors makes it easier for

Figure 41.5 Respimat[®] soft mist inhaler. (Figure kindly supplied by Boehringer Ingelheim Ltd.)

patient to coordinate actuation with their inhalation [130]. Respimat[®] SMI has been shown to deposit up to 50% of the dose in the lungs (several times greater than that achieved by CFC-based pMDI) [131,127], and clinical trials have confirmed that it is possible to treat asthma and COPD effectively with correspondingly smaller doses [132,133]. Respimat[®] SMI was the only SMI to have reached the market by the end of 2005.

Dry powder inhalers

Types of dry powder inhaler

The first DPIs to be introduced commercially were the single-dose devices containing drug powder in gelatine capsules. In 1969, Fisons introduced the Spinhaler [134], and this was followed a few years later by the Rotahaler (Glaxo) [135]. Subsequently, inhalers containing multiple doses, either in individual blisters or in a bulk storage reservoir, have become the DPIs of choice for routine use by patients with asthma and COPD [136]. Owing to the cohesive nature of micronized drug particles, most dry powder formulations also contain a carrier substance (usually large lactose particles), which improves the flow properties of the powder [137]. All currently marketed DPIs are 'breath-actuated', using the patient's inhalation to disperse the drug powder, and to deliver it into the lungs [138]. This gives DPIs two inherent advantages over pMDIs:

- 1 they do not require propellants to form the aerosol cloud; and
- 2 it is not necessary for patients to 'press and breathe' simultaneously.

Table 41.3 Dry powder inhalers marketed somewhere in the world in 2005.

<i>Single dose</i> (capsules, blisters)
Spinhaler (Fisons, now Sanofi Aventis)
Rotahaler (GlaxoSmithKline)
Aeroliser (Novartis; a.k.a. Cyclohaler, Pharmachemie)
Inhalator (Boehringer Ingelheim)
Handihaler (Boehringer Ingelheim)
<i>Multiple unit dose</i> (multiple capsules, blisters)
Diskhaler (GlaxoSmithKline)
Diskus (GlaxoSmithKline; a.k.a. Accuhaler)
E-haler (Sanofi Aventis)
Inhalator-M (Boehringer Ingelheim)
<i>Multidose</i> (metered from powder reservoir)
Turbuhaler (AstraZeneca)
Easyhaler (Orion)
Novolizer (ASTA Medica, now Viatrix)
Pulvinal (Chiesi)
Twisthaler (Schering-Plough)
Clickhaler (Innovata)
Airmax (Ivax)
Jethaler (Ratiopharm)

Several of the pharmaceutical companies most active in inhaled drug delivery for asthma and COPD appear to be prioritizing DPI development over pMDIs at the present time.

By 2005, more than 15 DPIs had been marketed in at least one country, and a number of others were in development (Table 41.3). New single-dose devices are still being introduced, notably the Handihaler DPI for delivery of inhaled tiotropium bromide [139]. However, most new DPIs contain either multiple unit doses or powder reservoirs. Multiple unit dose devices include the Diskus or Accuhaler (GlaxoSmithKline) [140], while reservoir devices include the Turbuhaler (AstraZeneca) [141]. The relative merits of multiple unit dose and reservoir systems have been debated [142]. Multiple unit dose devices have two potential advantages over reservoir devices:

- 1 it is generally possible to fill individual doses into blisters in the factory more accurately than doses can be dispensed by the patient from a reservoir; and
 - 2 doses contained in blisters should provide better protection for the powder against the effects of moisture.
- However, it should be borne in mind that both multiple unit dose and powder reservoir devices have an excellent track record in clinical practice. Combination DPI products containing both a bronchodilator and a corticosteroid are gaining popularity, partly because of increased convenience of giving two drugs concurrently, but also because of possible drug synergies in the combined formulation [143].

Drug delivery from dry powder inhalers

DPIs either deposit drugs in the lungs with similar efficiency to a pMDI, or with greater efficiency [144], thereby allowing lower maintenance doses to be used [145]. However, as in the pMDI, optimal drug delivery depends on inhalation technique. While breath-actuation in DPIs is seen as an advantage, it is linked to a disadvantage, because patients should inhale with maximal inspiratory effort when using most DPIs. Maximal inspiratory effort ensures optimal deaggregation of drug particles or of drug–lactose complexes, and hence improves fine particle dose and deposition in the lungs. This may appear paradoxical, because increased respiratory effort would be expected to increase particle deposition in the oropharynx, but the effect upon particle deagglomeration seems generally to be greater. To give an example, lung deposition from Turbuhaler DPI averaged 27% and 14% of the dose at a peak inhaled flow rates of 60 and 30 L/min, respectively [146]. Other DPIs may show greater [147] or less [148] dependence of lung deposition on peak inhaled flow rate. Reduction in peak inhaled flow rate through a DPI may lead to a lower clinical response [149]. While achieving a high peak inhaled flow rate through a DPI is important, it is also desirable that the time taken to attain peak inhaled flow rate should be as short as possible [150]. The magnitude of the peak inhaled flow rate associated with maximal inspiratory effort varies from device to device. Turbuhaler has a fairly high resistance to airflow, and a peak inhaled flow rate of 60 L/min through this device approximately represents maximal inspiratory effort. Higher flows can be achieved through other DPIs with lower resistances, although there is no clear evidence that devices with low resistance are inherently either superior or inferior to those with high resistance.

In order to minimize the inhaled flow rate dependence of DPIs, novel particle formulations, which can be dispersed easily without using maximal inspiratory effort, have been developed [151,152]. Over 50% of the dose may be deposited in the lungs using these formulations, a much higher percentage than with conventional formulations. Several 'active' DPIs, in which the powder is dispersed by either compressed air [153] or an electric motor [154], have been described. These very sophisticated formulations and devices are likely to be relatively expensive, and may be better suited to delivery of novel therapies such as inhaled peptides and proteins, rather than to daily maintenance therapy of obstructive airways disease.

The need to inhale from most DPI systems with maximal inspiratory effort has raised concerns that some patients with more severe disease might be unable to use them satisfactorily. Recent data suggest that some patients with COPD may have difficulty attaining the required peak inhaled flow rates through Turbuhaler DPI [155], although

in another study peak inhaled flow rates were similar in COPD patients to those reported in asthmatic patients [156]. In a recent review, it was concluded that although more data have been obtained in asthmatics than in patients with COPD, the peak inhaled flows attained via DPIs in both asthmatic and COPD patients are probably little different to those obtained in healthy subjects, and that asthmatic children, adults with acute asthma and patients with severe COPD can all use DPIs effectively, and gain good clinical benefit [157]. It has been suggested to use Turbuhaler DPI, rather than a nebulizer, to deliver high-dose domiciliary terbutaline treatment in most patients with severe COPD [158], but this suggestion is controversial.

Conclusions

The range of inhaler devices available is increasing, although the rate of growth of new inhaler technology brought about by the phase-out of CFC propellants now appears to be slowing down. While the proliferation of new inhaler devices with differing instructions for correct use may cause confusion among patients if not carefully managed, patients are now likely to be provided with a range of devices that meet individual needs and preferences. Each category of inhaler has advantages and disadvantages, so that it is unlikely that there will ever be a 'perfect' inhaler device appropriate to all patients and to all circumstances.

Recent evidence-based guidelines concluded that while each type of inhaler can be equally effective if used correctly, choice of inhaler should consider a range of factors, including likelihood of correct use, cost and preference [159].

The efficiency with which inhaler devices deposit drug in the lungs has increased dramatically over the last two decades, from approximately 10–20% of the dose for most CFC-based pMDIs and nebulizers, to more than 50% of the dose for some novel devices and formulations. The development of 'formulation integrated dry powder inhalers', combining an efficient inhaler device with an easily dispersible formulation, may lead to further improvements in device efficiency [160]. These technological advances may be of limited value in the maintenance therapy of COPD with inhaled bronchodilators, but are highly relevant for other inhaled therapies in COPD including antibiotics and alpha-1 antitrypsin. Taken as a whole, there is little doubt that the use of inhaled drug therapy will have a major role for the foreseeable future in patients with COPD.

CHAPTER 42

Gastro-oesophageal reflux

John K. DiBaise

Gastro-oesophageal reflux disease (GERD) reflects a spectrum of disease that is among the most common gastrointestinal conditions seen in a variety of physician practices. Its importance, however, lies not only in its prevalence but also in its diversity of clinical presentations, potential for morbidity and mortality, and high rate of health-care utilization. Much progress has been made in our understanding of the pathophysiology of GERD over the last two decades and the recent introduction of potent antisecretory agents and laparoscopic and endoscopic techniques to treat GERD has resulted in increased interest in this disorder from both lay and scientific communities.

GERD can have a major impact on pulmonary disease. While the association between GERD and pulmonary disease has been best characterized in asthma, GERD has been associated with a variety of other respiratory symptoms and disorders, including chronic obstructive pulmonary disease (COPD). This chapter is intended to provide a general overview of GERD including its prevalence, pathophysiology, presentation, diagnosis and treatment. In the process, a more focused review of the association between GERD and COPD is provided.

Epidemiology and risk factors

Information regarding the prevalence of GERD in the general population has been assessed in a number of epidemiological studies that have typically used the classic symptoms of GERD – heartburn and acid regurgitation – as indicators of the disease. A recent survey of residents from Olmsted County, Minnesota found that the prevalence of heartburn or regurgitation occurring on a yearly, monthly and weekly basis was approximately 60%, 40% and 20%, respectively [1]. In contrast to other studies that suggest an increased prevalence of GERD in males and with increasing age, no significant differences were found relative to gender or age

in this study, although a trend was noted for an inverse association between heartburn and increasing age. The actual prevalence of GERD is probably even higher if those patients with GERD but without heartburn or regurgitation are taken into account. Indeed, patients with so-called ‘extraoesophageal’ or ‘atypical’ presentations of GERD are commonly encountered in clinical practice and often do not complain of associated heartburn or regurgitation [2].

GERD is not unique to the USA as similar findings have been reported in Europe [3]. Interestingly, GERD appears to be less common in persons of Asian origin [4], suggesting an influence by cultural factors. Nevertheless, it should be noted that a study from China suggests a prevalence similar to that of Western countries [5]. Certainly, these differences may be explained, at least in part, by differences in the definitions of GERD that were used. Our knowledge of GERD prevalence in minority populations within the USA remains relatively poor.

The role of genetic factors in GERD is unknown. Recently, a gene for severe GERD in children was mapped to chromosome 13q14 [6]. A familial relationship to GERD has been suggested as the prevalence of GERD increases substantially in persons with first-degree relatives with Barrett’s oesophagus or oesophageal adenocarcinoma, two complications of GERD [7]. Interestingly, in this study, first-degree relatives of patients with reflux oesophagitis were not more likely to have GERD compared with spouse control relatives, suggesting that there may be genetic predisposition to the development of GERD in families of patients with Barrett’s oesophagus and oesophageal adenocarcinoma, but that environmental factors may be more important for uncomplicated reflux. A genetic influence is also supported by a recent report showing an increased concordance for GERD in monozygotic compared with dizygotic twins [8]. It was concluded that genetic influences may account for approximately 31% of the liability to GERD.

Table 42.1 Potential risk factors for developing gastro-oesophageal reflux disease (GERD).

Hiatal hernia
 Obesity
 Alcohol use
 Cigarette smoking
 Nasogastric intubation
 Medications
 Pregnancy
 Hypersecretory states
 Delayed gastric emptying
 Connective tissue diseases
Helicobacter pylori

A number of risk factors for developing GERD have been described (Table 42.1). For several of these putative risk factors the evidence supporting their role is weak, while for others the mechanism(s) by which they act to cause reflux remains unclear [9].

Pathogenesis

The fundamental prerequisite for the development of GERD is movement of the gastric refluxate into the oesophagus. A complete understanding of the pathophysiology of GERD, which is multifactorial and consists primarily of both oesophageal and gastric factors (Table 42.2), requires consideration of both the determinants of oesophageal acid exposure and the defence mechanisms of the oesophageal epithelium [10]. The major factor responsible for reflux is a defect in the antireflux barrier, which is composed of the lower oesophageal sphincter (LOS), diaphragm and supporting ligaments. The integrity of the antireflux barrier has been attributed to maintenance of intrinsic LOS pressure, contribution by the crural diaphragm to the resting tone of the LOS and its augmentation of this tone during inspiration, preservation of the intra-abdominal location of the LOS, the integrity of the phrenoesophageal ligament, and maintenance of the angle of His which represents the angle of entry of the oesophagus into the stomach. It seems likely that it is an accumulation of abnormalities involving these mechanisms that leads to incompetence of the antireflux barrier and subsequent oesophageal acid exposure.

The occurrence of inappropriate, non-swallow-related LOS relaxation, also known as transient LOS relaxation (tLOS) rather than a hypotensive LOS or a hiatal hernia is currently believed to be the most common cause of reflux events in both healthy individuals and patients with GERD [11]. Nevertheless, recent evidence suggests that the dominant mechanism may vary depending upon the disease

Table 42.2 Pathophysiology of gastro-oesophageal reflux disease (GERD).

Antireflux barrier
 Lower oesophageal sphincter
 increased frequency of tLOS

 Presence of *Helicobacter pylori* (?)

tLOS, transient lower oesophageal sphincter relaxation.

severity, with tLOS being the main mechanism with mild disease and a hypotensive LOS or hiatal hernia dominating with more severe disease [12]. Major differences between tLOS and swallow-induced LOS relaxation include that tLOS occurs without pharyngeal contraction, is not accompanied by oesophageal peristalsis and persists longer. Interestingly, not all tLOS is accompanied by acid reflux. The major stimulus for tLOS is gastric distension and it is now clear that tLOS has a major role in the venting of gas from the stomach (i.e. belching).

A hypotensive LOS may result in either strain-induced reflux or free reflux. Free reflux occurs when the LOS pressure is very low, typically less than 4 mmHg, and is characterized by a fall in intraoesophageal pH without a change in LOS or intragastric pressure. In contrast, strain-induced reflux occurs when a more modestly hypotensive LOS, typically less than 10 mmHg, is overcome by a sudden increase in intra-abdominal pressure. The crural diaphragm has an important role in the competence of the oesophagogastric junction by contributing to the resting tone of the LOS and by augmenting this tone during inspiration [13,14]. A hiatal hernia results in the absence of these additive effects on the LOS and may also impair oesophageal emptying resulting in the re-reflux of hernia contents by permitting retrograde flow of gastric material during LOS relaxation. Recently, it has been shown that the susceptibility to reflux correlates with both weak LOS pressure and with hiatal hernia size [13]; however, a hiatal hernia is neither necessary nor sufficient for the development of reflux oesophagitis.

In addition to the actual occurrence of reflux episodes, oesophageal acid exposure is also related to the process of oesophageal clearance. Therefore, defects in oesophageal clearance mechanisms such as can occur with impaired peristalsis, the presence of a hiatal hernia and impaired salivation increase the susceptibility to GERD. Another oesophageal mechanism that may have a role in the pathogenesis of GERD, particularly as it relates to tissue defence, is altered oesophageal mucosal resistance. This includes luminal factors such as the mucous layer and surface bicarbonate and elements within the epithelium such as the cell membrane and intercellular junctional complex that limit damage during contact of the refluxate with the oesophageal epithelium [15]. Abnormalities in oesophageal epithelial resistance may provide an alternative explanation for the development of GERD in patients with normal oesophageal acid exposure on ambulatory pH testing, as this would seem to imply normally functioning antireflux and clearance mechanisms. Lastly, the contribution of altered mucosal sensitivity to the pathogenesis of GERD remains unclear.

Gastric factors also have a role in the pathogenesis of GERD. The presence of gastric contents such as acid, pepsin, bile salts and pancreatic enzymes in the oesophagus is necessary for oesophageal injury to occur. While acid is clearly important, in the vast majority of GERD patients, there is no evidence of gastric acid hypersecretion. Bile salts and pancreatic enzymes enter the stomach by what is referred to as duodenogastric reflux. While the role of pepsin and bile remains controversial [16], it is currently believed that these substances may contribute to the injury and symptoms that occur as a consequence of gastro-oesophageal reflux, but are unlikely to cause these problems without the aid of acid. The rate of gastric emptying may also be of pathophysiological importance in GERD. Delayed gastric emptying exists commonly in patients with GERD [17] but is suspected to be of pathogenetic importance in only a small proportion. A final gastric factor that has generated considerable interest recently in relation to the pathogenesis of GERD is *Helicobacter pylori*. While there appears to be no excess of *H. pylori* infection in GERD patients when compared with age-matched controls, theory and accumulating circumstantial evidence suggest that this infection may be relatively protective against reflux when it produces gastritis severe enough to cause a major reduction of gastric acid secretion [18,19]. Similarly, when *H. pylori* infection is cured, a significant component of gastritis resolves, acid secretion increases and, theoretically, GERD may be provoked or worsened in the setting of a compromised antireflux barrier [20]. Because of the conflicting data regarding the role of *H. pylori* in GERD, the decision to test for and treat *H. pylori* should be based on other clinical indicators for eradication [21].

Diagnosis and evaluation

GERD is defined as symptoms or tissue injury resulting from exposure of the oesophagus to gastric contents. While a variety of tests are available to aid in the diagnosis of GERD (Table 42.3), there is currently no diagnostic gold standard for reflux disease. In the paragraphs that follow, the tests most clinically useful to diagnose and evaluate GERD are discussed.

The diagnosis of GERD is usually straightforward when classic symptoms are present; however, uncertainty and confusion may result when a patient presents with atypical symptoms as both classic symptoms and oesophagitis are frequently absent [2]. Additionally, not all patients with GERD are symptomatic. For example, the elderly and those with Barrett's oesophagus may be completely asymptomatic until they present with a complication. This may be a consequence of reduced sensitivity to oesophageal acid [22]. Therefore, while symptom evaluation is extremely important for diagnosis of GERD, its sensitivity falls far short of a gold standard [23].

The role of direct visualization of the oesophagus by means of endoscopy in the diagnosis of GERD is also limited because as much as two-thirds of reflux patients, even with classic symptoms, will have a normal endoscopy, both grossly and microscopically [1,24]. Furthermore, symptoms alone cannot reliably distinguish between GERD patients with and without oesophagitis on endoscopy, and the severity of GERD symptoms correlates poorly with endoscopic findings.

Ambulatory oesophageal pH testing, while frequently considered to be the gold standard, is also not so. While pH

<i>Usefulness remains to be determined</i>
Combined ambulatory pH-impedance test

testing has many theoretical advantages over other forms of reflux testing, a persistent problem with this technique is that there exists no absolute cut-off value that reliably identifies the presence of GERD [25]. Its use is particularly problematic in patients with atypical symptoms of suspected GERD and endoscopy-negative reflux patients as several studies have demonstrated considerable overlap in oesophageal acid exposure times between asymptomatic controls and patients with these conditions and the documentation of the presence of reflux does not prove causality of symptoms [24].

Recently, an empirical trial of antisecretory therapy has been evaluated as a diagnostic test for GERD [26]. This approach was made available by the introduction of a potent class of antisecretory medications known as proton pump inhibitors which profoundly reduce gastric acid production and the time to heal oesophagitis. With this approach, when symptoms disappear with therapy and return when the medication is stopped, the diagnosis of GERD may be assumed. This approach has been shown to have good sensitivity and specificity in patients presenting with classical reflux symptoms and in patients with suspected reflux-related non-cardiac chest pain [27,28] and has shown economic benefits compared with upfront testing in patients with non-cardiac chest pain and chronic cough [28,29]. Nevertheless, while seemingly more tolerable and cost-effective than ambulatory pH testing or endoscopy, the empirical medication trial approach does not appear to offer any diagnostic superiority. The major disadvantages of this diagnostic approach include false-positive results brought about by a placebo effect from the medication and a lack of direct assessment of either the oesophageal mucosa or oesophageal acid exposure.

The evaluation of GERD depends upon the patient's clinical presentation. Those with classic symptoms and no alarm symptoms usually require no confirmatory testing and should be treated empirically. Further testing should be performed in the following situations: presence of alarm symptoms (Table 42.4), lack of symptom response to medical therapy, need for continuous therapy in a patient at risk for Barrett's oesophagus and prior to antireflux surgery. Additionally, a more aggressive approach in the elderly is

Table 42.4 Alarm symptoms suggesting need for further evaluation.

Dysphagia
Odynophagia
Bleeding
Weight loss
Chest pain

warranted because their disease presentation is typically more severe despite milder symptoms.

A number of tests are available to aid in the evaluation of patients with GERD. These tests should be applied selectively to the individual, based upon the information desired (Table 42.5). The barium oesophagram is useful when evaluating dysphagia, particularly with suspected oropharyngeal or non-obstructive oesophageal (dysmotility) types. It is also more sensitive than endoscopy in detecting subtle mucosal (Schatzki) rings in the distal oesophagus that are associated with GERD and may result in intermittent dysphagia. Suspected obstructive oesophageal dysphagia is better off evaluated initially by endoscopy because, in addition to its overall higher diagnostic sensitivity and ability to biopsy, endoscopy allows therapeutic intervention [30]. The role of endoscopy in GERD patients without alarm symptoms is more controversial. In the era of potent therapeutic options, routine endoscopy is not advocated in all GERD patients prior to treatment and it remains an area of heated debate whether 'once-in-a-lifetime' endoscopy is necessary in patients with GERD symptoms for more than 5 years in order to identify Barrett's oesophagus, an important risk factor for oesophageal adenocarcinoma [31–33].

Oesophageal manometry provides information on the contractile activities of the oesophageal body and the upper and lower oesophageal sphincters both at rest and during swallowing. Oesophageal manometry is most helpful to localize the lower oesophageal sphincter before oesophageal pH testing and, possibly, to evaluate peristalsis prior to

antireflux surgery [34], although this latter indication remains controversial [35]. In this regard, the recent introduction of a combined manometry–impedance catheter system to more thoroughly assess oesophageal function holds the potential to improve on our current ability to predict postoperative dysphagia in patients undergoing antireflux surgery [36]. Oesophageal manometry is not useful in the diagnosis of GERD or any of its complications [34].

Similarly, ambulatory oesophageal pH testing is most useful to confirm GERD prior to antireflux surgery in endoscopy-negative patients and to evaluate patients not responding to medical therapy or with recurrent or persistent symptoms after antireflux surgery [25]. An abnormal test while on medical treatment suggests the need for more aggressive therapy, while a normal test points toward an alternative diagnosis. Oesophageal pH testing is not needed in patients with existing or a known history of reflux oesophagitis.

A therapeutic trial with a proton pump inhibitor, as opposed to initial pH testing, seems to be more useful in identifying a causal relationship between reflux and extra-oesophageal or atypical presentations. Ambulatory pH testing while on medical therapy can then be reserved for those patients not responding [37].

The concept that symptoms or complications of GERD may be related to the reflux of non-acid contents has also received recent attention. This is particularly true in the group of patients whose symptoms, whether they are classic or atypical, persist despite aggressive antisecretory therapy or those with symptoms thought to be brought about by reflux but who have a normal pH test. Until recently, there were no sufficiently sensitive tests to detect duodenogastro-oesophageal or non-acid reflux. Two tests are now available that may assist in the detection of non-acid reflux: bilirubin monitoring and combined pH and multichannel intraluminal impedance monitoring.

Bilirubin monitoring is performed much like ambulatory oesophageal pH testing; however, the catheter contains a fiberoptic probe and a spectrophotometer measures the absorption of certain wavelengths in order to detect bilirubin. The presence of bilirubin as a surrogate marker of bile suggests the presence of duodenogastro-oesophageal reflux. Because bilirubin reflux has been found to consistently parallel acid reflux in patients with an intact stomach [38], at the present time, bilirubin monitoring has demonstrated little clinical utility and is used primarily as a research tool.

The combination of standard pH testing with multichannel impedance measurements in the same catheter was recently approved for clinical use. This technique is performed much like pH testing; however, the addition of impedance technology allows for the detection of all types

of refluxate within the oesophagus, not just acidic [39–41]. While a promising technique, it remains to be seen whether combined pH–impedance testing will be a clinically useful tool or primarily a research tool.

Clinical presentations and complications

The spectrum of GERD symptoms is diverse and ranges from classic heartburn and acid regurgitation to the less common oesophageal symptoms of dysphagia, odynophagia, water brash, belching, nausea, hiccups and chest pain. In addition, a multitude of extraoesophageal symptoms and conditions that seem to be related to reflux disease are being increasingly recognized (Table 42.6). Given the prevalence of GERD, multiple oesophageal complications of the disease are frequently encountered in clinical practice. The major oesophageal complications of GERD include varying degrees of oesophagitis, peptic stricture and Barrett's oesophagus. Non-cardiac chest pain is also sometimes considered in this category.

The prevalence of oesophagitis seen in patients who undergo endoscopy for reflux symptoms varies considerably; however, it appears to be less than 50%, and probably less than 25% [42]. Presenting symptoms typically include a long history of heartburn and may also include dysphagia, odynophagia, anorexia and chest pain. Reflux oesophagitis is characterized endoscopically by beginning

at the oesophagogastric junction and progressing proximally (Fig. 42.1). When severe, oesophagitis can obscure underlying Barrett's oesophagus. The incidence of brisk bleeding as a consequence of oesophagitis, regardless of the severity, is uncommon. It has been suggested that the elderly, those with chronic renal insufficiency and those using anticoagulants or non-steroidal anti-inflammatory drugs (NSAIDs) may be at increased risk of bleeding from oesophagitis [43]. Another obscure and frequently overlooked cause of gastrointestinal bleeding in GERD patients may be seen in those with a large hiatal hernia. Cameron's erosion or ulceration occurs at the diaphragmatic hiatus of a large hiatal hernia and may result in brisk hemorrhage or, more commonly, chronic occult blood loss and iron deficiency anaemia [44].

Peptic strictures (Fig. 42.2) generally occur at the squamocolumnar junction and may occur in up to 10% of patients with GERD who receive medical care and approximately 20% of patients with reflux oesophagitis. While there are currently no reliable risk factors for the development of peptic strictures, the incidence seems to increase with age, those using NSAIDs and in Caucasian men [45–47]. One curious aspect of peptic strictures is that they often develop in patients who have few classic GERD symptoms. This further emphasizes the point that there is little correlation between the severity of GERD symptoms and

Figure 42.2 Endoscopic photograph of a peptic stricture. Note the circumferential ulceration and narrowing at the gastro-oesophageal junction.

severity of findings on endoscopy. Presenting symptoms typically include dysphagia with solids and, less often, odynophagia and food impaction. While either barium oesophagography or endoscopy can be used to diagnose a peptic stricture, endoscopy has the advantage of having both diagnostic and therapeutic capabilities [30]. Barium oesophagography can then be reserved for complex strictures including those that do not allow passage of the endoscope. Peptic strictures can usually be effectively treated and recurrence prevented by aggressive antireflux therapy in the form of a proton pump inhibitor [48] or surgery combined with intermittent dilatation as needed. The need for redilatation varies markedly; some patients will require only a single dilatation while others may need weekly dilatations for several months and still others require less frequent maintenance dilatations to avoid recurrent dysphagia or food impactions. For patients with strictures refractory to repeated dilatation, oesophageal resection may be necessary. For those who are poor surgical candidates, oesophageal stenting has been proposed as an alternative to surgery [49].

Barrett's oesophagus is a condition in which specialized columnar epithelium (with goblet cells), also referred to as intestinal metaplasia, replaces the damaged squamous epithelium in the distal oesophagus (Fig. 42.3). It is now generally accepted that this results from long-standing severe GERD and is the single most important risk factor for oesophageal adenocarcinoma [50,51]. In this regard, it

Figure 42.3 Endoscopic photograph of Barrett's oesophagus. Note the mucosa extending upward from the gastro-oesophageal junction.

should be noted that a large case-control study conducted in Sweden recently found that there is a strong and probably causal relationship between GERD and oesophageal adenocarcinoma, independent of the presence of Barrett's oesophagus (odds ratio 43.5; 95% confidence interval [CI], 18.3–103.5) in individuals with long-standing and severe symptoms of reflux [52]. Because of the dramatic increase in the incidence of oesophageal adenocarcinoma, estimated at 300–500% over the last 30–40 years, these data underscore the importance of early recognition and appropriate management of GERD. Nevertheless, in 2002, only half of the 13 100 anticipated oesophageal cancers are expected to be adenocarcinoma. Therefore, despite the increase in incidence, oesophageal adenocarcinoma remains an uncommon tumour and thus represents a small risk for an individual patient [33].

The frequency of Barrett's oesophagus varies depending upon the population studied but usually ranges from 10 to 20% [53]. There is a strong male and Caucasian predominance with an average age at diagnosis of approximately 55 years. The prevalence of adenocarcinoma in Barrett's oesophagus is approximately 10%, while the annual incidence rate in those with known Barrett's undergoing surveillance is approximately 0.5% [54]. Endoscopic surveillance for cancer and dysplasia, the precursor to cancer, is currently considered the standard of care; however, its usefulness and cost-effectiveness remains highly controversial [33]. While surveillance is unlikely to be effective for the GERD population as a whole, endoscopic screening of

all persons with GERD would seem to be infeasible and cost-prohibitive. Nevertheless, a recent cost-utility analysis concluded that screening for Barrett's oesophagus in a high-risk population of 50-year-old white men with symptoms of GERD is cost-effective compared with other accepted medical interventions [55]. Recent recommendations suggest endoscopy for all persons with typical GERD symptoms for at least 5 years, particularly middle-aged Caucasian men, to screen for Barrett's [31]. Alternative methods of screening for Barrett's oesophagus such as cytologic sampling via a transoral balloon-tipped catheter in an unsedated patient, much as is performed in China when screening for squamous cell oesophageal cancer, are currently undergoing investigation in humans [56]. In order to improve our existing screening and surveillance strategies, much investigation is currently being directed at the discovery of biomarkers other than dysplasia that have an improved degree of predictability for the subsequent development of cancer.

The management of patients with Barrett's oesophagus consists of treatment of the associated GERD symptoms, endoscopic surveillance to detect and follow-up dysplasia, and treatment of dysplasia [32]. It remains controversial whether aggressive antireflux therapy, medical or surgical, will lead to regression of Barrett's or dysplasia, or prevent the development of cancer. While techniques exist to ablate the metaplastic and dysplastic epithelium such as photodynamic therapy, argon plasma coagulation and multipolar electrocoagulation, their complication rates are substantial, their overall benefit remains unclear and, as such, these methods are considered investigational [32,33].

The oesophagus may be implicated in almost half of those patients with non-cardiac chest pain. Several mechanisms have been postulated including GERD, dysmotility, ischaemia and abnormal oesophageal sensation or perception. Primary oesophageal motor disorders are very uncommon in these patients [57]. While recent studies suggest that GERD is by far the most common cause of non-cardiac chest pain, opinion seems to be shifting more toward sensory or perception dysfunction. In general, after exclusion of a cardiac source, which is usually not possible based upon historical information alone, it may be reasonable to proceed with an empirical trial of high-dose antisecretory therapy in these patients, particularly if they have typical reflux symptoms [28]. Further evaluation can then be reserved for those without improvement.

Physicians are becoming increasingly aware that GERD may have respiratory and ear, nose and throat manifestations (see Table 42.6). Unfortunately, a direct relationship between GERD and these conditions has been difficult to establish. Other factors contributing to this dilemma include the findings that approximately 40% of these patients will deny any classic reflux symptoms and reflux oesophagitis is

generally absent [58,59]. Indeed, the high prevalence of absence of concomitant classical GERD symptoms or oesophagitis in patients with these conditions has led some individuals to refer to this condition not as GERD, but rather as laryngopharyngeal reflux. Two mechanisms have been implicated in the pathogenesis of these extraoesophageal presentations: direct acid contact as a consequence of reflux of gastric contents through the upper oesophageal sphincter (reflux theory) or a vagally mediated reflex initiated by acid exposure in the oesophagus (reflex theory) [60]. Evidence supporting these mechanisms is rather scanty and generally indirect. The degree of importance each of these proposed mechanisms has in causing the various extraoesophageal manifestations remains unclear but probably differs depending upon the condition. Data from our motility laboratory do not support the hypothesis that the nature of the clinical presentation of GERD is related to different patterns of oesophageal acid exposure or oesophageal motility as measured by conventional manometry and dual-channel pH testing [61]. The role of tLOSr in the pathophysiology of extraoesophageal complications of GERD remains unknown at this time.

Ambulatory oesophageal pH testing has been considered to be the best diagnostic tool for identifying extraoesophageal complications of GERD. This technique offers the best opportunity to document the amount and proximal extent of acid reflux. Nevertheless, continuing controversy exists regarding a number of issues related to this technique including the need for single versus multichannel pH monitoring, the optimal position of the proximal probe (pharyngeal versus upper oesophagus) if used, the lack of well-established normal values, poor reproducibility and the occurrence of artefacts involving the proximal pH sensor. There also seems to be a tendency for false-negative tests; thus, a negative test may not confidently exclude the diagnosis. Lastly, and perhaps most importantly, a positive test only confirms that an abnormal amount of gastro-oesophageal reflux is present and does not prove a causal relationship. This can only be assured with confidence when the atypical symptom of suspected GERD shows sustained, dramatic improvement following aggressive treatment of GERD. Therefore, at the present time, there are no sufficiently reliable diagnostic tests that can accurately predict which patients have GERD-related extraoesophageal complications. As a consequence, controlled therapeutic trials may be the only method currently available to answer this question.

GERD and COPD

While there is sufficient evidence showing an association between GERD and chronic cough and asthma [62], GERD

may also have a role in many other common pulmonary disorders. The close anatomical relationship and common embryonic origins of the oesophagus and tracheobronchial tree may aid in the explanation of this association. There is a small body of data to suggest a relationship between GERD and COPD. A recent retrospective case-control study from 172 Veterans Administration hospitals involving more than 200 000 discharges found that patients with a diagnosis of oesophagitis or oesophageal stricture had a higher likelihood of having a number of pulmonary diseases than a control group without oesophageal disease, including COPD (odds ratio 1.22; 95% CI, 1.16–1.27) [63]. Another prospective study examined the relationship between hiatal hernia and reflux oesophagitis hospitalization and a subsequent hospitalization with respiratory outcomes in persons free of respiratory disease at baseline and at their first hospitalization [64]. They found odds ratios of 1.8 (95% CI, 1.2–2.7) for chronic bronchitis and 2.9 (95% CI, 1.5–5.5) for emphysema. Similar to the increased prevalence of COPD in patients with GERD, a recent prospective study evaluated the prevalence of GERD in patients with COPD using a validated symptom questionnaire [65]. They found an increased prevalence of frequent heartburn and/or regurgitation (19 vs 0%), dysphagia (17 vs 4%) and antireflux medication use (50 vs 27%) in COPD patients compared with a control group. Therefore, the current evidence suggests that patients with GERD have a higher prevalence of COPD than patients without GERD and patients with COPD have a higher prevalence of GERD than those without COPD.

The role of GERD in the pathogenesis of COPD remains poorly understood. In contrast to asthma patients, oesophageal acid perfusion does not seem to alter airway responsiveness in patients with COPD [66,67]. Aspiration related either to GERD [68] or to alterations in oropharyngeal swallowing [69,70] has been suggested as a contributory factor in the pathogenesis of chronic bronchitis. Additional research is needed on oropharyngeal dysfunction in patients with COPD and its relationship with aspiration and COPD exacerbations.

There have been no controlled studies examining the effect of GERD treatment on the pulmonary outcome in patients with COPD. However, a recent study assessed respiratory symptoms in patients with chronic bronchitis treated with either a proton pump inhibitor ($n = 89$) or antireflux surgery ($n = 119$) and found that, although patients treated medically did not experience symptom relief, those who underwent surgery had a pronounced reduction in symptoms [69]. Further research is needed in this area.

Lung transplantation has emerged as a viable treatment option for patients with a variety of end-stage pulmonary disorders, including COPD. Upper gastrointestinal tract

dysmotility and GERD appear to occur commonly following lung transplantation [71,72] and GERD-related aspiration has been suggested to be a potential contributing cause of chronic allograft rejection (bronchiolitis obliterans) [73,74]. Antireflux surgery has recently been shown to improve both reflux symptoms and lung function following lung transplantation [75]. The role of antireflux medications in this clinical scenario remains undefined.

Treatment

The major acute and long-term goals of GERD therapy are to relieve symptoms and to heal oesophagitis, thereby preventing complications. The primary treatment options include lifestyle modifications, pharmacological agents and antireflux surgery (Table 42.7). Recently, several endoluminal treatments have also been added to the therapeutic armamentarium (see Table 42.7). The vast majority of reflux patients never seek medical care and instead self-medicate using over-the-counter agents such as antacids, alginate and H₂-receptor antagonists on an as needed basis. For those who do seek medical care, the traditional (step-up) approach has been to start with lifestyle modifications and progress to medications and then surgery for persistent symptoms. A more recent alternative (step-down) approach is to start with the most potent and effective medical therapy and, when symptoms are controlled, to attempt

to change therapy to a less potent or less costly agent. The better overall approach remains hotly debated; however, it has been suggested that the step-down approach is more cost-effective [76]. Ultimately, deciding whether a step-up or step-down approach is most appropriate should be based on a case-by-case evaluation.

Lifestyle modifications, which minimize reflux and maximize acid clearance, are listed in Table 42.6. Patient compliance with such changes is often poor. While the scientific evidence supporting these adaptations is generally weak, there may be some patients who benefit and do not require any pharmacological therapy as a result. In addition, many of these measures are useful in treating other diseases and in maintaining overall body health.

A number of pharmacological agents are available to treat GERD (see Table 42.7). In general, the main classes of medications are aimed at either improving the underlying motility disorder (prokinetics) or reducing the noxious effects of the gastric refluxate (antisecretory agents). Mucosal protectants such as sucralfate have demonstrated limited clinical efficacy in GERD and are uncommonly used. Antacids, which briefly neutralize acid, and alginic acid, which mixes with saliva to form a viscous layer that floats on the surface of the gastric pool acting as a mechanical barrier, are useful for treating mild and infrequent reflux symptoms. They do not, however, heal oesophagitis. Nevertheless, a large proportion of GERD patients can be adequately treated with such easily available over-the-counter therapies.

When approved in the late 1970s, H₂-receptor antagonists (H₂RAs) achieved the first real breakthrough in the treatment of GERD [77]. H₂RAs interfere predominantly with the histamine receptor at the level of the parietal and enterochromaffin-like cells, ultimately inhibiting one pathway of parietal cell activation. All four available H₂RAs are equally effective and act to decrease gastric acid production. While symptomatic improvement can be achieved in up to 60% of patients using these agents, healing of oesophagitis occurs less commonly. The over-the-counter doses of H₂RAs, although longer lasting, are generally equivalent to antacids. Higher and more frequent doses of H₂RAs do not seem to be more effective than standard doses in improving severely symptomatic patients [78] and become less cost-effective than a single daily dose proton pump inhibitor. This may be related, at least in part, to the development of tachyphylaxis. In contrast, H₂RAs are highly efficacious in decreasing nocturnal acid secretion and may be the preferred agent in those patients with persistent symptoms despite twice daily proton pump inhibitor therapy and a pH test demonstrating nocturnal acid breakthrough [79].

Prokinetic agents may work by a number of mechanisms which include increasing LOS pressure, reducing tLOS frequency, improving oesophageal peristalsis, increasing

Table 42.7 Available treatments of gastro-oesophageal reflux disease (GERD).

Lifestyle modifications

Elevate head of bed 10–15 cm (4–6 inches)
 Eat smaller meals with less fat content
 Avoid recumbency for 3 h after eating
 Weight reduction
 Avoid smoking and alcohol
 Avoid adverse medications and foods
 Avoid wearing tight clothing

Pharmacological therapy

Antacids, alginate, over-the-counter H₂-receptor antagonists
 H₂-receptor antagonists
 Prokinetic agents
 Proton pump inhibitors

Surgery

Laparoscopic (or open) fundoplication

Endoscopic/endoluminal therapy

Transoral delivery of radiofrequency energy
 Transoral suturing system
 Transoral injection of inert substance

salivary flow and improving gastric emptying. In general, the overall efficacy of prokinetic agents has been similar to H₂RAs. A prokinetic agent may be most useful in patients with typical reflux symptoms plus associated bloating and early satiety suggesting dysmotility. The most useful of the prokinetic agents was cisapride, a 5-HT₄ agonist that exerted its prokinetic action through the indirect release of acetylcholine in the myenteric plexus. Because of concerns over its safety, specifically because of several reports of fatal cardiac dysrhythmias associated with the combination of cisapride and several medications and medical conditions, cisapride was withdrawn from the market in July 2000. As a consequence, there is currently no suitable prokinetic agent available for long-term use. Metoclopramide, a dopamine antagonist, is currently the only prokinetic agent available for use in the USA but has, at best, modest efficacy in relieving symptoms, no proven efficacy in healing oesophagitis and a significant incidence of side-effects. The results of ongoing clinical trials evaluating the efficacy and safety of new prokinetic agents are eagerly awaited.

Proton pump inhibitors (PPIs) profoundly diminish acid secretion by inhibiting the H⁺-K⁺ ATPase (proton pump), the final step in acid production. Given that the primary determinants of oesophageal healing and symptom relief are the duration of treatment and the proportion of time the intraoesophageal pH is maintained at over 4, it is no wonder that PPIs are more effective than H₂RAs [80]. While some differences exist, the five currently available PPIs seem to be equally effective with regard to symptom improvement and healing of oesophagitis. PPIs have been shown to be highly effective in both symptom reduction and healing rates of oesophagitis (up to 90%). Indeed, they are currently considered first-line treatment in complicated GERD cases. The timing of PPI ingestion seems to be important. These agents seem to be most effective at reducing gastric acid secretion when taken in the morning at least 30 min before breakfast. PPIs do not completely eliminate acid production. Dose escalation is often necessary, particularly in those patients on the more severe end of the GERD spectrum and in those with extraoesophageal complications. When administered twice daily, these drugs should be ingested at least 30 min before the morning and evening meals in order to maximize pump inhibition. Acute side-effects include headache, abdominal cramping and diarrhoea. Side-effects of long-term use are uncommon; concerns over development of gastric carcinoid tumours and atrophic gastritis have not been realized in studies following patients on high-dose omeprazole for over 12 years. Finally, while the use of a prokinetic agent in combination with an H₂RA has recently been shown to have an additive effect on maintenance of healing of reflux oesophagitis, the combination of a prokinetic agent with a PPI does not seem to provide much advantage over a PPI alone [81].

Since the introduction of laparoscopic fundoplication in the early 1990s, there has been renewed interest in antireflux surgery. While PPIs can effectively treat the most severe forms, GERD can only be cured by surgery. With the availability of the laparoscopic approach, the morbidity of antireflux surgery is greatly reduced compared with open fundoplication. The main indications for antireflux surgery include the refractory GERD patient, those who will not or cannot afford to take a daily medication long-term, and the young patient who would otherwise require a very long course of medical treatment. Because the availability of PPIs has made the truly refractory GERD patient rare, a search for an alternative diagnosis in such patients should be entertained prior to proceeding with antireflux surgery. Indeed, it is those patients who respond well to medical therapy who seem to have the best outcome following fundoplication [82]. In experienced hands, laparoscopic fundoplication is safe and highly effective; however, the long-term success rate for the laparoscopic approach is unknown and certain side-effects, such as dysphagia and the gas-bloat syndrome, may be more frequent. Current data suggest that PPI therapy and antireflux surgery are approximately equal for maintaining remission in GERD [83]. Indeed, available evidence suggests that antireflux surgery has no clear advantage over medical therapy for GERD in terms of symptom control, oesophageal healing, efficacy in preventing complications, safety and cost [84]. Ultimately, the decision to undergo surgery should be determined on an individual basis taking into account the goals, expectations and risks involved.

Recognizing the importance of tLOS_R in the pathogenesis of GERD, there is now substantial interest in the development of treatments that modulate tLOS_R as potential therapy for GERD. Several recent reports indicate that a number of pharmacological agents such as a loxiglumide, baclofen, morphine and atropine can reduce the frequency of tLOS_R in healthy individuals and patients with GERD [85]. While none of the agents tested thus far are suitable for long-term clinical use, this remains an intriguing area likely to see major developments in the treatment of GERD.

Three novel transoral endoluminal approaches to the treatment of GERD have recently become available for clinical use. One utilizes a suturing system attached to the tip of the endoscope, the second delivers thermocouple-controlled radiofrequency energy to the region of the gastro-oesophageal junction via a bougie catheter delivery system, and the third method involves the endoscopic implantation of a biocompatible non-biodegradable liquid polymer to the same region. Preliminary studies have demonstrated encouraging results for all three techniques [86–88]. Where these therapies will fit into the overall treatment strategy remains to be determined.

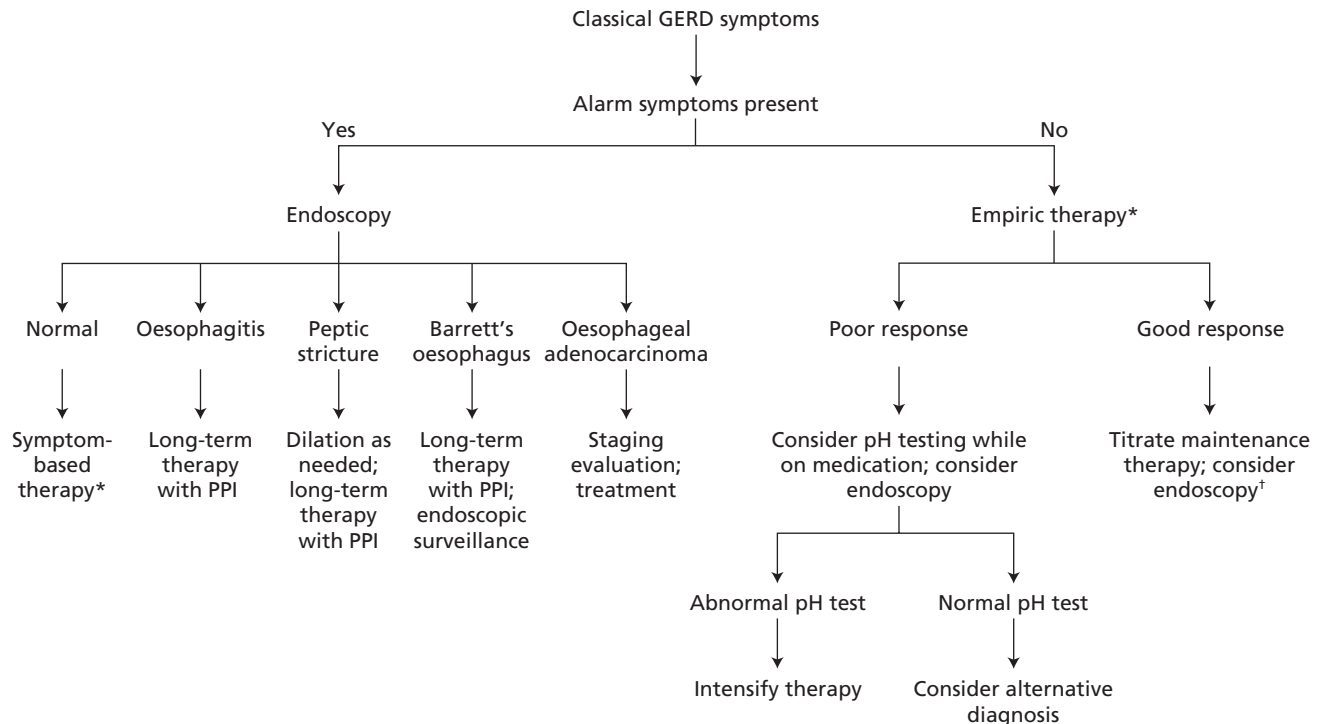

Figure 42.4 Algorithm for the acute and long-term management of the patient with classical gastro-oesophageal reflux disease (GERD) symptoms. Alarm symptoms include dysphagia, odynophagia, weight loss and bleeding. PPI, proton pump inhibitor. * Guided by symptom severity. † To evaluate for Barrett's oesophagus.

Practical approach to evaluation and management

Figure 42.4 illustrates a suggested approach for managing the patient with classic GERD symptoms. Initially, these patients should be evaluated for the presence of alarm symptoms. If present, further diagnostic evaluation, usually endoscopy, is necessary. If absent, empirical therapy guided by symptom severity should be commenced. In those who require long-term therapy for severe symptoms, endoscopy should be considered, even in those with good symptom relief and without alarm symptoms, in order to evaluate for the presence of Barrett's oesophagus. If the patient responds poorly to therapy, further diagnostic testing should be considered. In this setting, endoscopy may be useful to evaluate for other potential aetiologies of the symptoms and oesophageal pH testing, while on therapy, may be useful to assess its adequacy. The management of oesophagitis without Barrett's oesophagus, endoscopy-negative GERD and Barrett's oesophagus is based primarily on symptom relief. Finally, at the present time, patients with Barrett's oesophagus should be enrolled into an endoscopic surveillance programme.

A similar approach to the management of patients with atypical manifestations of GERD, including chest pain, pulmonary and ear, nose and throat symptoms, is illustrated in Figure 42.5. Management of these conditions tends to require higher doses of antisecretory agents for prolonged periods of time [2]. At this time, there are insufficient data to declare any one approach as best. Previously, early oesophageal pH testing, particularly in those patients who did not have concomitant classic GERD symptoms, was recommended as the best initial test for identifying abnormal oesophageal acid exposure and correlating these symptoms with reflux episodes. However, as addressed earlier, several problems arise when oesophageal pH testing is used to identify the potential role of reflux in patients with suspected atypical GERD-related conditions. As a result of the complex relationship of symptoms, presence of GERD and causality, the use of aggressive therapeutic trials, typically with a twice daily PPI, has been advocated to identify patients with true GERD-related atypical symptoms. This approach has been supported by recent reports suggesting that an empirical trial of a twice daily PPI for 2–3 months may be more cost-effective than early testing [29,89]. If no response is seen after this extended therapeutic trial, oesophageal pH testing, while on therapy, is

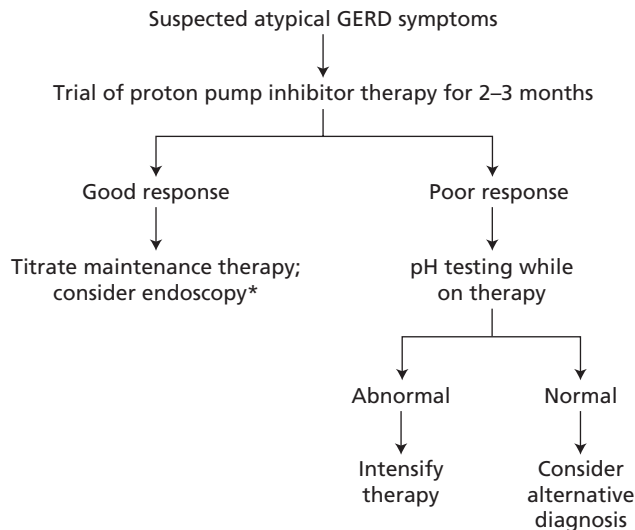

Figure 42.5 Algorithm for the management of the patient with suspected atypical gastro-oesophageal reflux disease (GERD) symptoms with or without concomitant classical GERD symptoms. * To evaluate for Barrett's oesophagus.

suggested in order to assess its adequacy. For those who do respond, gradual titration of the therapy downward is recommended.

Conclusions

GERD is a common condition with a diversity of clinical presentations, potential for morbidity and mortality, and a high rate of health-care utilization. On the basis of its pathophysiology, GERD is most appropriately considered to be an upper gut motility disorder. Nevertheless, it is acid and possibly other factors present within the gastric refluxate that cause GERD symptoms and oesophageal inflammation. The goals of GERD therapy are to relieve symptoms, heal oesophagitis and prevent complications. Acid suppression is now established as first-line therapy, with antireflux surgery being considered in selected circumstances. While those with classical symptoms and without alarm symptoms may be treated empirically, endoscopy may be useful to identify Barrett's oesophagus even in those who respond well to therapy. Atypical symptoms that fail to respond to PPI therapy and poorly responsive classic symptoms are best evaluated by ambulatory oesophageal pH testing while on therapy. The role of combined multichannel intraluminal impedance testing with oesophageal manometry and pH testing in the evaluation of oesophageal function and non-acid reflux remains to be determined. Further study regarding the optimal cost-effective diagnostic and therapeutic strategies in GERD is needed.

CHAPTER 43

Upper airway diseases

Maria Rappai and Richard deShazo

Histologically similar respiratory epithelium extends posteriorly from the nasal septum and the lateral walls of the nasal fossa to the nasopharynx, larynx, trachea, bronchi and bronchioles. There is increasing evidence that the nose, sinus and lower airway have similar physiology and function and are indeed, one airway [1]. However, for the purposes of discussion, we will define the upper airway as the nose and sinuses. The clinical relationships between the upper and lower airway will be a theme of this chapter.

Rhinosinusitis and asthma are comorbidities, linked by epidemiological, pathological and physiological characteristics and by a common classification and therapeutic approach. Although not universally accepted, the term 'allergic rhinobronchitis' has been proposed to link the association between allergic asthma and rhinitis. Some have even suggested that asthmatic individuals are a subgroup of the population of patients with rhinitis [2]. Because of the impact of rhinitis on asthma, allergic rhinitis has been reclassified to reflect the classification of asthma (Table 43.1) [3].

Rhinitis is a common condition that may occur on an allergic or non-allergic basis. Of all patients with rhinitis, 43% have allergic rhinitis, 23% have non-allergic rhinitis and 34% have combinations of the two [4]. Allergic rhinitis accounts for at least 2.5% of all physician visits; 2 million lost school days per year, 6 million lost workdays and 28 million restricted workdays per year. Rhinitis occurs in more than 75% of subjects with allergic asthma and 80% of those with non-allergic asthma [5].

Sinusitis is the most common chronic disease in adults in the USA. It results from infectious and non-infectious causes of inflammation and is almost always associated with obstruction of the osteomeatal complex [6]. Rhinosinusitis is a more appropriate term than sinusitis, as sinusitis is inevitably associated with coexistent rhinitis [7].

In this chapter we discuss rhinosinusitis and its relationship to asthma, some other common diseases that involve both the upper and lower airways and newer information on the relationship between the swallowing reflex and obstructive lung disease.

Table 43.1 Classification of allergic rhinitis by frequency and severity.

Frequency		Severity	
Intermittent	Persistent	Mild	Moderate-severe
< 4 days/week < 4 weeks/year	> 4/week > 4 week/year	Absence of disruption of sleep, no impairment of school or work, daily activity, leisure or sport	Sleep disturbance, impairment of daily activity, leisure and/or sport, impairment of school and work Troublesome symptoms

Classification of allergic rhinitis according to frequency and severity of symptoms parallels the classification of asthma. Therefore allergic rhinitis may be mild intermittent, mild persistent, moderate intermittent, moderate persistent, severe intermittent or severe persistent using this classification.

Anatomy and physiology of the nose and sinuses

The nasal cavity is divided into two separate air passages by the nasal septum. The lateral nasal wall has three turbinates: the superior, middle and inferior turbinates (conchae), which divide the nasal cavity into meati. During quiet breathing, the nasal airflow is predominantly directed around the inferior turbinate along the floor of the nasal cavity (Fig. 43.1). The superior meatus drains the posterior ethmoid air cells and the sphenoid sinus. The area under the middle meatus into which the frontal, maxillary and anterior ethmoid drain is the osteomeatal complex. The inferior meatus receives drainage from the nasolacrimal duct (Fig. 43.2).

The biological function of the nose is still debated, but the physiology of the nose has been studied extensively. The nose is lined by pseudostratified epithelium resting on a basement membrane, which separates it from deeper (submucosal) layers. Mast cells are present in both layers. The submucosa contains mucous, seromucous and serous glands [8]. Small arteries, arterioles and arteriovenous

anastomoses determine regional blood flow. Capacitance vessels, consisting of veins and cavernous sinusoids, determine nasal patency. The sympathetic nervous system regulates the venous capacitance vessels. The cavernous sinusoids lie beneath the capillaries and venules, are most dense in the inferior and middle turbinates, and contain smooth muscle cells that are also regulated by the sympathetic nervous system. Loss of sympathetic tone or, to a lesser degree, cholinergic stimulation causes this sinusoidal erectile tissue to become engorged and leads to nasal obstruction. Cholinergic stimulation causes arterial dilatation and promotes the passive diffusion of plasma proteins into glands and the active secretion by mucous glands in cells.

The classic mediators of immediate hypersensitivity and novel neurotransmitters, including substance P, calcitonin gene-related peptide and vasointestinal peptide, have been detected in nasal secretions after nasal allergen challenge of patients with allergic rhinitis [9]. Antidromic stimulation of sensory nerve fibres in the nose can release a variety of neurotransmitters including substance P, a mediator of increased vascular permeability. Because neurotransmitters also produce changes in regional blood flow and glandular secretion, their role in rhinitis may be important.

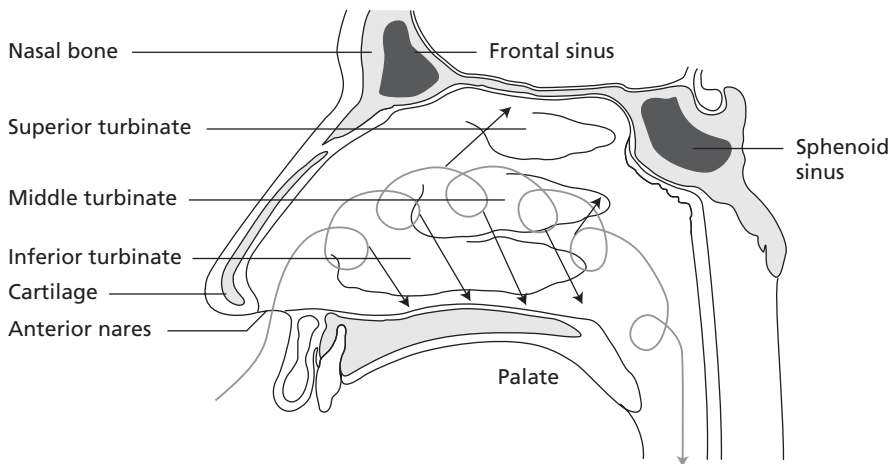

Figure 43.1 Airflow through the nasal air passages. Turbulence of airflow at higher velocities of inspiration leads to impaction of particles in the inspired air on the nasal mucosa. (From Howarth [99], with permission from Elsevier's Health Sciences, Philadelphia.)

Figure 43.2 The structure of the sinuses.

Mechanisms by which the upper airway influences the lower airway

The upper and lower airway share common features over and above the respiratory epithelium. This includes the ability to entrap particles and irritants in the mucociliary blanket and the nitric oxide system. The nasal airway and sinuses are especially effective in warming and humidification of inspired air and serves a protective function for the protection of the lower airway. For instance, children with mild to moderate asthma had lower decreases in forced expiratory volume in 1 s (FEV_1) while breathing through their nose compared with those breathing orally during exercise [10]. The upper airway influences the lower through the nasobronchial reflex, drainage of inflammatory material and through systemic propagation of mediators of nasal inflammation. The nasobronchial reflex provides a direct pathway for interaction between the upper and lower airway. Animal studies demonstrate reflexes arising from nose and nasopharynx, mediated by the afferent sensory components of the trigeminal and glossopharyngeal nerves and efferent bronchoconstrictor fibres to the vagus nerve. Human studies have shown increased airway resistance after nasal insufflation of silica, an effect prevented by premedication with atropine [11], bronchial hyperresponsiveness after intranasal allergen challenge [12] and significant falls in FEV_1 after nasal insufflation of histamine [13], further supporting the nasobronchial reflex theory. Lower airway remodelling has also been demonstrated in non-asthmatic patients with allergic rhinitis, further supporting the interaction of upper and lower airways [14].

Nitric oxide serves important functions in both the upper and lower airway. These include antiviral and bacteriostatic activity, bronchodilatory effects, vasodilatation, improvement in oxygenation and modulatory effects on lower airway responsiveness [15]. Data on the roll and function of nitric oxide in upper airway inflammation are conflicting. Patients with uncontrolled asthma have increased expiratory nitric oxide [16] concentrations while patients with sinusitis have been reported to have decreased nitric oxide concentrations [17].

Sinobronchial syndromes

The sinobronchial syndromes have simultaneous upper and lower airway involvement and may be classified as congenital or acquired (Table 43.2). The most recently described syndrome is sinobronchial allergic bronchopulmonary mycosis, the SAM syndrome [18]. This syndrome occurs in patients with concomitant allergic fungal sinusitis and allergic bronchopulmonary mycosis.

Table 43.2 Sinobronchial syndromes.

Congenital	Acquired
Cystic fibrosis	Wegener granulomatosis
Kartagener syndrome	Relapsing polychondritis
Immotile cilia syndrome	Sarcoidosis
Young syndrome	Sinobronchial allergic mycosis (SAM)

Allergic fungal sinusitis results from a hypersensitivity response to inhaled fungal allergens in the paranasal sinuses much like allergic bronchopulmonary mycosis. It shares many clinical features with sarcoidosis with concomitant upper and lower airway involvement including chronic sinusitis, nasal polyposis, obstructive airway disease and response to corticosteroids [19]. Both require histopathological evaluation to confirm the diagnosis.

Syndromes of rhinosinusitis

Syndromes of rhinitis may be divided into allergic, infectious, perennial non-allergic and miscellaneous categories (Table 43.3) [20]. Allergic rhinitis should be differentiated from other forms of rhinitis because the approach to management is different. A working knowledge of the aeroallergens present in the patient's geographical location and the allergens in the patient's home and work areas is essential in clinical differentiation of these conditions (Table 43.4).

Allergic rhinitis

Symptoms of allergic rhinitis include paroxysms of itching of the eyes, nose and palate, sneezing, clear rhinorrhoea and nasal obstruction. Postnasal drip, cough, irritability, disordered sleep and fatigue are also common [20–22]. Symptoms develop when persons inhale airborne antigens (allergens) to which they have previously been exposed and against which they have made immunoglobulin E (IgE) antibodies.

Episodic allergic rhinitis results from episodic exposure to inhaled allergens, such as cat dander, that can provoke acute allergic symptoms. If allergen exposure is seasonal, and symptoms are predictable and reproducible, seasonal allergic rhinitis may be diagnosed by the history. Perennial allergic rhinitis is associated with nasal symptoms for more than 2 h/day more than nine months of the year [20]. The latter usually reflects allergy to indoor allergens such as dust mites, cockroaches or animal dander, although aeroallergens may cause perennial rhinitis in tropical or

Table 43.3 Classification of rhinitis.

Allergic rhinitis
seasonal
perennial
occupational
episodic
Infectious rhinitis
<i>Acute</i> : viral, bacterial
<i>Chronic</i> : bacterial, fungal, associated with immunodeficiency (antibody deficiency, cystic fibrosis, ciliary abnormalities, etc.)
Perennial non-allergic rhinitis
eosinophilic forms
non-allergic rhinitis with nasal eosinophilia (NARES)
non-allergic rhinitis with blood eosinophilia (BENARS)
non-eosinophilic forms
<i>Idiopathic</i> : vasomotor rhinitis
<i>Hormonal</i> : pregnancy, hypothyroidism, oestrogen replacement treatment
<i>Drug-induced</i> : associated with aspirin respiratory sensitivity, rhinitis medicamentosa (vasoconstrictor nose sprays), antihypertensives, antidepressants
<i>Food associated</i> : gustatory, immunoglobulin E-mediated
<i>Atrophic rhinitis</i> (<i>Klebsiella ozaenae</i>), post-surgical
<i>Mechanical</i> : hypertrophied turbinates, deviated nasal septum, foreign body, nasal polyps
<i>Granulomatous</i> : Wegener granulomatosis, sarcoidosis, midline granuloma

subtropical climates. This form is common in subtropical regions with long pollinating seasons and ever-present mould and dust mite allergens, and with occupational allergen exposure [23]. Perennial allergic rhinitis may be difficult to distinguish from non-allergic forms and can require diagnostic testing for accurate diagnosis.

Eleven per cent of patients with rhinitis have seasonal symptoms, 33% have perennial symptoms with seasonal exacerbation and 56% have perennial symptoms alone [24,25]. Seventy eight per cent of patients with seasonal symptoms have an apparent allergic cause, and 68% of patients with perennial symptoms with seasonal exacerbation have a probable allergic cause. Fifty per cent of patients with rhinitis and perennial symptoms alone have allergic rhinitis.

Immunological mechanisms of allergic airways disease

Allergic rhinitis has an autosomal dominant pattern of inheritance with incomplete penetrance. Allergic individuals demonstrate physiological dominance of the Th2 subpopulation of helper T cells in immune responses with the production of interleukin 4 (IL-4), IL-5 and IL-13, and

Table 43.4 Allergens commonly associated with allergic rhinitis.

Allergen	Season	Examples
<i>Seasonal aeroallergens (outdoor)</i>		
Weed pollen	Fall	Ragweed
Grass pollen	Late spring	Rye, Bermuda, Bahia, Johnson
Tree pollen	Spring	Mountain cedar, Elm, Oak, Birch
Mould spores	Spring and summer	<i>Alternaria</i> , <i>Cladosporium</i> sp.
<i>Perennial allergens (indoor)</i>		
Insects		
House dust mite		<i>Dermatophagoides farinae</i> , <i>D. pteronyssinus</i>
Cockroach		
Pets		Cat saliva, rat urine
Moulds		<i>Aspergillum</i> and <i>Penicillium</i> sp.
<i>Occupational</i>

other cytokines that favour the production of IgE and mast cell dependent, eosinophil-rich, allergic inflammation [9]. Cross-linking of two or more molecules of IgE by allergen on the mast cell surface leads to rapid degranulation and mediator release, which occurs in a calcium-dependent process. The stored (histamine) and generated (leukotrienes and prostaglandins) mast cell derived mediators stimulate epithelial cells, blood vessels, nerves and glands to cause the clinical manifestations of allergic rhinitis and feedback to other elements of the immune system to perpetuate the process. Mast cells release a variety of stored mediators immediately after exposure to allergen within minutes. However, experimental nasal insufflation of histamine reproduces all of the symptoms of acute allergic rhinitis. Generated mediators are released 6–8 h later and produce a second wave of symptoms and an eosinophil-rich inflammatory response called the late phase allergic reaction (Fig. 43.3).

The inflammatory response noted in the mucosa of patients with allergic rhinitis is often present in the sinuses, even when symptoms are not present [9]. The ethmoid sinus appears to have a higher expression of RNA for IL-4 than the maxillary sinus, thus promoting eosinophil infiltration by increased expression of endothelial VCAM-1 in such subjects. The final common pathway by which allergic inflammation causes symptoms of rhinosinusitis is the production of mucosal oedema and hypertrophy and

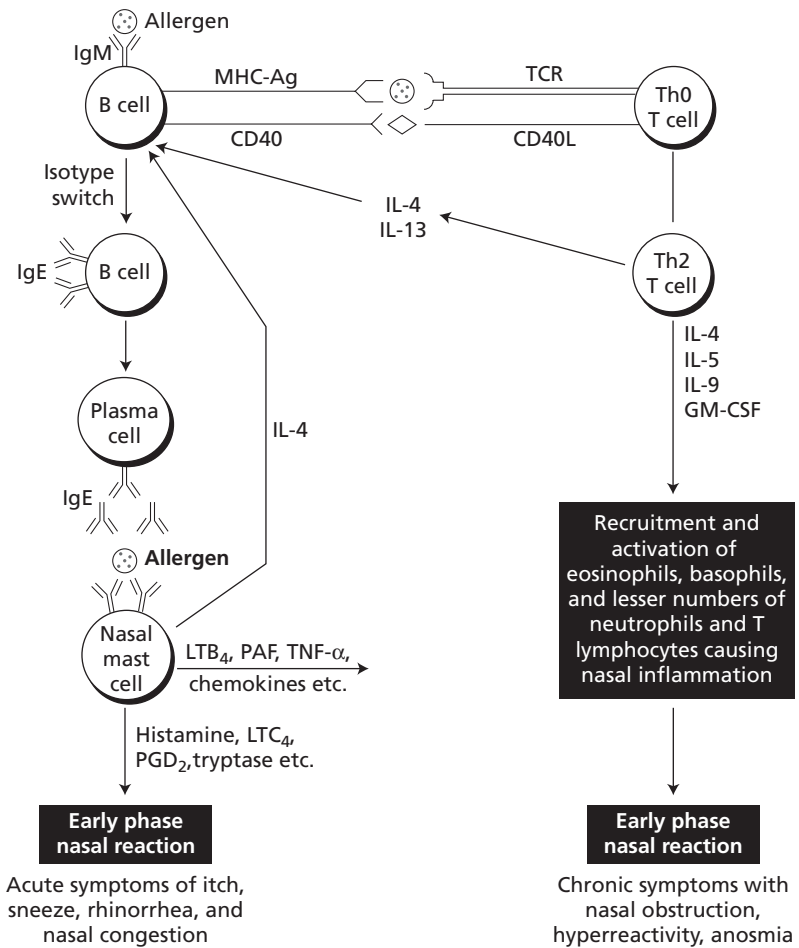

Figure 43.3 Pathophysiology of the allergic rhinitis. GM-CSF, granulocyte-macrophage colony-stimulating factor; IgE, immunoglobulin E; IgM, immunoglobulin M; IL-4, interleukin 4; IL-5, interleukin 5; IL-9, interleukin 9; IL-13, interleukin 13; LTB_4 , leukotriene B_4 ; LTC_4 , cysteinyl leukotriene; MHC-Ag, major histocompatibility complex antigen; PAF, platelet activating factor; PGD_2 , prostaglandin D_2 ; TCR, T-cell receptor; $TNF-\alpha$, tumour necrosis factor α . increased mucous production resulting in obstruction to air flow. In the sinuses, this often obstructs the osteomeatal complex and disables mucociliary clearance mechanisms (Fig. 43.4) and sinusitis occurs.

Risk factors

A host of risk factors for allergic rhinitis have been identified [26]. These include a family history of atopy, male sex, birth during the pollen season, firstborn status, early introduction of formula and food, early use of antibiotics, maternal smoking exposure in the first year of life, exposure to indoor allergens such as animal dander, a serum IgE of more than 100 IU/mL before age 6 and the presence of allergen-specific IgE. Cord blood mononuclear cells of infants who subsequently develop allergic diseases in the first year of life secrete lower levels of γ -interferon, when compared with those who do not. γ -Interferon inhibits the expansion of Th2 lymphocytes and thereby limits production of IgE. There is some evidence that allergic diseases result from specific genetic abnormalities of normal γ -interferon production [27].

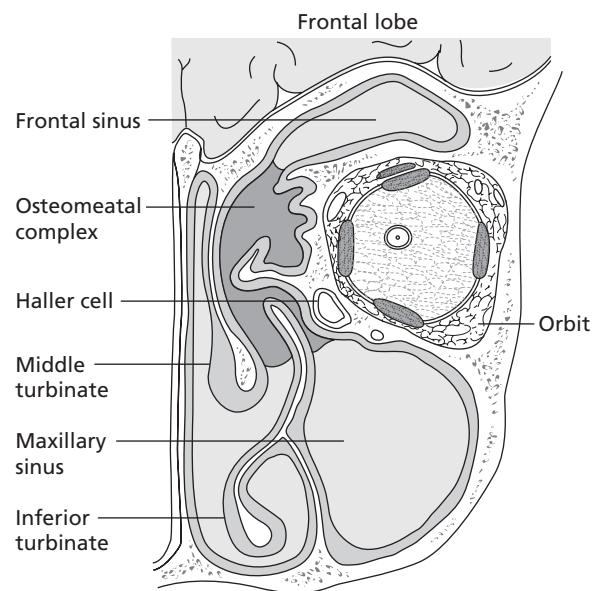

Figure 43.4 The osteomeatal complex. (From Kennedy [101], with permission from Johns Hopkins University, Baltimore.)

Signs and symptoms

Patients with allergic rhinitis most often complain of nasal pruritus and rhinorrhoea while patients with non-allergic rhinitis complain more of nasal obstruction. In univariate statistical analysis, purulent rhinorrhoea, purulent postnasal drip and pain in a maxillary tooth are the only features of the history that have a high sensitivity and specificity for culture-proven rhinosinusitis [28].

In patients with active rhinitis, application of a topical decongestant spray (oxymetazoline) is often required in order to visualize the nasal mucosa well. The pale blue–grey mucosa common in seasonal allergic rhinitis contrasts to the boggy red mucosa often present with non-allergic rhinitis. In patients older than 5 years, flexible fiberoptic rhinoscopy may facilitate examination. It allows inspection of the nasal cavity for septal deviation or other anatomical abnormalities, the inspection of middle meatus to exclude purulent discharge associated with sinusitis, and the detection of polyps, tumours or foreign bodies.

Diagnosis

The diagnosis of allergic rhinitis is made on clinical grounds by the history, the presence of the symptoms and signs and the detection of allergen-specific IgE by skin tests or *in vitro* methods. In the most severe cases, there is intense nasal itching associated with nose rubbing, excoriation of the external nares, pushing the tip of the nose up with the hand (the allergic salute) and a transverse nasal crease [29]. Both infraorbital oedema and darkening resulting from subcutaneous venodilatation (allergic shiners) and accentuated lines or folds below the lower lids (Denie–Morgan lines) suggest concomitant allergic conjunctivitis. While adults and older children frequently blow clear mucus from their noses, young children have persistent rhinorrhoea and often snort, sniff, cough and clear their throats. Some scratch their itchy palates with their tongues producing a clicking sound (palatal click). Clear rhinorrhoea may be visible anteriorly or, with nasal obstruction, dripping down a posterior pharynx that resembles cobblestones and reflects lymphoid hyperplasia. Giemsa or Hansel's stains of these nasal secretions show cell populations to be predominately eosinophils. A highly arched palate, mouth breathing and dental malocclusion are common, especially in children. Symptoms are reproducible on exposure to allergens to which the patient has been sensitized. Most patients have strong family histories of allergic disease.

Allergen-specific IgE may be demonstrated by immediate hypersensitivity skin tests using commercial allergic extracts or *in vitro* assays such as the radioallergoabsorbent test (RAST). Sensitization may occur at allergen levels below those that provoke symptoms. Positive tests indicate sensitization but not necessarily allergy, as symptoms do not always occur on re-exposure to allergens causing

sensitization to allergen [20]. For research purposes, allergic rhinitis may be diagnosed with standardized nasal provocation tests using allergen to which the patient has specific IgE. Because such large numbers of patients with allergic rhinitis have an additional non-allergic contribution to their allergic rhinitis (mixed rhinitis), increasing attention has been focused on syndromes of non-allergic rhinitis [30]. Fortunately, topical nasal steroids [31] and topical antihistamines (e.g. azelastine) have been shown to be effective in the treatment of both allergic and perennial non-allergic rhinitis in controlled trials [32]. Thus, a positive response to a therapeutic trial of either does not establish a diagnosis of allergic rhinitis.

Perennial non-allergic rhinitis may be subdivided into eosinophilic and non-eosinophilic forms. Non-allergic rhinitis with nasal eosinophilia syndrome (NARES) occurs in as many as 15% of patients with rhinitis and is characterized by perennial symptoms, an older average age than in patients with allergic rhinitis (39 versus 25 years), and milder symptoms of nasal itching and sneezing [33]. The clear nasal secretions contain more than 25% eosinophils, but the role of eosinophils in the disorder is unclear. Fifty per cent of patients with NARES have sinusitis, 33% have nasal polyps and 14% have asthma. IgE to inhalant allergens is usually absent but anaphylactoid reactions to aspirin may occur. Blood eosinophilia–non-allergic rhinitis syndrome (BENARS) is a variant of NARES [25].

Patients with vasomotor rhinitis complain of chronic nasal congestion intensified by rapid changes in temperature and relative humidity, odours or alcohol. A hypersecretory variant with persistent rhinorrhoea exists [25]. Several lines of evidence suggest that patients have nasal autonomic nervous system dysfunction [34]. They have little nasal itching or sneezing, but headaches, anosmia and sinusitis are common. A family history of allergy or allergic symptom triggers is uncommon. Positive immediate hypersensitivity skin tests to inhalant allergens and nasal eosinophilia are unusual.

Atrophic rhinitis is a syndrome of progressive atrophy of the nasal mucosa in elderly patients who report chronic nasal congestion and constantly perceive a bad odour. Mucosal colonization with *Klebsiella ozaenae* has been associated with this condition. This condition also occurs in patients who have undergone multiple sinus surgeries and lose normal mucosal ciliary function. Rhinitis medicamentosa is a complication of chronic use of vasoconstrictor nasal sprays or intranasal cocaine abuse. Chronic nasal obstruction and nasal inflammation develop and are manifested as swollen, beefy red nasal membranes on physical examination.

Rhinitis of pregnancy and rhinitis associated with birth control pills or hypothyroidism reflect nasal obstruction that occurs because of the influence of hormones. Nasal

obstruction may also be a side-effect of antihypertensive drugs. Unilateral rhinitis or nasal polyps are uncommon in uncomplicated allergic rhinitis. Unilateral rhinitis suggests the possibility of nasal obstruction by a foreign body, tumour or polyp.

The presence of nasal polyps suggests NARES, chronic bacterial sinusitis, allergic fungal sinusitis, aspirin hypersensitivity, cystic fibrosis or primary ciliary dyskinesia (immotile cilia syndrome). Prolonged use of neuroleptics, certain antihypertensives including β -blockers, anti-convulsants and some antidepressants may also contribute to rhinitis syndromes.

Sinusitis

Sinusitis is inflammation of one or more of the paranasal sinuses. Acute sinusitis is defined as the presence of symptoms for less than 4 weeks' duration, subacute for 4–12 weeks and chronic as the presence of symptoms for longer than 12 weeks. Recurrent sinusitis refers to repeated episodes of acute sinusitis three times or more per year [35].

Sinusitis remains a clinical diagnosis and there is no consensus on diagnostic criteria, classification or treatment. Sinus aspiration with culture is the gold standard for diagnosis of bacterial sinusitis, but is impractical. Aspiration can be associated with complications and without biopsy, lavage or special culture technique does not exclude viral or non-infectious inflammatory mechanisms such as Wegener granulomatosis. Computed tomography (CT) imaging is useful in following chronic sinusitis, but has a high false-

positive rate in acute sinusitis [36]. Rhinoscopy with sterile antral aspiration and culture has promise as a diagnostic technique, but requires further evaluation [37]. Moreover, not all sinusitis is bacterial.

Acute sinusitis is more often associated with purulent nasal discharge or postnasal drip, fever or facial pain. Chronic sinusitis is associated with anosmia, fatigue, facial fullness, persistent halitosis, exacerbation of asthma or no obvious symptoms [38]. Nasal smears show sheets of polymorphonuclear cells and bacteria. When air fluid levels are present (acute sinusitis) or mucosal thickening is greater than 8 mm (chronic sinusitis), plain X-rays of the sinus correlate with antral punctures confirming bacterial infection; sinus opacification is seen with either [39]. This correlation is clinically useful in children over 1 year of age, although less so in adults. Unfortunately, plain X-rays provide little detail of the osteomeatal complex, obstruction of which is usually the root cause of the problem. Limited (coronal) CT studies of the sinuses provide more information, less radiation and generally cost no more than a standard series of plain films [40]. Cautious interpretation of sinus CT is required as temporary opacification of the sinuses and obstruction of the osteomeatal complex are common with upper respiratory tract infections (Fig. 43.5) [41].

Most sinusitis, including non-allergic sinusitis, is associated with mucosal eosinophilia of varying degrees. The syndrome of chronic nasal polyposis, aspirin intolerance, asthma and (sinusitis) is called Samter's triad (Tetrad) and usually occurs in individuals with no identifiable allergic sensitivity.

Some investigators have suggested that chronic fungal

Figure 43.5 Sinus computed tomography (CT). (a) Coronal CT of the paranasal sinuses in patient with rhinosinusitis demonstrating diffuse mucoperiosteal thickening with opacification of the right maxillary sinus. (b) CT of the same patient after 6-week trial of topical corticosteroids and antihistamines, showing near-complete resolution of the mucoperiosteal thickening. infection may be the underlying cause of all chronic rhinosinusitis, a hypothesis not supported by available data.

Rhinosinusitis and other conditions

Although allergic rhinitis has not been shown to cause asthma, there is evidence for a causal association (Table 43.5). Conditions commonly associated with rhinosinusitis include asthma, nasal polyposis, lower respiratory tract infection, dental malocclusion, sleep disorders [30,42] and anosmia. Allergic rhinitis is strongly associated and is a contributing factor to eustachian tube dysfunction causing concomitant serous and acute otitis media [43]. Allergic rhinitis often occurs concomitantly with other common allergic conditions, including allergic conjunctivitis, allergic asthma and atopic dermatitis (eczema). Twenty-eight to 50% of patients with asthma and up to 30% with eczema have allergic rhinitis. The genetic predisposition to develop these conditions has been termed 'atopy' and patients who have them are often called 'atopic'.

Rhinosinusitis and asthma

Non-specific bronchial hyperreactivity on bronchial challenge with methacholine, histamine or cold air is present in individuals with allergic rhinitis with no symptoms of asthma and normal spirometry. Treatment of asthmatic children treated with topical nasal steroids for perennial rhinitis decreases non-specific bronchial hyperreactivity and nocturnal asthma symptoms [26]. Several mechanisms have been proposed to explain the association between rhinosinusitis and asthma:

- 1 Nasal inflammation causes bronchospasm via the naso-bronchial reflex.
- 2 Increased expression of intracellular adhesion molecules (ICAM-1) associated with nasal inflammation increases the

frequency of viral infections including rhinovirus which binds directly to ICAM-1.

3 Inflammatory nasal cytokines from the nose are aspirated into the lower airway inducing bronchial inflammation.

4 Nasal inflammation contributes to T-cell homing to the lower respiratory tract where these lymphocytes foster inflammation [44].

The persistent inhalation of cold dry air because of mouth breathing may also contribute [20,45].

Acute sinus infection can worsen asthma and therapy for sinus disease can improve asthma when the two conditions coexist. Sinusitis is present in 40–75% of patients with asthma. As in asthma, eosinophilic mucosal infiltration and deposition of major basic protein is present in chronic sinusitis [46] and the same inflammatory mediators identified in allergic rhinitis have been identified in sinusitis. The cultures obtained from the maxillary sinus of asthmatic patients with maxillary sinus radiographical abnormalities often grow no organisms, suggesting that the eosinophilic inflammation present may cause chronic obstruction of the osteomeatal complex without bacterial superinfection. The role of the eosinophil in this process is under intense investigation.

No clear association has been established between sinus disease and chronic obstructive pulmonary disease (COPD).

Management of rhinosinusitis

General

The treatment of rhinosinusitis centres on decreasing nasal inflammation and maintaining patency of the osteomeatal complex [47]. Consensus guidelines have been published

for the management of allergic rhinosinusitis [20,48]. The approach to management is based on differentiation of allergic from non-allergic causes of rhinosinusitis. Sinusitis should be suspected in all cases of rhinitis refractory to the usual management. In such cases, rhinoscopy or CT should be considered.

Treatment of non-allergic rhinitis

Because non-allergic rhinitis is usually perennial, the use of topical nasal steroids is the treatment of choice. Although the topical antihistamine Astelin® is effective in the treatment of these conditions, oral antihistamines have little salutary effect. Leukotriene inhibitors often improve symptoms in the subset of patients with nasal polyposis and aspirin hypersensitivity and may inhibit polyp growth.

Treatment of allergic rhinitis

Allergen avoidance

The first step in the treatment of allergic rhinitis is allergen avoidance, when possible and practical. This may be facilitated by maintaining the relative humidity at 50% or less to limit house dust mite and mould growth and avoiding exposure to irritants such as cigarette smoke. Appropriately maintained air conditioners decrease concentrations of pollen, mould and dust mite allergens in indoor air. Removing carpets and furry pets may diminish allergic symptoms to house dust mite faeces. Covering mattresses, box springs and pillows with plastic, and washing bedding in water hotter than 54.4°C (130°F) once weekly may be helpful although the data supporting these are limited and conflicting. Ordinary vacuuming and dusting has little effect, although vacuum cleaners with high-efficiency particulate air (HEPA) filters may be useful [49]. HEPA air cleaners may reduce airborne animal allergen, but are not helpful in the reduction of dust mite allergens, which settle too rapidly for capture.

Pharmacological treatment of allergic rhinitis

If allergen avoidance is not adequate, drug therapy is the next step. Corticosteroids given orally or parenterally abolish symptoms of allergic rhinitis, but are unacceptable for long-term or frequent use. Topical intranasal steroid therapy is the most effective single maintenance therapy and causes few side-effects at recommended doses (Table 43.6). Topical nasal steroids are more effective than cromolyn, second-generation antihistamines and leukotriene inhibitors in treating allergic rhinitis and improve the symptoms of seasonal asthma in patients with concomitant seasonal allergic rhinitis and seasonal allergic asthma [50,51]. Topical nasal corticosteroids are more effective than antihistamines in reducing nasal blockage because of their vasoconstrictor effects but are not effective in reducing symptoms of allergic conjunctivitis.

Antihistamines help control sneezing, rhinorrhoea and itching associated with the early nasal reactions but may not provide adequate relief from nasal obstruction associated with the late phase reaction. First-generation antihistamines commonly produce sedation and other central nervous system symptoms that may adversely affect learning in children and may cause drying of the mouth and urinary hesitancy. Adverse effects on driving include decreased performance on tests of divided attention, working memory, vigilance and speed (Table 43.7). These effects occur less commonly with second-generation antihistamines other than cetirizine and azelastine [52].

Nasal decongestant sprays are not recommended in the treatment of allergic rhinitis as tachyphylaxis develops after 3–7 days and rebound nasal congestion results. Continued use causes rhinitis medicamentosa. They may occasionally be helpful for periods of a week or less when used just prior to the administration of topical nasal steroids for patients with severe nasal obstruction.

Cromolyn and nedocromil decrease allergic inflammation by inhibiting the intermediate conductance chloride channel pathways of mast cells, eosinophils, epithelial and

Table 43.6 Intranasal steroids available in the USA.

Name (Trade name)	Dose approved
Flunisolide (Nasalide, Nasarel)	2 sprays (50 µg) in each nostril b.i.d.–t.i.d.; max 400 µg/day
Beclometasone dipropionate (Beconase, Vancenase, Beconase AQ, Vancenase AQ)	1 spray (42 µg) in each nostril b.i.d.–q.i.d.; max 336 µg/day
Triamcinolone acetonide (Nasacort)	2 sprays (110 µg) in each nostril once a day; max 440 µg/day
Budesonide (Rhinocort)	2 sprays (64 µg) in each nostril once a day; max 256 µg/day
Fluticasone (Flonase)	2 sprays (100 µg) in each nostril once a day; max 200 µg/day
Mometasone furoate monohydrate (Nasonex)	2 sprays (50 µg) in each nostril once a day; max unclear
b.i.d., twice daily; max, maximum; t.i.d., three times daily; q.i.d, four times daily.	

Table 43.7 Adverse effects of antihistamines and decongestants.

	Antihistamines	Decongestants
Anticholinergic	Dry mouth and eyes Impotence Urinary hesitancy Glaucoma	Urinary hesitancy Irritability
Central nervous system	Sedation Stimulating rare (children) Confusion and cognitive impairment in older patients	Headache Insomnia Nervousness Nausea
Miscellaneous	Weight gain Prolonged QT interval Ventricular arrhythmias	
Cardiovascular system		Palpitation Hypertension Tachycardia

endothelial cells, fibroblasts and sensory neurons [53]. They inhibit mast cell mediator release. Cromolyn but not nedocromil is available in the USA.

Ipratropium is more useful in non-allergic rhinitis with predominant rhinorrhea as it does not block sneezing, pruritus or nasal obstruction. The positive effects of ipratropium may be mediated in part by its ability to decrease the release of substance P, a congener of atropine in a 0.03% nasal solution [54].

Antileukotrienes such as montelukast provide effects similar to that of loratadine and has been approved for use in allergic rhinitis. It appears to have additive benefits in the combination with non-sedating antihistamines [55] but the combination appears no more effective than topical nasal steroids alone [56,57].

Allergen immunotherapy

Allergen immunotherapy involves the subcutaneous administration of increasing doses of therapeutic vaccines of allergens to which a patient is known to be allergic. It is maintained at an arbitrary 'maintenance' dose [58]. There is increasing evidence that administration of allergens by the oral route may be effective as well. A number of allergenic vaccines have been standardized and are available in the USA and are dispensed as bioequivalent allergy units (BAU).

Immunotherapy should be considered when avoidance of allergens and pharmacotherapy fail to resolve the symptoms of allergic rhinitis or when pharmacotherapy produces unacceptable side-effects or is not cost effective. High-dose immunotherapy for allergic rhinitis has been

shown in controlled studies to relieve symptoms of allergic rhinitis effectively [59]. It should be strongly considered in patients with perennial symptoms, perennial rhinitis with seasonal exacerbations, constitutional symptoms (such as severe fatigue) or in patients with associated sinusitis, allergic conjunctivitis or asthma.

Immunotherapy modulates the immune response to allergen. It decreases IL-4 and IL-5 production by CD4⁺ T lymphocytes, generates IgE-modulating CD8⁺ T lymphocytes, increases allergen-blocking IgG antibodies (particularly of the IgG 4 class) and reduces the movement into and the number of mast cells and eosinophils in nasal inflammatory reactions [60]. Immunotherapy blunts the seasonal rise of allergen-specific IgE, decreases up to 75% of the release of mast cell mediators in allergen challenge studies [61] and the expression of messenger RNA for interferon on nasal allergen challenge. These findings reflect a shift away from a Th2 type response associated with allergic inflammation. The clinical result in the inhibition of both the immediate and late nasal allergic response increases [62,63].

Treatment of sinusitis

Treatment studies of sinusitis reflect an empirical diagnosis and empirical treatment based on the most probable infectious agents. *Streptococcus pneumoniae*, *Moraxella catarrhalis* and *Haemophilus influenzae* have been associated with acute sinusitis and most studies suggest these organisms plus anaerobic bacteria have been implicated in chronic sinusitis [35]. However, the role of antibiotics in the treatment of clinically diagnosed acute sinusitis is not presently evidence-based. The choice of antibiotics is dictated by local patterns of microbial sensitivity because antibiotic resistance to these common microbes is a growing problem.

A course of appropriate antibiotic therapy for 7–10 days for acute and 21 days for chronic allergic sinusitis plus full dose of topical nasal corticosteroids appears appropriate. Three to five days of a topical nasal decongestant to facilitate the entry of corticosteroids into the upper airway is often helpful. Use of oral or nasal antihistamines or oral decongestants may be useful but has not been substantiated. Treatment of sinusitis should be followed by radiological or rhinoscopic studies to establish that the infection has been cleared and the osteomeatal complex is open. Traditionally, patients who fail a single course of treatment have a second prolonged course of appropriate antibiotics and topical nasal steroids. Consultation with an otolaryngologist is appropriate if infection persists. Individuals with recurrent acute sinusitis or chronic sinusitis should receive an allergy evaluation and be considered for immunodeficiency evaluation and allergen immunotherapy.

We feel that treatment of concomitant allergic inflammation in the nose and sinus is essential to successful treatment

of sinusitis in allergic individuals. In some individuals, anti-inflammatory treatment alone results in radiologically demonstrable clearing of the sinuses. However, there are limited data to substantiate that treatment of allergic inflammation associated with allergic sinusitis produces a better result than treating the associated infection alone. In a study of patients with allergic rhinosinusitis randomized to treatment with antibiotic for 14 days versus antibiotic with loratadine, oral corticosteroids or placebo for 28 days, patients treated with loratadine had less nasal obstruction and sneezing at day 28 but were otherwise similar [64]. In another study, patients with either acute or chronic sinusitis were treated with 3 weeks of antibiotics plus flunisolide or placebo for 7 weeks. The time to resolution of overall symptoms and normalization of radiological abnormalities in the two groups were similar although patients receiving flunisolide had less nasal obstruction [65].

Results of treatment of coexistent rhinosinusitis and asthma

A number of uncontrolled studies have shown that successful medical treatment of rhinosinusitis in patients with coexistent asthma and rhinosinusitis is associated with improvement of asthma [66]. The uncontrolled studies have reported that surgical treatment of chronic sinusitis by functional endoscopic techniques or sphenoidectomy improves coexistent asthma. In one such study of 79 patients with intractable sinusitis who had functional endoscopic sinus surgery (FESS) procedures, 86% had improvement of rhinosinusitis and 80% had improvement of coexistent asthma [67].

Novel treatments for allergic rhinosinusitis

Theoretically, inhibitors of production or depletion of these cytokines associated with allergic inflammation should improve allergic symptoms. A recent trial of a monoclonal antibody to IL-5 in asthmatic patients resulted in depletion of circulating eosinophils but had no effect on bronchial response to allergic challenge [68]. Recombinant human monoclonal antibody to IgE (rhuMAB-E-25) binds circulating IgE and prevents the interaction of IgE with surface receptors on mast cells. Controlled studies of anti-IgE therapy have been shown to lower IgE levels, decrease early and late phase reactions to allergen challenge, and to improve allergen rhinitis and allergic asthma [69].

Phosphodiesterase-4 (PDE4) inhibitor agents are presently under investigation in both allergic rhinitis and asthma. A recent blinded cross-over study of roflumilast has shown favourable effects in rhinitis. The role of a PDE₄ inhibitor in asthma and COPD is also under investigation [70]. Other therapies under consideration include tryptase inhibitors and chemokine and adhesion receptor inhibitors [71].

Swallowing

The association between pulmonary parenchymal diseases, including COPD, and oropharyngeal function is of increasing interest. Swallowing is a complex physiological process and shares a close anatomical and developmental association with the airway and gastrointestinal tract. The swallowing reflex is co-ordinated by the medulla and involves oral preparation followed by an oral voluntary phase, followed by an involuntary pharyngeal and oesophageal phase [72]. Timing and co-ordination of swallowing is crucial for transfer of food into the oesophagus and for airway protection, and involves complex interactions between various muscles and nerves. Both respiration and swallowing are under complex voluntary and involuntary control. Alterations in the harmonic relationship between respiration and swallowing can result in dysphagia and aspiration. Microaspiration may cause bronchoconstriction or the introduction of bacteria into the upper airway [73].

Techniques for evaluation of swallowing

Many techniques have been used to evaluate swallowing, so many as to suggest that present studies leave much to be desired. The gold standard for evaluation of swallowing is video fluoroscopy. Quantification of pharyngeal contractile forces, incomplete upper oesophageal sphincter (UOS) relaxation and intrabolus pressure during swallowing requires pharyngeal and upper oesophageal manometry. Use of manometry with video fluoroscopy is optimal for a comprehensive approach. Manometry assesses pharyngeal muscle contraction, UOS relaxation and relative timing and coordination of the pharyngeal muscles and UOS relaxation events [74].

Nasal endoscopy visualizes the tongue base, epiglottis, superior pharyngeal wall and the laryngeal vestibule below the epiglottis [73], and can also be used for the evaluation of initiation of pharyngeal swallowing and residue if microaspiration is suspected. Indirect signs of aspiration include accumulated oropharyngeal secretions and dye staining of the subglottic airway [75].

Other techniques that may be useful include:

- 1 air pulses to assess supraglottic and pharyngeal sensation [76];
- 2 monitoring of the onset of swallowing with a submental electromyogram (EMG) of the myohyoid–geniohyoid muscle complex;
- 3 evaluation of chewing with an EMG of the masseter muscle [77]; and
- 4 oesophageal pressure manometer and inductance plethysmography for evaluation of the relationship of swallowing to respiration and respiratory effort [78].

Table 43.8 Available studies on swallowing in COPD.

Study population	Abnormality	Comments	Reference
Moderate–severe COPD with frequent exacerbations	Dysphagia, GERD, cricopharyngeal dysfunction	Cricopharyngeal myotomy decreased exacerbations Medication, sex and age were confounding factors	80
Smokers vs non-smokers	Increased threshold for swallowing initiation in smokers	Overinflation of lungs and laryngeal elevation may have impact on swallowing in COPD	78
COPD vs normal controls	Swallowing is coupled with expiration in normals but altered in COPD during exacerbation	Swallowing co-ordination during exacerbation abnormal	81
COPD vs controls	COPD patients used spontaneous protective manoeuvres during swallowing	No obvious aspiration noted	82

GERD, gastro-oesophageal reflux disease.

Available data on swallowing and COPD

Additional research is required to determine whether COPD is associated with altered function of the oropharynx leads to episodes of microaspiration and if these episodes have a role in COPD exacerbations and lung function decline (Table 43.8). One study demonstrated cricopharyngeal dysfunction in COPD patients with frequent exacerbations and improvement with cricopharyngeal myotomy [79]. Co-ordination of swallowing with the phases of respiration can be altered during exacerbations in COPD patients [80]. Patients with COPD were shown to use spontaneous protective swallowing manoeuvres more frequently than controls, but no increase in aspiration during stable stage of COPD [81] was demonstrated. When present, treatment of hiatal hernia and gastro-oesophageal reflux with fundoplication and diaphragmatic crural repair showed improvement in cough in a group of patients with chronic bronchitis [82]. Smokers have been shown to have an increased threshold volume for the initiating of the pharyngo-UOS contractile reflex. Active smoking results in further increase of the threshold volume although aspiration has not been shown [83].

Key points

- 1 Inflammation in the upper airway is associated with inflammation in the lower airway and vice versa.
- 2 Patients with asthma should be evaluated for coexistent rhinosinusitis and, if present, rhinosinusitis should be treated.
- 3 Topical nasal corticosteroids are the most effective drugs for the treatment of non-infectious rhinosinusitis.

4 A few studies suggest that abnormal oropharyngeal function and swallowing may have a role in COPD.

CHAPTER 44

Acute pulmonary embolism

Victor F. Tapson

Venous thromboembolism (VTE) represents the spectrum of disease including deep venous thrombosis (DVT) and pulmonary embolism (PE). While other substances such as tumour cells, fat, air and carbon dioxide can embolize to the lung, our focus is on VTE. Issues involving the interrelationship of VTE and chronic obstructive pulmonary disease (COPD) are emphasized.

Chronic cardiopulmonary disease, including COPD or congestive heart failure, are often present in patients with VTE, and the resulting reduced mobility is very likely a key underlying predisposition. Pulmonary embolism accounts for 100 000–200 000 deaths per year in the USA, but occurs worldwide. Patients often present with fatal PE as the initial presentation, and the poor sensitivity and specificity of the history and physical examination often lead to diagnostic and therapeutic delays. Autopsy studies emphasize the high frequency with which PE has gone unsuspected and thus undetected [1]. Specific risk factors are generally present in patients developing VTE, but the disease may appear to be idiopathic [2–4]. In the latter cases, an underlying thrombophilia may be present, although yet undescribed. Prophylaxis continues to be dramatically underutilized [3].

Pathophysiology

Over 150 years ago, Rudolf Virchow described the triad of stasis, hypercoagulability and intimal injury, and one or more of these is present in most all patients [5]. Deep vein thrombi frequently originate in the calf veins and propagate proximally before embolizing. Emboli may occasionally originate directly from calf vein thrombi, but more than 95% of thrombi that embolize to the lungs detach from a proximal deep vein of the lower extremities (including and above the popliteal veins). Pulmonary embolism may originate from an axillary subclavian source.

When PE occurs, its physiological effect depends upon

the embolic load and the resultant cross-sectional area of the pulmonary arterial bed that is occluded. The presence or absence of underlying cardiopulmonary disease also contributes. A patient with COPD and a forced expiratory volume in 1 s (FEV_1) of 30% is less likely to tolerate massive emboli than a patient with milder disease. More than 50% obstruction of the pulmonary arterial bed is usually present before there is substantial elevation of the mean pulmonary artery pressure [6]. When the extent of obstruction of the pulmonary circulation approaches 75%, the right ventricle must generate a systolic pressure in excess of 50 mmHg and a mean pulmonary artery pressure of greater than 40 mmHg to preserve pulmonary perfusion. A normal right ventricle is rarely able to achieve this and hence fails. Death from PE is caused by right ventricular failure.

COPD and pulmonary embolism

COPD is a common comorbidity and/or risk factor for VTE. In DVT-Free, a 5451 patient DVT registry, 668 (12.3%) had COPD as a comorbid condition [3]. The risk of VTE during acute exacerbations of COPD appears to be substantial [7,8]. The DVT rate in 196 COPD patients admitted to a respiratory intensive care unit was 10.7% but it was likely underestimated by the poor sensitivity of ultrasound for asymptomatic DVT. Pulmonary embolism accounts for approximately 10% of deaths in stable COPD patients on chronic oxygen therapy [9]. The frequency of PE during acute COPD exacerbations has not been evaluated by large randomized clinical trials, but it may be as high as 29% [10].

Plasma fibrinogen increases have been reported in COPD exacerbations [11]. The increase compared with baseline has been shown to be significant ($P = 0.001$) and the increased levels of fibrinogen were associated with purulent sputum, increased cough, a higher baseline fibrinogen and

age. This correlation is not surprising but the statistical significance does not verify that the demonstrated increase of 0.36 g/L is clinically significant. Of interest, however, is that plasma levels of fibrinogen increased further with exacerbations in association with raised interleukin 6 (IL-6) levels [11]. In view of the procoagulant effect of IL-6, it is possible that this represents an important link to VTE. While it seems possible that elevated levels of fibrinogen may contribute to an increased rate of VTE, the nature of the relationship between smoking and elevated fibrinogen levels appears much clearer. Indeed, it would appear that cigarette smoking is the strongest known environmental influence on plasma fibrinogen concentration and has consistently been linked to elevated plasma fibrinogen levels [12]. A dose–effect relationship between the number of cigarettes smoked per day and plasma fibrinogen concentration has been reported [13]. Conversely, cessation from smoking results in a rapid reduction in plasma fibrinogen [12].

Clinical manifestations of venous thromboembolism

History and physical examination

The history and physical examination are insensitive and non-specific for both DVT and PE, making the clinical diagnosis difficult [14,15]. Patients with lower extremity DVT may not have erythema, warmth, pain, swelling or tenderness. When present, these symptoms are non-specific, but may still merit further evaluation. Pain with dorsiflexion of the foot (Homans' sign) may be present in the setting of DVT but this finding is neither sensitive nor specific. The most common symptom of acute PE is dyspnoea which is often sudden in onset. Pleuritic chest pain and haemoptysis occur more commonly with pulmonary infarction resulting from smaller, peripheral emboli. Palpitations, cough, anxiety and lightheadedness are among the non-specific symptoms of acute PE and may result from a number of other entities, contributing to the difficulty in making the diagnosis. Syncope and/or sudden death may occur with massive PE. Tachypnoea and tachycardia are common signs of pulmonary embolism but are non-specific. Dyspnoea, tachypnoea and hypoxaemia in patients with concomitant cardiopulmonary disease (such as congestive heart failure, pneumonia or COPD) may be caused by the underlying disease or be a result of superimposed acute PE. Symptoms and signs consistent with PE (Tables 44.1 and 44.2) [16] should be particularly heeded in the setting of risk factors for VTE such as reduced mobility [17], the hospitalized medical setting [18], trauma or the postoperative state [19,20], concomitant malignancy [21], recent prolonged travel [22] or pregnancy [23].

Table 44.1 Symptoms of acute pulmonary embolism. The symptoms listed were based upon data from the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study [14,15] and modified from tables presented in Stein [16].

	All patients (%) (n = 383)	No previous cardiopulmonary disease (%) (n = 117)
Dyspnoea	78	73
Pleuritic chest pain	59	66
Cough	43	37
Leg pain	27	26
Haemoptysis	16	13
Palpitations	13	10
Wheezing	14	9
Angina-like pain	6	4

Table 44.2 Signs of acute pulmonary embolism. The clinical signs listed were based upon data from the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study [14,15] and modified from tables presented in Stein [16].

	All patients (%) (n = 383)	No previous cardiopulmonary disease (%) (n = 117)
Tachypnoea (20/min)	73	70
Crackles	55	51
Tachycardia (> 100/min)	30	30
Leg swelling	31	28
Loud P2	23	23
DVT	15	11
Wheezes	11	5
Diaphoresis	10	11
Temperature (≥ 38.5°C)	7	7
Pleural rub	4	3
Fourth heart sound	–	24
Third heart sound	5	3
Cyanosis	3	1
Homans' sign	3	4
Right ventricular lift	–	4

DVT, deep venous thrombosis; P2, pulmonic component of second heart sound.

Laboratory tests and electrocardiography

Hypoxaemia is common in acute PE. Some individuals, particularly young patients without underlying lung disease, may have a normal arterial oxygen tension (P_{aO_2}) and even rarely a normal alveolar–arterial difference [14,15].

The diagnostic utility of plasma measurements of circulating D-dimer (a specific derivative of cross-linked fibrin) in patients with acute PE has been extensively evaluated [24,25]. A normal enzyme-linked immunosorbent assay (ELISA) appears sensitive in excluding PE, particularly when the clinical suspicion is relatively low. A D-dimer level of 500 µg/L or greater may have a sensitivity for PE as high as 96–98% but the specificity is much lower. A positive D-dimer test means that DVT or PE is possible, but it is by no means proof. Similarly, while a negative D-dimer may strongly suggest that VTE is absent, a high clinical suspicion should not be ignored.

The use of clinical probability scores based upon simple clinical parameters have been used together with a negative D-dimer to help exclude PE. In a recent prospective clinical trial, the SimpliRed D-dimer test (a rapid red blood cell agglutination D-dimer assay) was used together with simple scoring parameters readily available in the emergency department [25]. Of the 437 patients with a negative D-dimer result and low clinical probability in this study, only one developed PE during follow-up (Table 44.3).

Both cardiac troponin T and troponin I levels have been found to be elevated in acute PE [26,27]. This enzyme is specific for cardiac myocyte damage, and the right ventricle appears to be the source of the enzyme elevation in acute PE and, in particular, in more massive embolism in which myocyte injury resulting from right ventricular strain might be expected. Troponin levels cannot, however, be used like D-dimer testing; they are not sensitive enough to rule out PE when clinical suspicion is relatively low without additional diagnostic testing. Brain natriuretic peptide levels may be increased in acute PE. Preliminary data suggest that elevated levels may predict or indicate right ventricular dysfunction in acute PE [28]. While electrocardiographic findings are present in the majority of patients with acute PE, they are non-specific. Only one-third of patients with massive or submassive emboli have manifestations of acute cor pulmonale such as the S1–Q3–T3 pattern, right bundle branch block, P-wave pulmonale or right axis deviation [15].

Chest radiography

The chest radiograph is often abnormal but is nearly always non-specific in acute PE. Atelectasis, pleural effusion, pulmonary infiltrates and mild elevation of a hemidiaphragm may be present [15]. Findings of pulmonary

Table 44.3 Determining pretest probability of acute pulmonary embolism using point system and D-dimer result [25].

Variable	Points

PE as or more likely*	3.0
HR > 100 beats/min	1.5
Immobilization/surgery†	1.5
Previous DVT or PE	1.5
Haemoptysis	1.0
Malignancy	1.0
<i>Total score</i>	<i>Pretest probability‡</i>
< 2.0	Low
2.0–6.0	Moderate
> 6.0	High

DVT, deep venous thrombosis; HR, heart rate; PE, pulmonary embolism.

* PE as likely or more likely than an alternative diagnosis.

Physicians were told to use clinical information, along with chest radiography, electrocardiography and laboratory tests.

† If in previous 4 weeks.

‡ Of the 437 patients with a negative D-dimer result and low clinical probability, only one developed PE during follow-up; thus, the negative predictive value for the combined strategy of using the clinical model with D-dimer testing in these patients was 99.5%.

infarction such as Hampton's hump or decreased vascularity (Westermarck's sign) are suggestive, but uncommon. A normal chest radiograph in the setting of severe dyspnoea and hypoxaemia without evidence of bronchospasm or anatomical cardiac shunt is strongly suggestive of PE. Neither symptoms, signs, radiographical findings, electrocardiography nor the plasma D-dimer measurement can be considered diagnostic of DVT or PE. When suspected, further evaluation is necessary.

Specific radiographical imaging for venous thromboembolism

Deep venous thrombosis

While venography has been the time-honoured gold standard test, ultrasound has a sensitivity of greater than 90% in the setting of symptomatic DVT and is by far the most common technique utilized for suspected DVT. Magnetic resonance imaging (MRI) has proven extremely sensitive for both acute and chronic DVT, although it is generally not necessary [29]. It is very reasonable to consider MRI in the

setting of suspected DVT when ultrasound cannot be effectively utilized. A major limitation of ultrasound is its reduced sensitivity in the setting of asymptomatic DVT. Thus, it is not generally used as a screening test.

Pulmonary embolism

The ventilation–perfusion (*V/Q*) scan had historically been the most common diagnostic test utilized when PE was suspected. A normal perfusion scan rules out the diagnosis with a high enough degree of certainty that further diagnostic evaluation is almost never necessary [30]. Low or intermediate probability (non-diagnostic) scans are commonly found with PE and in such situations further evaluation with pulmonary arteriography is often appropriate. In the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) when the clinical suspicion of PE was considered very high, it was present in 96% of patients with high probability scans, 66% of patients with intermediate scans and 40% of patients with low probability scans [14]. The diagnosis of PE should be rigorously pursued even when the lung scan is low or intermediate probability if the clinical setting strongly suggests the diagnosis.

Pulmonary arteriography remains the accepted gold standard technique for the diagnosis of acute PE. It is an extremely sensitive, specific and safe test [31]. Complications of pulmonary arteriography among 1111 patients suspected of PE in the PIOPED included death in 0.5% and major non-fatal complications in 1% [14]. It is utilized when PE must be diagnosed or excluded, but preliminary testing has been non-diagnostic. It is being used less frequently as CT has increasingly been employed.

Spiral computed tomography (CT) scanning is replacing *V/Q* at many centres. Some clinical trials have suggested very good sensitivity and specificity but others have been less favourable. Retrospective reconstructions can be performed. A contrast bolus is required for imaging of the pulmonary vasculature. A number of clinical trials have been conducted with somewhat variable sensitivity, and a recent large prospective Swiss study revealed a sensitivity of 70%, suggesting that a negative CT scan may not absolutely rule out smaller emboli [32]. Data from a large multicentre trial (PIOPED II) in the USA and Canada comparing CT (chest and legs) with *V/Q* scanning is currently being analysed. Spiral CT has the greatest sensitivity for emboli in the main, lobar or segmental pulmonary arteries. For subsegmental emboli, spiral CT appears less accurate. The outcome of selected patients with a negative CT in the setting of suspected PE appears to be good in published trials thus far [33]. An advantage of spiral CT over *V/Q* scanning and arteriography includes the ability to define non-vascular structures such as lymphadenopathy, lung tumours, emphysema and other parenchymal abnormalities as well as pleural and

pericardial disease. Patients with significant renal insufficiency cannot be scanned without risk of renal failure.

Magnetic resonance imaging has been utilized to evaluate clinically suspected PE but at present the excellent sensitivity and specificity for the diagnosis of DVT is the main advantage of MRI in this disease process [29,34].

Echocardiography in acute pulmonary embolism

Echocardiography can often be obtained more rapidly than other diagnostic tests and may reveal findings that strongly support haemodynamically significant PE [35]. Unfortunately, because these patients often have underlying cardiopulmonary disease such as COPD, neither right ventricular dilatation nor hypokinesis can be reliably used even as indirect evidence of PE in such settings. In the setting of documented acute PE, echocardiographical evidence of right ventricular dysfunction has been suggested as a means by which to determine the need for thrombolytic therapy [36]. Such cases need to be individualized and severe right ventricular dysfunction should lower the threshold for thrombolytic therapy once contraindications have been considered. Intravascular ultrasound imaging has been shown in both the experimental and clinical setting to image large emboli adequately and may be performed at the bedside [37]. Published guidelines are available for the diagnostic approach to acute PE, and these suggest that clinicians need to be given a certain degree of flexibility in this regard [38].

Treatment

Options for therapy of acute DVT and PE have evolved considerably over the past decade. Each approach has specific indications as well as advantages and disadvantages.

Heparin and low molecular weight heparin

Unfractionated heparin and low molecular weight heparin (LMWH) exert a prompt antithrombotic effect by accelerating the action of antithrombin III, preventing thrombus extension. These drugs do not directly lyse thrombus or emboli, but enable the fibrinolytic system to proceed unopposed and more readily reduce the size of the thromboembolic burden. There are substantial advantages of LMWH preparations over unfractionated heparin [39,40] and, because of these, use of the latter has decreased.

When VTE is strongly suspected, anticoagulation should be promptly initiated unless there are contraindications. Confirmatory diagnostic testing should soon follow. When standard unfractionated intravenous heparin is initiated, the activated partial thromboplastin time (APTT) should

be followed at 6-h intervals until it is consistently in the therapeutic range of 1.5–2.0 times control values, corresponding to a heparin level of 0.2–0.4 U/mL as measured by protamine sulphate titration. Achieving a therapeutic APTT within 24 h after the onset of treatment of PE has been shown to reduce the recurrence rate. Heparin can be administered as an intravenous bolus of 5000 units followed by a maintenance dose of at least 30 000–40 000 units per 24 h by continuous infusion [41]. The lower dose is administered if the patient is considered at high risk for bleeding. At least 5 days of intravenous heparin or LMWH overlap with warfarin is recommended. Heparin should be maintained at a therapeutic level until two consecutive therapeutic international normalized ratio (INR) values of 2.0–3.0 have been documented at least 24 h apart (Table 44.4).

The LMWH preparations have tremendous advantages over unfractionated heparin and have dramatically changed treatment of thromboembolic disease. Greater bioavailabil-

ity of the LMWH than standard heparin (with more predictable dosing) [39,40], the lack of need for an intravenous infusion (all indications are once or twice daily by the subcutaneous route) and the lack of need for monitoring of the APTT are among the important differences. The reduced frequency of heparin-induced thrombocytopenia with LMWH relative to unfractionated heparin is a very compelling reason to use LMWH instead of the latter whenever possible. A number of clinical trials as well as meta-analyses have strongly suggested the efficacy and safety of LMWH for treatment of established acute proximal DVT using recurrent symptomatic VTE as the primary outcome measure [42–45]. The incidence of DVT and recurrent bleeding in these trials indicate that LMWH preparations are at least as effective and as safe as unfractionated heparin. Meta-analytic data suggest that the use of LMWH might reduce bleeding as well as mortality compared with unfractionated heparin for treatment of established proximal DVT [44,45].

Anti-factor Xa levels appear reasonable to monitor in certain settings such as in morbidly obese patients, very small patients (less than 40 kg), pregnant patients and those with renal insufficiency. Because these drugs are renally metabolized, monitoring is important, particularly when the creatinine clearance less than 30 mL/min. With severe renal insufficiency, standard heparin should be considered. There is not clear agreement on a weight limit above which LMWH should not be used, but some feel that an upper limit of approximately 120–150 kg is reasonable, with intravenous standard heparin being used in larger patients. It is unnecessary to monitor other patients with anti-factor Xa levels. One LMWH, enoxaparin, now has specific recommendations for therapy when the creatinine clearance is below 30 mL/min. The dose is changed from 1 mg/kg every 12 h to 1 mg/kg once daily. Unfractionated heparin should be used when there are rapid, significant changes in renal function.

In the USA, at the present time, two LMWH preparations (enoxaparin and tinzaparin) are FDA-approved for use to treat patients presenting with DVT with or without acute PE. The most widely used LMWH, enoxaparin, is approved for both inpatient and outpatient use at a dose of 1 mg/kg subcutaneously every 12 h, or at 1.5 mg/kg once daily for inpatient use. Outpatient therapy is increasing and has proven safe in selected patients [46,47]. There is also experience with LMWH for treatment of patients presenting with PE [43]. Recently, the pentasaccharide ('ultra-low molecular weight heparin'), fondaparinux, has been approved for use in patients with acute DVT and PE [48]. It should be noted that the prophylactic doses of these agents differ from the doses used for treating active disease. The characteristics of LMWH compared with standard unfractionated heparin are shown in Table 44.5.

Documented proximal DVT or PE should be treated for 3–6 months. Treatment over a more extended interval

Table 44.4 Initiation of low molecular weight heparin for therapy of acute deep venous thrombosis and/or pulmonary embolism.

- Determine appropriateness of outpatient therapy*
- Begin LMWH by subcutaneous administration[†]
- Determine whether monitoring needed (extremes of weight, renal insufficiency, pregnancy)
- Warfarin from day 1; initial dose 5–10 mg, adjust according to INR
- Check platelet count between days 3 and 5[‡]
- Stop LMWH after ≥ 5 days of combined therapy, and when INR is ≥ 2.0 for 2 consecutive days
- Anticoagulate with warfarin for ≥ 3 months (goal INR 2.0–3.0)[§]

DVT, deep venous thrombosis; INR, international normalized ratio; LMWH, low molecular weight heparin; PE, pulmonary embolism.

* Potential outpatients should be medically stable without severely symptomatic DVT. They should be compliant, capable of self-administration (or have a family member or visiting nurse for administration), at low risk of bleeding and reimbursement should be addressed.

[†] Enoxaparin (Lovenox), tinzaparin (Innohep), and fondaparinux (Arixtra), are US Food and Drug Administration (FDA)-approved for treatment of acute venous thromboembolism. These preparations are often used for acute PE as well as acute DVT, and while clinical trials support these uses, the FDA-approvals read 'established DVT with or without PE' except for fondaparinux which is approved for patients presenting with either.

[‡] Heparin-induced thrombocytopenia.

[§] The duration of warfarin therapy should be at least 6–12 months in patients with idiopathic venous thromboembolism.

Table 44.5 A comparison of low molecular weight heparin with unfractionated heparin.

Characteristic	UFH	LMWH
Mean molecular weight	12 000–15 000	4000–6000
Protein binding	Substantial	Minimal*
Anti-Xa activity	Substantial	Substantial
Anti-IIa activity	Substantial	Minimal
Administration (treatment)	Intravenous	Subcutaneous
Administration (prophylaxis)	Subcutaneous	Subcutaneous
Monitoring during treatment	aPTT every 6 h	None in most settings†
Outpatient therapy	Difficult	Simplified
Incidence of HIT	3–5%	< 1%
Reversibility with protamine	Complete	Partial

aPTT, activated partial thromboplastin time; HIT, heparin-induced thrombocytopenia; LMWH, low molecular weight heparin; UFH, unfractionated heparin.
 * This implies significantly superior bioavailability of LMWH relative to UFH.
 † LMWH requires monitoring in renal insufficiency (creatinine clearance < 30 mL/min), significant obesity (> 150 kg), very small patients (< 40 kg), and pregnant patients. Anti-Xa levels are followed, and not the aPTT.

is appropriate when significant risk factors persist, when thromboembolism is idiopathic or when previous episodes of VTE have been documented.

Direct thrombin inhibitors

Unlike heparin and LMWH, which require antithrombin III as a cofactor, direct thrombin inhibitors are efficacious against fibrin-bound thrombin. Ximelagatran, an oral direct thrombin inhibitor, was studied extensively in hopes of simplifying the treatment of acute VTE. The oral delivery, rapid onset, lack of significant drug and food interactions, and lack of need for monitoring were among the advantages over warfarin. It proved effective [49,50] but several issues prevented FDA-approval in the USA. These included abnormal liver function tests resulting from the drug, and an increased incidence of rebound thrombotic events occurring after total joint replacement. Other direct thrombin and direct factor-Xa inhibitors are currently being studied. While ximelagatran is associated with transient elevation in hepatic transaminases between approximately 8 and 12 weeks, this is generally transient and reversible even with continued exposure to the drug. Liver function test monitoring will be recommended, at least temporarily.

The oral delivery, rapid onset, lack of significant drug and food interactions, and lack of need for INR monitoring are among the advantages over warfarin.

Heparin-induced thrombocytopenia (defined as a platelet count less than 150 000/mm³) typically develops 5 or more days after the initiation of heparin therapy, occurring in approximately 5% of patients [51]. The syndrome is caused by heparin-dependent immunoglobulin G (IgG) antibodies that activate platelets via their Fc receptors. If a patient is placed on heparin for VTE and the platelet count progressively decreases to 150 000 mm³ or less or to less than 50% of the initial platelet count, heparin-induced thrombocytopenia should be considered. The formation of heparin-dependent IgG antibodies and the risk of thrombocytopenia is lower with LMWH than with standard heparin [52].

Argatroban and lepirudin are FDA-approved for use in the setting of VTE with heparin-induced thrombocytopenia. The half-life of argatroban is prolonged in patients with hepatic dysfunction. Lepirudin is excreted by the kidneys so the dosage must be reduced in renal insufficiency. This drug has a short circulating half-life of 1.3 h in patients with normal renal function but it may be as long as 2 days in patients with advanced renal failure. A detailed discussion of heparin-induced thrombocytopenia is beyond the scope of this chapter.

Vena cava interruption

Inferior vena cava (IVC) filter placement can be performed to prevent lower extremity thrombi from embolizing to the lungs. The primary indications for filter placement include contraindications to anticoagulation, recurrent embolism while on adequate therapy and significant bleeding complications during anticoagulation [52]. Filters are sometimes placed in the setting of massive PE when it is believed that any further emboli might be lethal, particularly if thrombolytic therapy is contraindicated. Filters can be inserted via the jugular or femoral vein. These devices are effective and complications including insertion-related problems and migration are unusual. More recently, temporary filters are being placed in patients in whom the risk of bleeding appears short-term. Most of these devices can be removed up to 2 weeks later, and some may remain in place even longer with subsequent removal.

Thrombolytic therapy

Thrombolytic agents activate plasminogen to form plasmin which then results in fibrinolysis as well as fibrinogenolysis. These agents can dramatically accelerate clot lysis in acute PE (and DVT) clinical trials have culminated in the approval of streptokinase, urokinase and recombinant tissue-type plasminogen activator (t-PA) for the treatment of massive PE [53,54].

The clearly accepted indication for thrombolytic therapy has been PE with haemodynamic instability (hypotension) for the past several decades. Those with severely compromised oxygenation should also be considered. While thrombolytic therapy may result in rapid improvement of right ventricular function in patients with acute PE, there has been controversy as to whether or not patients with echocardiographic right ventricular dysfunction but without hypotension should receive this form of treatment. A recent clinical trial offered further evidence to support this concept, indicating a less frequent need for escalation of treatment when thrombolytic therapy was used in the setting of PE with right ventricular dysfunction [55]. The method of delivery of thrombolytic agents has also been investigated. While standard or low-dose intrapulmonary arterial thrombolytic infusions have been utilized in order to deliver a high concentration of drug in close proximity to the clot, intravenous therapy appears adequate in most cases [56]. More direct techniques, such as catheter-directed administration of intraembolic thrombolytic therapy have been utilized in small clinical studies but the data are inadequate to formulate recommendations [57,58]. Evolution of interventional techniques will encourage additional clinical trials. The use of thrombolytic therapy in patients with proximal occlusive DVT associated with significant swelling and symptoms is increasing. Catheter-directed techniques are often employed [59]. In DVT, such aggressive therapy with thrombolytics may reduce the frequency of postphlebotic syndrome.

Bleeding is the primary concern with thrombolytic therapy. Both lysis of haemostatic fibrin plugs and fibrinogenolysis can lead to bleeding complications which commonly occur at sites of invasive procedures such as pulmonary arteriography or arterial line placement. Invasive procedures should be minimized as much as possible. The most devastating complication associated with thrombolytic therapy is the development of intracranial haemorrhage which occurs in less than 1% of patients. Retroperitoneal haemorrhage may result from a vascular puncture above the inguinal ligament and may be life-threatening. The main contraindications to thrombolytic therapy include active bleeding, surgery within the previous 1–2 weeks (depending on specific procedure), intracranial pathology or previous surgery. When patients appear to be at extraordinary risk of rapid death from PE, clinical judgment should be individualized with regard to contraindications.

Management of unstable haemodynamics in massive PE

Once massive PE associated with hypotension and/or severe hypoxaemia is suspected, supportive treatment is immediately initiated. With hypotension intravenous saline should

be infused rapidly but cautiously because right ventricular function is often markedly compromised. Dopamine or noradrenaline (norepinephrine) appear to be the favoured choices of vasoactive therapy in massive PE and should be administered if the blood pressure is not rapidly restored [60]. Because death in this setting results from right ventricular failure, dobutamine may offer benefit. A vaso-pressor such as noradrenaline combined with dobutamine might offer optimal results and further exploration of such combined therapy would prove enlightening. Oxygen therapy is administered and thrombolytic therapy is considered as described above. Pulmonary embolectomy may be appropriate in patients with massive embolism who cannot receive thrombolytic therapy.

Prognosis

In the International Cooperative Pulmonary Embolism Registry of 2454 patients, all consecutive patients with a diagnosis of PE were included and PE was the principal cause of death [61]. The 3-month mortality was 17.5%. In the PIOPED, the mortality rate was approximately 15% but only 10% of deaths during the first year of follow-up were attributed to PE [14]. Mean 1 month mortality rates of treated and untreated PE have been estimated at 8% and 30%, respectively.

While a small percentage of patients with acute VTE will ultimately develop chronic thromboembolic pulmonary hypertension, most patients who survive the acute episode have no long-term pulmonary sequelae. However, chronic leg pain and swelling from postphlebotic syndrome may cause significant morbidity.

Prevention

Measures to prevent VTE appear to be grossly underutilized [2,3]. A substantial reduction in the incidence of DVT can be achieved when patients at risk receive appropriate prophylaxis. In one of the highest risk settings, total hip or knee replacement, the risk is 50% or greater without prophylaxis. The superiority of LMWH over unfractionated heparin has been demonstrated in these settings, and extending the duration of prophylaxis to approximately 1 month after surgery further reduces the DVT rate in total hip replacement [62]. Unfractionated heparin is not recommended in total joint replacement.

Hospitalized general medical patients are clearly at risk for VTE. Anticoagulant prophylaxis should always be strongly considered as the rate of DVT, based upon a venographic endpoint, is as high as 15% in medical patients receiving placebo [18]. The rate of DVT, including proximal

DVT, is statistically significantly lower when enoxaparin is administered compared with placebo [1]. Low molecular weight heparin (enoxaparin) has been compared directly with subcutaneous standard heparin (5000 units every 8 h) for medical patient prophylaxis and while clear superiority was not proven, VTE rates were lower with enoxaparin [63]. Although 5000 units of heparin every 12 h has been commonly used, there are fewer data to support this preventive regimen in medical patients. Intermittent pneumatic compression devices should be utilized when pharmacological prophylaxis is contraindicated. Both methods combined would be reasonable in patients deemed to be at exceptionally high risk, but an additional reduction in risk in such patients has not been well substantiated.

The efficacy of prophylactic therapy for VTE in COPD exacerbations has been studied, and administration of a LMWH prompted a 45% reduction in the incidence of DVT in acutely decompensated patients compared with placebo in a large prospective randomized trial [64]. Other studies have included large numbers of COPD patients and have confirmed the efficacy of LMWH in preventing VTE in this population [18]. A recent review has characterized the clinical problem of VTE in patients undergoing acute exacerbation of COPD [65].

Each hospitalized patient should be assessed for the need for such prophylactic measures and all hospitals should strongly consider formulating their own written guidelines for each particular clinical setting, based upon the available medical literature [66].

CHAPTER 45

COPD and lung cancer

Stephen G. Spiro and Frank McCaughan

Chronic obstructive pulmonary disease and lung cancer share a common dominant aetiological agent – tobacco smoking. Together they contribute substantially to the burden of lung disease. In this chapter we explore the links between these two important respiratory diseases.

Epidemiology

Lung cancer is now the leading cause of cancer-related mortality in the USA, and it is estimated that it will cause 160 440 deaths in 2004 [1]. This figure amounts to more than the estimated combined total mortality resulting from cancers of the colon, breast, pancreas and prostate. In the European Union (EU), lung cancer accounts for approximately 20% of all cancer deaths [2]. The age-standardized death rate from lung cancer across the EU is 37.6/100 000. There is a marked variation between different countries, with the death rate in the UK approximately double that of Sweden. In the UK, the 1-year survival for males and females with lung cancer is 20% compared with 79% in prostate cancer and 92% in breast cancer. Predictions for the future are also grim as the death rate from lung cancer is predicted to rise significantly worldwide by 2020, particularly in France and Mediterranean countries and it could reach epidemic proportions in China and South-East Asia [2]. The belief that the emergence of low-tar cigarettes would lower the incidence of lung cancer has been discounted [3].

COPD has been identified in a recent EU statement as a major public health issue [4]. Many patients with lung cancer have coexistent COPD and there is increasing evidence that patients with COPD are more likely to develop lung cancer. The number of patients with both these conditions will also rise in forthcoming years.

Prevalence of COPD in patients with lung cancer

There have been a number of observational studies reporting a high prevalence of COPD in patients diagnosed with lung cancer. The criteria for diagnosing COPD have evolved over the years, although recent guidelines have stressed the importance of spirometry and particularly the forced expiratory volume in 1 s (FEV_1) in making the diagnosis [5,6]. In one study, Tockman *et al.* [7] recruited male patients from two major trials: the Intermittent Positive Pressure Breathing (IPPB) Trial which examined the effect of this treatment for COPD and the John Hopkins Lung Project (JHLP) which was a lung cancer screening trial. All patients had a screening chest radiograph at baseline that did not reveal a lung cancer. In the IPPB Trial, 667 men aged 30–74 years were recruited and followed for a mean of 3 years. They all had an FEV_1 of less than 60% predicted and an $FEV_1 : FVC$ ratio of less than 60%. For the JHLP, 3728 men aged 45 years or more with a smoking history of at least 1 pack/day were recruited. They were followed for an average period of 1.2 years only. In total, 41 lung cancers were diagnosed in this group over the follow-up period and of these 66% had an FEV_1 of less than 60% predicted. There are some difficulties with this data. First, the 667 patients from the IPPB trial were already selected as having at least moderate COPD and they contributed 22 of 41 cancers. Secondly, the follow-up period was too short to learn about incidence cancer rates.

In another, much smaller study, Congleton and Muers [8] recorded spirometry in 57 patients who presented with a new diagnosis of lung cancer to a specialist clinic in a single centre in 1 year. They found that 49% of their patients had an FEV_1 of less than 70% predicted. They further prescribed bronchodilators to 15 of their patients with airflow

limitation and found that 8/15 had a significant (more than 15%) spirometric response and there was also an improvement in breathlessness scores.

The Copenhagen City Heart Study recruited 13 946 people between 1976 and 1978 and followed them for 10 years on average. In total, 225 developed lung cancer of which only seven were non-smokers. Of the 225, 52% had an FEV_1 recorded at enrolment in the study of less than 80% predicted [9].

In a recent review of these and other relevant studies using the then available methods of defining COPD, the likely prevalence in patients with lung cancer was estimated at between 50% and 64% [10].

Increased risk of lung cancer in patients with COPD

The major risk factors for lung cancer are age, smoking history, social class and FEV_1 . The latter has been explored in a number of series that have examined the risk of lung cancer for patients with COPD. They include older series, which used a variety of criteria for diagnosing COPD, and more recent studies which have used spirometric criteria. Although the results are not directly comparable, they consistently report a significantly increased risk of primary lung cancers in patients with COPD.

In a prospective population study in Renfrew and Paisley, Scotland, the investigators enrolled 7058 men and 8353 women aged 45–64 years between 1972 and 1976 and they were followed for at least 15 years [11]. The overall mortality was high in this cohort, mainly as a result of cardiovascular and respiratory disease. Subjects were stratified by FEV_1 into quintiles. The authors reported a significant correlation between a low FEV_1 and death from all causes. With respect to lung cancer, in men in the lowest quintile for relative FEV_1 (which was calculated in this cohort as an FEV_1 of less than 73% predicted), the relative hazards ratio for death from lung cancer compared with those men in the highest FEV_1 quintile was 2.53 (95% confidence interval, 1.69–2.79; $P < 0.001$). Despite correcting for smoking, social class and cardiovascular risk factors, there was a highly significant trend in both sexes for the risk of lung cancer to increase with a lower FEV_1 . Furthermore, the absolute number of patients with lung cancer may have been underestimated because subjects dying from other causes may have had synchronous undiagnosed lung cancers.

A more recent study [12] used the new GOLD guidelines to classify patients with COPD in an analysis of participants in the First National Health and Nutrition Examination Survey (NHANES 1). For this survey, 14 407 adults were recruited between 1971 and 1975. The investigators applied

the GOLD spirometric criteria to the cohort who had both participated in the cardiorespiratory survey and examination and also had respiratory function tests measured at entry. No subsequent spirometric data were available. Subjects with a history of cancer were excluded. A total of 5402 subjects fulfilled the criteria for entry to the study. (Subjects excluded because of an incomplete dataset tended to be older and were more likely to be non-white in ethnic origin – this group are known to have a higher incidence of lung cancer and this was shown again by subgroup comparison in this study.) The results showed that the presence of moderate or severe airflow obstruction (FEV_1 : FVC less than 70% and FEV_1 less than 80%) in a proportional hazards model adjusted for age, sex, race, education, smoking status and duration and intensity of smoking was associated with a significantly higher risk of incident lung cancer (hazards ratio, 2.8; 95% confidence interval, 1.8–4.4). Furthermore, those subjects with moderate or severe COPD at the initial survey developed lung cancer after a shorter interval (5.3 years) than those without COPD (12.4 years). Interestingly, despite this, the age at which lung cancer was diagnosed was higher in the COPD group.

There are other relevant studies summarized in Table 45.1 [9,13–15], which also confirm that the risk of lung cancer increases in smokers with a lower FEV_1 .

There are as yet no data available on whether the COPD phenotype has an influence on the risk of developing lung cancer.

Implications for the early detection of lung cancer

The goal of screening for lung cancer is the detection of cancers at an earlier stage, leading to a curative intervention and therefore improved lung cancer survival. To date, the results of lung cancer randomized screening studies have been disappointing and a recent consensus statement has advised that there is insufficient evidence to recommend screening for lung cancer [16]. This recommendation was based mainly on the trials of the 1970s in which chest radiographs and sputum cytology were used as screening tools, although these trials have been criticized because of methodological flaws. More recently, low-dose spiral CT scanning (LDCT) has been evaluated as a method of detecting early lung cancers [17,18]. These studies were hypothesis generating and produced a prevalence of 1.8–2.8% for lung cancers, almost all being stage 1 and adenocarcinomas. Two large randomized prospective studies are now in progress in the USA:

1 The Prostate, Lung, Colon and Ovary Trial has recruited 155 000 people and divided them into two groups: control

Table 45.1 Summary of studies describing an increased risk of lung cancer in subjects with chronic obstructive airways disease (COPD).

Authors	Year of publication	Reference	Trial summary	RR of lung cancer (95% CI) (adjusted for age and smoking history)
Lange <i>et al.</i>	1990	9	Divided male ($n = 6373$) and female ($n = 7573$) subjects into groups based on percentage predicted FEV_1 : $FEV_1 > 80\%$, 40–79%, < 40% Follow-up: average 10 years	$FEV_1 < 40\%$ RR 3.9 (2.2, 7.2) FEV_1 40–79% RR 2.1 (1.3, 3.4)
Kuller <i>et al.</i>	1990	13	Divided male smokers ($n = 6075$) into quintiles based on FEV_1 (absolute values) Follow-up: average 7.5 years	Lowest vs highest quintile RR 3.57 (0.94, 12.5)
Nomura <i>et al.</i>	1991	14	Divided male subjects ($n = 6317$) into quartiles based on percentage predicted FEV_1 Follow-up: 19 years	Lowest vs highest quartile RR 2.1 (1.3, 3.5)
Islam & Schottenfeld	1994	15	Divided male ($n = 1021$) and female ($n = 714$) smokers into quartiles based on percentage predicted FEV_1 Follow-up: 18–25 years	Lowest vs highest quartile RR 2.7

CI, clearance interval; FEV_1 , forced expiratory volume in 1 s; RR, relative risk.

and screened. Those in the screened group had a chest radiograph on entry and then annually for 2 years for non-smokers, 3 years for smokers [19].

2 The National Lung Screening Trial is comparing screening with either LDCT or a chest radiograph in a current or recent ex-smoking population aged between 55 and 74 years with a 30 pack-year smoking history [20].

The epidemiological link between COPD and lung cancer has never been used to set eligibility criteria for a large-scale screening trial. However, the data confirm the increased risk of lung cancer in patients with COPD and that the risk increases with worsening airways obstruction. It has therefore been proposed that screening should be targeted at a high-risk population to include heavy smokers with documented airflow obstruction [21]. One group has published data on screening in such a cohort with COPD and smoking histories of 40 or more pack-years. The authors suggested that a combination of screening modalities including sputum cytology, autofluorescence bronchoscopy and CT scanning could detect lung cancer in up to 4.9% of these high-risk patients [22]. One difficulty with this approach is that patients with severe COPD may not be fit for surgery or radical radiotherapy. However, increasing emphasis is being placed on local lung-sparing endobronchial techniques such as photodynamic therapy and brachytherapy and, secondly, the definition of 'fitness for surgery' with respect to patients with lung cancer and COPD is evolving.

Why is there an increased risk of lung cancer in patients with COPD?

The simple answer is tobacco smoking. However, the biological mechanisms underlying this link are as yet unclear. COPD is an inflammatory process and lung cancer a neoplastic process. Traditionally, these were thought of as distinct entities but it is becoming increasingly clear that there is a link between inflammation and cancer, with examples including Barratt's oesophagus, oesophageal cancer and genitourinary cancers as a result of chronic schistosomiasis infection [23,24]. It is therefore possible that the epidemiological link between COPD and lung cancer may be in part explained by the link between chronic inflammation and neoplastic transformation.

Tobacco smoke contains approximately 4000 separate compounds of which 60 are recognized as carcinogens [25]. A number of carcinogens, notably the polycyclic aromatic hydrocarbons and nitrosamines, have been implicated in the pathogenesis of lung cancer. These compounds can be metabolized to form activated derivatives that bind DNA, forming so-called DNA adducts. Such adducts predispose to mutations if the normal DNA repair mechanisms are evaded. The existing evidence in support of this mechanism has been summarized in a recent comprehensive review [26].

A second possible mechanism of tobacco-related carcinogenesis is oxidative damage where reactive oxygen species are generated as a result of the free radicals present in cigarette smoke. This has been associated both with DNA damage and therefore possible mutagenesis; in addition, tobacco-generated pulmonary and systemic oxidative stress is considered very important in the pathogenesis of COPD [27].

Approximately 11–24% of smokers will develop lung cancer [28] and 15–20% of smokers will develop COPD. The latter statistic is being revised with increasing evidence that 50% of people who smoke for long enough will develop COPD [29]. The determinants of the individual susceptibility of a particular smoker to develop either of these pathologies are unknown. For example α_1 -antitrypsin deficiency predisposes to COPD; other associations have been described between particular genes and susceptibility to COPD including glutathione S-transferases and microsomal epoxide hydrolase although results have not been consistent, especially from different populations [29]. Glutathione transferases are involved in detoxification including that of the activated metabolites of polycyclic hydrocarbons responsible for DNA adduct formation. There is also some evidence linking glutathione S-transferase polymorphisms with lung cancer [26]. It may be that for both conditions a polygenic inheritance including multiple susceptible gene polymorphisms will combine to produce a 'susceptible phenotype'.

Management of lung cancer in patients with COPD

A diagnosis of COPD can have a profound effect on the treatment options open to any patient with lung cancer. The primary goal of intervention is cure, but COPD may preclude a patient from a potentially curative treatment such as surgery or radical radiotherapy. Furthermore, performance status, to which COPD can be an important contributing factor, is a key predictor of outcome in lung cancer of any stage.

Preoperative assessment in patients with lung cancer and COPD

Surgery is the treatment modality most likely to cure lung cancer, particularly non-small cell lung cancer (NSCLC). Patients with lung cancer tend to be in their sixties and seventies at diagnosis and often have multiple comorbidities that render surgery hazardous. One of the most important roles of the chest physician, as part of the multidisciplinary team, is to help weigh the operative risk to an individual with operable lung cancer but significant COPD.

Spirometry, and in particular the FEV_1 , has been used as a screening test to determine if a patient has airways obstruction severe enough to preclude pulmonary resection. There are more data available on the use of FEV_1 to predict surgical risk than any other test of respiratory physiology [30]. FEV_1 can be measured either in absolute terms or as a percentage of predicted normal. Its use in three retrospective series in the 1970s comprising more than 2000 patients was evaluated by the British Thoracic Society [31]. There was a surgical mortality of less than 5% for a lobectomy or a pneumonectomy if patients had an FEV_1 of more than 1.5 or 2 L, respectively. Therefore, patients whose FEV_1 exceeds this criterion are deemed to be suitable for surgery without requiring further evaluation. Historically, studies have quoted absolute values but it is preferable if the FEV_1 is expressed as a percentage of the predicted value as this takes into account a patient's age, gender and height and allows more standardized comparisons between different cohorts. The accepted recommendation is that if the FEV_1 is more than 80% predicted then a patient is fit for a pneumonectomy [30].

Patients with severe COPD are at greater risk of perioperative morbidity and mortality. In such patients, investigations can be used to predict the postoperative FEV_1 (ppo FEV_1) [30] by attempting to determine what fraction of currently functioning lung will remain after surgery. To do this accurately, detailed respiratory function tests are mandatory in conjunction with further imaging.

The calculation of the ppo FEV_1 can be complicated if a tumour partially or completely obstructs a proximal airway. In such cases, the lung distal to the obstruction will not be contributing to the preoperative FEV_1 . However, other patients may have a tumour in a more peripheral location which will not influence the FEV_1 to any great extent. Lung cancer and COPD can both have a profound effect on the relative perfusion of a pulmonary segment, lobe or a lung. Ventilation/perfusion mismatch is well recognized in COPD and it has been shown that obstructing tumours can cause considerable underperfusion of the involved segment [32]. It is useful therefore to attempt to image the relative perfusion to the part of the lung that is earmarked for resection. Postoperatively the cardiac output will be channelled through the remaining pulmonary vasculature, which has implications for ventilation/perfusion matching, particularly in the case of a pneumonectomy when the whole cardiac output suddenly perfuses one lung. This is reflected by the increased KCO (coefficient of transfer of carbon monoxide calculated by dividing the transfer factor of carbon monoxide [DLCO] by the alveolar volume [VA]) postpneumonectomy and can cause pulmonary hypertension and respiratory failure if the pulmonary vasculature bed is not sufficiently compliant.

There are different approaches to calculating the

ppoFEV₁. These utilize ventilation and perfusion scans, quantitative CT scanning and simply counting the number of lung segments that are to be resected as a percentage of the remaining tissues. These methods generally arrive at similar values [33]. The current British Thoracic Society guidelines suggest using a perfusion scan. Recommendations [30,31] are based on the percentage of ppo (%ppo) values for FEV₁ and DLCO rather than absolute values. The commonly used equations for calculating %ppoFEV₁ are documented in Figure 45.1.

These calculations have been validated in some studies but others have noted that there is a tendency for the ppoFEV₁ to underestimate the actual ppoFEV₁ by a factor of up to 10%. Various authorities have advocated different cut-off values below which an operation may be considered high risk. A threshold ppoFEV₁ of 0.8 L was suggested [34] but, as discussed above, it is preferable to consider these issues in terms of %ppoFEV₁. A number of case series have shown that a %ppoFEV₁ of less than 40% can be associated with a poor outcome. Markos *et al.* [35], in a prospective series of 55 patients, reported that three of six patients with a %ppoFEV₁ of less than 40% died, whereas there were no deaths in those with a value greater than 40%. Similar outcomes using this threshold have been reported, but these kinds of results are by no means universal. Other groups have found that some patients with similarly poor respiratory function, if properly selected, can tolerate curative lung cancer resection. Ribas *et al.* [36] described 65 patients who, despite having a ppoFEV₁ of less than 40%, underwent a pneumonectomy ($n = 21$) or a lobectomy/wedge resection ($n = 44$). Despite their significant ventilatory impairment according to the standard criteria, only four subjects died postoperatively (6.2%).

There are therefore some problems associated with using the %ppoFEV₁ as the main criterion for accepting or refusing a patient for surgery. The first is that a diffuse interstitial process may coexist with both COPD and lung cancer so that in the presence of an interstitial infiltrate on a plain chest X-ray, or if there is reported exertional breathlessness inappropriate to the basic spirometric values, a DLCO should be measured. Secondly, there is some evidence to support the use of the DLCO rather than the FEV₁ as the most accurate predictor of postoperative problems. Thirdly, many patients who have survived a lobectomy or pneumonectomy would have been denied surgery on the basis of their %ppoFEV₁.

Ferguson *et al.* [37], who retrospectively reviewed lung function tests on 237 patients undergoing resection, questioned the reliance on basic spirometry. They found that a low preoperative DLCO, expressed as a percentage predicted, was a more accurate predictor of mortality than the percentage predicted FEV₁. They reported a respiratory complication rate of 45% and a mortality of 25% with a DLCO of less than 60% predicted. They extended these

observations in an analysis of 376 patients and identified a preoperative DLCO of less than 60% predicted or a %ppoDLCO of less than 50% as the most accurate predictors of postoperative respiratory complications and death [38].

The FEV₁ and DLCO are complementary investigations and should be considered for all candidates for surgical resection of lung cancer. In the patients who are borderline, it is recommended that both the %ppoFEV₁ and the %ppoDLCO are estimated. The British Thoracic Society and the American College of Chest Physicians (ACCP) recommend exercise testing if either of those values are less than 40% predicted, although the evidence for this approach is not strong [30,31]. An algorithm for the consideration of patients with lung cancer for lung resection has been published by the British Thoracic Society and is reproduced in Figure 45.1.

The aim of cardiopulmonary exercise testing (CPET) is to calculate a subject's maximum oxygen uptake or $\dot{V}O_{2max}$. Often this technique is only available in specialized centres. There are a number of studies that have stratified patients according to their $\dot{V}O_{2max}$. It has been shown that those with a value of more than 20 mL/kg/min are not at increased risk of complications or death, whereas the perioperative mortality in those who manage less than 10 mL/kg/min is relatively high [30]. Morice *et al.* [39] showed that a subgroup with a %ppoFEV₁ of less than 33% who managed a $\dot{V}O_{2max}$ of more than 15 mL/kg/min did well. Surrogate exercise tests have been used, with those patients who managed to climb five flights of stairs considered fit enough for a pneumonectomy and this may be considered an alternative to formal exercise testing although it is poorly standardized.

There is no predictive role for routine arterial blood gas analysis in the preoperative assessment.

Combined lung volume reduction surgery and lung cancer resection

There has been renewed interest in lung volume reduction surgery (LVRS) over recent years. This has led to speculation about the role of combined LVRS and surgical resection of lung cancer. It has been suggested that in patients with advanced COPD who previously would not have been considered for curative resection, a combined procedure might be curative with respect to the lung cancer and yield a secondary benefit with both functional and physiological improvements postoperatively. In 2003, the National Emphysema Treatment Trial study [40] reported a significant improvement after lung resection in a highly selected group of patients with heterogeneous emphysema affecting the upper lobes who were severely limited by dyspnoea. McKenna *et al.* [41] have published a series

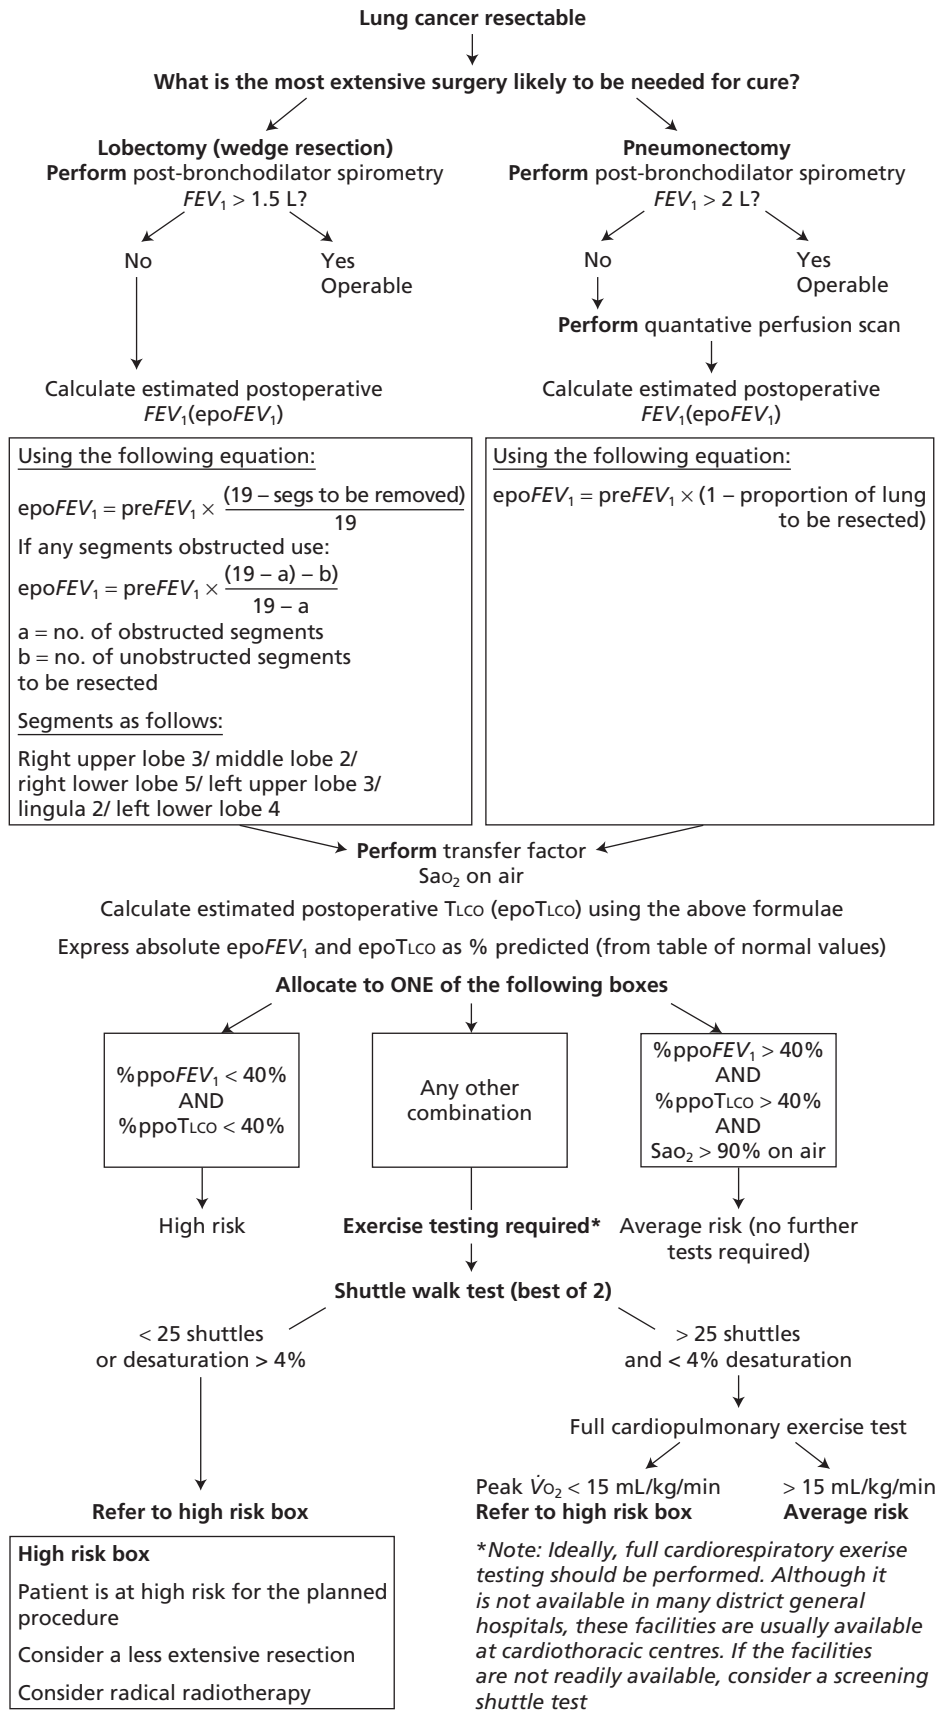

Figure 45.1 Guidelines on the selection of patients with lung cancer for surgery. (From British Thoracic Society and Society of Cardiothoracic Surgeons of Great Britain and Ireland Working Party Writing Group [31] with permission from the BMJ Publishing Group.)

of 325 patients who had LVRS, 51 (16%) of whom had a pulmonary mass in addition to severe emphysema. Of these, 11 (3%) were NSCLCs (seven squamous cell carcinomas, four adenocarcinoma). Three were referred specifically for the combined operation and one was an incidental histopathological diagnosis; therefore seven new cancers were picked up by the preoperative CT scan in this highly selected group. The results were impressive. There was no perioperative mortality and there was no recurrence of lung cancer after a follow-up period of 9 months. Furthermore, average preoperative FEV_1 was 0.65 L (range 12–29% predicted) compared with 1.08 L postoperatively and, of 11 patients, seven improved their dyspnoea score. The patients who benefited the most were the five who had the lung cancer in a lobe already targeted for removal at LVRS. The technique employed to excise the cancer was a wedge resection in eight patients and a formal lobectomy in the others.

The success in selected patients of LVRS indicates that some who were being denied curative surgery for lung cancer on the basis of severe COPD may have derived a physiological and functional benefit. Edwards *et al.* [42] have further explored this concept with the idea of 'lobar volume reduction surgery' to remove a lobe containing a cancer. They stratified patients on the basis of their predicted postoperative FEV_1 expressed as a percentage of their predicted value (%ppo FEV_1). The cut-off chosen was 40% based on earlier work by Markos *et al.* [35] who demonstrated a mortality of 50% in those with a ppo FEV_1 of less than 40%. Edwards *et al.* reported a higher perioperative mortality in the group with a ppo FEV_1 of less than 40%; two of 14 patients died as a result of postoperative pneumonia and empyema. There were no deaths in the other group (ppo FEV_1 of less than 40%). However, at a median follow-up of 12 months there was no difference in mortality between the groups. Furthermore, there was no difference between the pre- and postoperative FEV_1 in the first group; thus, the ppo FEV_1 significantly underestimated the actual postoperative value. The authors concluded that consideration of fitness for surgery in lung cancer should acknowledge the effect of lobar LVRS and that current methods of calculation may underestimate prediction of postoperative respiratory function and should not be clinically binding.

It must be stressed that this dual technique is only appropriate for a few, highly selected patients with COPD and operable lung cancer and that an operation is more likely to be successful if the cancer is in a part of the lung appropriate for LVRS. However, there are reports of successful procedures involving LVRS and an additional wedge resection of a cancer and the indications for surgery in these patients will evolve. It will be necessary to refine current guidelines to acknowledge both the role of surgery in patients with heterogeneous emphysema and lung cancer and that preoperative predictions can underestimate postoperative

function. Each patient should be considered carefully with a view to maximizing the number who undergo successful curative resections for lung cancer.

In conclusion, the association of lung cancer and COPD is substantial and their coexistence affects the management of lung cancer in many patients. All possible care should be taken in the evaluation of patients with lung cancer and COPD to offer a potentially curative resection. The association of these two conditions is likely to become more common as COPD is increasingly recognized and as lung cancer rates continue to rise in many countries of the world.

CHAPTER 46

Infection management and airflow obstruction

Alan M. Fein, Jill P. Karpel and Antonio Anzueto

COPD: interaction of infection and obstruction

Progression of COPD: relation to chronic inflammation and exacerbation

Chronic obstructive pulmonary disease (COPD) is a complex multifaceted disease process that continues to increase in incidence. Currently the fourth leading cause of death in the USA, COPD is also increasingly recognized in the developing world [1]. Conceptual definitions relevant to disease development and exacerbation have sought to emphasize three elements: some component of irreversible airflow obstruction; mixed pathology involving variable degrees of emphysema, large and small airway and vascular injury and remodelling; and inflammation encompassing both large and small airways and lung parenchyma [2]. The impact of chronic infection on damage to airways and lung parenchyma is not well defined and it may vary in individual patients. This may, in part, account for the myriad of clinical expressions of COPD.

COPD also has a systemic component that affects the nutritional balance, body habitus, muscle strength, cognition and mood of those affected. Characteristically, during stable periods, mediators of inflammation are increased within the lung as measured in bronchoalveolar lavage and breath condensate, and in the systemic circulation. Even higher levels of these mediators are detectable during acute periods of clinical deterioration termed acute exacerbation of COPD (AECOPD). Based on these findings, current opinion holds that inflammation is the most important contributor to the pathogenesis of COPD.

As COPD progresses, it is often complicated by pulmonary hypertension. Sustained elevation in pulmonary artery pressures is associated with increased mortality although the impact of mild elevations in pulmonary artery

pressures on dyspnoea and exercise performance is not clearly defined.

Cigarette smoking and air pollution, both indoor and outdoor, are recognized as important contributions to COPD. However, sex, bronchial hyperresponsiveness, genetic susceptibility, as observed in α_1 -antitrypsin (AAT) deficiency and other polymorphisms identified recently also interact to determine expression of disease. Recent data has suggested that patients who are atopic or have airways hyperresponsiveness experience greater declines in lung function over time [3]. Asthma, particularly when inadequately treated, is associated in some patients with ultimately irreversible lung disease. One study correlated duration of asthma with the degree of airflow limitation and hyperinflation in a cohort of elderly patients [4]. In an advanced clinical state, those problems may be indistinguishable from COPD in individual patients. While smoking contributes to the development of COPD, nearly 10% of patients dying of COPD are reported never to have smoked.

Other contributors thought to facilitate progression of COPD prominently include both viral and bacterial infectious agents (Table 46.1). The role of infection must be considered both from the perspective of disease initiation and modification. This chapter reviews the links between

Table 46.1 Factors resulting in progression of COPD.

- 1 Cigarette smoke
- 2 Genetic predisposition: α_1 -antitrypsin, possibly other polymorphisms
- 3 Infection: viral/bacterial – frequency and timing of exacerbations
- 4 Air pollution: indoor/atmosphere

infection and COPD progression, the relationship between infection and inflammation, and strategies to prevent and treat infection in COPD patients. The specific contribution of AECOPD to the pathophysiology of COPD and its progression is highlighted.

COPD exacerbation

COPD is characterized by progressive decline in lung function over many years. Although this may be gradual, resulting in cough, dyspnoea, mucus hypersecretion and slowly decreasing health-related quality of life, physiological decline may be subacute, acute or, rarely, precipitous. Until recently, AECOPD has been only loosely defined, reflecting its multiple putative aetiologies. It is the most common cause of hospitalizations in patients with COPD and has been frequently linked to acute airways infection, specifically bacterial tracheobronchitis [5,6]. Many component diseases under the COPD umbrella, including chronic bronchitis, emphysema, asthma and bronchiectasis, are also punctuated by episodic acute deteriorations in pulmonary physiological function. In this scenario, exacerbations are associated with changes in volume and quality of phlegm, as well as dyspnoea and systemic manifestations such as fever and change in mental status. Hypoxaemia, hypercapnoea and altered mental status are associated with severe exacerbations resulting in hospitalization [5–7].

The common clinical symptoms were used by Anthonisen *et al.* [8] to develop the most used clinical classification of AECOPD, the ‘Winnipeg Criteria’. Patients were categorized by the presence or absence of the three major clinical symptoms: breathlessness, sputum volume and purulence. Patients with all three symptoms were classified as type I; those with any two as type II; and those with only one symptom as type III. The American Thoracic Society and European consensus conference on standards for COPD management developed the following definition of AECOPD, building on previous concepts: ‘An event in the natural course of COPD characterized by a change in baseline dyspnoea, cough and/or sputum beyond day to day variability sufficient to warrant a change in management’. Severity was defined operationally as:

- *Level I*: ambulatory treatment.
- *Level II*: requiring hospitalization.
- *Level III*: acute respiratory failure.

This reflects the broad spectrum of this disease process, from mild episodes that often go unreported to the most severe episodes, where hospitalization and even intensive care may be required (Table 46.2).

In the setting of respiratory failure resulting in hospitalization, mortality rate was 11% while in hospital, 33% at 6 months and 43% at 1 year. In a comprehensive audit of outcomes of AECOPD, 14% of patients died within

Table 46.2 Definitions of COPD exacerbation.

Symptoms	Change	Consequence
<i>Major</i>	Acute	<i>Level I</i>

		Hospital treatment
<i>Minor</i>		
Fever		<i>Level III</i>
Reduced exercise capacity		Respiratory failure

3 months of admission. Once a threshold of physiological decline is reached exacerbations occur between two and four times per year. Previous exacerbation, underlying cardiopulmonary disease and mucus hypersecretion are predictive of repeat exacerbations [9,10].

Colonization and infection in the lungs of COPD patients

Again, the underlying cause of AECOPD may be multifactorial, including noxious environmental exposures, and occupational, indoor and outdoor air pollution, as well as structural injury to the lung, as in pneumothorax and pulmonary thromboembolism (Table 46.3). The findings during AECOPD of increasingly purulent sputum, within which are found high concentrations of bacteria, suggests but does not prove bacterial causation. Although respiratory infections are assumed to be mainly responsible for exacerbation of COPD, other considerations are also involved.

Acute viral and bacterial infection, in the setting of airways already colonized with bacteria, is thought to be the predominant mode of initiating an AECOPD. Bacterial

Table 46.3 Contributing factors in acute exacerbation COPD.

- 1 Viral infection: influenza A & B, rhinovirus, coronavirus, latent adenovirus
- 2 Bacterial infection: *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Moraxella catarrhalis*, Gram-negative bacteria, *Pseudomonas aeruginosa*, Enterobacteriaceae
- 3 Air quality, indoor and outdoor pollution: change in air quality, biomass fuels
- 4 Heart failure: left ventricular, right ventricular
- 5 Pulmonary embolism
- 6 Pneumothorax

colonization of the airways is a dynamic process, which has been correlated with the degree of airflow obstruction and a person's smoking status. A vicious cycle of infection and inflammation develops, causing acute or chronic injury to airways, parenchyma and vessels. Even when the COPD patient is stable, the infection–inflammation cycle may contribute to progressive bronchiolitis and irreversible airflow obstruction. Whether infection is a direct or indirect cause of airway injury or, conversely, is facilitated by an already compromised epithelium is not entirely certain. It is probable that airways already damaged are more easily infected and slower to recover than healthy ones. Bacterial infection promotes mucus hypersecretion and limits mucociliary clearance, an effect demonstrated in animal models of airway injury by *Haemophilus influenzae*, *Streptococcus pneumoniae* and *Pseudomonas aeruginosa*. Similarly, cell-free supernatants, consisting of non-typable *H. influenzae* and *P. aeruginosa*, result in ciliodyskinesia and stasis in isolated airway preparations. The latter may occur directly through the actions of bacteria or indirectly through stimulation of neutrophil migration and release of human neutrophil elastase [11].

Bacterial infection itself fosters conditions that favour persistent bacterial growth, termed colonization, and recurrent infection contributes to amplification of inflammation with subsequent airway and vascular remodelling. Neutrophil defensins predispose to enhanced *H. influenzae* adherence. *H. influenzae* has been demonstrated to localize to 'protected' sites within the airway as between cells. Such results make it unlikely that recovered bacteria are merely innocent bystanders in this process. The interrelationship of bacteria and viruses is also complex in the setting of COPD.

Studies utilizing quantitative bacterial cultures during AECOPD are considered most reliable; they have shown that as COPD becomes more advanced, bacteria are usually recovered in sputum, whereas normal airways are usually sterile. The stage in the natural history of COPD when

Table 46.4 Risk factors for bacterial colonization in COPD.

- 1 Recurrent viral infection, especially influenza
- 2 Severe COPD

- 4 Nutritional status
- 5 Immunosuppression: alcohol, steroids
- 6 Antibiotic use
- 7 Hospitalization

bacteria can be recovered consistently, however, is not specifically known. There is a relatively low frequency of persistent colonization with potentially pathogenic bacteria when COPD is only of mild or moderate severity. Rates of colonization rise as disease becomes more severe. In the most compromised patients as measured by pulmonary function, pathogenic Gram-negative organisms are often recovered [11–13].

Risk factors for colonization include heavy smoking (more than 1 pack/day), current smoking, severe airflow limitation and recurrent viral infection. In fact, isolation of viruses, particularly influenza, has been associated with higher rates of recovery of *S. pneumoniae* and *H. influenzae*. Other risk factors associated with colonization include nutritional status, alcohol use, antimicrobial treatment, hospitalizations and steroid use (Table 46.4). In the studies using bacterial cultures, the organisms most commonly isolated from patients with severe obstructive lung disease include Enterobacteriaceae and *Pseudomonas* sp., *Proteus vulgaris*, *Serratia marcescens*, *Stenotrophomonas maltophilia* and *Escherichia coli*. In contrast, significantly larger numbers of non-pathogenic microorganisms were isolated in the group with forced expiratory volume in 1 s (FEV_1) \geq 50% (Fig. 46.1). *H. influenzae* was cultured notably more often in patients who were currently smoking and *P. aeruginosa* was cultured more frequently in persons with poor lung

Figure 46.1 The relation of pathogens isolated in patients with COPD and the severity of lung function (forced expiratory volume in 1 s [FEV_1]). (Reprinted from Miravittles *et al.* [15], with permission.)

function. *S. pneumoniae* is a frequent isolate among groups of all severity [14,15]. In a minority of patients with AECOPD, atypical pathogens such as *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* are recovered. However, because of limitations with serological diagnosis, the true incidence of these organisms in AECOPD is not known. *Chlamydia pneumoniae* can be detected in significant numbers of peripheral blood mononuclear cells in patients with stable COPD [16].

Many asthma exacerbations and approximately one-third of COPD exacerbations are preceded by ‘colds’, presumably representing recent acquisition of viral infection. Compared with COPD patients with non-viral exacerbations, those with viral exacerbations have higher symptom scores ‘especially more fever’, at the start of exacerbation and require significantly more time (more than 50%) to resolve. ‘Cold’ symptoms occurred on average 2–3 weeks prior to exacerbation. Medical resource utilization increased more than twofold in AECOPD associated with viral infection of the airways [16,17].

Respiratory viruses were found in approximately half of COPD exacerbations and in three-quarters of asthmatic exacerbations, with respiratory syncytial virus (RSV), influenza, rhinovirus (RV) and coronavirus accounting for almost all episodes. Coronavirus infection in humans has been associated with wheezing and airways obstruction even in non-asthmatic persons. Patients with COPD are more likely to experience more frequent viral respiratory infections, with RSV, parainfluenza, influenza and coronavirus, which may also predispose them to pneumonia. Some researchers believe that chronic viral infection, particularly with DNA viruses, like adenovirus, may be responsible for inflammatory dysregulation observed in the obstructive airways syndromes [18].

Respiratory viral infection has both systemic and local consequences. Airways are reddened and swollen with injury, and ultimately desquamation of the mucosal epithelial surface occurs. Peripheral airways involvement is evidenced by impaired tests of small airway function and viruses are also linked to chronic excessive sputum production [19–21]. Markers of systemic inflammation like fibrinogen and interleukin 6 (IL-6) have been shown to increase during exacerbation [21]. Acute rhinovirus infection has been demonstrated to increase IL-6 in cell culture and in smokers through an NF-κB dependent pathway. Direct effects on airway smooth muscle have also been demonstrated in association with increased release of IL-5 and IL-1β. Interestingly, chronic viral infection in stable COPD patients has been associated with high circulating levels of plasma fibrinogen and IL-6 and more frequent exacerbations [21]. Because viral infection impairs host defences, colonization becomes more likely, a fact supported by increased recovery of *Haemophilus* and *Pneumococcus*

in sputum or throat cultures. It is likely that acute viral infection adversely affects mucociliary clearance and macrophage function.

Inflammation in asthma and COPD

Asthma and COPD, both diseases of airflow obstruction, cause chronic inflammation that involves both the lung parenchyma and airways. The inflammatory responses of the two diseases, however, differ from each other. Such differences involve the types of inflammatory cells and mediators responsible for the persistent inflammation; the ultimate response to therapy; and permanent changes that occur, notably airway remodelling (Table 46.5).

In allergic triggers of asthma, the sensitizing antigen interacts with mast cell specific immunoglobulin E (IgE) resulting in the release of histamine, leukotrienes, cytokines and granulocyte–macrophage colony-stimulating factor (GM-CSF). Local inflammatory cell recruitment occurs in the airway through interactions between chemokines, adhesion molecules (ICAM-1 and VCAM-1) and eosinophils derived from the bone marrow. Clinically, the increased levels of IgE, cytokines and inflammatory cells (Fig. 46.2) result in bronchial hyperreactivity, airway

Table 46.5 Inflammatory differences between asthma and COPD.

oedema and mucus secretion, all contributing to airways obstruction.

Activated eosinophils are the main cell responsible for the airway inflammation in asthma, and can be demonstrated in bronchial biopsies, bronchoalveolar lavage fluid and induced sputum [22]. The eosinophils do not in general participate in normal airway defence against viral or bacterial infection. Other important cells contributing to asthmatic inflammation include activated CD4⁺ T lymphocytes (T-helper type 2 cells), macrophages, mast cells, basophils and, to a lesser extent, neutrophils (see Fig. 46.2). These cells release multiple proinflammatory cytokines such as IL-4, IL-5, IL-9, IL-10, IL-13 and IL-25 and GM-CSF, which in turn recruit and activate eosinophils further. Lymphocyte activation also results in the production of chemokines, such as RANTES and exotoxin, which are also important in eosinophil recruitment. This self-perpetuating reaction characterizes chronic inflammation characteristic of asthma. The degree of airway inflammation varies with both the duration and severity of the disease and the response to treatment [23–26].

In general, acute inflammation is thought to be an expected non-specific tissue response to injury that results in repair of normal structure and function. In asthma, chronic inflammation leads to permanent structural and pathological changes, known as airway remodelling in the large and small airways. It is not understood whether such remodelling is the normal response to injury or if the response itself is abnormal. Furthermore, the underlying causes of airway remodelling have not been defined, although both genetic and environmental factors have been implicated. Remodelling includes alteration of the reticular basement membrane, smooth muscle hypertrophy

and hyperplasia, mucous gland metaplasia and increased vascularity [27–30]. These changes occur in children and are present early in the disease process [31,32].

Clinically, airway remodelling results in irreversible airway obstruction and enhances bronchial hyperresponsiveness. Remodelling is diagnosed when pulmonary function remains persistently abnormal, despite optimal therapy.

In contrast to asthma, the neutrophil is the primary affected cell linked to the pathology of COPD. Among the most important initiators of neutrophil-driven injury are infection and cigarette smoke, and neutrophils have been demonstrated to be present in increased numbers in the sputum and lavage fluids of patients with COPD and in smokers. Prominent in the disease process is the role of tumour necrosis factor α (TNF- α) which, when released by macrophages stimulates migration of other macrophages and neutrophils into the airway epithelium. In addition to its inflammatory effects, TNF- α also causes neutrophil degranulation and injures epithelial cells directly. It can also induce airway mucous-cell metaplasia and hypersecretion *in vitro* and *in vivo*, decrease intraepithelial binding, cause cell death *in vitro*, and induce release of other cytokines and chemokines [33].

Interestingly, the eosinophils are also likely to contribute to airway inflammation in COPD. Higher serum eosinophilia in newly diagnosed patients with COPD has been associated with an accelerated decline in FEV₁, especially in smokers. While airway and sputum eosinophilia is not as prominent in COPD as in asthma patients, the number of inflammatory cells in the airways increases during AECOPD. Eosinophilic mediators are capable of injuring the epithelium and interstitium of the lung [21].

Both macrophages and epithelial cells also produce

cytokines, including neutrophil chemotactic factors, such as IL-8 and leukotriene B₄ (LTB₄). These macrophages may recruit other macrophages via chemokines, such as macrophage chemoattractant peptide 1 (MCP-1 and MIP-1 α) and growth regulated oncogene- α (GRO- α). IL-8 and GRO- α stimulate further migration of neutrophils and CD8⁺ T cells to the airway epithelium. Such migration leads to degranulation of neutrophils and the release of free radicals, which, in turn, causes matrix and epithelial damage.

Additionally, the activated CD8⁺ T lymphocytes, epithelial cells and other macrophage mediators also release neutrophilic chemotactic factors. This ultimately causes the release of proteases such as neutrophil elastase and matrix metalloproteinases (MMPs). Both the proteases and free radicals damage the epithelium and underlying basement membrane, resulting in small airways disease (bronchiolitis), chronic bronchitis (mucus hypersecretions) and emphysema (alveolar destruction). Normally, a protective process that includes protease inhibitors such as α -1 antitrypsin and secretory leukoprotease inhibitor (SLP) counterbalances protease activity [33]. In COPD, however, the naturally occurring protective process, or protease-antiprotease balance, is disturbed [34–36]. The result is damage and remodelling of the lung, which may lead to alterations in tissue structure.

Although the relationship between chronic inflammation and remodelling, as well as the relation to infection, is poorly understood in COPD, remodelling is associated with metaplasia of the epithelium of the small airways, increased mucous glands and accompanying hypertrophy, increased smooth muscle mass, airway wall fibrosis, increased vascularity and emphysema. The predominant site of airway obstruction, which varies among individuals, is related to decline in lung function.

The inflammation and airway remodelling in COPD reflect the impact of neutrophilic mediators triggered by the interactions of cigarette smoking, acute and chronic infection, and air pollution. Remodelling and chronic injury to airways disrupt host defences and facilitate chronic growth of bacteria, which in turn amplifies neutrophil-mediated injury. A significant correlation exists between the severity of airflow obstruction and the degree of neutrophilic infiltration and degranulation. High concentrations of neutrophil-derived elastase are detectable in airway secretions during AECOPD.

Infection, inflammation and remodelling

The relationship between infection, inflammation and airway remodelling in both asthma and COPD has not been fully defined. It has been postulated that airway infection may have an important role in the disease process, leading to the decline in lung function. Both lower airway bacterial

colonization and chronic viral infection have been implicated as contributory factors.

A proportion of stable patients with advanced COPD (20–40%) experience lower airway bacterial colonization [37–39]. Organisms most commonly cultured include *H. influenzae*, *S. pneumoniae*, *Moraxella catarrhalis* and *P. aeruginosa*. Furthermore, evidence exists that, as well as being present in the airway, *H. influenzae* can be detected in the submucosa and intracellularly, increasing the difficulty of eradicating the organism [40].

Once lower airway colonization occurs it usually persists, especially if lung function is impaired, and leads to increased airway inflammation. Bacteria can affect the inflammatory process by reducing mucociliary clearance, increasing mucus production and damaging airway epithelium [41, 42]. This leads to an influx of neutrophils and the release of neutrophil elastase and other cytokine and chemokines, which further fuels the inflammatory cycle. As bacterial colonization increases so does airway inflammation, an effect that is more pronounced with colonization by *P. aeruginosa* than other bacterial species [42]. A relationship between prognosis and circulating antibodies to *P. aeruginosa* has been specifically demonstrated in bronchiectasis.

Bacterial airway colonization leads to airway inflammation depending on the colonizing load [42]. *H. influenzae* colonization was associated with increased airway inflammatory markers in chronic bronchitis patients who had airflow obstruction compared with those without airflow obstruction [43]. Thus, significant evidence exists that lower airway colonization can lead to chronic inflammation and deterioration in lung function even for stable COPD patients.

COPD exacerbations, which are characterized by increased dyspnoea and increased sputum volume and/or purulence, are also associated with increased airway bacterial loads [44,45]. As with the stable COPD patient, those changes in sputum are associated with increased sputum neutrophils and neutrophilic inflammation, leading to the release of elastase and other proteinases. Such release can result in epithelial damage, reduced mucociliary clearance, increased mucus secretion and increased airway oedema through changes in the bronchial mucosa [46]. LTB₄, however, has a more prominent role than IL-8 in acute exacerbations [45]. Additionally, TNF- α and GM-CSF are also increased in bronchoalveolar lavage fluid during AECOPD. Both of these affect neutrophil and macrophage activation, leading to further inflammation and permanent damage. Resolution of the neutrophilic inflammatory changes has been shown to occur within approximately 5 days of treatment [45].

Interestingly, biopsy studies have also demonstrated increased numbers of both eosinophils and CD4⁺ lymphocytes in the airway walls of AECOPD patients [21,47]. This

might explain why clinical outcomes are improved in COPD when patients are treated with systemic corticosteroids for exacerbations as opposed to the relative steroid resistance seen in stable patients.

Controversy exists as to whether or not bacteria truly have an important role in AECOPD; however, most studies support the conclusion that they do. Specifically, the proportion of COPD patients with positive bacterial cultures and high bacterial loads during AECOPD are increased in most studies. Previous investigations may not have detected changes in the strain of the same organism, which has been postulated as a cause of acute exacerbations. That possibility is further supported by the fact that treatment with antibiotics appears to improve clinical outcomes during AECOPD. Finally, if one differentiates acute exacerbations associated with purulent sputum from those associated with mucoid sputum, the incidence of positive cultures is markedly different (84 vs 38%) [44].

Most evidence therefore suggests that both chronic lower airway colonization and acute infection contribute significantly to airway inflammation and remodelling in COPD. Clinically, those changes are manifested by deterioration in lung function. Patients with COPD may also be prone to viral respiratory tract infections that, in turn, can lead to ongoing inflammation and lung damage (i.e. alteration of mucociliary clearance, increased mucus). As with bacterial infection, viral infection has been implicated in both chronic and stable COPD, and AECOPD. In addition, viruses can exacerbate COPD by causing increased airway hyperresponsiveness and affecting muscarinic receptors, resulting in bronchoconstriction [47,48]. Viral infection may also predispose patients to secondary bacterial infection.

Hogg *et al.* have postulated that adenovirus can contribute to lung inflammation and emphysema [49–52]. Adenovirus infects lung epithelial cells and remains latent while continuing to produce viral proteins, which cause an increase in CD8⁺ T cells. The reaction is further exacerbated by cigarettes and is associated with increasing emphysema, findings supported by experiments in the guinea pig demonstrating that latent infection with adenovirus was associated with chronic lung inflammation 7 weeks after inoculation with virus. This inflammatory response was composed of CD4⁺ and CD8⁺ T cells, B cells, macrophages and monocytes. When exposed to cigarette smoke, the inflammatory response was heightened and more emphysema was demonstrated in the lungs. The inflammatory response mirrors that seen in humans [53]. These studies suggest that latent adenovirus may have a role in the pathogenesis of COPD.

Some evidence supports the belief that viruses also contribute to AECOPD. Most investigations have used serological conversion at the time of the exacerbation as the basis of establishing infection. The largest study of rhinovirus

demonstrated that positive rhinovirus cultures were more commonly associated with exacerbations [54,55].

In summary, infection with bacteria, viruses and atypical organisms may contribute to chronic airway inflammation in COPD and result in progression of the underlying disease process.

Evidence of antibiotic efficacy

While antibiotics are the most commonly prescribed agents in AECOPD and are presumed to have short-term benefit by most clinicians, long-term disease modification has not been proven. The specific aetiology of AECOPD is difficult to determine in an outpatient setting on the basis of symptoms and signs in individual patients. The phenomenon of increasingly purulent sputum observed frequently during AECOPD, within which are found high concentrations of bacteria, suggests but does not prove causation. Although respiratory infections are assumed to be the main perpetrators of exacerbation, other elements are also involved. In addition, routine sputum studies may have significant limitations, including delay in obtaining the results, cost and lack of sensitivity and specificity. As a result of the above considerations, recent treatment guidelines for AECOPD reflect the lack of a high level of evidence to provide specific recommendations for antibiotic use. The GOLD guideline, NHLBI/WHO initiative for COPD [56], recommends antibiotic choices on the basis of local sensitivity patterns of the most common pathogens associated with AECOPD, but do not provide specific guidelines. Another recent guideline also suggested that commonly available inexpensive antibiotics such as amoxicillin are likely to be efficacious in all but the most advanced disease [5].

A number of clinical trials have examined the use of antibiotics in the treatment of AECOPD. Many of the earlier studies showed either no or minimal benefit when antibiotics were prescribed. More recent analysis demonstrated benefit during an acute exacerbation, but not in preventing exacerbations. A landmark study in 1987 utilized a large-scale placebo-controlled trial designed to determine the effectiveness of antibiotics in the treatment of AECOPD [8]. In the investigation, 173 patients with chronic bronchitis were followed for over 3 years. Patients were randomized to either antibiotics or placebo in a double-blind crossover fashion, and one of three oral antibiotics chosen by the primary physician were used for 10 days: amoxicillin, co-trimoxazole (trimethoprim–sulfamethoxazole) and doxycycline. Approximately 40% of all exacerbations were severe, 40% were moderate and only 20% were mild. Patients with severe exacerbations received a significant benefit from antibiotics, whereas there was no significant difference between antibiotic and placebo in patients with mild exacerbations. Overall, the antibiotic-treated patients

Figure 46.3 Effect sizes (mean differences in outcome divided by the pooled standard deviation) in nine studies of the use of antibiotics for exacerbations of COPD. Horizontal lines denote 95% confidence intervals (CI). The data indicate a significant improvement resulting from antibiotic therapy. (Reprinted from Saint *et al.* [58], with permission.)

showed a more rapid improvement in peak flow, and more overall improvement than those who received placebo. In addition, the length of illness was 2 days shorter for the antibiotic-treated group. However, no microbiology was performed and all antibiotics were assumed to be equivalent.

Allegra and Grassi [57] found significant benefit with the use of amoxicillin-clavulanate acid (Augmentin®) therapy compared with placebo in patients with severe disease. Patients who received this antibiotic exhibited a higher success rate and a lower frequency of recurrent exacerbations. In 1995, the results of a meta-analysis examined the role of antibiotics in the treatment of AECOPD (Fig. 46.3) [58]. The investigators analysed the results of nine randomized placebo-controlled trials published between 1957 and 1992. Comparing outcomes, such as mean number of days of illness, overall symptom score and the changes in peak expiratory flow rate indicated a clinically significant benefit for the antibiotic-treated patients. Analysis of the studies that provided data on expiratory flow rates, for example, noted an improvement of nearly 1 l/min in the antibiotic-treated groups. Antibiotic-associated improvement is likely to be especially relevant to patients who have low baseline peak flow rates and limited respiratory reserve, but the clinical significance of these changes is uncertain in the mildest of cases.

Antibiotic therapy for patients with AECOPD carries additional potential benefits [59]. Antibiotics can reduce the burden of bacteria in the airway. Bronchoscopic studies, using sterile protected specimen brush, have demonstrated that approximately 25% of stable COPD patients are colonized with potentially pathogenic bacteria [60–62]. A much larger percentage of patients with acute exacerbations have potentially pathogenic microorganisms in addition to significantly higher concentrations (frequently $\geq 10^4$ organisms)

of bacteria in the large airways [60–62]. Because treatment with appropriate antibiotics significantly decreases the bacterial burden, and frequently eradicates the organisms, the proper choice of antibiotic will likely reduce the risk of progression to pneumonia. The eradication of bacteria by antibiotics is thought to break the vicious cycle of infection, inflammation potentially leading to progression of the lung disease. In a high-risk group of patients with AECOPD, the antibiotic-treated group had a significantly lower in-hospital mortality rate and significantly reduced length of stay in the hospital compared with the placebo group [63]. In addition, patients receiving ofloxacin were less likely to develop pneumonia than those on placebo, especially during the first week of mechanical ventilation [64]. Patients with AECOPD demonstrating eradication of bacteria from the sputum had a significant improvement in inflammatory profile as exemplified by reduced exhaled NO and IL-8 [65].

Controversy existed as to whether or not the choice of antibiotic is an important determinant of outcome. While a study by Anthonisen *et al.* [8] assumed that all of the antibiotics were equivalent, and that therefore the specific agent prescribed was not important, subsequent evolution of antimicrobial resistance may have invalidated that assumption. As recommended in several clinical practice guidelines, adjusting antibiotic therapy based on local bacterial ecology is most prudent. However, antibiotic trials published more recently compare a new antibiotic with an established compound for the purpose of product registration and licensing. Because equivalence is the desired outcome of such trials, the agent chosen for comparison is not considered important. In addition, such trials frequently include patients with poorly defined disease severity (often without any obstructive lung disease) and acute illness of minor severity.

Another problem with interpreting the literature on AECOPD is the large variation in time frame (from 48 h to 28 days) used to assess either relapse or the resolution of symptoms [66,67]. The former can most clearly be defined as treatment failure necessitating further health-care utilization as the result of persistent or worsening symptoms. Many of these patients experiencing relapse, however, do not seek medical care despite persistent symptoms. The published relapse rates for patients with AECOPD range from 17% to 32%. One recent investigation evaluated the risk factors for therapy failure at 14 days after an acute exacerbation in an elderly cohort of patients with moderate to severe COPD. Most of the patients with severe symptoms received antibiotics, as opposed to only 40% with mild symptoms. The overall relapse rate defined as a return visit with persistent or worsening symptoms within 14 days was 22%. In multivariate analysis, the major risk factor for relapse was lack of antibiotic therapy. The type of antibiotic used was also an important variable associated with the 14-day treatment failure. Patients treated with amoxicillin had a 54% relapse rate compared with only 13% for the other antibiotics. Furthermore, treatment with amoxicillin resulted in a higher incidence of failure, even when compared with those who received no antibiotics. Other variables, such as COPD severity, types of exacerbation, prior or concomitant use of corticosteroids and current use of chronic oxygen therapy were not significantly associated with relapse. The study showed that the use of antibiotics is associated with a significantly lower rate of treatment failure and suggested that antibiotics are beneficial regardless of the severity of COPD. Patients who received antibiotics within 14 days had a significantly higher rate of hospital admissions than those not receiving antibiotics. Evolving resistance is likely to account for variable antibiotic efficacy at this time.

Destache *et al.* [68] reported the impact of antibiotic selection, antimicrobial efficacy and related cost in AECOPD in a retrospective review of 60 outpatients from a pulmonary clinic of a teaching institution who had the diagnoses of COPD and chronic bronchitis. The participants had a total of 224 episodes of AECOPD requiring antibiotic treatment. The antibiotics were arbitrarily divided into three types of agents: first-line (amoxicillin, co-trimoxazole, erythromycin and tetracycline), second-line (cephradine, cefuroxime, cefaclor, cefprozil) and third-line (amoxicillin-clavulanate, azithromycin and ciprofloxacin). The failure rates were significantly higher for the first-line agents compared with the third-line ones. When compared with patients who received the first-line treatment, those treated with the third-line agents doubled the time between exacerbations, had fewer hospitalizations and incurred considerably lower total costs.

Based on widespread reports of increasing antimicrobial

resistance to the common pathogens isolated in patients with AECOPD, appropriate antibiotic selection is likely to be important. Conventional endpoints for efficacy of antibiotic treatment in AECOPD include the symptoms and bacteriological resolution measured at 2–3 weeks after the treatment was started. Most of these endpoints rely solely on the subjective report of improvement of symptoms and lack clinical objectivity. Several reports suggest that the infection-free interval, or the time to next episode of AECOPD [69–72], may be a more relevant endpoint. Wilson *et al.* [73] reported that patients with AECOPD treated with gemifloxacin showed a significant increase in the infection-free interval as compared with clarithromycin. This endpoint may reflect the ability of the antibiotic to achieve adequate bacteriological eradication in the airway. Whether or not such improved outcome translates into reduced health-care costs and disease modification is uncertain [74].

An 'ideal' antibiotic for treating patients with AECOPD

Characteristics of the 'ideal' antibiotics that are important to consider when choosing an agent for patients with AECOPD include the following:

1 Significant activity against the most common pathogens isolated in patients with AECOPD and minimizing substantial gaps in the coverage of these organisms [75,76].

2 Adequate coverage of the most likely pathogens in patients with AECOPD based on patient profiles that define the most likely spectrum of causative pathogens. This is especially important in patients with severe underlying obstructive lung disease, who are more commonly infected with Gram-negative organisms than those with mild COPD. Thus, it is important to identify local patterns of colonization and infection. In addition, patients with risk factors for a more complicated course should be prescribed antibiotics with coverage for the pathogens in AECOPD, which may include Gram-negative organisms and methicillin-resistant *Staphylococcus aureus*.

3 Susceptibility of the antimicrobial agent to the likely pathogens in AECOPD. There is an increasing prevalence of *H. influenzae* and *M. catarrhalis*, which produce bacterial enzymes that render traditional β -lactam antibiotics inactive. In addition, a growing number of AECOPD pathogens are resistant to many antibiotics available currently. It is important to know which mechanisms of resistance can affect the treatment of patients with AECOPD. It is also critical to know the local resistance rates of those microorganisms prior to prescribing a specific antibiotic [76].

4 Good penetration into sputum, bronchial mucosa and epithelial lining fluid. The goal of antimicrobial therapy is to deliver the appropriate drug to the specific site of infection.

In AECOPD, the bacteria are found in the airway lumen, along the mucosal cell surfaces and within the mucosal tissue. Various antibiotic classes exhibit markedly different degrees of penetration into the tissues and secretions of the respiratory tract [77].

5 Good therapeutic-toxicity profile. In a 1995 survey of patient attitudes toward antibiotic use, compliance was shown to improve significantly when medications were given at most once or twice a day. In addition, shorter courses of therapy (less than 14 days) were associated with better compliance. Of the patients interviewed, more than 80% stated a preference for once or twice daily dosing and more than 54% admitted to non-compliance with the prescribed regimen [78]. Recent data have supported shorter antibiotic treatment courses in pneumonia. It is likely that shorter durations of treatment will be possible in AECOPD.

6 Cost-effectiveness beyond the initial purchase price of the antibiotics. Several economic considerations should come into play when selecting an antibiotic for patients with AECOPD. In addition to the acquisition outlay, the cost of treatment failures, including the need for further antibiotics and the days of lost work; the resources saved by preventing hospitalization; the duration of disease-free intervals; and the development of antimicrobial resistance must all be accounted for.

Prevention

The two most important measures for preventing AECOPD are smoking cessation and active immunizations, including influenza and pneumococcal vaccinations. Clearly, smoking cessation should be included in the therapy of all patients. The annual rate of decline of the FEV_1 of a smoker is approximately 80 mL/year, compared with a decline in non-smokers of 25–30 mL/year. The Lung Health Study showed that in middle-aged patients with normal or mild lung function impairment, smoking cessation resulted in an improvement in FEV_1 after 1 year. Of the patients who stopped smoking after the first annual visit, 35% registered an increased in mean postbronchodilator decline in FEV_1 compared with those who continue to smoke [79]. It is likely that smoking cessation would have significant effects on bacterial colonization in COPD at all stages. This is not yet supported by empirical data.

Patients who are able to remain smoking quitters experience fewer exacerbations and less profound decrements in pulmonary function. Because of major addictive potential of cigarettes, the vast majority of those who quit smoking relapse within months. Nicotine is the main addictive substance in cigarettes, thus most patients experience severe withdrawal symptoms when they abruptly stop smoking [80]. Nicotine replacement therapy is widely used to overcome the patient's withdrawal symptoms, but such

replacement therapy should always include behavioural modification programmes to increase the likelihood of success. Recently, it has been demonstrated that some antidepressants, especially amfebutamone (Zyban®), can be effective in initiating and sustaining quitting. There are several clinical practice guidelines on smoking cessation [81,82].

Viral infection often initiates AECOPD, which may reach epidemic proportions during the winter months. Epidemiological studies have shown that the frequency of lower respiratory infections and their associated morbidity and mortality are markedly reduced with influenza vaccination. In order to define the effects of influenza, and the benefits of influenza vaccination in elderly persons with chronic lung disease, a retrospective multiseason cohort study in a large managed care organization was undertaken. Patient vaccination rates of the organization were greater than 70%. The outcomes in vaccinated and unvaccinated individuals were compared after adjustment for baseline demographics and health characteristics. In unvaccinated persons, the hospitalization rates for pneumonia and influenza were twice as high in the influenza season as they were in the interim non-influenza periods. Vaccinated patients had fewer outpatient visits, fewer hospitalizations and fewer deaths. Influenza vaccine is therefore a cost-effective intervention in patients with COPD [83,84].

The polyvalent pneumococcus vaccine is effective in preventing invasive disease, particularly bacteraemia and meningitis [85]. Whether or not it prevents AECOPD is uncertain. The available 23 serotype vaccine has been shown to have an aggregate efficacy of more than 60%, although efficacy tends to decline with increasing age and immune state [86]. The vaccine is also recommended in patients with COPD. Jackson *et al.* [87] reported the results of a large cohort study of patients over the age of 65 years who were followed for 3 years. Use of the pneumococcal vaccine significantly reduced the incidence of pneumococcal bacteraemia, but did not alter the risk of outpatient community-acquired pneumonia. More recently, the introduction of the protein-polysaccharide conjugated pneumococcal vaccine in children resulted not only in a significant decrease in invasive pneumococcal disease in children, but also an 18% decrease in adults over age the of 65 years [88]. There are no contraindications for use of either pneumococcal or influenza vaccine immediately after an episode of pneumonia or AECOPD, and the vaccines can be given simultaneously without affecting their potency. There are no other vaccines currently available in adults to prevent lower respiratory tract infections. Vaccines intended to prevent infections resulting from non-typable *Haemophilus* sp. or *Pseudomonas* sp. are in development.

Recent studies have suggested a reduction in exacerbation rates when inhaled corticosteroids are used in advanced chronic COPD. This had led to the recommendation that

inhaled steroids be incorporated into the routine management of COPD patients who have an FEV_1 of less than 50% and who have more than two exacerbations per year. A recent meta-analysis has suggested that such an approach may limit the decline in lung function as a consequence of AECOPD [56,89,90].

CHAPTER 47

Mechanical ventilation for exacerbation of COPD

Andrea Rossi, Guido Polese and Lorenzo Appendini

Exacerbations of chronic obstructive pulmonary disease (COPD) may be of differing severity [1]. It ranges from a mild increase of usual symptoms to life-threatening decompensation. In patients with advanced COPD, exacerbations can often be associated with ventilatory failure (a rise in P_{aCO_2} above 45 mmHg or above baseline), stable hypercapnia if present and respiratory acidosis (pH less than 7.36) [2,3]. In those patients, in addition to optimal medical therapy and adequate oxygenation, mechanical ventilatory assistance may be required if there is evidence of the following:

- 1 Unbearable breathlessness at rest, often associated with:
 - tachypnoea (e.g. more than 30 breaths/min);
 - evident use of accessory respiratory muscles; or
 - Pradox breathing (i.e. inward movement of the abdomen during inspiration).
- 2 Arterial pH less than 7.36 and a P_{aCO_2} of more than 45 mmHg.
- 3 P_{aO_2}/F_{iO_2} less than 300 mmHg.

The aims of mechanical ventilation (MV), independent of the mode and settings selected, are to:

- support the overloaded ventilatory pump;
- improve arterial blood gases and pH;
- relieve dyspnoea and unload the respiratory muscles; and
- 'buy time', to sustain life until the medical therapy controls the event underlying the exacerbation (e.g. respiratory tract infection).

MV can be administered in different modes:

- 1 Invasive 'conventional' MV through an endotracheal tube bypassing the upper airway.
- 2 Non-invasive mechanical ventilation (NIMV):
 - non-invasive positive pressure ventilation (NPPV); or
 - negative pressure ventilation (NPV).

The indications for applying MV and the choice between conventional MV and NIMV, as well as the mode and settings of ventilatory assistance, depends not only upon the

severity of the exacerbations and respiratory acidosis, but also on many other factors such as the timing of the intervention, the characteristics of individual patients, the skill of the team and the available monitoring facilities [4,5].

A brief description of the pathophysiology of COPD exacerbations and ventilatory failure will help to elucidate the rationale underlying the need for mechanical ventilatory assistance as well as the choice of ventilatory mode and settings.

Pathophysiology of COPD exacerbations

By definition, COPD is characterized by airflow limitation (i.e. a significant reduction of forced expiratory flow resulting from a loss of lung elastic recoil and abnormal airway resistance) [6]. In many patients with advanced COPD, flow limitation exists even during tidal breathing as documented by the fact that tidal expiratory flow lies below the maximal flow volume envelope. Pulmonary hyperinflation (i.e. an increase of the functional residual capacity [FRC] above the predicted value) is also a common feature in patients with moderate to severe COPD [7].

When an exacerbation occurs, whatever the aetiology, the airway resistance increases and expiratory flow limitation may worsen. In these conditions, the rate of lung emptying is proportionally retarded and the tidal expiration cannot be completed within the time available between two inspiratory efforts (i.e. the next inspiratory effort ensues before the lungs decompress to the elastic equilibrium volume). Because of incomplete expiration, the tidal end-expiratory lung volume is established above the relaxed FRC. This condition is termed dynamic hyperinflation and adds to the existing pulmonary hyperinflation resulting from the loss of lung recoil [8]. The immediate consequence of the incomplete tidal expiration is that the end-expiratory alveolar pressure remains positive. The latter is termed auto- and/or intrinsic positive end-expiratory pressure (PEEPi) in

analogy with the positive end-expiratory pressure (PEEP) commonly set by the mechanical ventilator [9] because PEEPi was originally described in mechanically ventilated patients [10].

Low levels of dynamic pulmonary hyperinflation and PEEPi were found also in most patients with severe COPD in a stable condition [7,11]. However, the levels of PEEPi observed during exacerbations and ventilatory failure are much greater than in stable conditions, particularly in COPD patients requiring mechanical ventilation [11]. The first implication of dynamic hyperinflation is that the contracting inspiratory muscles must counterbalance PEEPi in order to create a negative pressure in the central airways and start the inspiratory flow. During exacerbations, the inspiratory threshold load provided by PEEPi can be quite substantial (i.e. more than 10 cm H₂O up to 20–22 cm H₂O) [12].

In patients with exacerbations of COPD, not only the mechanical load upon the ventilatory pump increases because of the higher airway resistance and PEEPi, but also the capacity of the respiratory muscles to generate pressure is diminished because of impaired length–tension relationship and reduced area of apposition, among other factors [8].

The net result of an excessive mechanical load and an impaired respiratory muscle pressure generating capacity creates a significant challenge for the ventilatory pump. Tachypnoea might represent a protective mechanism to prevent excessive work of breathing (WOB) by defending minute ventilation through a reduction in tidal volume and a rise in frequency. However, it is a very poor strategy. In fact, the smaller tidal volume will result in increased PaCO₂ and lower pH, while the shorter expiratory time resulting from the higher frequency of breathing will enhance dynamic hyperinflation and PEEPi, hence further increasing the mechanical load and decreasing the inspiratory muscles' capacity to bear the load. This sort of vicious circle, where the mechanical load progressively rises and the capacity of the respiratory muscles is progressively impaired, may lead to malfunction of the ventilatory pump and impending respiratory arrest [5]. Whether this may be considered 'respiratory muscle fatigue' or not remains a controversial issue which has been extensively reviewed in recent publications [8,12]. However, regardless of the nature of the mechanism leading to its failure, the ventilatory pump must be supported to prevent the ultimate life-threatening exhaustion, severe acidosis and respiratory arrest.

Mechanical ventilation

The widespread and early application of NIMV, not only in the intensive care unit (ICU) but on the medical (pneumological) ward for patients with ventilatory failure and respiratory acidosis resulting from exacerbations of COPD,

should be considered a major advance in clinical medicine. In fact, NIMV accomplishes a key goal in medicine: namely it saves human lives [13–16]. In particular it should be emphasized that among all patients with respiratory failure, those with decompensated COPD obtain the greatest benefit from NIMV [13,14,17]. Despite the widespread use and popularity of NIMV, many COPD patients still need endotracheal intubation and 'conventional' mechanical ventilation.

Invasive mechanical ventilation

For many years, conventional (i.e. 'invasive') MV through an endotracheal tube was the only mode of ventilatory assistance. Nowadays, invasive MV should be considered as the immediate mode of intervention only in some particular conditions, such as in:

- respiratory arrest;
- severe cardiovascular instability (hypotension, arrhythmias, myocardial infarction);
- impaired mental status, somnolence;
- inability to cooperate (e.g. excessive agitation);
- copious and/or viscous bronchial secretions;
- high aspiration risk;
- recent facial or gastroesophageal surgery;
- craniofacial trauma and/or fixed nasopharyngeal abnormality;
- extensive burns; and
- extreme obesity.

It is a common experience that many patients with severe exacerbations of COPD arrive at the emergency area either already intubated in the ambulance or urgently requiring intubation [18]. Refractory life-threatening hypoxaemia (PaO₂/Fio₂ less than 200 mmHg) and/or severe acidosis (pH less than 7.25) could be considered as indications for intubation and conventional MV, depending upon local conditions such as the skill of the team, the facilities available for monitoring, the immediate accessibility of intubation and an ICU [6]. Clearly, intubation must be considered when NIMV fails (i.e. arterial blood gas abnormality and respiratory acidosis persists despite aggressive medical therapy, oxygenation and NIMV).

Controlled mechanical ventilation

In the first hours of critical illness, the patient may need MV in the control mode to provide immediate rest for the respiratory muscles as well as relief of excessive dyspnoea and anxiety. It has been shown that the mechanical properties of the respiratory system are severely abnormal in the first day of ICU admission, such that even assisted ventilation may be problematic because of pathophysiological, clinical and often psychological reasons. In these conditions, a period of controlled mechanical ventilation (CMV) may be

warranted to provide adequate rest for the ventilatory pump as well as control of the haemodynamic instability. In some patients, light sedation may help if the level of anxiety does not allow good patient–ventilator interaction, at least in the first hours of MV. Heavy sedation and muscle paralysis should be avoided to prevent the severe complications often associated with those therapies [19]. As soon as the clinical condition of the patient improves, assisted MV can replace the control mode. However, the initial period of CMV, when needed, may be used to take measurements of respiratory mechanics, such as PEEPi, elastance and resistance, which may be helpful in understanding the condition underlying the acute decompensation as well as to plan strategy for ventilator settings, treatment and weaning [20]. Those measurements can be obtained with simple equipment and non-invasive techniques, even on-line [21–24].

In mechanically ventilated COPD patients, a major issue is to avoid, as much as possible, high levels of dynamic hyperinflation resulting from the ventilator settings. Dynamic hyperinflation may impair cardiac function severely [25]. It must be taken into account that high inflation volume and short expiratory duration enhance dynamic hyperinflation and PEEPi. Therefore, the ventilator settings should be adjusted accordingly to minimize dynamic hyperinflation. It has also been suggested that application of PEEP improves gas exchange in COPD patients during CMV [26]. Data from a patient’s respiratory mechanics may help to set the ventilator appropriately. It should also be remembered that dynamic hyperinflation can be substantially reduced by aggressive use of bronchodilators, whose effects can be measured and tuned to the targeted objective [27]. The correct ventilator settings and treatment can bring about a rapid transition from CMV to assisted ventilation. The latter is a ventilatory mode in which the patient triggers the ventilator and participates in the act of breathing.

Pressure support ventilation

Pressure support ventilation (PSV) is by far the most widely used mode of assisted ventilation [28] and is also an appropriate technique for weaning [3,4]. However, the level of PSV must be set appropriately to avoid both under- and overassistance, both of which may jeopardize the effectiveness of MV. In fact, over- and underassistance may fail one of the major aims of MV: to rest the overloaded ventilatory pump. With underassistance, the patient’s respiratory muscles continue to perform a substantial part of breathing to match the ventilatory demand, because of the insufficient support of the mechanical ventilator [29]. With overassistance, the lack of rest for the respiratory muscles can be the consequence of ineffective effort and patient–ventilator dyssynchrony [29]. A cause of bad patient–ventilator inter-

action is the dissociation between the patient’s central drive and the timing of ventilatory assistance. This occurs when the patient’s respiratory muscles stop contracting soon after triggering the ventilator, such that the mechanical inspiration is longer than the spontaneous inspiratory effort and the mechanical lung inflation goes into the neural expiration. In other words, the neural inspiration is much shorter than the mechanical inspiration which goes into the neural expiration. Under these circumstances, the patient’s inspiratory central control generates inspiratory efforts either during mechanical inflation or during expiration when the elastic recoil is too high to be counterbalanced and expiration proceeds despite the patient’s attempt to inspire. The dissociation between central timing and ventilator timing may cause patient–ventilator dyssynchrony and eventually lead to the ‘patient fighting the ventilator’ [30].

Apart from the unquestionable value of clinical observation and experience, some physiological measurements (e.g. the central drive as expressed by mouth occlusion pressure a 1/100th of a second; $P = 0.1$) may help to adjust the appropriate level of PSV to the individual patient [31].

Proportional assist ventilation

Some years ago, the proportional assist ventilation (PAV), a new mode of partial ventilatory assistance, was introduced to improve patient–ventilator interaction [32,33]. PAV is a patient-guided mode in which the pressure provided by the ventilator is proportional to patient’s instantaneous inspiratory effort in terms of both the intensity and the duration of the neuromuscular drive, such that the end of the effort brings about the end of the ventilatory assistance. However, despite its promising theoretic background and some interesting and favourable clinical studies [33], PAV has not succeeded in entering the real clinical world and it still considered a mode of MV more suitable for clinical research than for routine application.

Positive end-expiratory pressure

PSV is not the only condition in which patient–ventilator dyssynchrony can occur. Assisted controlled ventilation (ACV) and synchronized intermittent mandatory ventilation (SIMV) can be associated with similar events [9]. In addition, there is a condition in which patient–ventilator dyssynchrony may occur regardless the mode of MV (i.e. with high levels of intrinsic PEEP). If the negative intrathoracic pressure generated by the patient’s contracting inspiratory muscles is smaller than PEEPi, the effort does not generate sufficient pressure or inspiratory flow in the central airway to trigger the ventilator, remaining ‘ineffective’. To be effective for triggering, the negative pressure generated by the inspiratory muscles must be greater than the sum of PEEPi plus the negative triggering pressure [10]. The latter is in general very small, from -0.5 to -2 cm H₂O,

whereas the former may be rather substantial, often more than 10 cm H₂O and up to more than 20 cm H₂O [11]. For this reason – the consistent presence of PEEPi – it has been suggested that some levels of PEEP should be set by the ventilator to counterbalance PEEPi and prevent ineffective efforts [29,34,35]. The level of PEEP sufficient to counterbalance most of PEEPi without worsening hyperinflation can be decided either by measuring PEEPi, which might not be easy in an actively breathing patient because it requires the use of the oesophageal balloon technique [29,34,35], or by observing empirically that each patient's effort actually triggers the ventilator. A more detailed discussion on the causes and consequences of PEEPi as well as the technique of adjusting the adequate levels of PEEP may be found elsewhere [10,11,23].

In synthesis, patients with exacerbations of COPD matching the criteria for conventional invasive MV may need a short initial period of CMV. Clearly, heavy sedation and particularly muscle paralysis must be avoided to prevent severe neuromuscular complications [19]. However, that period could be used to obtain some measurements of respiratory mechanics by means of non-invasive techniques [9]. As soon as possible, the patient should be switched to AMV, in general PSV with low levels of PEEP to counterbalance PEEPi. Along these lines, Appendini *et al.* [29] found that the same level of pressure assistance (e.g. 15 cm H₂O) determined a greater reduction of the WOB if PEEP was set (i.e. 5 cm H₂O PEEP + 10 cm H₂O PSV) than ventilation with more than 15 cm H₂O PSV. In addition, they found little advantage in terms of reduction of the inspiratory effort with the increase of PSV from 15 to 25 cm H₂O, either with or without PEEP. These data should call attention to the risk of undue overassistance by setting PSV at excessive levels.

Traditionally, mechanically ventilated patients with exacerbation of COPD present difficulty in weaning and are exposed to the risk of prolonged MV-related complications [36]. Almost half of the time spent by COPD patients on MV is because of the weaning procedure. Furthermore, among patients with difficult weaning, COPD patients represent the clear majority [37]. Weaning from MV is discussed in a separate section.

Non-invasive mechanical ventilation

Currently, invasive MV is applied much less than it used to be in COPD patients, because of the widespread utilization and popularity of NIMV. Recent publications have extensively reviewed this issue [38]. A recent meta-analysis concluded that NIMV should be considered as the first-line treatment for patients with exacerbation of COPD and respiratory acidosis and should be offered to those patients [16] with a favourable cost-effectiveness balance [39].

Several randomized clinical trials, on which high-quality meta-analyses were based [15,40], have shown that the early institution of NIMV when respiratory acidosis is still moderate not only improves arterial blood gases and pH, relieves dyspnoea and unloads the respiratory muscles, but also reduces the rate of intubation, reduces the rate of ventilator-related complications, reduces the length of ICU stay and reduces in-hospital and 1-year mortality.

NPPV is by far the most widely used technique of ventilatory assistance in patients with exacerbations of COPD and moderate respiratory acidosis [4]. However, NPV has been successfully used in some patients by a few well-trained groups that have documented good clinical [41,42] as well as physiological results [43,44]. At present, NPV is still limited to those groups and has not really gained wider popularity. One of the reasons could be that the iron lung, which is the most commonly used equipment to deliver NPV, is cumbersome and makes access to the patient difficult. In addition, the technology of ventilators used to deliver NPPV has improved greatly in recent years. Some latest generation ventilators are very user-friendly and also offer important monitoring facilities and leak compensatory mechanisms [45–47]. The association of positive clinical results and good technology has undoubtedly promoted NIMV and particularly NPPV in the real world. In some European countries, NIMV became the key treatment by which pulmonologists gained a reputation in the treatment of critically ill patients and found a role in intensive care medicine [48,49].

Non-invasive positive pressure ventilation

Whereas the role of NPPV in the management of acute respiratory failure remains somehow controversial [17], its role in the treatment of ventilatory failure resulting from exacerbations of COPD seems well established: it may actually represent 'a new gold standard' [50].

NPPV is defined as any form of ventilatory support applied without the use of an endotracheal tube, and it includes:

- 1 Continuous positive airway pressure (CPAP) with or without:
 - inspiratory pressure support; or
 - proportional assist ventilation.
- 2 Volume and pressure cycled systems.

The mechanisms through which NPPV improves arterial blood gases and unloads the inspiratory muscles has been carefully investigated in physiological studies [34,51,52].

Physiological basis of NPPV

It has been shown that NPPV improves arterial blood gases through an increase in alveolar ventilation, without significant modifications in the \dot{V}/\dot{Q} mismatching and gas

exchange capability of the lungs [51]. However, NPPV can significantly reduce cardiac output [51], such that the final net effect on P_{aO_2} depends upon the magnitude of interaction among intrapulmonary (\dot{V}/\dot{Q} mismatching, shunt, diffusing capacity) and extrapulmonary (cardiac output, oxygen consumption, mixed venous P_{O_2} and minute ventilation) determinants of oxygenation. The decrease in cardiac output reduces mixed venous P_{O_2} and causes a decrease in P_{aO_2} ; on the other hand, the increase in alveolar ventilation reduces P_{aCO_2} and improves P_{AO_2} and hence P_{aO_2} . The available data support the conclusion that the effect of greater alveolar ventilation on P_{aO_2} is not impaired by the decrease in cardiac output such that NPPV eventually improves P_{aO_2} [51].

NPPV does not affect passive pulmonary mechanics (i.e. it has a negligible effect on resistance and elastance), although the latter slightly decreases because of the greater tidal volume compared with spontaneous breathing [34]. By contrast, NPPV has a great effect on the respiratory muscles because it substantially reduces the WOB by taking over most of the mechanical load [34]. However, in patients with respiratory acidosis resulting from exacerbations of COPD, elastance and resistance are only a portion of the ventilatory load. PEEPi can contribute considerably to the magnitude of the inspiratory effort, in some studies making up almost half [30]. Not surprisingly, application of CPAP to counterbalance PEEPi significantly improves the effect of NPPV on WOB [34]. There is general agreement that some levels of CPAP should be associated with inspiratory pressure support, not only to reduce the amount of the patient's inspiratory effort, but also to improve patient-ventilator interaction. In fact, the appropriate level of CPAP (i.e. slightly lower than PEEPi) reduces the amount of negative pressure that the patient's inspiratory muscles must create to trigger the ventilator and hence abolishes the ineffective efforts not able to trigger the mechanical breath.

When PEEPi is measured, either non-invasively or by means of the oesophageal balloon technique, it is simple to set the appropriate level of CPAP by establishing a value slightly lower than PEEPi [34]. Without measurement, it is reasonable to observe the patient and to set a level of CPAP sufficient to trigger the ventilator with minimal effort. It has also been suggested that PEEPi may be estimated non-invasively on the basis of clinical observation [53]. However, the validity of this method to set the level of CPAP has not yet been tested on a large group of patients. In common clinical practice, levels of CPAP between 4 and 8 cm H_2O seem appropriate for most patients without the risk of worsening hyperinflation [54].

Clinical studies of NPPV

Almost 100 papers document the wide popularity and success of NIMV since the pioneering work by Meduri

et al. [55,56]. The majority are observational studies, but some well-conducted prospective randomized clinical trials (RCTs) also confirm that NIMV, and particularly NPPV, is an effective treatment for ventilatory failure resulting from exacerbations of COPD. Good quality meta-analyses on the RCTs further support this conclusion [15–17,40]. However, it should be noted that patients at the two extremes (i.e. either with mild or very severe COPD exacerbations) do not seem to benefit from NPPV [6,15]. In the former group, application of NPPV did not show any advantage compared with standard medical therapy, while in the latter group NPPV may unduly delay intubation. Among observational studies the work by Benhamou *et al.* [57] is worth mentioning because NPPV was successfully administered in very elderly patients.

The published RCTs have three known limitations which, however, do not affect the validity and robustness of the results. First, a placebo was not administered such that it becomes difficult to distinguish between the effect of NPPV itself and that of the greater attention that the caregivers' team might devote to ventilated patients compared with those receiving standard, more conventional treatment. Secondly, patients participating in RCTs are selected according to predetermined criteria and might not be truly representative of the heterogeneous population of COPD patients with exacerbations. Thirdly, the condition of an RCT might not reflect what is happening in actual clinical practice, because the procedures are standardized, the patients are selected, the team is motivated, and so on. Nevertheless, all the studies and meta-analyses provide consistent positive results favouring NPPV, with only patients with mild exacerbations not benefiting [15]. The percentage of NPPV success is consistently in the range 75–80% compared with 40–50% for patients receiving standard medical treatment. The definition of success includes the following:

- The acute episodes resolves without the need for endotracheal intubation.
- Mechanical ventilation can be discontinued.
- The patient is discharged from hospital.

Factors associated with success of NPPV are likely to be:

1 Appropriate selection of patients (see exclusion criteria and/or indications for conventional MV):

- younger age;
- ability to cooperate; and
- lower acuity of illness.

2 Experience of clinicians.

3 Availability of resources.

It is considered that NPPV fails when the patient either needs intubation or dies because intubation is not performed for ethical reasons (e.g. patient's consent, older age, terminal condition) or because it is not available.

Intubation and the institution of conventional MV

should be considered when, after optimization of medical therapy, including MV:

- Arterial blood gases and/or pH do not improve after 4 h or even worsen after 1–2 h [58].
- Other complications either appear or do not resolve (e.g. metabolic abnormalities, sepsis, pneumonia, pulmonary embolism, barotrauma, massive pleural effusion).

Observational studies as well as RCTs on NPPV were performed in different settings. This is important because the availability of monitoring resources as well as the ability of clinicians to bear the workload varies between the general (pneumological or medical) ward and the ICU, and it has been shown that this must be seriously considered [59]. Between the two settings (ward and ICU), some institutions have a level of intermediate care generally referred to as respiratory intermediate care units (RiCU) [48,49], whose specific aim is the treatment of patients with acute (or acute on chronic) respiratory failure without severe multiorgan complications or failure.

In a historical overview of the application of NPPV in exacerbations of COPD, some studies should be mentioned in particular. In 1990, Brochard *et al.* [60] published a study that was not an RCT, but had a historical control group. Nonetheless, because of the excellent reputation of the group of investigators and the high profile of the journal, this work is commonly considered to be the landmark study that gave NPPV a real scientific role. The same group published a large RCT a few years later [18]. Bott and Carroll [61] performed the first RCT by comparing NPPV with conventional medical therapy in a general ward. More recently, Plant *et al.* [62] reported a large multicentric trial conducted in the UK in a respiratory ward and not in intensive care areas. That study favoured NPPV over standard medical therapy, documenting that patients receiving NPPV had lower mortality and rate of intubation than controls. The relevance of this study is that it demonstrated that the application of NPPV in patients with moderate acidosis can be performed successfully with little training and outside of special environments such as ICU and RiCU. On the other hand, the study by Conti *et al.* [63], which is the only RCT comparing conventional MV and NPPV, reported that in an ICU, NPPV could be as successful as conventional MV in terms of treatment of ventilatory failure, but with a significant lower rate of complications, particularly infectious complications. However, the results of that comparison cannot be extrapolated outside of the ICU and could be significantly affected by the extensive experience of that particular team of investigators. Among recent published studies, the one by Thys *et al.* [64] is noteworthy because it is the only one with a control ventilation to the standard therapy group, suggesting that the success of NPPV was not a result of the greater attention of the team. More recently, Jolliet *et al.* [65] reported an RCT in which a helium–oxygen (He–O₂)

mixture was compared with an air–oxygen mixture for NIMV in decompensated COPD patients. Although He–O₂ determined a slightly shorter hospital stay, the rate of intubation did not differ, and the authors concluded that further studies would be needed before recommending He–O₂ as a routine NIMV strategy in the ICU.

The physiological study by Vitacca *et al.* [66] used PAV with low levels of CPAP and showed that, in the short term, arterial blood gases were improved while the inspiratory muscles were significantly unloaded. However, two RCTs comparing PSV and PAV in a heterogeneous group of patients with acute respiratory failure, including COPD, failed to show any significant advantage of the latter over the former, although some patients tolerated PAV better than PSV [67,68]. More recently, Wysocki *et al.* [68] focused on decompensated COPD patients rather than on the usual heterogeneous group of patients with acute respiratory failure. They failed to observe any significant difference between non-invasive PAV and PSV for any of the physiological variables considered in the study. However, they found that all 12 patients declared feeling more comfortable with PAV than with PSV. At present, the data to support widespread regular use of PAV are scanty.

PSV with low levels of CPAP (e.g. 5 cm H₂O) remains the most popular and widely used mode of delivering NPPV. The individual setting of PSV remains easier than the setting of PAV, which requires the adjustment of two variables, flow and volume, while PSV requires only the setting of pressure. Probably, the additional time-consuming burden for clinicians [46] would need stronger evidence to make PAV preferable to PSV in a routine clinical environment, although repeated reports on greater patient comfort with PAV encourages further clinical studies.

In summary, NPPV can be delivered in different clinical settings:

- 1 Medical ward** [61,62]: patients with moderate acidosis (pH < 7.36, > 7.30) and hypercapnia (Paco₂ > 45, < 60 mmHg).
- 2 Intermediate or high-dependency respiratory unit** [69,70]: patients who present with moderate to severe acidosis (pH < 7.30), the facilities for rapid endotracheal intubation and institution of conventional MV are promptly available.
- 3 Intensive care unit** [18]: patients with severe respiratory acidosis (pH < 7.25). In this particular setting, NPPV may be as effective as conventional MV in reversing acute respiratory failure resulting from COPD [63].

Weaning

It is well known that COPD patients belong to the category of difficult-to-wean patients and some may even become ventilator dependent [36]. In this context, it is particularly attractive to consider the use of NPPV to improve weaning

and complete discontinuation of MV [71]. Three recent RCTs have shown that the application of NPPV to replace conventional MV after only 24–48 h of intubation resulted in shorter total duration of MV and length of ICU stay, less need for tracheostomy, lower incidence of complications and improved survival [72–74]. In particular, the most recent study by Ferrer *et al.* [74] documented the effectiveness of NPPV to govern the transition from MV to spontaneous breathing in patients with persistent conventional weaning failure. Clearly, many factors are involved in persistent weaning failure and NPPV should not be regarded as the panacea or ultimate solution; however, it provides an additional approach that might be valuable for certain patients [71]. Unfortunately, PAV has not been tested in weaning studies. Theoretically, the greater patient comfort with PAV should favour the transition from MV to spontaneous breathing. In fact, with PAV, it is the patient who adjusts the level and timing of assistance to his or her capacity to sustain the act of breathing completely.

Practical aspects

As in many other fields of respiratory medicine (e.g. asthma, COPD, pneumonia), practice guidelines for the application of NPPV in patients with respiratory failure are available [4,13,14]. There are several clinical choices that must be made when initiating NPPV. Practice guidelines have the intention of facilitating the procedure, particularly in less experienced centres. Key points are as follow:

- 1 Careful selection of patients:
 - to prevent waste of resources and discomfort in patients with milder exacerbations; and
 - to avoid undue delays in patients in need of intubation.
- 2 Choice of equipment, ventilator settings and monitoring facilities. When NPPV was first developed it was thought that more sophisticated ICU ventilators would guarantee better success than simpler, more user-friendly, so-called 'home' ventilators, until it was shown that this was not the case [62].
- 3 Choice of interface (e.g. facial or nasal mask, full face mask, helmet).
- 4 Motivation of the team, because in the first hours NPPV requires the same workload and degree of attention by clinicians as conventional invasive MV.
- 5 Some particular issues, such as the use of humidifiers in the ventilator circuits and valves to prevent rebreathing.

These aspects are extremely important to improve the comfort of the patient as much as possible not only to accept, but also to actively cooperate with the NPPV. The patient's collaboration is fundamental for the success of NPPV. In fact, NPPV is generally set 'at patient's comfort'

in most studies, to assure a satisfactory patient–ventilator interaction. In this connection it should be noted that NPPV is an evolving technological process and that practice guidelines should also be interpreted as a dynamic tool.

Adverse events

Although some adverse events and complications were reported in patients receiving NPPV, these are much less severe and less common than the well-known complications of conventional MV, in particular barotrauma and infectious complications. Strictly speaking, it cannot be considered a complication or an adverse event, but an inaccurate selection of patients to whom to offer NPPV and an undue delay in intubation might expose the critically ill patient to a life-threatening situation. When applying NPPV, there should always be rapid access to intubation and an ICU, unless NPPV remains the only option (e.g. ICU bed not available). In this circumstance, clinicians should give adequate information to the patient or the next of kin.

The most common complications of NPPV are the following:

- facial skin erythema;
- nasal congestion;
- nasal bridge ulceration;
- sinus/ear pain;
- nasal/oral dryness;
- eye irritation;
- gastric irritation/ aspiration pneumonia; and
- poor control of secretions.

Despite the lower levels of intrathoracic pressure with NPPV than with conventional MV, cardiac output may be decreased in some patients either in stable [75] or in acute conditions [51]. Although the lower cardiac output could decrease Pao_2 , it seems that the rise in alveolar ventilation is sufficient to defend and even increase Pao_2 .

Nasal bridge ulcerations are frequent and not only create great discomfort for the patient, but also impair the continuation of NPPV. Lesions are caused by excessive pressure of the nasal/facial mask on the thin nasal skin. The best prevention is to reduce the local pressure of the mask on the nose by accepting some leaks. In fact, modern ventilators have very effective leak compensatory mechanisms such that it is no longer necessary to fix the mask with excessive pressure [47]. Alternatively, full face masks and helmets may be of help, depending on the patient's, and sometimes the clinician's comfort with the interface. It is worth stressing that a comfortable interface is a substantial component in the success of NPPV. The condition of the patient's nose should also be adequately considered [76].

Another unpleasant consequence of NPPV is that of gastric distension, which can impair the inspiratory movements of

the patient, at least in part. A decrease in the inflation pressure might help to resolve or reduce the patient's discomfort.

The success of NPPV relies substantially on a good relationship between a cooperative patient and a dedicated caregiver team. First, the ventilator should be set to achieve the best balance between the clinical and physiological targets and the comfort of the patient. Secondly, patients on NPPV must be cared for as the critically ill patients they are. The tendency to consider NPPV as a second-class mode of ventilatory assistance for less severe patients in comparison with the dramatic picture of the intubated, often sedated and paralysed 'really' severely ill patients, should be abandoned. A great amount of effort should be made to obtain success with NPPV because the prevention of intubation substantially reduces endotracheal tube-related infectious complications and mortality.

Chronic home NPPV

This is still a matter of controversy and no definitive conclusions can be presented [77]. Chronic NPPV should not be systematically prescribed for COPD patients with chronic ventilatory failure, although it could produce some benefits in selected patients whose characteristics are not yet clearly defined [78]. A few patients with end-stage COPD undergo tracheostomy and become chronically ventilator dependent [36].

Conclusions

1 NPPV benefits patients with ventilatory failure and respiratory acidosis resulting from exacerbations of COPD. It should be noted that for these patients the evidence is stronger than for other groups of patients with respiratory failure of different aetiology [14,17]. Intubation, mortality and the length of ICU stay are with fewer complications than conventional MV [50].

2 NPPV should be offered early in the course of COPD decompensation, according to locally available monitoring facilities, skill of the team and characteristics of the patient [16].

3 NPPV does not seem to benefit patients with milder exacerbations [15]. On the other hand, patients with more severe acidosis (i.e. pH < 7.25) should be considered for intubation and conventional MV, unless particular local conditions and skills support the use of NPPV [61].

4 NPPV may be valuable for selected patients in the weaning process [71].

5 NPPV is a cost-effective treatment [39], although in the

first hours of treatment the load on the clinical team is similar to conventional MV.

6 Careful selection of patients, the skill of the clinical team and availability of monitoring facilities as well as ICU admission are substantial components in the success of NPPV [14].

CHAPTER 48

Comorbidity

Martin Sevenoaks and Robert A. Stockley

Associations have recently been noted between chronic obstructive pulmonary disease (COPD) and other systemic diseases including cardiovascular disease [1], diabetes mellitus [2], osteoporosis [3] and peptic ulcer disease [4]. These links persist even when common aetiologic factors such as cigarette smoking and steroid usage have been controlled for, raising the possibility of a common physiologic process.

The GOLD guidelines define chronic obstructive airways disease (COPD) as '... airflow limitation that is not fully reversible. This airflow limitation usually is both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases' [5].

The severity of this airflow obstruction, as assessed by the forced expiratory volume in 1 s (FEV_1), is a predictor of overall health status [6] and mortality from both respiratory disease [7] and all causes [8].

The inflammatory response to cigarette smoke is well known, yet it does not explain why only approximately 15% of smokers develop clinically important airflow obstruction. This suggests a genetic predisposition and elastase released from activated neutrophils has long been thought to be a significant mediator of the disease in this regard [9], especially in α_1 -antitrypsin deficiency. The smoking mouse model has been used in recent studies to further elucidate the process and the mechanism appears to be driven by proinflammatory cytokines of which tumour necrosis factor α (TNF- α) seems key [10]. The role of these cytokines and the associated inflammation has been proposed to extend beyond the chest in COPD.

For reasons that are not clear, patients with COPD have higher baseline levels of several circulating inflammatory markers [11]. Whether the systemic inflammation is a primary or secondary phenomenon is also unknown at present. Specific subsets of patients with COPD have been identified and those with increased resting energy expenditure and decreased fat-free mass have more marked elevation of the acute phase C-reactive protein (CRP) and

lipopolysaccharide binding protein in the stable state [12]. Furthermore, patients with higher levels of systemic inflammation lack a response to nutritional supplementation [13].

It was initially thought that a low-grade systemic inflammation was produced by the 'overspill' of inflammatory mediators during the establishment of lung inflammation. However, the concentrations of soluble tumour necrosis factor receptor (sTNF-R) or interleukin 8 (IL-8) in sputum and plasma do not correlate, suggesting that a simple overspill explanation cannot be correct [14].

The central role of TNF- α in respect of this systemic inflammation is not only supported by animal models [10], but has also been implicated in the COPD phenotype with low body mass index [3]. Cytokine production by macrophages is increased by *in vitro* hypoxia [15] and systemic hypoxia may therefore explain the inverse correlation between arterial oxygen tension and circulating TNF- α and sTNF-R [15]. This would suggest that the systemic acute phase response is a secondary phenomenon.

Cardiovascular disease

The relative risk for future cardiovascular events has recently been shown to correlate to baseline CRP [16]. High levels of CRP and IL-6 have also been shown to significantly increase the risk of coronary heart disease in both men and women [17]. Individuals whose baseline value was greater than 3 mg/L had a relative risk of 1.79.

CRP is a type I acute phase protein and also part of the innate immune system. It is involved in the activation of the classic complement pathway by binding to bacteria. Complement binding can then occur, leading to bacterial phagocytosis or death. The protein has the ability to increase its concentration up to 1000-fold in the days following the start of an inflammatory process. It is known

Figure 48.1 The inflammatory processes involved in atherosclerotic plaque formation. Endothelial cells bind CRP via the Fc γ receptor ①. It is then internalized and aids monocyte binding via the production of the chemokine MCP-1 ②. Activation continues leading to further cytokine release (including IL-6 and TNF- α) and differentiation of the monocytes into macrophages ③. CRP (in the presence of oxidized LDL) is also involved in the production of foam cells ④, which form the basis of an atherosclerotic plaque ⑤. Vascular occlusion can be amplified by increased thrombus formation ⑥. CRP, C-reactive protein; IL-6, interleukin 6; LDL, low density lipoprotein; MCP-1, monocyte chemotactic protein 1; TNF- α , tumour necrosis factor α .

to bind and cause lattice formation and precipitation leading to passive haemagglutination.

Macrophages have receptors for CRP, and CRP can increase cytokine production [18,19]. Recent work has pointed to the role of the Fc γ receptor in the actions of CRP [20], which may account for its effect on macrophages. During atherogenesis, CRP may deposit directly on to the arterial wall, assisting monocyte adherence through the production of the monocyte chemokine MCP-1. Production of other proinflammatory cytokines and differentiation of the monocytes into macrophages can occur with further activation. CRP can also facilitate foam cell production if oxidized low-density lipoproteins are present and foam cells are the building blocks of atherosclerotic plaques (Fig. 48.1).

Following a systemic respiratory tract infection, a well-recognized acute inflammatory response and increase in cytokine production occurs. The risk of having a myocardial infarction increases nearly fivefold and cerebrovascular event over threefold within the first 3 days of such an event [21]. Not only is the baseline CRP greater than 3 mg/L in almost half of COPD patients, but the rise during an acute exacerbation [22] is also associated with a rise in fibrinogen [23], which increases the prothrombotic risk.

These changes may explain the increased risk of vascular events and cardiovascular mortality in COPD, both in the stable state and particularly within a few months of hospital admission for an acute exacerbation [24]. These concepts have been related to those of the inflammatory mechanisms of insulin resistance [25].

Diabetes mellitus

Patients with COPD are nearly twice as likely to develop type 2 diabetes [26]. Indicators of inflammation in the absence of COPD can predict the development of diabetes and glucose disorders [2,27], and patients with type 2 diabetes mellitus are known to have increased circulating levels of TNF- α , IL-6 and CRP [28]. Because of these observations, the role of circulating cytokines in the pathogenesis of diabetes and insulin resistance has received increasing interest.

Numerous adipokines are secreted from adipose tissue, which markedly influence lipid and glucose/insulin metabolism. These include TNF- α and an adipose tissue-specific antagonist, the 'protective' adiponectin.

Nuclear factor- κ B (NF- κ B) is a transcription factor that is inactive when bound to its inhibitor but which can be activated by inflammatory cytokines including TNF- α [29]. Activation results in cytokine production, up-regulation of adhesion molecules and increased oxidative stress. These effects may provide a stimulating pathway that interferes with glucose metabolism and insulin sensitivity. Adiponectin antagonizes this pathway by reducing NF- κ B activation [30].

Several clinical and experimental observations support the concept that inflammation, glucose intolerance and insulin resistance are intimately associated. This concept is summarized in Figure 48.2, which is derived from the proposal of Sonnenberg *et al.* [31]:

(a) In patients with weight gain and insulin resistance, TNF- α expression is increased [32]. This could represent a modulating effect because TNF- α stimulates lipolysis [33] but raised TNF- α levels are associated with hyperinsulinemia and insulin resistance [34].

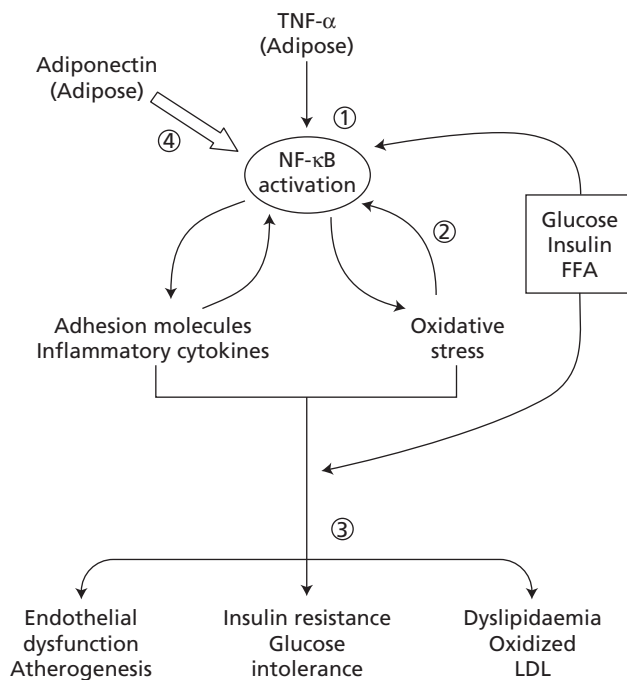

Figure 48.2 The roles of TNF- α , adiponectin and NF- κ B in the metabolic syndrome. NF- κ B activation is stimulated by TNF- α secreted from adipose tissue in conjunction with circulating glucose, FFA and insulin ①. The resulting increase in inflammatory cytokines, adhesion molecules and oxidative stress induce further activation of NF- κ B ②. These pathways end with the clinical manifestations of the metabolic syndrome ③. Adiponectin directly antagonizes the effect on NF- κ B ④. FFA, free fatty acid; LDL, low-density lipoprotein; NF- κ B, nuclear factor κ B; TNF- α , tumour necrosis factor α . Open arrows indicate inhibition; solid arrows stimulation.

(b) Obese patients have an increased acute phase response and associated insulin resistance [35].

(c) Reduced adiponectin levels, associated with insulin resistance and hyperinsulinemia [36] are seen in obese patients.

(d) In the obese insulin-resistant mouse, TNF- α inhibition improves insulin sensitivity [32].

Studies using thiazolidinediones have not only demonstrated decreased levels of inflammatory markers including TNF- α , soluble intercellular adhesion molecule 1 (ICAM-1), macrophage inflammatory protein 1 (MIP-1) and CRP, but also improved insulin action [37–39]. ICAM-1 is a member of the immunoglobulin superfamily and is involved in leukocyte recruitment and inflammation. MIP-1 is a proinflammatory cytokine of the CC subfamily and plays a key role in the induction and modulation of inflammatory responses. These results are consistent with a common inflammatory process or pathway linking COPD and type 2 diabetes [2] and are also in keeping with the theory that acute phase proteins have a predictive role in the development of type 2 diabetes.

Cachexia

Low body mass index (BMI), age and low arterial oxygen tension are known to be significant independent predictors of mortality in COPD [40]. Indeed, BMI is the first of the four variables used in the BODE index predicting the risk of death in COPD [41]. Loss of fat-free mass (FFM) is detrimental to respiratory and peripheral muscle function, exercise capacity and health status, and is an important supplementary prognostic parameter [42]. Both weight loss and loss of FFM are seen more commonly in emphysema and appear to be the result of a negative energy balance [43].

Patients can certainly become so breathless with severe COPD that maintaining an adequate oral intake becomes difficult. However, one physiologic response to starvation is a reduction in resting energy requirements [44]. In contrast, many COPD patients have been noted to have increased resting energy expenditure, associated with systemic inflammation [12,45]. In addition, cachectic patients exhibit preferential loss of FFM, enhanced protein degradation [46] and poor responsiveness to nutritional interventions [47,48]. Moreover, altered protein, lipid and carbohydrate metabolism is seen in cachexia and is thought to be related to systemic inflammation [48,49].

Muscle wasting in COPD therefore shows similarities to the cachexia seen in many other conditions including chronic heart failure, renal failure, cancer and acquired immunodeficiency syndrome. In these conditions, cachexia is not only associated with reduced survival [47,50–52], it is also related to poor functional status and health-related quality of life [53]. In all these conditions, circulating levels

of proinflammatory molecules including TNF- α , IL-1, IL-6, IL-8 and γ -interferon (INF- γ) are increased while levels of anabolic hormones including insulin-like growth factors and testosterone are decreased [53].

TNF- α has a key role in the muscle wasting and weight loss seen in COPD. It has several direct effects (anorexia, altered levels of circulating hormones and catabolic cytokines, and altered end organ sensitivities to them) that could promote muscle wasting [54]. These appear to be secondary to its main effect which is via the ubiquitin pathway.

This process is also mediated by NF- κ B via the pathway previously described. In muscle cells, NF- κ B can inhibit MyoD expression and thus interfere with skeletal muscle differentiation and repair. The MyoD gene plays a key role in the differentiation and determination of all skeletal muscle lineages. It can also increase ubiquitin/proteasome activity leading to increased protein loss (Fig. 48.3).

Reactive oxygen species (ROS) cause changes in TNF- α /NF- κ B signalling, although their significance is not yet understood [55]. Inflammation and ROS do, however, appear to have a synergistic action on muscle breakdown [49] and because COPD is associated with increased oxidant stress [56] it is likely that this factor also has a role.

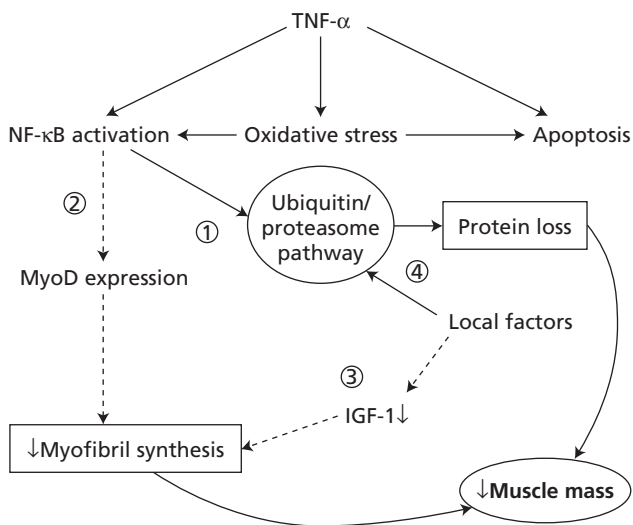

Figure 48.3 Pathogenic process implicated in muscle wasting in COPD. Circulating TNF- α binds to peripheral muscle cell receptors, thereby stimulating apoptosis and the production of ROS. The receptor binding also stimulates NF- κ B activation, possibly enhanced by ROS. This results in protein loss, both directly through increased ubiquitin activity ①, or indirectly via decreased MyoD expression reducing myofibril synthesis ②. A decrease in muscle use will reduce IGF-1 production, decreasing myofibril synthesis ③, as well as increasing ubiquitin activity ④, amplifying protein loss. IGF, insulin-like growth factor; NF- κ B, nuclear factor κ B; ROS, reactive oxygen species; TNF- α , tumour necrosis factor α ; TNFR, tumour necrosis factor receptor.

Smoking has been shown to have negative effects on markers of oxidative stress, as has COPD, particularly during exacerbations [57,58]. This increased oxidative stress may result in the inactivation of antiproteases, mucus hypersecretion, airspace epithelial damage, increased influx of neutrophils into lung tissue and the expression of pro-inflammatory mediators [59,60].

Inflammatory cell changes in peripheral blood have also been reported, including neutrophils and lymphocytes [61]. Patients with COPD have increased numbers of neutrophils in the lungs, increased activation of neutrophils in peripheral blood and an increase in circulating TNF- α and sTNF-R. It has been suggested that this indicates the importance of a TNF- α /neutrophil axis in maintaining the COPD phenotype [55,62].

Peptic ulcer disease

Patients with chronic bronchitis and emphysema are more likely to develop peptic ulceration [63]. Furthermore, studies in patients with gastric ulcers have found a decrease in FEV_1 and vital capacity in both smokers and non-smokers [4]. More recently, *Helicobacter* sero-positivity has been found to be increased in COPD patients (77.8 vs 54% in control subjects) [64]. In addition, genetic diversity between strains of *Helicobacter pylori* affects their virulence. Sero-positivity to the more proinflammatory phenotype expressing cytotoxin associated gene A (CagA) was present in almost twice as many patients as controls.

It has been hypothesized that the chronic activation of inflammatory mediators induced by *H. pylori* could amplify the development of COPD, although once again these associations may simply represent common factors such as smoking and socioeconomic status. The increased prevalence of the CagA-positive strain supports a common pathway hypothesis because this strain can stimulate the release of IL-1 and TNF- α [65], which may enhance the endothelial adhesion and migration of inflammatory cells into the lung. Whether such a process enhances the inflammatory response to cigarette smoke in the lungs is not known.

An alternative hypothesis is that overspill of *H. pylori* or its exotoxins may be inhaled into the lungs, leading to chronic airway inflammation and hence tissue damage. However, there is no direct evidence of this phenomenon in COPD.

Osteoporosis

Vertebral fractures are present in up to 50% of steroid naive males with COPD [66]. More recently, osteopaenia has been confirmed to be a feature of COPD and associated with an increase in circulating TNF- α [3]. Again, the association suggests a cause and effect.

High serum levels of IL-6 and TNF- α are related to postmenopausal osteoporosis [67]. Macrophages can differentiate into osteoclasts in the presence of marrow mesenchymal cells. Mesenchymal cells release the cytokine RANK ligand (RANKL), which is a member of the TNF- α superfamily. This process is enhanced by TNF- α and IL-1. TNF- α and IL-1 can also induce RANKL expression in marrow stromal cells and act synergistically with RANKL in osteoclastogenesis [68], although IL-6 can induce osteoclast formation independent of RANKL [69]. Other inflammatory conditions such as rheumatoid arthritis [70] and periodontal disease [71] produce RANKL via T-cell induction and it is therefore likely that a similar process occurs in COPD.

Proinflammatory cytokines may therefore have a central role in the osteoporosis associated with inflammatory disease. A close association between the proinflammatory processes and osteopaenia is supported by data confirming that raloxifene was able to decrease TNF- α transcription and serum levels while increasing bone density [67].

Conclusions

In summary, several diseases are associated with similar inflammatory pathophysiology and coexist more commonly, suggesting that a common process is responsible for the clinical overlap. It is of course possible that the systemic inflammatory response to COPD precipitates disease processes at distant sites. Patients with COPD may present to other specialties because of the comorbidity and the diagnosis may be missed because of common symptoms in the overlapping conditions (e.g. dyspnoea as a result of cardiovascular disease or obesity). As effective anti-inflammatory therapy becomes available for COPD, it will be of importance not only to monitor the effect on the lungs but also any associated comorbidities. This may explain why inhaled corticosteroids in COPD are associated with decreased cardiovascular mortality [72] but clearly further studies are warranted to dissect this process in detail.

SECTION 6

Current and future
treatment

CHAPTER 49

Primary care

Daryl Freeman and David Price

Epidemiology

The facts and figures behind the disease processes collectively known as COPD are bleak. COPD is a progressive chronic condition and is already the third most common cause of death in the UK. By 2020 it is expected to be the third most common cause of death worldwide [1,2]. The most important cause of COPD in the developed world is cigarette smoking.

COPD is a major cause of morbidity and mortality. Approximately 6% of deaths in men and 4% in women are attributed to COPD [1]. There are approximately 30 000 deaths from COPD annually in the UK; approximately 5% of all deaths [3]. Of more concern, however, is the fact that COPD is the only common cause of death that is increasing [2].

Aetiology

COPD is an umbrella term encompassing chronic bronchitis and emphysema, and patients may have elements of both of these conditions. It is a chronic, slowly progressive disorder characterized predominantly by airways obstruction [4]. There is structural narrowing of the airways that is predominantly irreversible, with a combination of fibrosis, mucus hyperplasia and some alterations in vagal bronchomotor tone.

Agents (predominately cigarette smoke) causing COPD damage the airways and impair the defence and repair mechanisms within the respiratory system [5]. In addition, inflammation increases the thickness of the airway walls (an effect of smooth-muscle hyperplasia), which increases airways resistance throughout the lungs.

Diagnosis

Although a thorough history can give a reasonable indication of the diagnosis, spirometry is the gold standard [4,6].

A diagnosis of COPD is likely with a history of progressive symptoms: cough, dyspnoea, exacerbations and a smoking history of more than 20 pack-years in patients over the age of 40 years [4,6]. (One pack-year is the equivalent of smoking 20 cigarettes a day for 1 year.) The higher the number of pack-years, the greater the risk of COPD. The patients who are most likely to benefit from aggressive smoking cessation therapies are probably those with mild disease; however, these patients have relatively few symptoms at this stage and one of the challenges of caring for patients with COPD is identifying those with early disease. Many patients with COPD could be identified in primary care by targeting:

- smokers with symptoms (dyspnoea, cough, wheeze);
- patients on respiratory medication (particularly those with a positive smoking history); and
- patients who attend mainly in the winter months with symptoms or signs suggestive of a chest infection and a positive smoking history.

The late presentation of patients with COPD is a problem leading to underdiagnosis and under treatment [7]. A high index of suspicion is needed to identify patients earlier with COPD, and so management interventions, such as smoking cessation and drug therapies, can be instituted early. The presence of comorbid conditions is a frequent problem. In particular, other smoking-related illnesses such as heart failure and lung cancer, often coexist with COPD and often a generalist approach to 'the breathless patient' is needed at first.

Spirometry

A diagnosis of COPD depends on demonstrating an irreversible airway obstruction. Spirometry measures lung function and is the most reliable method for diagnosing COPD [8].

Spirometry measures the presence of airflow limitation. The two principal measurements are the forced expiratory volume in 1 s (FEV_1) and the forced vital capacity (FVC), which is the total volume of air that can be expelled from the lungs from maximum inhalation to maximum exhalation.

Table 49.1 Principles of interpreting spirometry.

- 1 Reduced $FEV_1 : FVC$ ratio ($< 70\%$) demonstrates obstructive lung disease
- 2 Postbronchodilator $FEV_1 < 80\%$ predicted suggests COPD
- 3 A rise in FEV_1 of > 400 mL following an adequate dose of bronchodilator suggests a diagnosis of asthma
- 4 A normal $FEV_1 : FVC$ ratio with reduced FEV_1 indicates restriction and should prompt a referral to specialist care

FEV_1 forced expiratory volume in 1 s; FVC , forced vital capacity.

Airflow obstruction (and this may represent COPD or asthma) is suggested by a reduction in the $FEV_1 : FVC$ ratio to less than 70%; in addition, if the postbronchodilator FEV_1 is less than 80% predicted this signifies likely COPD.

Guidelines generally use FEV_1 as the method to assess severity. As far as assessing the severity of COPD is concerned, the NICE guidelines suggest that in addition to the lung function, other matters should be used to assess severity [9]. These include features such as breathlessness, body mass index (BMI), exacerbations, exercise limitation and presence/absence of cor pulmonale. Increasing severity of disease is associated with increasing morbidity and mortality (Table 49.1).

Smoking cessation

Smoking is the most preventable cause of premature death and disability in the developed world. One in four smokers will develop COPD, with the risk proportional to tobacco exposure [10]. Stopping smoking is the only intervention that has been shown to substantially slow the overall decline in lung function seen in COPD [11]. Brief smoking cessation advice given by GPs has been shown to be simple and effective [12]. The use of pharmacotherapy will further increase the cessation rates.

Nicotine replacement therapy

Nicotine replacement therapy (NRT) increases the chances of smoking cessation success [12] and over 80 research articles have shown a benefit. It gives smokers the opportunity to break their nicotine addiction by gradually reducing the amount of nicotine in the body. NRT is available as gum, patches, nasal sprays, inhalators and sublingual tablets.

Antidepressant therapy

Two drugs used to treat depression, bupropion SR (amfebuta-

mone) and nortriptyline have been used in smokers trying to quit. Bupropion SR is an antidepressant licenced in the USA, studies have shown that it may double cessation rates [13]. Side-effects include an increased risk of epileptiform seizure and the drug should be avoided in anyone at potential risk. Trials of nortriptyline also suggest that this can double cessation rates. Side-effects include nausea, sedation and urinary retention [14].

Treatment of stable COPD

The measurement of COPD severity is largely dependent on FEV_1 but a more holistic approach, including BMI, symptoms, exacerbations and exercise tolerance is more appropriate.

These same issues are important when assessing a response to a given treatment. As COPD is, by definition, a largely irreversible obstructive lung disease, it is unusual to see a significant spirometric response (and indeed an improvement of more than 400 mL with a trial of therapy would suggest a diagnosis of at least coexisting asthma). Other outcome measures are important in assessing response to treatment; these may include health status, symptoms, exacerbation rates and exercise tolerance (Table 49.2).

Drug therapy

Bronchodilators

Bronchodilators are the mainstay of pharmacological treatment for COPD. They are thought to reduce breathlessness by deflating the lung and reducing air trapping [16]. β_2 -Agonists, anticholinergics and theophylline are effective bronchodilators; the choice of therapy depends on the individual's response to treatment.

Short-acting β_2 -agonists (salbutamol, terbutaline)

Short-acting β_2 -agonists (SABAs) help to relieve the symptoms of COPD. Studies have shown that SABAs can reduce dyspnoea, increase exercise capacity and improve health status [17].

Table 49.2 The Global COPD (GOLD) guidelines aims of treatment [15].

- 1 Prevention of disease progression
- 2 Relief of symptoms
- 3 Improved exercise tolerance
- 4 Improved health status
- 5 Prevention and treatment of complications
- 6 Prevention and treatment of exacerbations
- 7 Reduction of mortality from COPD
- 8 Prevention and reduction of side-effects of treatment

Long-acting β_2 -agonists

The long-acting β_2 -agonists (LABAs) formoterol and salmeterol work in a similar way to SABAs but have a longer duration of action, lasting up to 12 h. Studies have shown that in COPD, LABAs can increase FEV_1 , increase exercise tolerance, improve health status, improve night-time symptoms and reduce exacerbation rates [3,18,19].

Short-acting anticholinergics (ipratropium bromide)

Ipratropium bromide is an effective bronchodilator, lasting approximately 4–6 h in patients with COPD; it may have additional beneficial effects such as drying of mucus. The drug is often used in combination with SABAs.

Long-acting anticholinergics (tiotropium)

Tiotropium is a once daily, anticholinergic bronchodilator. Early research suggests that it offers more sustained bronchodilatation, improves dyspnoea, health-related quality of life and exacerbations than four times daily treatment with ipratropium bromide [20,21].

Methylxanthines

Methylxanthines such as theophylline are usually reserved for more severe disease because of their narrow therapeutic range and the risk of side-effects. Multiple drug interactions (antibiotics, cigarette smoking), and the need for regular plasma drug levels, practically limit their use in everyday practice.

Inhaled corticosteroids (budesonide, fluticasone, beclometasone)

Inhaled corticosteroids (ICS) reduce exacerbations in COPD and may reduce decline in pulmonary function [22]. ICS should be used in patients with $FEV_1 \leq 50\%$ predicted who have frequent exacerbations (two or more in the preceding 12 months) [9].

Combination therapy for COPD

Combinations of drugs are now available: SABAs and anticholinergics, ICS and LABAs. Current guidelines support their use where the individual agents are recommended [23,24].

Mucolytics (carbocysteine, mecysteine hydrochloride)

Mucolytics may be considered in patients where production of sputum is a problem. The role of this class of therapy has recently been re-evaluated and recommended for consideration in patients with a chronic productive cough [9].

Antioxidants

N-acetylcysteine has been shown in recent studies to reduce exacerbations of COPD. However, its effectiveness has yet to be proven [25].

Oxygen therapy

As COPD progresses so does the likelihood of the patient developing pulmonary hypertension as a consequence of chronic hypoxaemia. Two studies have demonstrated the benefits of long-term oxygen therapy (LTOT) in this condition [26,27], and the last 20 years have seen a steady growth in the use of domiciliary LTOT.

There are clear criteria for referral for LTOT (see below) and assessment is usually carried out in secondary care.

Assessing the need for long-term oxygen therapy

LTOT assessment is indicated in patients who have a Pao_2 of less than 7.3 kPa when stable, or Pao_2 more than 7.3 kPa or less than 8.0 kPa when stable and one or more of the following: secondary polycythaemia, nocturnal hypoxaemia, oxygen saturation of less than 90% for more than 30% of the time, peripheral oedema, pulmonary hypertension.

Clearly, most primary care physicians do not have capillary gas analysers in their practice, so an empirical approach is required when deciding who may need referring for a LTOT assessment. The following are indications for referral for an LTOT assessment:

- Patients with oxygen saturation $\leq 92\%$ on air
- Patients with signs of central cyanosis
- Patients with evidence of polycythaemia
- Patients with evidence of right heart failure (peripheral oedema, raised jugular venous pressure)
- Patients with severe COPD (FEV_1 less than 30% predicted)
- Some patients with moderate airflow obstruction may develop pulmonary hypertension, so assessment may be necessary in this group too.

LTOT is usually delivered via an oxygen concentrator backed up by a large cylinder and a smaller portable cylinder to maintain independence and mobility.

Exacerbations

COPD is not a stable disease and patients experience occasional worsening of symptoms or exacerbations. Most patients with an exacerbation can be managed at home by the primary health care team. Indications for consideration of admission include: ability to cope at home (requires assessment of support from carers), degree of breathlessness, presence of oedema and/or cyanosis, altered level of consciousness/increasing confusion or significant comorbidities (diabetes, heart failure, psychiatric problems).

Exacerbations also have an impact on health-care resources. For example, during the winter hospital admissions for COPD can increase the problem of bed shortages and lead to cancellation of surgical operations.

Treatment of exacerbations

Exacerbations are treated by increasing the dose of short-acting bronchodilator. This is usually a hand-held device, e.g. metered dose inhaler (MDI) + large volume spacer, but some patients may require a nebulizer (if the patient is hypercapnic this should be driven by air – not oxygen) [28]. In the absence of contraindications, a short course of oral steroids (prednisolone 30 mg/day for 10–14 days) should be used for patients with exacerbations – both at home and in those admitted to hospital [29]. The presence of green, purulent or excessive sputum suggests the presence of infection and so an antibiotic (choice of agent used should be based on advice from local prescribing/microbiology services) should be considered for 10–14 days.

Non-pharmacological treatments of COPD

Pulmonary rehabilitation

Pulmonary rehabilitation is a structured, individualized programme of exercise, physiotherapy and education for patients with COPD. It should be offered to all patients who are functionally disabled by their condition (in practice this means those with a Medical Research Council [MRC] score of 3 or above).

Pulmonary rehabilitation does not alter the course of the disease, or have any impact on mortality. However, it improves exercise capacity, physical functioning, quality of life and the patient's perception of control over their disease [30,31]. Pulmonary rehabilitation has been shown to reduce both symptoms and health-care utilization [32,33]. Indications for referral to pulmonary rehabilitation include:

- Confirmed diagnosis of COPD;
- MRC grade 3 or more (Table 49.3);
- Optimal medical treatment;
- No contraindications to exercise programme (e.g. unstable angina);

Table 49.3 The Medical Research Council (MRC) dyspnoea scale.

1	Not troubled by breathlessness unless on strenuous activity
2	Short of breath when hurrying or walking up a slight hill
3	Walks slower than contemporaries on the level because of breathlessness or has to stop for breath when walking at own pace
4	Stops to take a breath after approximately 100 m or a few minutes on the level
5	Too breathless to leave the house or breathless on dressing and undressing

- Able and willing to attend all the sessions;
- Neither use of LTOT nor being wheelchair bound due to COPD are contraindications and such patients should be encouraged to take part in rehabilitation programmes.

Anxiety and depression

Patients with COPD have many problems in addition to their medical condition; COPD strikes them at a time in their lives when they may have been looking forward to relative financial independence, retirement and more time to devote to their interests. It is not surprising therefore that studies of psychological factors in patients with COPD indicate that anxiety, depression and psychiatric symptoms are common [34].

Palliative care

Palliative care for patients with COPD is at best patchy. In the UK, 75% of people die from non-malignant causes and yet 95% of palliative care resources are used for malignant disease.

The care of the patient with terminal COPD is often up to the general practitioner or the patient's family or carers. Drugs used to treat breathlessness include benzodiazepines and opioids.

As with other aspects of managing the patients with COPD, a multidisciplinary approach to terminal care is vital and may involve the home nursing team, social services, charities such as the Marie Curie service and the primary health care team.

Structuring respiratory services in primary care

A regular structured review of asthma patients is shown to improve health outcomes regardless of whether the review is undertaken by a GP or a respiratory trained practice nurse [35].

Routine assessment

The most important part of assessing a patient with COPD is probably during the diagnosis, where the value of a thorough history followed by relevant examination and investigations cannot be overemphasized.

The routine follow-up of the patient with established COPD, however, takes a different course. Structured review is essential, and ideally will follow some form of protocol or computer template. Issues that should be covered during review appointments include those listed in Table 49.4. Clearly, not all these issues need reviewing at every

Table 49.4 Issues that could be covered during review appointments.

Routine review
<p><i>Medication review</i></p> <p>Understanding of drugs prescribed and when to take them</p> <p>Inhaler technique assessment</p> <p>Physician check for side-effects and possible interactions with other drugs or conditions (e.g. urinary retention with anticholinergics)</p> <p>Use of rescue medications and use of self-management plans where used</p>
<p><i>Review of disease progression</i></p> <p>Review of symptoms including objective score where possible (e.g. MRC dyspnoea score)</p> <p>FEV₁ and FVC measurement</p> <p>Review need for other investigations (e.g. CXR, FBC)</p> <p>Review possibility of other diagnoses</p> <p>Review need for referral for pulmonary rehabilitation</p> <p>Review need for referral for long-term oxygen assessment</p> <p>Exacerbations since last review</p>
<p><i>Immunization review</i></p> <p>Has pneumococcal vaccination been given?</p> <p>Does patient attend for annual influenza vaccination?</p>
<p><i>Smoking status</i></p> <p>Encourage patient to give up smoking if still current smoker</p> <p>Offer relevant smoking cessation therapies</p>
<p><i>Holistic review</i></p> <p>Many patients become depressed as a consequence of the impact COPD has on their lives. Identification and treatment of depression should be part of the continuing review process</p> <p>Many patients need encouragement to continue their everyday activities in spite of their breathlessness. Much of this is covered in a pulmonary rehabilitation programme, but advice about exercise, diet and walking should be part of the primary care structured review process</p> <p>The patient's nutritional state should be reviewed at least annually. This should include recording their BMI and a review of their diet and appetite</p>
<p>BMI, body mass index; CXR, chest X-ray; FBC, full blood count; FEV₁, forced expiratory volume in 1 s; FVC, forced vital capacity; MRC, Medical Research Council.</p>

appointment, but each clinic should have some form of formal annual review and a shorter intermediate review programme. Importantly, the patient, and not their disease, must remain at the centre of this process. It is often easier to discuss lung function and treatment options than to listen to the patient and try to understand their concerns, worries and expectations.

The future for the patient with COPD is looking brighter than it has for some time. There is increasing interest in the management of COPD, not only from the pharmaceutical industry, but governments are at last recognizing it as a priority area to target and treat (e.g. the British Department of Health has introduced a scheme whereby GPs are financially rewarded for diagnosing COPD). However, the management of patients with COPD remains a challenge and a responsibility for all in primary care.

CHAPTER 50

Pulmonary rehabilitation

Richard ZuWallack

Definition and rationale

Individuals with chronic respiratory disease such as COPD often have distressing symptoms such as dyspnoea and fatigue, significant limitations in exercise capacity, limitations in activities of daily living and impaired quality of life. Pharmacological therapy, although a cornerstone in the symptomatic treatment of COPD [1], may fall short in the treatment in some or all of these important areas. Pulmonary rehabilitation complements this standard medical therapy.

Pulmonary rehabilitation was defined in the 1999 American Thoracic Society Statement on Pulmonary Rehabilitation as 'a multidisciplinary program of care for patients with chronic respiratory impairment that is individually tailored and designed to optimize physical and social performance and autonomy' [2]. It involves a spectrum of therapeutic strategies, including exercise training, self-management education, nutritional intervention, psychosocial support and promotion of long-term adherence, that are integrated into the lifelong management of the patient.

Pulmonary rehabilitation programmes involve patient assessment, exercise training, education, nutritional intervention and psychosocial support. In a broader sense, pulmonary rehabilitation includes a spectrum of intervention strategies integrated into the lifelong management of patients with chronic respiratory disease and involves a dynamic, active collaboration between the patient, family and health-care providers. These strategies address both the primary and the secondary impairments associated with respiratory disease.

This comprehensive interdisciplinary patient-centred intervention has virtually no effect on the lung function or respiratory physiological abnormalities of COPD, yet it frequently provides substantial and clinically meaningful benefits in important outcome areas such as dyspnoea, exercise performance, functional status and health-related

Table 50.1 Some systemic effects of chronic respiratory disease that might be improved with pulmonary rehabilitation.

Nutritional depletion and body composition abnormalities, especially decreased muscle mass in the lower extremities [81,82]
Reduction in peripheral muscle oxidative enzymes [83]
Alterations in peripheral muscle fibre type [84]
Cardiovascular deconditioning
Poor pacing techniques
Maladaptive coping skills
Fear of dyspnoea-producing activities, depression
Adoption of a sedentary lifestyle with decreased participation in social events

quality of life. Pulmonary rehabilitation is effective because a considerable portion of the dyspnoea, fatigue, exercise limitation, and reductions in functional and health status is caused by the associated morbidity and comorbidity – which often responds to treatment. For example, while a patient with COPD has (by definition) some component of irreversible airflow limitation, he or she likely has deconditioning of the peripheral muscles resulting from inactivity [3], the use oral corticosteroids [4] or the presence of systemic inflammation associated with COPD [5]. These peripheral muscle effects contribute to the exertional dyspnoea and exercise limitation of COPD, and respond to exercise training. Table 50.1 lists some of the associated morbidities in COPD that potentially are responsive to comprehensive pulmonary rehabilitation.

Established positive outcomes from pulmonary rehabilitation

Pulmonary rehabilitation has proven to be a highly effective therapy that has positive outcomes in several areas

Table 50.2 The effectiveness of pulmonary rehabilitation in multiple outcome areas.

1	Reduced exertional dyspnoea and dyspnoea associated with daily activities [36,85,86–88]
2	Increased exercise endurance of the lower extremities [16,36,66,89]
3	Increased upper extremity endurance [22]
4	Increased peripheral muscle strength [29,30]
5	Increased strength and endurance of respiratory muscles [31,89]
6	Increased self-efficacy for walking [36]
7	Improved health status [9,22,66,88]
8	Reduced health-care utilization and increased cost effectiveness [66,90,91]

(Table 50.2). Note that this list of positive outcomes does not include improvement in pulmonary function or prolonged survival. Favourable changes in symptoms, exercise performance, activity levels and health-related quality of life occur despite this lack of change in pulmonary physiological measurements, such as the forced expiratory volume in 1 s (FEV_1). This reflects the effectiveness of pulmonary rehabilitation on the associated morbidity, such as peripheral muscle deconditioning. The lack of a demonstrated effect of pulmonary rehabilitation on survival probably reflects the limited number of controlled trials evaluating this variable (with relatively small numbers of randomized controlled trials), making them statistically underpowered to detect this change.

A brief history of pulmonary rehabilitation

Well before the advent of modern evidence-based medicine, clinicians had recognized that pulmonary rehabilitation or its components are effective in the treatment of chronic respiratory disease [6,7]. However, it has only been in the last decade or two that this intervention has become widely accepted as a state-of-the-art, scientifically proven therapy for chronic respiratory disease. This rise to prominence is underscored by the following:

1 Two major evidence-based reviews – by the combined efforts of the American College of Chest Physicians and the American Association of Cardiovascular and Pulmonary Rehabilitation [8], and a Cochrane meta-analysis [9] – that clearly demonstrate the effectiveness of pulmonary rehabilitation.

2 The National Emphysema Treatment Trial (NETT) [10], which considered pulmonary rehabilitation to be the gold standard of therapy with which lung volume reduction surgery was compared.

3 The endorsement of pulmonary rehabilitation by the Global Initiative for Obstructive Lung Disease (GOLD), by placing it in their treatment algorithm for individuals with moderate COPD [1].

A brief listing of several studies in the development of the science of pulmonary rehabilitation is given in Table 50.3. These studies, and others, have documented the effectiveness of pulmonary rehabilitation in multiple outcome areas. Current research has now shifted away from proving that pulmonary rehabilitation works, to determining ways to make it even more effective.

The process of pulmonary rehabilitation

Selection of candidates

Pulmonary rehabilitation is generally indicated for individuals with chronic respiratory disease who have persistent respiratory symptoms, decreased exercise capacity, a reduction in functional status (activity) or impairment in health-related quality of life despite standard medical therapy (Fig. 50.1), taken from the combined American Thoracic Society–European Respiratory Society statement, *Standards for the Diagnosis and Management of COPD* [11]. Note that a specific pulmonary physiological impairment, such as a reduced FEV_1 , is not in the above listing. Rather, the presence of distressing respiratory symptoms, activity limitation and reductions in participation dictate the need for pulmonary rehabilitation. Because the physiological measurements such as the FEV_1 correlate poorly with these important outcome areas [12], there are no specific pulmonary function inclusion criteria for pulmonary rehabilitation [13].

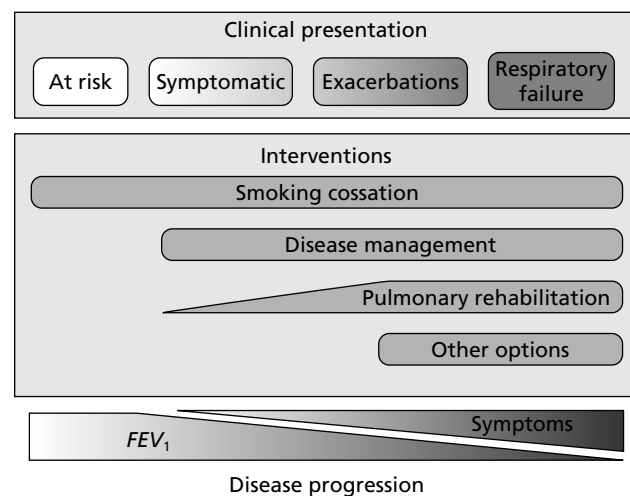

Figure 50.1 The combined American Thoracic Society–European Respiratory Society algorithm for management of stable COPD. FEV_1 , forced expiratory volume in 1 s.

Table 50.3 Key studies in the development of the science of pulmonary rehabilitation.

Study	Design and findings
Casaburi <i>et al.</i> [16]	COPD patients randomized to exercise training involving higher work rates showed significantly more training effect than those with lower levels of exercise training. This was seen despite equalizing total amounts of work. This was the first randomized controlled study to show that physiological benefit from exercise training is possible in COPD patients and that this effect is dose-dependent
Reardon <i>et al.</i> [87]	COPD patients referred for pulmonary rehabilitation were randomized to either 6 weeks of pulmonary rehabilitation or standard therapy. Those who completed pulmonary rehabilitation had significant decreases in exertional dyspnoea and questionnaire-rated dyspnoea with activity. This is the first study to show that pulmonary rehabilitation improves dyspnoea. Subsequent studies by O'Donnell <i>et al.</i> [85] replicated these findings, and demonstrated that this improvement results from reduced ventilatory demand at iso-work levels
Goldstein <i>et al.</i> [88]	A randomized controlled trial demonstrating that pulmonary rehabilitation resulted in improvements in exercise performance and health-related quality of life
Ries <i>et al.</i> [36]	This was a large randomized trial comparing comprehensive pulmonary rehabilitation with education alone. It demonstrated the effectiveness of pulmonary rehabilitation in several areas, including exercise performance, dyspnoea, and self-efficacy for walking. It also showed that this improvement declined over time, reaching control group by 18–24 months
Maltais <i>et al.</i> [92]	This controlled study demonstrated the positive effect of exercise training on oxidative enzymes in peripheral muscles. This biochemical improvement correlated with reduced lactic acid production during exercise
Griffiths <i>et al.</i> [66]	This randomized trial of 200 Welsh patients with chronic respiratory disease compared outpatient pulmonary rehabilitation with standard medical therapy. In addition to showing an increase in exercise performance and health-related quality of life, pulmonary rehabilitation was shown for the first time in a prospective randomized trial to result in decreased health-care utilization: fewer days in the hospital and fewer primary care home visits. A subsequent study by this group demonstrated cost effectiveness of pulmonary rehabilitation [94]
Bourbeau <i>et al.</i> [91]	This large prospective randomized controlled trial compared a structured self-management programme with standard therapy for COPD. The intervention led to a reduction in health-care utilization and improved quality of life. This important study provides evidence that the self-management strategies employed in comprehensive pulmonary rehabilitation are effective, and provides support to the concept that pulmonary rehabilitation is more than just exercise training

Pulmonary rehabilitation should be considered as a potential intervention when standard (usually primarily pharmacological) therapy falls short in effectiveness. At present, patients with COPD comprise, by far, the largest group of respiratory disease referred for pulmonary rehabilitation. Patients referred to pulmonary rehabilitation often have one or more of the following symptoms, activity limitations or participation limitations [14]:

- 1 Severe dyspnoea and/or fatigue;
- 2 Decreased exercise capacity;
- 3 Limitations in functional status, especially higher order activities of daily living;
- 4 Impaired health-related quality of life;
- 5 Interference with performance in employment;
- 6 Nutritional depletion and body composition abnormalities, such as COPD-associated cachexia;
- 7 Increased medical resource consumption resulting from chronic respiratory disease or its comorbidities.

Often, the referral to pulmonary rehabilitation had been

reserved for advanced lung disease. While patients in this category will benefit from the intervention as long as they can participate in the programme [15], an earlier referral is preferable, because preventative strategies such as smoking cessation could be emphasized and different modes and higher intensities of exercise training could be utilized.

Exclusion criteria for pulmonary rehabilitation fall into two general areas:

- 1 An associated condition that might interfere with the rehabilitative process, such as disabling arthritis, or severe neurological, cognitive or psychiatric disease.
- 2 An associated condition that might place the participant at undue risk from exercise training, such as unstable angina. While a low level of motivation is a relative contraindication, it might improve with the intervention. Most – but by no means all – pulmonary rehabilitation programmes now allow active cigarette smokers to participate; in this circumstance the smoking cessation intervention becomes an important component of the process.

Components of a comprehensive pulmonary rehabilitation programme

Exercise training

Endurance and strength training of the upper and lower extremities is an essential component of comprehensive pulmonary rehabilitation [2]. Exercise performance in patients with COPD is frequently limited by peripheral muscle abnormalities and cardiovascular deconditioning, adding to the limitation imposed by airflow limitation, volume constraints related to hyperinflation and gas-exchange abnormalities. Thus, an early onset of anaerobic metabolism with lactic acidosis during low or moderate levels of exercise is observed [16]. The peripheral muscles in COPD are not frequently depleted [17], and also have alterations in fibre-type distribution and decreased metabolic capacity [18].

Exercise training for COPD is based on standard principles of intensity (higher levels of training produce more results), specificity (only those muscles trained show an effect) and reversibility (cessation of regular exercise training leads to loss of training effect) developed from studying normal individuals [19]. These principles have been applied to COPD patients, although there are relatively few studies that have evaluated exercise duration, exercise session duration or the number of sessions per week in this population. A dose-related increase in oxidative enzymes in the peripheral muscles accompanies the physiological adaptations to training [20], and this increase correlates with the concomitant reduction in lactic acid production [21]. A training effect is attainable in many patients with COPD, and higher levels of exercise results in a greater reduction in ventilation and lactate production at iso-work levels [16]. However, the greater increases in exercise performance from higher levels of training do not necessarily result in greater improvements in dyspnoea or health status [22].

Most pulmonary rehabilitation programmes emphasize endurance training of the lower extremities, often advocating sustained exercise for approximately 20–30 min, two to five times weekly. This type of training may utilize a stationary cycle ergometer, motorized treadmill, stair climbing or walking on a flat surface. Training is usually performed at levels at or greater than 50–60% of the estimated maximal workrate. For those unable to maintain this intensity for the recommended duration, interval training, consisting of 2–3 min of high intensity (60–80% maximal exercise capacity) training alternating with equal periods of rest, has similar results with less dyspnoea [23,24].

Few studies have evaluated the optimal duration of exercise training in pulmonary rehabilitation. One study showed that, on average, 7 weeks of pulmonary rehabilitation leads to a greater improvement in exercise performance than a 4-week intervention [25]. Recent COPD

guidelines (GOLD) recommend (without providing much supportive evidence) at least 8 weeks of exercise training as part of a pulmonary rehabilitation programme. The total duration of exercise, although it is often standardized to the individual programme, should depend on the patient's underlying respiratory disease, the level of physical and cardiovascular conditioning, and continued demonstrated progress made during the exercise training sessions.

Although the strength of the upper extremity muscles is relatively preserved compared with that of the lower extremities in COPD [26,27], these muscles are very important in many activities of daily living and their use is associated with considerable dyspnoea. Both strength and endurance training of the upper extremities are probably important. Training is often through the use of arm ergometry, lifting free weights or dowels, or stretching elastic bands.

Because peripheral muscle weakness and/or depletion contribute to the exercise limitation in patients with COPD [28], strength training is a rational component of exercise training during pulmonary rehabilitation. Consequently, the current practice of pulmonary rehabilitation usually adds strength training to standard aerobic training. Weightlifting exercises training alone, involving the upper and lower extremities, increases muscle strength and endurance performance on a cycle ergometer [29]. This combination increases muscle strength and mass, but its additive effect on health status has not been proven [30].

Inspiratory muscle training increases strength and endurance of the inspiratory muscles in COPD [31,32]. However, the link between improvement in respiratory muscle strength or endurance and improvement in dyspnoea, exercise performance or health status is not firmly established [33]. Newer approaches that emphasize endurance training of the respiratory muscles at more precise percentages of maximal capacity are promising, although not yet proven.

Education and self-management strategies

Education is an integral component of virtually all comprehensive pulmonary rehabilitation programmes, providing information to the patient and the family on the respiratory disease and its treatment and helping to develop coping skills [34,35]. It encourages active participation in health care (collaborative self-management), thereby promoting adherence and self-management skills [36,37].

Education is usually provided both in both small group settings and on a one-to-one basis, tailored to the needs of the individual patient [38]. Advance directive discussions are an important component of pulmonary rehabilitation [39,40]. Generally, a number of standard topics are addressed in the educational sessions [41]; some of these are outlined in Table 50.4.

Table 50.4 Examples of educational topics in pulmonary rehabilitation [93].

Normal pulmonary anatomy and physiology of the lungs
Types of lung disease
Description and interpretation of medical tests
Breathing retraining techniques
Bronchial hygiene
Medications
Principles of exercise
Activities of daily living, energy conservation techniques
Nebulizers and supplemental oxygen
Symptom assessment and management
Proper nutrition
Psychosocial issues, dealing with fear of dyspnoea-producing activities
Ethical issues and advance directives
Recognizing and dealing with the acute exacerbation of COPD

Because education is integral to virtually all comprehensive pulmonary rehabilitation programmes, the effect of this specific component has not been adequately studied. However, a recent study evaluating self-management strategies (which are prominent in comprehensive pulmonary rehabilitation) applied to the home setting showed this form of therapy to be effective in improving health status and reducing utilization of medical resources.

Nutritional support

Decreased body weight and/or depletion in lean body mass are present in 20–35% of patients with stable COPD [42–44]. There are multiple causes of body composition abnormality in this disease, including increased energy expenditure [45,46] and systemic inflammation [5]. Nutritional depletion and body composition abnormalities are associated with decreased respiratory muscle strength [47,48], handgrip strength [49], exercise tolerance [47,50] and health related quality of life [51]. Additionally, depletion is a significant predictor of mortality in COPD, independent of FEV_1 [52]. Because of the associations with morbidity and mortality, nutritional intervention is a recommended component to comprehensive pulmonary rehabilitation.

Simple nutritional supplementation to underweight COPD patients has not met with much success, as evidenced by a recent meta-analysis that demonstrated only a 1.65-kg increase in weight following this type of intervention [53,54]. Because of these disappointing results with calorie supplementation alone, adjunctive treatment with anabolic steroids has been tried [54,55]. This has led to increases in weight, lean body mass, respiratory muscle strength, and arm and thigh muscle circumference [56]. To

date, however, improvements in these areas of impairment have not been convincingly demonstrated to be associated with improvements in exercise tolerance or functional status. Of considerable importance is a recent study that demonstrated that therapeutic increases in weight in COPD patients following therapy are related to increased long-term survival [57]. Further studies are needed to determine the optimal approach to treatment of nutritional depletion in chronic lung disease.

Psychosocial support

Psychosocial problems, including anxiety, depression, poor coping skills and decreased feelings of self-efficacy, contribute to the morbidity of COPD [58–60]. Intervention in these areas varies widely among pulmonary rehabilitation programmes, but often focuses on areas such as coping strategies [34,61] or stress management techniques such as muscle relaxation techniques, stress reduction and panic control. Improvement in anxiety may have the additional advantage of further decreasing dyspnoea [62]. Participation by family members or friends in pulmonary rehabilitation support groups is encouraged. Informal discussions of symptoms frequently present in chronic lung disease and common concerns may provide emotional support to patients and their families. Patients with substantial psychiatric disease as comorbidity should be referred for appropriate professional care outside of the programme.

There are only few studies evaluating the specific effect of pulmonary rehabilitation on psychological outcome [63], and none that evaluate this specific component of comprehensive rehabilitation on traditional outcomes. A randomized controlled trial of comprehensive pulmonary rehabilitation failed to demonstrate a significant effect on depression. However, in one non-controlled study of pulmonary rehabilitation, depression and anxiety levels decreased following 1 month of pulmonary rehabilitation. This programme included psychological counselling and stress management sessions twice weekly, in addition to standard exercise training and educational topics [64]. Of potential considerable importance, self-efficacy for walking increases with exercise training [36,65].

Promotion of long-term adherence

Pulmonary rehabilitation has impressive positive short-term effects in exercise capacity, dyspnoea relief and health-related quality of life. However, long-term effectiveness of this therapy tends to wane with time, with these outcomes often approaching those of the control group by 18–24 months [36,66–70]. Two factors are probably responsible for a substantial portion of this drop-off in effectiveness:

- 1 Exacerbations of underlying lung disease, leading to prolonged symptoms and a reassumption of a more sedentary lifestyle;

Table 50.5 Some examples of outcome assessment for pulmonary rehabilitation.

Exertional dyspnoea	Borg scale [94] or visual analogue scale [87] during exercise testing
Dyspnoea associated with daily activities	Modified Medical Research Council (MRC) questionnaire [95] Baseline and Transitional Dyspnoea Indexes (BDI/TDI) [96,97] San Diego Shortness of Breath Questionnaire [98]
Functional exercise capacity	Six-minute walk test, shuttle walk tests [99,100]
Laboratory measures of exercise performance	Cardiopulmonary exercise testing, treadmill endurance time [36,89]
Health-related quality of life	Chronic Respiratory Disease Questionnaire (CRQ) [101] St. George's Respiratory Questionnaire (SGRQ) [102] Medical Outcomes Study Short Form 36 (SF-36)
Functional performance	Pulmonary Functional Status Scale (PFSS) [103] Pulmonary Function Status and Dyspnoea Questionnaire (PFSDQ) [104]
Nutritional status/body composition	Body mass index, body composition using bioelectrical impedance or dual energy X-ray absorption (DEXA)
Psychological variables	Measurement of anxiety and depression using the Hospital Anxiety and Depression (HAD) questionnaire

2 A gradual decline in adherence with the post-rehabilitation exercise prescription [71].

Pulmonary rehabilitation programmes now routinely employ strategies to promote long-term adherence with post-rehabilitation instructions. One approach is to actively incorporate the principles of pulmonary rehabilitation such as regular exercise training into the home setting, with the hope that this would promote better long-term adherence with this intervention. This is supported indirectly by studies of home-based programmes, which suggest that gains achieved in this setting may be longer lasting than those of outpatient hospital-based programmes [72]. Additionally, giving a second course pulmonary rehabilitation following an exacerbation of COPD, emphasizing short periods of supervised exercise training to return the patient to baseline performance, might be a reasonable intervention in selected cases. Studies evaluating the potential effectiveness of these strategies or others are needed.

Outcome assessment

Outcome assessment is frequently performed in a pulmonary rehabilitation programme as part of a generalized audit of the effectiveness of the individual programme. Outcome areas often include dyspnoea, exercise performance and health-related quality of life. A listing of some commonly used outcome measures is listed in Table 50.5. Exercise tests such as the timed walk test, or the assessment of dyspnoea or health-related quality of life by a standardized questionnaire may also provide some information on the individual patient's response to therapy. Whether these outcome measures, which have been validated using groups of patients and are routinely used in overall pro-

gramme assessment, are useful in this individualized setting is not clear. Traditional one-on-one clinical assessment remains necessary for determining the effectiveness of pulmonary rehabilitation in the individual patient. Other outcome areas, such as health-care utilization or mortality, would require the collaboration of multiple pulmonary rehabilitation programmes to accrue the necessary number of patients for analysis.

Newer, adjunctive strategies in pulmonary rehabilitation

Non-invasive positive pressure ventilation (NPPV), through its effect in helping unload the respiratory muscles, may improve breathlessness in COPD [73,74]. In one study of patients with more severe lung disease, this form of therapy allowed for exercise at a higher intensity, resulting in the achievement of a greater maximum exercise capacity [75]. Its role in pulmonary rehabilitation remains to be defined.

Some patients with very severe COPD, especially after a prolonged hospitalization for an exacerbation of the disease or those with substantial comorbidity, are unable to participate in exercise training effectively. One potential way around this is neuromuscular electrical stimulation using low-intensity electrical current to specific muscle groups, especially those of the lower limbs. To date, two trials have evaluated this modality of treatment [76,77]. In both studies, of respiratory patients with severe muscle weakness, transcutaneous neuromuscular electrical stimulation of lower limb muscles led to significant increases in skeletal muscle strength and exercise capacity.

Maximal bronchodilator therapy for COPD reduces the resistive work of breathing through increasing the calibre of airways and the elastic work of breathing through decreasing static and dynamic hyperinflation. These effects should allow for ventilatory-limited patients to exercise at higher training intensities. Because the training effect from exercise is dose-dependent, maximal bronchodilator therapy during pulmonary rehabilitation should improve outcome in this area. This was demonstrated in a recent study comparing exercise performance following pulmonary rehabilitation in a group of COPD patients who received the long-acting bronchodilator, tiotropium, with a group that received standard therapy with short-acting β -agonist bronchodilators. The group receiving the long-acting anticholinergic drug had a substantially greater improvement in treadmill endurance time.

Supplemental oxygen therapy reduces exertional dyspnoea in COPD, partly through reducing ventilatory drive [78,79]. A recent study demonstrated that supplemental oxygen therapy of non-hypoxaemic COPD patients allowed for exercise training at a higher intensity, resulting in greater gains from this therapy [80]. Whether this beneficial effect will continue when the patient finishes pulmonary rehabilitation and stops using supplemental oxygen remains to be determined.

CHAPTER 51

Social support

Robin Stevenson

Many diseases have become prevalent because of society's failure to organize itself equitably. In the past, dysentery, cholera and tuberculosis were often related to overcrowding, poverty and poor sanitation. In the present time, the prevalence of COPD has a marked socioeconomic bias, greater than that described for ischaemic heart disease [1,2], and perhaps greater than for any other major disease [3]. The role of social support in COPD therefore merits close scrutiny.

By the 1950s, it was clear that there were marked social and occupational factors in the aetiology of COPD [1]. From 1930 until 1970, COPD mortality in men was consistently higher (approximately fourfold) in the UK than in the USA, whereas migrants from the UK to the USA had COPD mortality similar to the indigenous population [4]. From 1970 until the turn of the century, COPD mortality in UK men fell steadily, but a study using a general practice database showed that from the mid-1990s, prevalence rates for COPD in men appeared to plateau, whereas the prevalence in women rose and, by 1997, was similar in both men and women [5]. These epidemiological data indicate the importance of the socioeconomic component to COPD, which has been more obvious in the UK than in other Western countries and has resulted in COPD being described as the 'British Disease'. The precise nature of the environmental factors responsible for excess UK mortality has never been discovered. Current data since 1995 suggest that the UK is now behaving more like the USA [2].

Social bias in the prevalence of respiratory symptoms was described in 1979 [6]. Further studies from the 1970s onwards demonstrated a relationship between socioeconomic status and lung function impairment that was independent of smoking habits [7–12]. In a US study of male non-smokers, the difference in forced expiratory volume in 1 s (FEV_1) between the highest and lowest social classes was approximately 400 mL [13], and in the Copenhagen City Heart Study similar results were found after allowing for

smoking and were associated with a threefold increased risk of admission for COPD in the lowest socioeconomic group [14]. The risk factors related to social disadvantage include low birth weight, intrauterine effects of maternal smoking, frequency of childhood respiratory infections, poor housing conditions and atmospheric pollution [3,15]. Although these factors may contribute to the development of COPD, smoking is the main cause and the population-attributed risk of smoking for COPD in men is approximately 80%. In modern society, smoking is increasingly associated with low socioeconomic status. In the 1950s, cigarette smoking was common in all social strata, but since then it has become increasingly restricted to the lower end of the socioeconomic gradient. In 1998, 44% of men who lived in unskilled manual households smoked cigarettes, compared with 15% from professional households. Men from the unskilled manual group smoked on average 120 cigarettes per week whereas those from the professional group smoked an average of 91. In addition, men from manual socioeconomic groups were more likely to smoke high-tar cigarettes and to have started smoking at an earlier age [16]. Professional and managerial culture has become intolerant of smoking and this may account for the greater success of the higher social classes in quitting smoking [17].

If it is accepted that COPD increasingly occurs in the disadvantaged sections of society, then it would be expected that patients would be denied the benefits of the social support that is a feature of successful and prosperous population groups. There is evidence that social support is indeed less adequate in COPD than in other comparable diseases. A comparison between end-stage patients with cystic fibrosis and COPD who were awaiting lung transplantation showed that the cystic fibrosis patients had lower anxiety levels and better social support than the COPD patients [18]. In a series of health-related quality of life interviews of patients with COPD and non-small cell lung cancer, the latter group were less depressed and anxious and functioned better

socially. Thirty per cent of the cancer patients had access to palliative care, whereas none of the COPD patients had similar support [19]. In a further comparative study of COPD and coronary artery disease, the COPD patients were less socially active, felt more disabled and had poorer health perception [20]. COPD patients on long-term oxygen therapy (LTOT) had poor quality of life which was partly attributed to social isolation [21], and hypoxaemic COPD patients showed impairment of quality of life associated with a reduction in social interaction and recreational pastimes [22]. In a study of patients with exacerbations of COPD, almost half lived alone and one-third still smoked [23]. In a small qualitative study, wives of patients with COPD complained of lack of support from friends, family and health-care providers [24].

There seems little doubt that patients and their carers feel that social support is lacking, but it is reasonable to ask if the provision of support is known to be beneficial and, not surprisingly, the evidence suggests that it is. A COPD questionnaire study found that high levels of social support correlated with reduced depression and anxiety [25] and quality of life has been shown to be related to family bonds, local neighbourliness and freedom from fear [26]. Patients with COPD who were dissatisfied with their level of social support or who felt isolated were less likely to adhere to a pulmonary rehabilitation programme [27]. From a literature search on rehabilitation between 1966 and 1996, an analysis of 22 randomized controlled trials (RCTs) showed that the inclusion of psychosocial support in the rehabilitation programme promoted compliance with the exercise regimen and improved quality of life [28]. A meta-analysis of 65 studies showed that rehabilitation plus a variety of psychosocial and behavioural interventions improved well-being, functional status and breathlessness [29]. In a population study, a correlation was found between social stress and COPD mortality [30], and early relapse after exacerbations of COPD has been shown to be more likely in widowed, separated or divorced patients [31].

The social environment is therefore not only instrumental in causing COPD, but also fails to provide support to the patients who contract the disease. If we accept the premise that society itself is largely responsible for creating the conditions under which COPD develops, then society should accept responsibility for the provision of appropriate support. Unfortunately, the criteria by which support can be considered appropriate are poorly defined. Cigarette smoking is the main risk factor for COPD and it would seem obvious that social support should be targeted primarily at smoking abstinence and cessation. Tobacco addicts have never received the degree of social support that has been available to alcohol or opiate addicts, perhaps because their addiction does not represent a threat to the civil order and does make a major contribution to government tax income.

There is little evidence that centrally funded social or behavioural interventions influence the use of addictive drugs such as tobacco, alcohol or opiates by socially deprived groups. Equally, the reduction in smoking in the more affluent classes probably owes more to peer pressure and the smoking behaviour of spouses and partners [17] than to health warnings on cigarette packets or to government-sponsored television campaigns. It may therefore be more profitable for society to support smoking cessation in individuals who are known to be at risk of COPD.

While it is true that quitting smoking benefits most smokers, the main effect on mortality relates to cardiovascular disease [32]. In patients with established COPD, mortality from respiratory disease may not be affected by smoking cessation and the benefit in terms of aborting the progress of COPD may be restricted to individuals with measurable impairment of lung function who are relatively asymptomatic [33]. There is good evidence that smoking cessation in patients with mild COPD reduces the rate of decline of FEV_1 to that of never-smokers [34], but the effect of quitting in patients with severe disease is not known.

Smokers with mild impairment of lung function will not easily be identified by GPs and many regions in the UK are now embarking on spirometry screening programmes organized by public health departments. Smoking cessation is more likely to be successful if an individual, recently apprised of his or her impaired spirometry, believes that he or she will benefit, rather than may benefit from smoking cessation. In the UK, nicotine replacement therapy and bupropion SR (amfebutamone) are now available on prescription but a community-based infrastructure is still needed to supply advice and support [35]. The continuation of spirometry screening will only be justified if at-risk people are recruited to a successful smoking cessation programme.

The priority for social support may be in relation to smoking cessation aimed at those with subclinical or mild disease, but it is clear that patients with established COPD not only lack support, but also would benefit if it were available. Low socioeconomic status is associated with weak family bonds, urban ghetto culture and juvenile street crime. Patients disabled by COPD are often afraid to leave their homes and become socially isolated. Some of these patients find support from the Internet. There are more than 6000 COPD support websites and almost 2000 COPD chat rooms in the UK. The British Lung Foundation created the Breathe Easy Club in 1991 and 120 Breathe Easy groups have been established in England, Scotland and Wales since 1992. Members of the club receive a quarterly magazine and are encouraged to meet together and to join the Penpals scheme. Breathe Easy also provides a banner under which patients with COPD can lobby for social support (Fig. 51.1).

COPD is a disease of inexorably worsening lung function

Figure 51.1 Breathe Easy Club members petitioning for liquid oxygen.

causing increasing disability. The majority of patients suffer from exacerbations which may occur as infrequently as once a year, but many will have three or more exacerbations annually. When assessed by the St. George's Respiratory Questionnaire, patients with frequent exacerbations have a poorer quality of life than those with less frequent exacerbations [36]. Exacerbations that require hospital admission may only affect a small proportion of the COPD population (less than 2% in one study) but the cost is disproportionate [37]. Hospital admissions are said to account for 35% of the annual health-care costs of COPD [38]. It is therefore understandable that many therapeutic interventions are designed to reduce exacerbation frequency or to minimize the length of hospital stay.

There have been various studies of domiciliary support by nurses and physiotherapists who have made regular home visits to stable COPD patients to provide support, education and monitoring of symptoms and treatment. Three RCTs have shown no benefit in exacerbation frequency or hospital admission [39–41]. However, three uncontrolled studies reported reductions in hospital admissions and emergency room attendance as a result of regular home visits by nurses or respiratory therapists [42–44]. In a Spanish RCT of COPD patients on LTOT, the intervention group had regular telephone calls and home visits with additional home or hospital visits on demand. The intervention group had fewer than one-third of the emergency department visits and slightly more than one-third of the hospital admissions of the control group in the follow-up period of 1 year, but did require many home and hospital visits [45]. This study may have shown a positive result because the patients were more severely ill than those in

the other RCTs and therefore the effect of an intervention was more likely to be clinically evident. The authors felt that it was important that the same team was responsible for both hospital and home care.

The interventions above were described as hospital-based home care programmes, but similar initiatives are categorized as disease-specific self-management interventions. In a recent Canadian RCT of patients with advanced COPD who had at least one hospital admission for exacerbation in the previous year, the intervention group were assigned to a comprehensive education programme over a 2-month period with monthly telephone follow-up. Hospital admissions for COPD exacerbations were reduced by 40% in the intervention group compared with the usual care group and health status in the intervention group was also improved. Although admissions for exacerbations were reduced in the intervention group, the numbers of exacerbations in the two groups were not significantly different. The authors felt unable to separate the effect of education from the effect of direct support and counselling [46]. In other studies on less severely unwell patients, which have concentrated on self-management education without continuing support, inconclusive results on health-related quality of life have been observed [47].

The results of two studies from Spain and Canada [45,46] are important and need to be confirmed. However, they suggest that there are reasonable grounds for believing that continuing domiciliary support for patients with advanced stable COPD is cost-beneficial in reducing hospital admissions and may allow patients to cope with their disease more effectively.

In recent years, other interventions have received great attention because they are alleged to reduce exacerbation frequency. Several of the trials of inhaled steroids in stable COPD used exacerbation rate as a primary or secondary outcome measure. ISOLDE demonstrated a significant reduction of approximately 25% in exacerbation frequency [48]. The long-acting bronchodilator salmeterol reduced the time to first exacerbation [49] and two further large studies, comparing tiotropium with placebo [50] and ipratropium [51] have demonstrated a reduction in exacerbation rate. There are several observational studies that suggest that pulmonary rehabilitation reduces the frequency of COPD exacerbations [52–55]. An RCT showed that outpatient rehabilitation reduced the frequency of exacerbations but not the number of hospitalizations over a 2-year period [56].

Inhaled steroids, long-acting bronchodilators and pulmonary rehabilitation may therefore reduce exacerbation frequency, but domiciliary support may reduce hospitalization without necessarily affecting exacerbation frequency. These different forms of intervention may be complementary and domiciliary support may be just as important as, if

Figure 51.2 Exacerbation scores.

not more important than the more established treatment modalities.

Domiciliary support or 'hospital at home' has also been applied to the management of exacerbations of COPD. Many patients with exacerbations are suitable for home treatment with respiratory nurse supervision, because sophisticated monitoring is unnecessary, sudden deterioration is unlikely and once-daily observation is usually sufficient. Initial hospital assessment is important to confirm the diagnosis and exclude uncompensated respiratory acidosis. An uncontrolled study of home treatment by an acute respiratory assessment service (ARAS) showed that this development was safe, effective and popular with patients and GPs [57]. An exacerbation score derived from a European Respiratory Society consensus statement [58] was used to assess disease severity (Fig. 51.2).

Since the initial observational study, there have been six RCTs of hospital at home treatment carried out by specialist respiratory nurses [59–64]. All showed reduction in hospital admissions or bed utilization with no increase in morbidity, mortality or readmission rate. Of the larger studies, eligibility for home care averaged 35% and tended to correlate inversely with the FEV_1 at assessment. Direct GP referral achieves higher eligibility (approximately 70%) but it is not known how many of these patients would actually have been admitted to hospital [57]. The study design has varied, with some centres assessing patients on the day after admission with a view to early supported discharge

[59,63] and others identifying patients in emergency departments with the intention of preventing admission altogether [60,61]. Of the various approaches, the early supported discharge model is the simplest and most efficient. It targets patients who are using hospital resources and is economical of nurses' time because they do not need to be immediately available for prompt patient assessment in the emergency department. It also increases eligibility because improvement in FEV_1 is maximal in the first 24 h in hospital [65]. In a postal survey of UK hospitals in 2001, 28% of respondents offered a hospital at home service, most of which were run as early discharge schemes with only a minority relying solely on GP or emergency department referrals [66].

In conclusion, social support is relevant to all aspects of COPD. Its absence at the lower end of the socioeconomic gradient encourages the development of the disease and once established renders it more difficult to endure. When available, social support ameliorates the suffering caused by COPD, encourages smoking cessation and improves quality of life. It also reduces the cost and burden of hospital dependency and has earned its place in the front rank of COPD treatment modalities.

CHAPTER 52

Long-term invasive mechanical ventilation

Gerard J. Criner

Patients receiving chronic invasive ventilation present an interesting set of problems because of the complex underlying medical or surgical disorders precipitating respiratory failure, coupled with the need for ventilation. As a result of devastating underlying medical or surgical illness, and a period of prolonged immobilization, and depending on whether the disorder requires treatment with high-dose systemic steroids or aminoglycosides, patients have substantial weakness of the extremities, as well as of respiratory and swallowing muscle groups. Therefore these patients pose unique and complex problems to the treatment team that mandates the use of a multidisciplinary approach to wean them successfully from mechanical ventilation, and to restore them to their prehospital functional status.

In this chapter, we detail our approach to the patient who requires chronic invasive ventilation. We emphasize the use of a multidisciplinary treatment plan.

Outcome of patients

Although several studies have reported on survival following long-term, chronic or prolonged mechanical ventilation, the studies vary significantly depending upon the definition of 'long-term' or 'chronic'. Some studies report chronic ventilation as being longer than 2 or 3 days, whereas others report as chronic those patients who have been ventilated for 30 days or longer. Regardless of the study definition of the period of ventilation, however, the mortality associated with prolonged ventilation is fairly high. Data previously published by the Health Care Financing Administration (HCFA) in the USA reported a mortality of 51% in Medicare beneficiaries who received mechanical ventilation for any length of time [1]. Previous studies reporting survival at hospital discharge in patients ventilated for 48 h or more, show mortalities that range anywhere from 36%

to 59%. Beside the duration of ventilation, patient age, the type of underlying medical or surgical illness precipitating respiratory failure and patient severity of illness are all important factors that may affect outcome of patients receiving chronic ventilation. All of these factors vary substantially between studies.

Knaus [2] reported a hospital mortality rate of 59% in patients who were ventilated for at least 7 days with mean Acute Physiology and Chronic Health Evaluation II scores (APACHE II) of 11–15. Patients who were ventilated for comparable lengths of time but were more severely ill (APACHE II scores of 21–25) had significantly higher mortality (77%), in contrast with those with lower APACHE scores (APACHE II scores 1–15) who had decreased mortality rates (10%). These data suggest that the severity of illness is an important factor determining mortality in patients receiving prolonged ventilation.

Age has also been reported to be a significant factor affecting the outcome of patients receiving mechanical ventilation. Although some authors found a direct correlation between greater patient age and mortality [3], others have not observed such a relationship [4]. These studies commonly failed to control for other variables that may affect outcome, such as severity of illness or underlying disease-precipitating respiratory failure. As a result, the influence of age itself as an independent factor influencing mortality in patients receiving prolonged ventilation is not clear at the present time.

The disorder precipitating respiratory failure, however, seems to be important in affecting patient outcome. Patients with malignancy and respiratory failure who require mechanical ventilation have extremely limited survival of only several months, with mortality at 6 months approaching 100%. Several studies have shown improved survival and functional status in those patients receiving chronic ventilation for restrictive lung disorders, such as post-polio syndrome, muscular dystrophy and kyphoscoliosis. By

contrast, patients with obstructive disorders, such as chronic obstructive pulmonary disease (COPD) or bronchiectasis, have been reported to have a reduction in survival of the order of 50% compared with those with restrictive disorders [5]. In a study by Czorniak *et al.* [6], chronic ventilated COPD patients discharged home were less independent and more likely to require repeated hospitalization than patients discharged home with mechanical ventilation for neuromuscular chest wall disorders. In addition, COPD patients receiving home ventilation had a decrease in survival compared with those with neuromuscular diseases. Other reports have also confirmed the poor outcome of chronic ventilated patients with COPD [7].

The prehospital functional status may also be an important factor determining outcome in patients receiving prolonged ventilation. Carson *et al.* [8] reported the outcome in 133 consecutive patients who were admitted to a long-term acute care hospital where they received mechanical ventilation for 14 days or longer. Patients not functionally independent before admission had a much higher 1-year mortality compared with those who were functionally independent.

When reviewing data across studies, it appears that unselected patients receiving prolonged ventilation when not screened by the severity or nature of the underlying disease, evidence of multiple organ dysfunction, lack of rehabilitative potential and poor functional pre-admission status have much reduced survival and limited improvement in functional status and quality of life. Therefore, the outcome of prolonged mechanical ventilation, the treatment plan and the goals of patient care are heavily influenced by the patient population that is being described. With this in mind, the focus of this chapter is on those patients receiving chronic ventilation who are considered to have rehabilitative potential, lack multiorgan dysfunction and have a satisfactory pre-admission functional status.

Impact of multidisciplinary units on patient outcome

Several reports have shown that patients receiving prolonged ventilation are not relegated to a uniformly dismal outcome in terms of mortality and functional status, when patients are properly selected and receive aggressive rehabilitation. Data from two of the HCFA Chronic Ventilator Demonstration sites suggested that the survival of some patients requiring invasive long-term ventilation is better than previously reported. Gracey *et al.* [9] reported the outcomes in 206 consecutive patients admitted to the Mayo Clinic, Ventilator-Dependent Unit, during a 5-year study period. Two hundred and six patients who received mechanical ventilation for at least 6 h/day for 21 consecut-

ive days were admitted; 92% (190) survived to be discharged from the hospital, of whom 77% returned to their homes; 153 of the patients were weaned totally from mechanical ventilation, whereas 37 remained completely or partially ventilator dependent. Of the patients receiving mechanical ventilation at discharge, 73% received it only nocturnally. The 4-year survival of the patients was 53%. A significant percentage of the patients, however, suffered prolonged ventilation from postoperative conditions (60%), which may have been responsible for skewing the results to a more optimistic outcome than other reports covering a heavier concentration of medical patients.

The report from our HCFA Chronic Ventilator Demonstration Project clinical unit comprised 77 patients [10]. Of these, 74% had medical causes as the reason for ventilator dependence: neuromuscular disease (26%), advanced lung disease (29%), congestive heart failure (5%) and a variety of other medical disorders (40%). In spite of the differences between the two populations, our results were similar to those of Gracey *et al.* [9]. Ninety-three per cent of these HCFA patients were discharged alive, 82% were still alive at 6 months and 61% at 1-year follow-up. Eighty-six per cent of the patients were completely weaned from mechanical ventilation, whereas 11% required continuous ventilation and 10% had nocturnal ventilation at discharge. In patients discharged alive, there was a significant increase in functional status at 6 and 12 months' follow-up.

Overall, both of these studies suggest that when patients receiving chronic mechanical ventilation are properly selected, and following correction of the underlying process causing respiratory failure, they have an acceptable clinical outcome with a return to pre-admission functional status and successful home discharge.

Location of care

Generally, patients receive long-term ventilation benefit when that care is provided in a non-intensive care unit (non-ICU) location that is geared toward multidisciplinary rehabilitation. The advantages that a non-invasive

Table 52.1 Advantages of a non-invasive respiratory care unit over standard intensive care unit (ICU) care.

- Less expensive
- Unlocks ICU beds
- Transitions patients to home care
- Emphasis is on achieving maximal functional status despite the requirement for ventilator support
- Extend capabilities of medical/surgical programmes to treat patients with advanced lung disease

Table 52.2 Criteria for transfer of ventilator-dependent patients from intensive care unit (ICU) to ventilatory rehabilitation unit (VRU). (From Make *et al.* [11], with permission.)

	Respiratory stability	Non-respiratory medical stability
Airway	Tracheostomy for invasive ventilation, minimal aspiration	Sepsis controlled
Secretions	Manageable with infrequent suctioning	No uncontrolled haemorrhage No arrhythmias, CHF, unstable angina
Oxygen	Adequate oxygenation with $FiO_2 < 60\%$, $PEEP \leq 10$ cm H_2O ($SpO_2 \geq 90\%$)	
Ventilator settings	Stable, no sophisticated modes	No coma
Patient assessment	Comfortable, no increased WOB or dyspnoea	Secure IV access
Weaning technique	Tracheal collar	Secure alimentation route
NPPV	Tolerates breaks off, stable settings	

CHF, congestive heart failure; FiO_2 , fractional inspired oxygen concentration; IV, intravenous; NPPV, non-invasive positive pressure ventilation; PEEP, positive end-expiratory pressure; SpO_2 , saturation of oxygen by pulse oximetry; WOB, work of breathing.

respiratory care unit has over standard ICU care include a less expensive location and more effective transition for patients to eventual home care, or discharge to a non-acute care location (Table 52.1). The emphasis in those units is placed on achieving maximal functional status despite requirements for ventilatory support. Effective use of these units, moreover, extends the capabilities to treat patients having severe lung disease with advanced medical and surgical therapies in ICUs.

Before patients are transferred to a non-ICU location for ventilator care, they must meet certain requirements for respiratory and non-respiratory medical stability [11]. Criteria for respiratory–non-respiratory medical stability are shown in Table 52.2. In all cases, patients must have a stable airway place, as afforded by a tracheostomy; they must also have manageable secretions. They should not be on sophisticated modes of mechanical ventilation and have only modest requirements for supplemental oxygen or positive end-expiratory pressure (PEEP). In addition, patients should not have uncontrolled cardiac arrhythmia or ischaemia, unstable haematological or fluid and electrolyte disorders, and have secure routes for parenteral access for medications and also for alimentation.

At our facility, which was one of the four HCFA Chronic Ventilator Demonstration units, the complex problems of chronic ventilator patients are addressed by a team comprised of specialists including respiratory nurses, nutritionists, psychologists, respiratory physical speech therapists and social workers. The medical staff includes a rotating board certified pulmonary and critical care attending physician and a fellow in training. Weekly meetings are attended by all team members and are led by the medical director of

the unit. Patients who are admitted to this unit have been ventilated for at least 21 consecutive days, at least 6 h/day, and are required to have previously undergone at least two attempts at weaning from mechanical ventilation that failed. The emphasis in this unit is placed on rehabilitation and restoration of functional status, despite requirements for prolonged ventilation.

Special patient needs

Special needs of patients who require chronic invasive ventilation include evaluation of the optimum form of ventilator support. In addition, special attention must be paid to swallowing dysfunction, impaired communications skills, psychological dysfunction, optimization of nutrition, respiratory and whole body reconditioning and ever-changing medical conditions (Table 52.3).

Table 52.3 Special needs of chronically ventilated patients.

Need some form of mechanical ventilation or special respiratory treatment device
Patients requiring invasive ventilation require special attention to:
<ul style="list-style-type: none"> • Swallowing dysfunction • Impaired communication skills • Psychological dysfunction
Renutrition
Respiratory and whole body reconditioning
Close attention to new or changing medical conditions

Table 52.4 Psychological dysfunction in ventilator-dependent patients.

<i>Intensive care unit (ICU) environmental factors</i>
Monotonous, meaningless sensory input (e.g. alarms)
Sensory deprivation
Sleep deprivation
<i>Factors associated with mechanical ventilation</i>
Hypoxaemia, illness, medication-induced short-term memory loss
Most report that inability to communicate is most important factor contributing to fear, or inability to rest or sleep
Lack of normal bodily function (e.g. eating, social interaction, ambulation)

In an effort to improve patient mobility and facilitate whole body rehabilitation, patients are transferred to a portable mechanical ventilator shortly after their admission to the unit. This enables patients not only to maximize their functional capabilities, but also to accustom those who require chronic intermittent or home mechanical ventilation to adjust their ventilator settings and receive instructions in its use if eventual home discharge with ventilation is required. In all cases, based on the underlying pathology causing respiratory failure, patients are evaluated for transition to nocturnal invasive ventilation or to the use of non-invasive ventilation.

Psychological dysfunction is an important issue in patients who receive chronic ventilation (Table 52.4). This is caused by a number of factors related to permanence in ICU, such as continuous input of monotonous sensory input from multiple audio alarms, sensory deprivation afforded by the sterile visual environment of an ICU and, finally, sleep deprivation – a significant and common finding in an ICU setting. Prior studies have shown that ICU patients are susceptible to sleep deprivation because of multiple factors, including the underlying disease, its severity, the administration of medications and the environment used to treat the disorder. Bentley *et al.* [12] demonstrated that the noise levels in the ICU compared negatively with that of a general medical floor. Furthermore, the noises are substantially greater and sustained throughout a 24-h period, a potentially important factor that could lead to a prolonged state of sleep deprivation while in the ICU. Other factors associated with the use of mechanical ventilation can also contribute to psychological dysfunction (see Table 52.4).

Most patients who survive an episode of respiratory failure requiring mechanical ventilation report that the inability to communicate is one of the single most important factors contributing to fear, or the inability to rest or sleep. Also, a lack of capability to perform normal bodily functions such as eating, talking or ambulation can also

contribute to a feeling of apathy, disorientation and social withdrawal.

In a study previously reported from our unit, Criner and Isaac [13] measured cognitive deficits in 28 consecutive ventilator-dependent patients. A significant number of them (40%) had problems with orientation, long- and short-term memory, language processing and reasoning. It was rare that a patient had no cognitive disorder, and more common that patients had multiple cognitive disorders.

Orientation techniques may be useful in helping to reverse the disorientation that accompanies the process of mechanical ventilation, as well as the environmental issues precipitated by the ICU environment. Visual orientation clues include large clocks, calendars and also a daily care plan, with personal effects such as pictures and other family items, and may orientate the patient back into the environment. Also, it has been shown that a nearby window open to the outside provides patients with visual clues such as the time of day and the season of the year, decreasing the incidence of delirium by two-thirds in ICU patients compared with those without visible windows to the outside [14].

Because speech is such an important issue in patients who have been chronically ventilated, attempts should be made to restore verbal communication in patients as soon as possible. At least, patients can communicate by verbal gestures such as mouthing, and if their hands are not impaired by disease, by writing. In a ventilated patient, however, a buccal resonator, electrolarynx or a one-way valve (Passy–Muir valve) worn over a deflated tracheostomy tube in line with the ventilator circuit, or while the patient is spontaneously breathing, can afford self-initiated speech. Patients who can communicate verbally are less likely to be anxious, and thus require less sedation, further fostering participation in rehabilitative efforts and hastening the weaning process.

Swallowing dysfunction is an important issue that faces patients who receive chronic invasive ventilation. We previously demonstrated that, in 35 consecutively ventilated patients receiving prolonged ventilation, swallowing dysfunction was common even in those not having an underlying neurological disease [15]. In that study, 34% of patients showed evidence of aspiration on bedside swallow evaluation, with 83% of them having abnormalities that would predispose them to aspiration of oropharyngeal contents on modified barium swallow using three different textures of barium (liquid, semi-solid and solid). The abnormalities in swallowing observed on bedside examination, or during the modified barium swallow, are shown in Tables 52.5 and 52.6.

In some patients who are unable to travel to a radiology suite to have a modified barium swallow, bedside fiberoptic endoscopic evaluation of swallowing (FEES) while patients are fed liquid, solid or semi-solid substances can provide

Table 52.5 Abnormalities found on bedside examination. (From Tolep *et al.* [15], with permission.)

useful information. After local anaesthesia of the nares, glottic examination using a laryngoscope or paediatric bronchoscope can determine whether there is decreased sensation of the oropharyngeal region, oedema of the arytenoids or larynx, pooling of secretions above the vocal cords, normal movement of the vocal cords, problems with premature spillage of oropharyngeal contents into the glottis or gross aspiration.

At our centre, patients who receive prolonged invasive ventilation are not allowed any oral intake until jointly evaluated by the speech therapist and pulmonologist at a bedside examination. Fiberoptic endoscopic evaluation of swallowing or modified barium swallow with videofluoroscopy is used to evaluate swallowing function. The oropharyngeal and hypopharyngeal stages of swallowing with liquid, semi-solid and solid food textures are comprehensively

evaluated, and rehabilitative techniques are developed as needed to minimize aspiration.

In some chronic ventilated patients, inspiratory muscle training may have a significant impact. At our institution, when patients are able to tolerate tracheal collar or T-piece weaning for at least 2 h/day, they begin inspiratory muscle training with an inspiratory muscle trainer; the load of which is placed at one-third of the maximum inspiratory pressure. The duration of breathing against the load is progressively increased to 15 min twice daily. The load and duration of inspiratory muscle training is then increased as the patient's tolerance increases. In a report by Aldrich *et al.* [16], inspiratory resistive training was used in 27 consecutive patients, ventilated for longer than 3 weeks. In the group as a whole, increases in maximum inspiratory pressure and vital capacity were observed. Patients who successfully underwent respiratory muscle training had a higher partial or total weaning rate than those who could not be trained. Inspiratory muscle training in chronically ventilated patients has not been studied in a prospective randomized controlled way. Most of the data suggest that patients with chronic respiratory failure suffer from respiratory muscle weakness rather than respiratory muscle fatigue, and that respiratory muscle training may have a reconditioning effort on restoring respiratory muscle strength and enhancing the patient's ability to wean from mechanical ventilation.

Besides inspiratory muscle training, focus is also placed on training the large groups of accessory inspiratory muscles of the chest wall, including the pectoralis, trapezius and serratus anterior muscles, which may act as accessory muscles of respiration. Several investigators [17–19], as shown in Table 52.7, have shown an increase in ventilatory muscle endurance, an increase in maximum inspiratory pressure and increased ability to cough after training the pectoralis muscles in normal individuals, cystic fibrosis patients or low tetraplegic patients. Although training the upper extremity muscles has not been validated in a perspective randomized controlled fashion, in chronic ventilator-dependent patients, it appears logical that strengthening and reconditioning skeletal muscles used as either primary or accessory muscles of ventilation may have a significant beneficial impact in those patients who suffer from chronic respiratory failure. As a result, patients admitted to our institution for chronic invasive ventilation have as part of their rehabilitative approach, upper extremity strengthening exercise performed to facilitate the inspiratory and expiratory actions of the pectoralis muscles, as well as improving the respiratory actions of other neck and chest wall muscle groups.

We believe that a multidisciplinary systematic approach to the global reconditioning of patients on prolonged mechanical ventilation will not only have a positive impact

Table 52.7 Effect of upper extremity training on ventilatory muscle strength and endurance.

Author/year [Ref.]	Subject	Results
Keens <i>et al.</i> 1977 [17]	Cystic fibrosis ($n = 7$)	57% increase in ventilatory muscle endurance
Clanton <i>et al.</i> 1987 [18]	Female swimmers ($n = 16$)	25% increase in MIP, 100% in ventilatory endurance
Estenne <i>et al.</i> 1989 [19]	C ₁ -C ₈ quads ($n = 6$)	6 weeks of isometric pectoralis major training, increased ERV by 47%

ERV, expiratory reserve volume; MIP, maximum inspiratory pressure.

on improving function status and facilitate weaning from mechanical ventilation, but it also can have an important effect on the perception of patients and families about the care delivered while they receive chronic mechanical ventilation.

In one study, we measured the perception in patients and families about care delivered to the same group of patients cared for by the same team of pulmonary and critical care physicians in the ICU compared with the non-invasive respiratory care unit [20]. Interestingly, patients and families perceived the cognitive impairment (efforts to wean the patient) was less, and patient encouragement was greater in the Ventilator Rehabilitation Unit compared with the ICU. This had nothing to do with the change in the patient's severity of illness or change in the approach by the doctors, but was predominately related to the change in focus of care towards the patient as a whole, and that the environment of a non-invasive respiratory care unit was more conducive to rehabilitative efforts than the acutely intensive and chaotic environment of the ICU.

Data examining the outcome of patients who survive prolonged mechanical ventilation is limited, and there are many questions regarding the cost of care, their morbidity and mortality, and whether their quality of life is acceptable. We have recently reported on 25 consecutive patients who survived long-term invasive mechanical ventilation, and solicited information regarding their quality of life 18 months post-discharge from our non-invasive respiratory care unit [21]. Overall, we found that using Short Form 36 (SF-36) Sickness Impact Scores as a measure of quality of life, these patients were comparable to those patients suffering from hypothyroidism or rheumatoid arthritis, and substantially better than those who had chronic diseases such as COPD. Overall, the long-term survivors had satisfactory performance in the physical, psychological and social interaction domains of the SF-36 measures of quality of life. These data, although limited, suggest that patients who survive long-term invasive ventilation achieve a good quality of life that makes worthwhile the extraordinary efforts that they, their families and the staff made in their care during the period of prolonged mechanical ventilation.

Conclusions

Patients who require prolonged invasive mechanical ventilation pose a unique set of circumstances to the pulmonary and critical care practitioner. This requires a delineation of the primary cause for respiratory failure and, in most cases, a comprehensive multidisciplinary approach to the management of not only the primary disturbance causing respiratory failure, but the consequences that immobility, illness and prolonged ventilation have on swallowing and ambulatory function, psychosocial interaction and the ability to wean from mechanical ventilation.

The development of multidisciplinary rehabilitative units for patients requiring prolonged mechanical ventilation have showed not only a reduction in hospital costs and lengths of stay, but also an improvement in patient survival, functional status, reduction in ventilator days or need for mechanical ventilation at discharge and, overall, the achievement of a satisfactory quality of life.

CHAPTER 53

Smoking cessation

Philip Tønnesen

Smoking cessation is a main intervention area in COPD in all stages. As stated in the GOLD guidelines: 'Smoking cessation is the single most effective – and cost-effective – intervention to reduce the risk of developing COPD and stop its progression (Evidence A)' [1].

However, for many years the intervention in this area had a low priority. This was likely because of clinicians' lack of knowledge that cigarette smoking results from an addiction to nicotine, combined with lack of skills in the area of smoking cessation. In addition, some clinicians adopted an unprofessional attitude towards smokers, blaming or scolding patients in the belief that quitting smoking was only a matter of willpower. Recently, increased attention has focused on both COPD per se and also on smoking cessation. In part, this may be because of the involvement of the pharmaceutical industry through the development of new therapeutic agents for these conditions. Also, several clinical guidelines about smoking cessation have helped focus attention in this area [2–4]. Despite this, relatively little research has focused on smoking cessation specifically in COPD. As a result, current approaches are generally similar to the approach in other smokers. Nevertheless, the major problem in smoking cessation for COPD patients is adequate implementation of current 'state of the art' care in daily clinical practice.

Nicotine receptors and the effect of nicotine

Tobacco dependence is a complex behaviour with both environmental and genetic influences. From twin studies, a substantial genetic component (approximately 50%) has been estimated [5]. The enzyme CYP 2A6 metabolizes nicotine to cotinine and smokers with a defective variant metabolize nicotine more slowly and exhibit reduced smoking.

Other candidate genes that affect smoking have been suggested, but inconsistent data exist regarding the effect of subgroups of dopamine receptors and function on the likelihood of initiation of smoking and nicotine dependence.

Nicotine acts on specific nicotine acetylcholine receptors, which consist of α - and β -subunits. In the brain, nicotine receptors are distributed in the mesolimbic system with particularly high density in the nucleus accumbens where nicotine augments the release of dopamine. Nicotine potentiation of neuronal dopamine release requires the β_2 -subunit of the nicotine receptor. Mice lacking this subunit will not self-administer nicotine, supporting the concept of the increase in dopamine release associated with the acute rewarding effect of nicotine [6].

However, noradrenaline, acetylcholine, serotonin, glutamate, γ -aminobutyric acid and opioid peptide release are also affected by nicotine and these other mediators may also have a role in nicotine addiction [7]. Chronic smoking leads to an up-regulation of nicotine receptors which are also distributed in the prefrontal cortex and outside the central nervous system (CNS). Nicotine has peripheral actions, via nicotine receptors, that include release of adrenaline and stimulation of the carotid and aortic bodies with a slight increase in blood pressure and heart rate, tachypnoea and increased intestinal peristalsis. Nausea results from CNS stimulation. A lethal single dose of nicotine is approximately 60 mg and nicotine intoxication leads to central stimulation, respiratory paralysis and circulatory collapse.

Basic elements in smoking cessation

Cigarette smoking is a complex habit with nicotine dependence as the main component; however, psychological factors and habituation also have a role. Nicotine dependence is most often assessed by the use of a paper and pencil

Table 53.1 Fagerström Test for Nicotine Dependence (FTND) [8].

Item	Answers	Score
1 How soon after you wake up do you smoke your first cigarette?	Within 5 min	3
	6–30 min	2
	31–60 min	1
	61+	0
2 Do you find it difficult to refrain from smoking in places where it is forbidden (e.g. in church, at the library, in the cinema)?	Yes	1
	No	0
3 Which cigarette would you hate most to give up?	The first one in the morning	1
	All others	0
4 How many cigarettes per day do you smoke?	1–10	0
	11–20	1
	21–30	2
	31 or more	3
5 Do you smoke more frequently during the first hours after waking than during the rest of the day?	Yes	1
	No	0
6 Do you smoke if you are so ill that you are in bed most of the day (or absent from work)?	Yes	1
	No	0
	<i>Total score</i>	<i>0–10</i>

questionnaire (i.e. the Fagerström Test for Nicotine Dependence [FTND]) with a possible score from 0 to 10, where 6–10 reflects high nicotine dependence (Table 53.1) [8]. The most important of the seven questions seems to be ‘Smoking within 30 minutes after awakening in the morning’ corresponding to a low plasma nicotine concentration at that time.

Approximately 4–8 h after quitting smoking, varying degrees of withdrawal symptoms appear including irritability, anxiety, restlessness, difficulty in concentration, depressed mood, increased appetite and craving for cigarettes. These peak in intensity after 1 week and then decline over several weeks to months [9,10].

The relapse rate for smokers following cessation is very similar to that for alcoholics and heroin users following abstinence. Relapse is highest during the first 3–6 weeks and then gradually declines (Fig. 53.1) [11]. This emphasizes the importance of support during the first few weeks after a quit day and that it is crucial the patient does not underdose nicotine replacement therapy (NRT) in the initial period after the quit date.

To accomplish this, a test period of NRT a few days before the quit day might help smokers become more familiar with how to use the NRT product. Underdosing of NRT is

**Figure 53.1** The classic relapse curve in addictive disorders such as cigarette smoking. (After Hughes [11].)

most often the case even in trials where the NRT is free of charge. Use of nicotine gum, inhaler or sublingual tablets on a fixed schedule (once or twice per hour) during the first 6–8 h of the day might increase nicotine substitution and enhance efficacy.

Support for smoking cessation should address the following elements: the use of pharmacological smoking cessation agents, handling of withdrawal symptoms, relapse prevention, weight gain and the benefits of quitting cigarettes. For many long-term COPD smokers, the first months after quitting is particularly hard and many miss the relaxing effect of smoking. The cigarette has been a friend for many years that the smoker will miss, and he or she will have to fight the withdrawal symptoms. In this situation, it is important for the clinician to have a supportive, positive and emphatic attitude to reinforce the quitter's motivation to stay abstinent.

The intensity of support provided to the smoker making a quit attempt will vary for many reasons. However, there is a dose–response effect of the time of each session and the number of sessions, and success rate increases with the intensity of intervention (Table 53.2) [2].

Table 53.2 Intensity of intervention from Clinical Practice Guideline, *Treating Tobacco Use and Dependence* [2]. Based on meta-analysis ($n = 45$ studies).

Minimal (< 3 min) is effective (A) [1-year quit rate: No contact: 11%; < 3 min: 13%]
Dose–response effect (person-to-person) (A) [1-year quit rate: < 3 min: 13%; > 10 min: 22%]
Four or more sessions especially effective (A) [1-year quit rate: 0–1 sessions: 12%; 4–8 sessions: 21%]

The treatment for smoking cessation consists of two elements: a pharmacological agent – NRT or bupropion SR (amfebutamone) – for 3 months which suppresses the withdrawal symptoms, thus allowing the subject to cope with the behavioural and psychological aspects of smoking; and a behavioural component consisting of advice, support and follow-up.

One of the most basic and important ‘rules’ is a complete abstinence from cigarettes from the quit day and avoidance of smoking even a single cigarette during the following 2 weeks. Consumption of only a few cigarettes in this period is predictive of relapse. In the CEASE study enrolling 3575 healthy smokers in 37 lung clinics in Europe, the 1-year success rate in subjects who smoked a few cigarettes during the first 2 weeks was 3% compared with 25% in subjects who were abstinent during the initial period [12].

Identification of the smoking COPD patient

To implement a smoking cessation programme in the individual chest unit it is important that the manager/chair of the department support the idea and allocate the necessary resources. Smoking cessation in the chest unit – inpatient or outpatient department – is best achieved with a team approach where all clinicians work together to potentiate the effect of intervention, as different types of clinician seem to be more efficacious in promoting smoking cessation than a single clinician type [2]. Another important element is the prescription of NRT or bupropion SR (Table 53.3).

Results from nine studies showed that the estimated intervention rate by clinicians with their patients who smoke increased from 39% to 66% with a screening system in place to identify smoking status [2]. Different systems have been used to increase identification rate. Stickers in nursing notes and/or in patient medical files can be useful.

Table 53.3 Smoking cessation in the chest unit for COPD patients.

Smoke-free units
Teamwork between different types of clinicians
Systematic identification of smokers
Strong advice to quit from physician
Smoking cessation counsellors
NRT and bupropion SR free of charge
Carbon monoxide assessments
Tobacco habits in medical file
Follow-up: clinic visits

NRT, nicotine replacement therapy.

Table 53.4 Example of medical file for smoking habits.

History	Action to be taken
Tobacco: never smoker	
Ex-smoker	Do not start (again)
Quit since: ___/___/___	Stop here
_____ cig./day	Advise to quit: yes/no
Pack-years: _____	NRT: dose/duration
Motivation to quit: no/maybe/yes	Bupropion SR: dose/duration
FTND-1: (0–3): ___	Prescribe counselling
CO: ___ ppm (<6–10)	Brochure (diff. choices)
	Follow-up: visit/letter/phone/nurse/etc.

CO, carbon monoxide; FTND, Fagerström Test for Nicotine Dependence; NRT, nicotine replacement therapy.

Table 53.5 Proposal for accreditation standard for carbon monoxide assessment.

Standards	Specifications
Carbon monoxide air	1 app. per unit
Instruction for use	In national language
Training of staff	One responsible
Calibration	Every 3 months/log book
False-positive	Lactose malabsorption
False-negative	Too short breath holding/cut-off too high
A-puncture	Severe COPD/cut-off?
Cut-off for smokers	6–10 ppm

Routine inclusion of smoking habits in all patient medical files is another way of emphasizing the importance of this area (Table 53.4). It is important that one person have the responsibility for the smoking cessation programme when first implemented. Accreditation standards for smoking cessation programmes that include all elements required might facilitate programme implementation. An example of such an accreditation standard is the one proposed for the assessment of carbon monoxide (CO) in Table 53.5.

Verification of smoking status

The patient’s report of smoking status combined with a biochemical verification of smoking status (CO and/or cotinine) is the usual way to confirm abstinence. A detailed history of smoking should be obtained: age when smoking started, number of cigarettes smoked per day, pack-years ([cigarettes per day × years, which may not be constant

over the smoking history] : 20), prior quit attempts, prior use and effect of NRT and/or bupropion SR, motivation to quit, measure of nicotine dependency (question 1 in FTND: How soon after you wake do you smoke: within 5 min (3), within 6–30 min (2), within 31–60 min (1), later (0)) (Table 53.1). During examination of the patient, the smell of tobacco smoke in clothes, hair or skin, and yellow fingertips as well as a cigarette box is indicative of recent smoking.

CO is a product of combustion, and smokers have elevated levels of CO in both blood and expiratory air, while subjects using smokeless tobacco and/or NRT have levels indicative of non-smoking. The plasma half-life of CO is approximately 2 h during activity and 8 h during sleep. The CO level in expired air is 1–4 ppm in most non-smokers compared with 15–25 ppm in regular smokers, with a parallel increase in CO levels with increasing cigarette consumption. Through exposure to environmental tobacco smoke (ETS), non-smokers can attain expiratory CO levels of 6–9 ppm [13] and the cut-off between non-smokers and smokers is 8–10 ppm in most smoking cessation studies.

The correlation between arterial blood CO levels and expiratory air CO levels is high but in more severe COPD patients with decreased diffusion capacity, expiratory air CO might underestimate the blood levels and in light smokers, smoking 3–6 cigarettes daily, CO levels might be below 10 ppm.

The portable CO analyser is a relative simple, cheap and quick method to assess the CO level in expiratory air. It is important to hold the breath for 15–20 s to attain equilibrium between capillary and alveolar CO levels. The result is displayed immediately. False-positive values may be observed in subjects with lactose malabsorption and although an ethanol filter is present, high concentrations of ethanol in the breath may interfere with measurements. Drifting of the zero point may be observed if many smokers are tested consecutively. Calibration of the CO analyser is indicated every 3 months with a 50 ppm CO test gas. Without CO monitoring, approximately 10% of relapsers may state that they do not smoke.

Whenever an arterial blood sample is obtained in COPD patients on long-term oxygen therapy (LTOT), the CO level should also be analysed to identify smokers. Such individuals should be encouraged to stop smoking and should be specifically warned of the risk of fire.

The mean baseline expiratory air CO level in the CEASE study was 27 ppm (mean), (SD, 10 ppm) in 3575 smokers with a mean consumption of 27 cigarettes/day (SD, 10 ppm), all smokers consuming >14 cigarettes/day [12]. In an Italian study of 550 consecutive patients with COPD and 100 patients on LTOT, arterial carboxyhaemoglobin was more than 2% (= 10 ppm) in 26% of the 550 COPD patients and in 21% of the patients on LTOT who smoked [14].

Plasma, saliva or urinary nicotine can be used to determine smoking status when taken in the afternoon; however, because of its short half-life of 2 h its not useful in assessing smoking more than 8–12 h previously. Cotinine, the major metabolite of nicotine with a half-life of 16–36 h, has a high specificity for tobacco use with a cut-off level indicating smoking of 15 ng/mL in saliva and plasma and 50 ng/mL in urine, if the patient does not use NRT.

Thiocyanate, with a half-life of 3–14 days, is a reasonable biomarker for heavy smoking, but is not good for detecting light smoking because of the contribution from dietary sources. The cut-off level of 78–88 $\mu\text{mol/L}$ in plasma is commonly used [15].

Treatment

Figure 53.2 is a flow diagram for the management of the individual smoking COPD patient. All smoking COPD patients should be advised to quit smoking by the physician and the message should be repeated on subsequent visits and the advice to quit should be personalized and related to the individual patient (degree of reduced lung function, daily respiratory symptoms, other smoking-related risk factors). The advice to quit should be given independently of the smoker's motivation to quit.

If the smoker wants to quit, a target quit day should be set. If the patient is hospitalized – this should be regarded

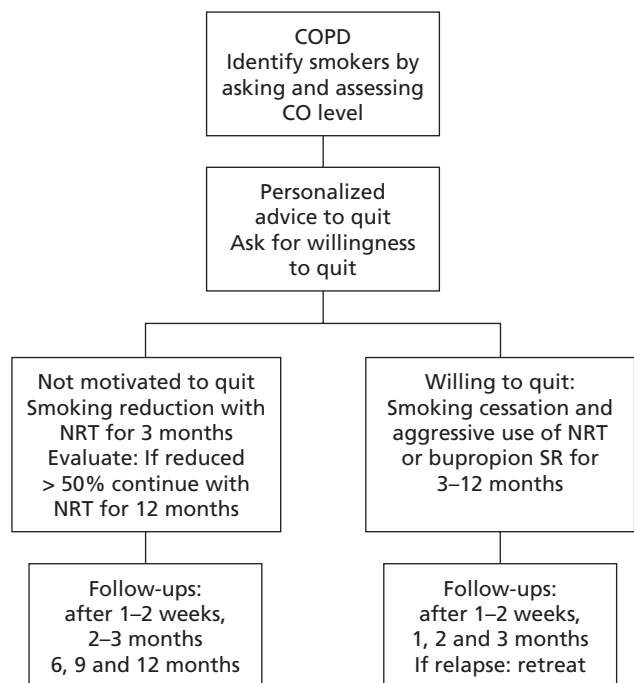

Figure 53.2 Handling of smoking in COPD patients. CO, carbon monoxide; NRT, nicotine replacement therapy.

as a window of opportunity – and a quit attempt should be started at once, irrespective of the patient's motivation to quit. Smoke-free units facilitate this process and should be implemented worldwide.

Nicotine replacement therapy

Nicotine is liberated from the acid cigarette smoke as a gas, inhaled to the lungs, transferred via the alveoli to the blood and is measurable in the brain in less than 8 s after inhalation. All the nicotine products that are used for the purpose of smoking cessation are absorbed through the skin or mucous membranes. The delivery of nicotine by these routes is much slower than by inhalation, and does not give the quick plasma concentration as does cigarette smoking. In addition, acidification of the mouth (e.g. by acidic food or beverages), by increasing the fraction of nicotine that is ionized, will further decrease absorption of oral formulations. Six hours after a 21-mg transdermal patch is applied, the blood level is approximately 10–17 ng/mL, in contrast to approximately 15–25 ng/mL within minutes after a cigarette [16].

The rapid absorption from cigarette smoke results in a transient high blood concentration. This has a greater psychoactive effect and likely biological effect that reinforces addiction, compared with the equivalent dose of nicotine delivered from gums or patches [17]. Compared with cigarette smoking, NRT produces lower plasma nicotine levels (i.e. one-third to half of the levels attained over several hours) and without the high peak levels. The slower absorption of nicotine from these products does not produce the same cardiovascular stimulation as does nicotine delivered by cigarette smoke [18].

The average 12-month success rate reported in most smoking cessation studies is approximately 15–25% [2].

The efficacy of NRT from a Cochrane meta-analysis reported an odds ratio for success of NRT compared with controls of 1.73 (95% CI, 1.62–1.85), with no statistical differences across the different formulations (Table 53.6) [19].

Nicotine transdermal patch

Absorption of nicotine from the transdermal nicotine patch is approximately 1 mg/h nicotine for 16 h (daytime patch) or for 24 h (24-h patch). Nicotine substitution is approximately 50% of the smoking level (21-mg patch/24 h and 15-mg patch/16 h) [16]. It is much easier to administer and use the patch than the gum. The recommended treatment duration is 8–12 weeks. Side-effects are mainly self-limited, mild, local skin irritation, occurring in 10–20% of users. A few per cent of subjects will terminate patch use because of more persistent and severe skin irritation in the nicotine

Table 53.6 Meta-analysis of controlled trials with nicotine replacement therapy from The Cochrane Register. Success rates sustained for 1 year [19,37].

<i>NRT versus placebo</i> (108 studies)	1.73 (95% CI, 1.62–1.85)
Nicotine gum	1.66

patch area [17]. Wearing the patch during waking hours (approximately 16 h/day) has been found to be as effective as wearing it for 24 h/day and there is no evidence that tapered therapy is better than abrupt withdrawal.

While the patch is a fixed delivery system, the delivered dose from the gum, inhaler, nasal spray and lozenge is dependent on the frequency of dosing. A basic advantage of these four products is the ability to self-titrate the dose as opposed to the patch, which delivers a fixed dose. Thus, it is possible to administer a dose whenever needed during the day; however, the principal disadvantage is potential underdosing. These products may also replace some of the habit patterns associated with smoking (e.g. handling reinforcement) along with providing nicotine replacement.

Nicotine chewing gum

With the use of nicotine gum throughout the day, blood levels of approximately one-third (for 2-mg gum) and two-thirds (for 4-mg gum) of the nicotine obtained through smoking are achieved.

In most studies the gum has been used for at least 6–12 weeks and, in some, up to 1 year, but individualization of treatment duration is recommended. As many as 10% of successful quitters still use the gum after 12 months [20–22]. While controversial, many believe that this long-term substitution of gum has fewer health risks than continued smoking.

Instruction in gum use is very important to increase effectiveness and adherence to therapy. Gum users should chew a piece of gum only 5–10 times until they can taste the nicotine. At that point, they should then let the gum rest in the cheek for a few minutes, while the nicotine is absorbed. This occurs through the buccal mucosa, and swallowing should be avoided. After this, they can chew again to expose a new surface of the gum, which will

release more nicotine. Overexuberant chewing may release too much nicotine, which may be swallowed and may contribute to gastric side-effects. The gum can be chewed for approximately 20–30 min and, with proper use, approximately 0.8–1.0 mg nicotine is absorbed from a piece of 2-mg nicotine gum and 1.2–1.4 mg nicotine from a 4-mg piece. The principal disadvantage of gum use is potential underdosing, which might explain the lack of effect in several trials. Programmes with more intense counselling generally get better results with the gum, perhaps because these programmes include training in its use. The approximate dose equivalent with most nicotine patches is approximately 20 pieces of 2-mg gum, whereas the mean number of pieces of gum used daily is only around 5–6 in most studies, consistent with the general underdosing of the gum.

Side-effects of the gum consist mainly of mild, transient, local symptoms in the mouth, throat and stomach due to swallowed nicotine (e.g. nausea, vomiting, indigestion and hiccups). After adequate instruction most smokers can learn to use the gum properly but without instructions many will discontinue use or underdose themselves.

In the Lung Health Study, among 3094 smokers who were followed for 5 years, the use of the 2-mg gum appeared safe and did not produce cardiovascular problems or other adverse events even in subjects who continued to smoke and still used nicotine gum [23].

It is suggested that smokers be instructed to use the nicotine gum on a fixed schedule (e.g. every hour, from early morning, for at least 8–10 h) and use extra pieces of gum whenever needed.

Nicotine inhaler

An inhaler consists of a mouthpiece and a plastic tube with a porous plug impregnated with nicotine, which releases nicotine vapour when air is drawn through the plug. Most of the nicotine released by this device is absorbed through the mucosa of the mouth and throat. Very little of the nicotine is contained in particles of sufficient size to be inhaled into the lung. Each inhaler contains 10 mg nicotine and can release approximately 4–5 mg nicotine. In clinical use, each inhaler releases approximately 2–3 mg nicotine and the number of inhalers used daily averages 5–6. Thus, nicotine levels comparable with those found with use of the 2-mg nicotine gum are attainable (i.e. relatively low concentrations are achieved).

The inhaler may replace some of the habit patterns associated with smoking (e.g. oral and handling reinforcement) along with providing nicotine replacement. Current recommendations suggest at least four inhalers should be used per day, with the goal being 4–10 per day. The duration of use is generally 3 months with another 3 months of downtitration if needed. With rapid and frequent puffing

it is possible to increase the delivered dose of nicotine. It has been suggested that the number of puffs on the inhaler should be around 10 times that of the usual puffing on a cigarette to get a similar amount of nicotine.

The efficacy of the inhaler in clinical trials is in the same range as the other NRT products [24–27].

Nicotine lozenge (sublingual tablet)

One to two sublingual tablets should be placed under the tongue where they will disintegrate within 20–30 min. The free nicotine released from the tablets will be absorbed through the oral mucous membrane. The dose delivered from the tablet is comparable with the 2-mg nicotine chewing gum. One tablet per hour is the recommended dosage, up to 20 per day (i.e. up to 2 tablets per hour). In highly dependent subjects, a maximum dose up to 40 tablets per day can be used. Swallowing results in delivery of nicotine to the stomach, which can cause side-effects but does not contribute to efficacy. Mild transient side-effects include hiccups, nausea and dyspepsia, and gingival bleeding. The tablets should be used for up to 3 months. The dosage is 8–20 (40) tablets per day or 1–2 tablets per hour, depending on withdrawal symptoms and craving [28].

Nicotine nasal spray

Nicotine nasal spray is an aqueous solution of nicotine (10 mg/mL) that delivers 0.5 mg nicotine per actuation [2]. When sprayed in the nose, nicotine is absorbed across the nasal mucosa, with peak blood levels being achieved in approximately 10 min. This delivery is much more rapid than that of other forms of NRT. In clinical trials, however, cessation rates are comparable with other NRT trials, with quit rates about double that of placebo. Side-effects include nasal irritation, which may be severe and is extremely common. The usual regimen is two actuations per dose (1 mg total) once or twice per hour, with a maximum total dosage of 40 mg/day.

Combination of NRT products and dose–response effects

There is conflicting evidence regarding the efficacy of the combination of two different nicotine products. In some studies the use of combinations has increased short-term cessation rates, but there is no consistent evidence of a long-term effect [19]. However, available data suggest that combinations can be used safely without symptoms of nicotine overdose such as weakness, nausea, sweating, palpitations and diarrhoea.

A small dose–response effect has been observed with the nicotine gum and patch. For highly nicotine-dependent

Table 53.7 Suggestions for use of four different nicotine replacement products.

	Patch	Gum	Inhaler	Lozenge
Absorption	Skin	Mouth	Mouth, throat	Mouth
Principle*	Fixed	Ad lib	Ad lib	Ad lib
Daily dose	1 patch 15–25 mg	1 piece/h 10–20 mg	6–10, 10–15 mg	8–20 tablets, 16–40 mg
Dose per piece	15 mg/16 h, 21 mg/24 h	2/4 mg	10 mg	1 mg/2 mg
Delivered dose	15 or 21 mg	0.8/1.4 mg	3–5 mg	0.8–1.0 mg
Duration of use	3 months	3 months (12 months)	3 months (6 months)	3 months (6 months)
Side-effects	Skin irritation	Hiccups, irritation in mouth, dyspepsia	Irritation in throat	Irritation in mouth, hiccups, dyspepsia
Precautions	Eczema	Dentures	Pharyngitis	Oral disease
Low dependency	+++	+++	+++	++
High dependency	+	+++	++	++

Combination treatment: patch plus either gum/inhaler or lozenge.
 Long-term treatment or relapse situations: gum, inhaler or lozenge.
 High-dependent subjects: patch 25 mg/16 h or 21 mg/24 h; 4 mg gum.
 * Nicotine 'infusion' through the skin is constant with the patch.

smokers, 4-mg nicotine gum has been shown to result in a higher success rate than the 2-mg gum.

In subjects who relapse, repeated treatment should be undertaken at the earliest appropriate occasion. The success rate seems higher for subjects who had tried to quit previously without nicotine products, but most smokers achieve long-term abstinence only after several attempts.

In the Lung Health Study, where 3000 subjects were exposed to nicotine gum for up to 5 years, the concomitant use of cigarettes and NRT appeared to be safe and unrelated to any cardiovascular illness or other serious side-effects [23].

Thus, the current recommendation is to use one NRT product in most smokers. In the heavily dependent smoker, a combination of the patch with gum, inhaler or lozenge can be tried.

If the smoker has not tried NRT before, initial use of the patch is reasonable. First, it is easier for the patient and the physician. Secondly, self-selection of an NRT product does not increase success rate. If a patient has tried one of the NRT products earlier, a reasonable recommendation would be to try bupropion SR (see below) or another NRT product (Table 53.7). A test period with NRT for a few days before the target quit day to habituate the patient to the product might facilitate adequate initial dosing, which is important for success.

Effect of support

The effect of intensity of support is shown in Table 53.8. Three studies with a more intensive supportive programme

Table 53.8 Intensive group therapy or low intervention combined with nicotine replacement therapy or placebo. Continuous 12-month success rates. (Data from Hjalmarson *et al.* [25,29,30] and Tønnesen *et al.* [24,31,32].)

<i>Intensive support (Hjalmarson)</i>		<i>Intensive support (Hjalmarson)</i>	
Gum	29%	Placebo	16%
Nasal spray	27%	Placebo	15%
Inhaler	28%	Placebo	18%
<i>Low support (Tønnesen)</i>		<i>Low support (Tønnesen)</i>	
Inhaler	15%	Placebo	5%
Patch	17%	Placebo	4%
Bupropion SR	21%	Placebo	11%

with weekly group meetings showed high continuous success rates in both active NRT and placebo groups. In contrast, two other NRT studies with lower support but a very similar design reported much lower success rates, although the relative effect of NRT versus placebo was maintained [24,25,29–31]. The support in the bupropion SR study is moderate as are the success rates (Table 53.8) [32]. A meta-analysis evaluating behavioural interventions does not suggest that group therapy is more effective than individual counselling, but the total contact time per patient may be higher during group treatment [2].

Hypnosis and acupuncture have not proven to be of any effect in smoking cessation.

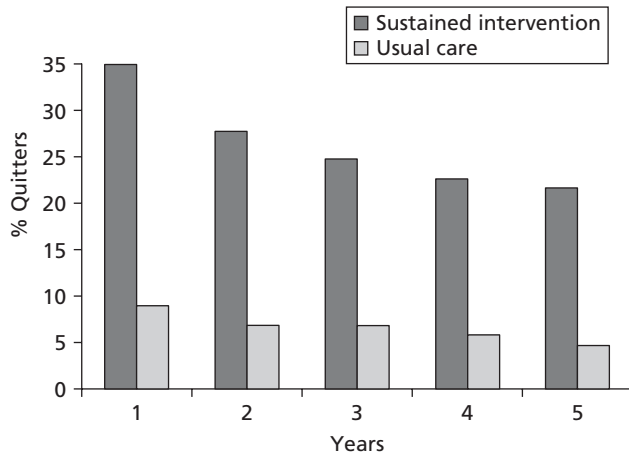

Figure 53.3 Lung Health Study: sustained abstinence ($n = 5587$.) (Data from Anthonisen *et al.* [33].)

Figure 53.4 Lung Health Study: point prevalence ($n = 5587$) (Data from Anthonisen *et al.* [33].)

Lung Health Study I

The Lung Health Study I was a multicentre randomized study evaluating the rate of decline of lung function. It compared the effect of a smoking intervention versus usual care and also tested an inhaled anticholinergic bronchodilator or placebo. The study enrolled a total of 5887 subjects with mild COPD: a mean forced expiratory volume in 1 s (FEV_1) of 75% predicted (2.7 L [SD, 0.6 L]). They had a mean age of 48 years, with a smoking history of 40 pack-years [33]. During the first 3 months, an intensive 12-session smoking cessation programme took place, with the use of nicotine chewing gum plus adjunctive behavioural modification, with a relapse prevention programme every 4 months for 5 years. At entry, strong physician advice to quit was given, and a target-quit day was set. Two milligram nicotine gum was used aggressively.

The sustained quit rate was high in the intervention group and declined as usual over the years of the study. Continuous abstinence rates in the intervention group were 35% after 1 year, but had declined to 22% after 5 years. These compared with 10% after 1 year and 5% after 5 years in the control group (Fig. 53.3). However, the cross-sectional quit rate increased slightly during the 5 years of the study to 39% in the intervention group and 22% in the control group (Fig. 53.4). This supports the importance of subsequent quit attempts.

A major finding of the Lung Health Study I was that smoking cessation significantly reduced the age-related decline in FEV_1 . The change in FEV_1 was -72 mL over 5 years for sustained quitters and -301 mL over 5 years for continuing smokers. Follow-up after 11 years showed that 22% (odds ratio [OR] = 4.45) of the subjects assigned to the inter-

vention group maintained abstinence versus only 6% in the control group [34].

Overall, this large well-conducted study showed that aggressive and intensive smoking cessation programmes can produce high long-term quit rates in smokers with mild airway obstruction. Also, the improvement in the rate of the decline of FEV_1 supports the concept that smoking cessation is the first and most important intervention in smokers with mild COPD.

Bupropion SR

Bupropion SR (Zyban®, GlaxoWellcome) is an older antidepressant drug – an amino-ketone agent – with an inhibitory effect on noradrenaline and dopamine reuptake. In addition, it may also have direct effects on nicotine receptors. However, the exact mechanism by which bupropion SR aids in smoking cessation is not known.

Bupropion SR for 7–12 weeks is more effective than placebo. When combined with moderate behavioural support (weekly clinic visits during the first 7 weeks and follow-up), a 1-year sustained quit rate of 18–25% was observed for bupropion SR and 10% for placebo [35,36]. A meta-analysis of 16 studies found OR 1.97 (95% CI, 1.7–2.3) for 1-year success rate for active versus placebo therapy. This efficacy is in accordance with the success rates found in many studies with NRT that provided support in the same range. Thus, bupropion SR and NRT seem to be equally effective for smoking cessation (Table 53.6) [37]. Although when used for 1 year bupropion SR prolongs time to relapse, this difference in continuous abstinence rate was not significant from week 36 through to month 24 [38]. Thus, 7–12 weeks' treatment with bupropion

SR seems an adequate treatment duration for smoking cessation, although longer treatment prolongs time to relapse.

The recommended regimen for bupropion SR is 150 mg a.m. for 6 days prior to the quit date, in order to establish adequate brain levels. Therapy should then continue with 150 mg b.i.d. for 7–12 weeks. Success has been achieved in some individuals with a reduced dosage of 150 mg/day.

Although body-weight gain is significantly reduced during the drug treatment period with bupropion SR, this effect is lost after 1–2 years.

Recycling (i.e. repeated treatment with bupropion SR) in smokers treated previously with bupropion SR should be tried as this increased successful outcome in a randomized controlled trial of 450 smokers. In this study of relapsed smokers, a 6-month continuous success rate of 12% was observed for the bupropion SR group and 2% for the placebo group [39].

The most common adverse events from bupropion SR are insomnia (42%) and dry mouth (11%). In clinical trials, in approximately 10–12% of subjects, the treatment was stopped because of adverse events. The most serious adverse event was major motor seizures, which have been reported in 0.1% of patients treated with bupropion SR, and allergic reactions (1–2) with 0.1% of serious cases of hypersensitivity [40].

Bupropion SR is not indicated for individuals with an increased risk of seizures (e.g. epilepsy, history of head trauma, anorexia nervosa). Similarly, it is important not to increase the dose above 300 mg, and to administer the daily dose divided with an interval of at least 8 h. The last dose should not be taken later than 6 p.m. if insomnia is a problem.

In summary, bupropion SR is of similar efficacy to NRT and is generally well tolerated in smoking cessation. It is regarded a first-line medication in some guidelines [2]. As bupropion SR has a more severe side-effect profile, more contraindications and is only available on prescription, NRT is often regarded as first-line medication and bupropion SR as a second-line, although this is a matter of personal judgement. Some physicians who are comfortable with the medication will use bupropion SR as a first-line medication.

As another antidepressant, nortriptyline, has been shown to be effective in smoking cessation, it is not clear if the effect in smoking cessation of these two agents is drug-specific or a class effect. The dosage of nortriptyline in smoking cessation is 75–150 mg/day. However, several other antidepressants including selective serotonin reuptake inhibitors have not been found to be effective in smoking cessation (e.g. doxepin, fluoxetine, sertraline, moclobemide and venlafaxine) [37].

Figure 53.5 Continuous quit rate in COPD patients with bupropion SR (BUP) versus placebo ($n = 404$). * = p -values of 0.002, 0.021, 0.04. (Data from Tashkin *et al.* [41] and Jarvis *et al.* [42].)

Bupropion SR COPD Study

One study has specifically evaluated bupropion SR in COPD patients. In this study, 404 COPD patients (15+ cigarettes per day) in 11 centres in the USA were allocated to bupropion SR for 3 months or placebo in a design that included moderately intensive behavioural support (i.e. 10 visits) with weekly individual sessions during the first 7 weeks (Fig. 53.5) [41]. Most patients had COPD with an $FEV_1 > 50\%$ although 15% had an $FEV_1 < 35$ –49%. Cigarette consumption averaged 28 cigarettes per day and subjects had smoked an average of 52 pack-years. These subjects were relatively highly addicted with an average Fagerström score of 7 (maximal score 11). Abstinence rate was significantly higher at 6 months in the bupropion SR group versus placebo (16 vs 9%). After 1 year the significance was lost with a success rate of 10 vs 8%. These abstinence rates are much lower than those observed in similar studies with bupropion SR in healthy subjects [42], suggesting that COPD patients may be relatively 'hard core'. Nevertheless, the data support use of bupropion SR in this group.

Lung clinic interventions

Two large trials were conducted by the British Thoracic Society (BTS) in the UK in 1983 and 1990. One study comprised 1618 outpatients with respiratory disease attending a chest clinic [43]. Four methods were evaluated: physician advice, plus a booklet, plus placebo gum, and plus 2-mg nicotine chewing gum. The overall 1-year success rate for

the entire population was 9.7% (95% CI, 8.3–11.3%) with no significant differences between the four groups.

The other study included two multicentre trials with outpatients attending hospital or chest clinics [44]. A total of 87% of the enrolled patients suffered from respiratory disease, mainly chronic bronchitis and emphysema.

In study A, the effect of physician advice to stop smoking was compared with the same advice plus a signed agreement to stop smoking by a target quit day plus two visits by a health visitor plus several letters. These two interventions were found to be equally effective. In study B, four groups were compared: physician advice versus advice plus a signed agreement versus advice plus letters versus advice plus letters plus a signed agreement. A signed agreement did not affect outcome but letters increased successful outcome from 5.1% to 8.7%. A secondary stratification and analysis of the two studies combined found that 5% stopped with advice alone; postal encouragement increased the success rate by more than half as much again; and outpatient visits seemed to increase the success rate. In conclusion, physician advice supported by encouraging letters and follow-up was found to be more effective than advice alone in a group of outpatients with respiratory disease.

In the lung clinic of the author, we have observed that minimal intervention (i.e. advice by nurses) increased 1-year quit rates from 3.6% to 8.7% [45] and that a nurse-directed smoking cessation programme which included nicotine patches increased quitting from 6% to 16% [46]. Similar programmes could easily be implemented as routine in most lung clinics.

Weight gain

Weight gain can be regarded as a withdrawal symptom. It occurs in part because of increased hunger and increased caloric intake, but metabolic effects may also have a role. As a result, a weight gain of 4–5 kg for abstainers after 1 year is found in most studies. About half of the participants in smoking cessation studies are specifically afraid of gaining weight, a problem that may be more prominent for females. Both NRT – especially nicotine gum – and bupropion SR can delay post-cessation weight gain. However, when NRT or bupropion SR are stopped, the ex-smoker will eventually end up with a similar weight gain as quitters who had not used medication [19,37].

In the Lung Health Study sustained quitters gained 5.2 kg (women) and 4.9 kg (men) in year 1 and experienced an additional gain of 3.4 kg (women) and 2.6 kg (men) in years 1–5. Over 5 years, 33% of the abstainers gained 10 kg in weight [47]. A weight gain after 3 months of 4.5 kg in men and 3.6 kg in women was found in the study with COPD patients and bupropion SR or placebo [41]. Weight

gain prevention using caffeine plus ephedrine or a serotonergic anorexic drug – difenfluramine – did not increase the success rate for abstinence and, while weight gain was less in the prevention group during active treatment, there were no differences at 1 year [48]. In an open smoking cessation study with 287 females, nicotine gum combined with a behavioural weight control programme including a very low energy diet versus a control group without the diet resulted in an increase in success rate although there was no difference in weight gain after 1 year [49]. Thus, diet intervention and daily exercise might be a way to control excessive weight gain in the long term. For those COPD patients with low body mass index (BMI), this post-cessation weight increase might be an advantage together with increased appetite.

From the Lung Health Study it was reported that the weight gain in sustained quitters had a small negative effect on lung function; a reduction of forced vital capacity (FVC) of 17 mL/kg (men) and 11 mL/kg (women), and for FEV_1 of 11 mL/kg (men) and 6 mL/kg (women), respectively [50], but compared with the beneficial effect of smoking cessation this effect of weight gain is small.

Profile of COPD smokers

Why do COPD smokers achieve a lower success rate in smoking cessation? This might in part be because of selection, as the more motivated and less nicotine-dependent smokers with COPD probably successfully quit smoking when they suffered acute respiratory symptoms or were advised to stop smoking by their physician. In support of this, in a random population sample of smokers, subjects with COPD had a higher nicotine dependence and higher CO levels compared with smokers without COPD [51]. In addition, nearly half of all patients with COPD experience some depressive symptoms and 20% have had at least one major depressive episode. Depression is a predictor of relapse in smoking cessation, and the prevalence of this comorbidity may contribute to the refractoriness of smoking in COPD patients. Finally, there is an overrepresentation of the lower socio-economic classes among COPD patients, who also often have a poor social network and support system. Both lower social class and poor social support are predictors of failure in smoking cessation [52].

Approximately one-third of moderate to severe COPD patients evaluated in many clinical trials are still smoking. In a 1-year study of formoterol/budesonide with 812 COPD patients with a mean FEV_1 of 36% predicted normal, 34% were smokers [53]. In another 3-year study with fluticasone with 391 with mild COPD ($FEV_1 = 1.6$ L), 35% were smokers. Among 359 with severe COPD ($FEV_1 = 1.0$ L), 41% were smokers [54]. This group consists of more heavily

dependent and persistent smokers and is representative of the group of COPD patients with frequent exacerbations and hospitalizations. Anticipated quit rates among these COPD patients would be lower than among healthy self-referred smokers enrolled in most smoking cessation studies.

There are limited data on the efficacy of smoking cessation interventions in COPD patients. Bupropion SR has efficacy in COPD patients compared with placebo, although quit rates are lower than in healthy subjects [41]. In two studies with patients with COPD and cardiovascular diseases, no effect of NRT was found, but NRT was used for an interval that was likely less than optimal (3 weeks and 4–6 weeks, respectively) [55,56].

A meta-analysis of 17 trials of smoking cessation interventions for hospitalized patients showed that ‘intensive intervention’ (inpatient contact plus follow-up for at least a month) was associated with higher quit rates than in controls (OR 1.82; 95% CI, 1.49–2.22, six trials). Results of NRT treatment in this group of patients were compatible with data from other trials, suggesting that NRT increases quit rates [57].

From a review of five smoking cessation studies with COPD patients, two of which were of high quality (see the discussion of the BTS studies above), it was concluded that a combination of psychosocial and pharmacological intervention was superior to no treatment or psychosocial therapy alone [58]. In a recent trial 370 COPD patients were enrolled in a smoking cessation study with low and high support and use of sublingual nicotine of placebo for 12 weeks [59]. They smoked a mean of 19.6 cigarettes/day with a mean of 42.7 pack-years and with a mean FEV_1 of 56% predicted. The 6 and 12 month point-prevalence abstinence rate for nicotine sublingual vs placebo was 23 vs 10% and 17 vs 10%, respectively. This success rate is in the same range as healthy smokers. Quality of life assessed by the *St. Georges’s Respiratory Questionnaire* score improved significantly in abstainers vs non-abstainers; the changes in mean scores were –10.9 vs –2.9 for total score, and –28.6 vs 2.3 for symptom score, respectively. This is the first trial documenting that NRT is also effective in a COPD population.

Smoking reduction

The rationale for smoking reduction is as follows:

- 1 By using this approach it should be possible to recruit a new segment of smokers (i.e. smokers low in motivation to quit).
- 2 It should be possible to induce a permanent change in the smoking habit to maintain the reduced smoking level.
- 3 Compensatory smoking is not 100% so that reduction in smoking will result in reduced toxin exposure.
- 4 This concept will not interfere with smoking cessation.

Figure 53.6 Smoking reduction (patient NN). CO, carbon monoxide.

Four randomized controlled trials used nicotine inhalers and nicotine gum and reported – surprisingly – a smoking cessation rate of approximately 10% after 2 years and a low reduction rate of 6% [60,61]. An example of a smoker who reduced and then quit is shown in Fig. 53.6. Regarding reduction, an analysis of 19 trials reported a reduction in cigarettes per day (CPD) of 25% (8 cigarettes) to 55% (23 cigarettes) in NRT groups compared with 13% (3 cigarettes) to 26% (8 cigarettes) in control groups [62].

However, there is no consistent evidence that smoking reduction per se will be followed by harm reduction. In a prospective population study, self-reported smoking reduction was not associated with lower risk of hospital admission for COPD, while quitting smoking was associated with a relative hazard of 0.57 for hospitalization [63]. In the same population, with a 16-year follow-up it was observed that smoking cessation reduces mortality and morbidity risk while smoking reduction did not [64].

An approach for COPD smokers not motivated to quit could be to prescribe NRT – nicotine gum or inhaler – for 2–3 months and recommended to reduce the number of cigarettes by at least 50% during the first 1–2 weeks and then to try to reduce further, although this concept has only been tested in healthy smokers. If the smoker has not reduced by more than 50% after 3 months NRT should be stopped. The goal is that smoking reduction will motivate this group of recalcitrant smokers to quit during this process.

Another way to attain smoking reduction and reduce the harm of smoking could be through tobacco product modification. The use of such products, however, raises a number of extremely controversial issues [65]. At the present time, there is no evidence supporting health benefits from their use. However, as it is likely that smoking will remain a highly prevalent condition, the development of a less hazardous cigarette might be an advantage. How such a product should be regulated and used will require careful scrutiny.

Research recommendations

There is a strong need to increase our knowledge of the efficacy of NRT and bupropion SR in COPD patients. Long-term treatment that includes combination pharmacotherapy and group therapy might be of special value for the more severe COPD patient with a vulnerable social network. The influence of depression and psychiatric comorbidity on smoking cessation in COPD should be further explored. Correlation between nicotine dependence, motivation to quit and severity of COPD is another unexplored area.

The design of the Lung Health Study needs to be applied in studies enrolling severe COPD patients.

Pathophysiological studies need to be performed in smokers with mild to severe COPD before and after quitting, looking at lung function, inflammatory mediators and pulmonary imaging.

Studies of implementation of smoking cessation programmes in the chest clinic and quality control of this therapy could increase interest in this area. Standards for smoking cessation interventions and formal accreditation of this area might be a way to increase implementation of smoking cessation.

Several new agents for smoking cessation are being tested in clinical trials and these agents should also be tested in the COPD population. Although lower success rates may be observed among COPD patients compared with healthy smokers, knowledge of how these treatments work in special populations is crucial.

Conclusions

In summary, smoking cessation should be an integral part of the treatment of COPD patients. This is clearly stated in the recently published COPD guidelines: all COPD patients still smoking, regardless of age, should be encouraged to stop smoking and offered help with appropriate support to do so at every opportunity [65].

Every chest clinic should be smoke-free and have a teamwork-oriented organization for smoking cessation. As a result, every smoking COPD patient should be identified, advised to quit smoking and, if willing to quit, instructed in the use of NRT or bupropion SR and follow-up for the smoking cessation arranged. Every quit attempt should be given the maximal chance for success. Because both NRT and bupropion SR double long-term success in smoking cessation when used for 3 months, at least one should be used on every attempt.

The programme used in the Lung Health Study with an intensive initial smoking cessation programme with NRT, followed by boosters during subsequent visits, seems to be a

design with a high sustained quit rate in COPD patients. Smoking should be regarded as a chronic relapsing disorder, and it might be necessary to make several cessation attempts before permanent cessation is obtained. The COPD patient should be regarded as a hard-core smoker with the need for more aggressive therapy both with regard to NRT and behavioural support and might be a candidate for long-term NRT substitution.

CHAPTER 54

Oxygen therapy in COPD

Brian Tiep and Rick Carter

Long-term oxygen therapy (LTOT) serves a critical role in the clinical management of patients with advanced lung disease. A map of the multiple considerations for LTOT is presented in Figure 54.1. Clinicians prescribe oxygen to protect the patient from the deleterious effects of tissue hypoxia. In addition, they prescribe it to improve survival, control dyspnoea, enhance exercise performance and maximize functional ability. The survival benefit of LTOT for severe hypoxaemia is well established [1,2]. There does not appear to be a survival benefit for patients with mild to moderate hypoxaemia [3]. However, there are other hypothesized benefits that await confirmation through well-designed clinical trials.

Oxygen for severely hypoxaemic patients appears to reduce hospitalization [4], improve pulmonary haemodynamics [5,6] and enhance psychomotor performance [7–10]. Nocturnal oxygen administration for patients who desaturate but who do not have obstructive sleep apnoea prevents nocturnal desaturations [11]; yet its impact on longevity remains unclear. Oxygen used during exercise prevents exercise-induced desaturation while improving exercise performance; however, its long-term benefits have not been fully defined. Providing oxygen during air travel in patients whose oxygen requirement on the ground is borderline, suggests good clinical judgement within the scope of our present state of knowledge, but its overall protective benefit is not yet known.

It is important to bear in mind that the introduction of oxygen into the lung is only the first of a series of steps that include oxygen transport, uptake and utilization at the cellular level. The movement of oxygen across the alveolar–capillary membrane, haemoglobin uptake and release, cardiovascular dynamics, cell membrane transport and mitochondrial utilization are essential processes of cellular respiration and life. These are also sites of potential barriers to oxygen transport. It is common for clinicians to focus attention on maintenance of arterial oxygen saturation

because the data are easy to obtain, it is non-invasive and provides ongoing monitoring capabilities. However, that perspective should be widened to include haemoglobin and cardiovascular transport, while observing for adequate end-organ function. Therapeutically, aerobic exercise improves the totality of oxygen transport and thus becomes an essential intervention in maintaining cellular oxygenation while maximizing efficiency of the cardiopulmonary and bioenergetic systems.

Exercise imposes a higher metabolic demand, with a corresponding increase in oxygen uptake. In health, the lungs are quite capable of rapidly responding to the increase in metabolic demand and thereby do not impose a limitation to oxygen transport. In severe COPD, there is minimal lung function reserve as a result of the presence of airway obstruction with or without alveolar capillary block. An increase in ventilatory response often leads to progressive hyperinflation, contributes to ventilation–perfusion (\dot{V}/\dot{Q}) mismatching, higher V_D/V_T and a shortened red cell transit time – thereby widening the $A-\bar{a}$ gradient. These adjustments undermine the competency of gas exchange. Hyperinflation places the respiratory muscles at a mechanical disadvantage, elevating the work of breathing and its associated metabolic needs. This effect, along with progressive muscle weakness – also a characteristic of this illness – creates a weaker and less effective ventilatory pump at a time of greater metabolic demand.

The collaborative benefits of oxygen therapy, exercise and an active lifestyle [12], while accommodating for an increase in metabolic requirement for oxygen, suggests that oxygen systems should adequately oxygenate patients during exertion and be very portable. The ideal portable system should be minimally intrusive and support an active lifestyle with moment-to-moment adjustments conforming to the physiological requirements.

Patients who require oxygen are frequently self-conscious and avoid social gatherings. To complicate the picture,

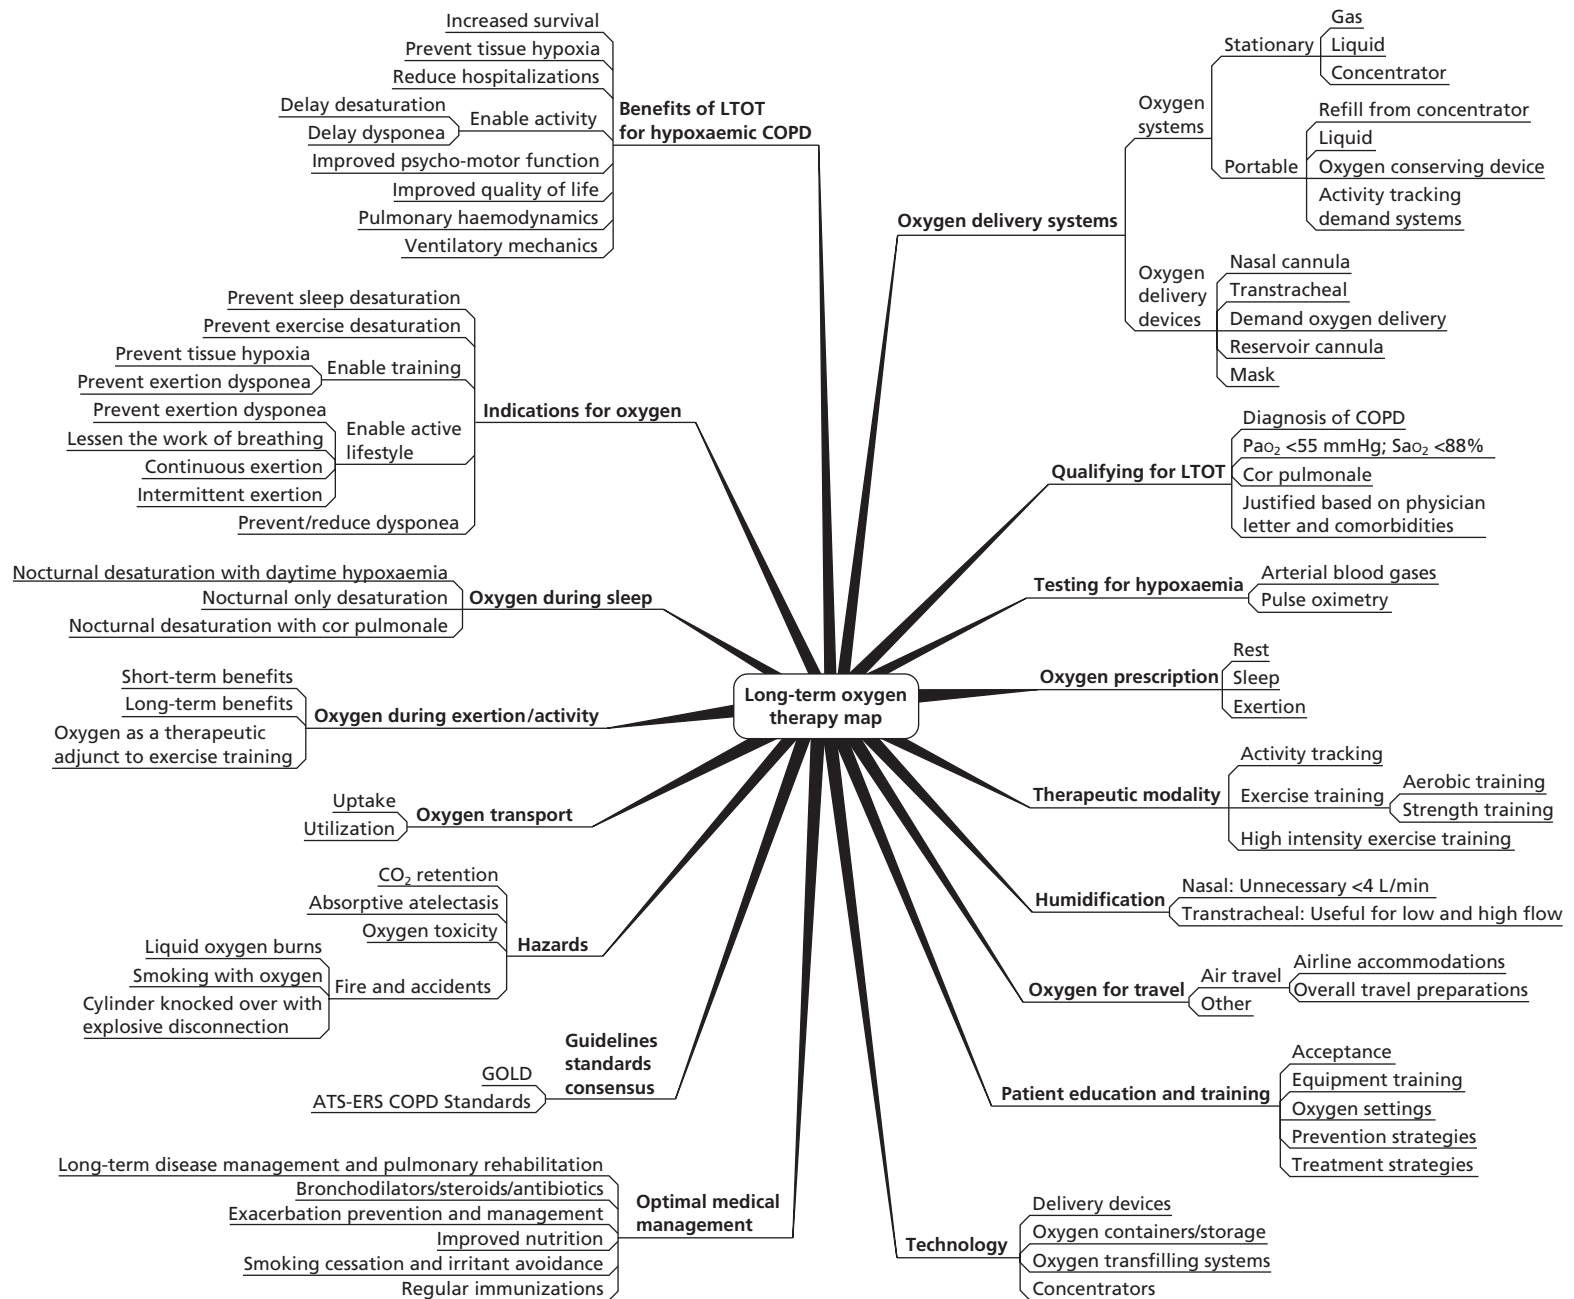

Figure 54.1 Map of considerations for long-term oxygen therapy (LTOT). ATS-ERS, American Thoracic Society and European Respiratory Society; CO₂, carbon dioxide; GOLD, Global Initiative on Obstructive Lung Disease; PaO₂, partial pressure of arterial oxygen (mmHg); Sao₂, arterial oxygen saturation (%).

patients often regard oxygen as a grim reminder that they have a relentlessly disabling illness. Consistent with the therapeutic goal, oxygen must be presented as being enabling. The patient must understand that oxygen serves a protective function and supports an active lifestyle. The patient should fully accept their oxygen and adhere to its prescription.

Physiological considerations

The cause of hypoxaemia bears on the clinical expectations from LTOT [13]. A low fraction of inspired oxygen (F_{iO_2}), such as experienced at higher altitudes, is easily corrected by supplemental oxygen or return to sea level where the fractional content/driving pressure of oxygen in air is greater. Hypoventilation, which occurs during sleep apnoea, promotes a concomitant increase in P_{aCO_2} . Measures to improve ventilation are effective for improving oxygen transport and carbon dioxide (CO_2) removal. Diffusion impairment, which worsens during exercise – particularly in patients with pulmonary fibrosis – presents a major challenge to maintaining arterial oxygenation during exertion. Ventilation–perfusion mismatching is the usual reason why COPD patients become hypoxaemic and may also contribute to CO_2 retention, and usually responds to supplemental oxygen. Patients with a significant arterial–venous shunt defy correction of their hypoxaemia.

The consequences of hypoxaemia and tissue hypoxia are dependent on multiple factors. Severe acute hypoxia can cause rapid and irreversible tissue damage. Chronic hypoxia will variably impair cellular function and may progress to necrosis. This depends on the target tissue or cell line affected. Initially, the oxygen-deprived cell will resort to anaerobic glycolysis, with a resulting lactic acidosis. Cells can function temporarily within an anaerobic environment, but they do so inefficiently and uncomfortably. A rapid return to oxidative metabolism is necessary for re-establishment of a normal pH through removal of anaerobically generated lactic acid.

Recognition of signs of tissue hypoxia depends on the affected tissue [14]. Brain tissue hypoxia manifests as a loss of short-term memory, followed by euphoria, and impaired judgement. Severe cerebral hypoxia will trigger cerebral oedema, which is life-threatening. Cardiac muscle hypoxia is accompanied by tachycardia, a reduction in stroke volume, atrial and/or ventricular arrhythmia and congestive heart failure. Hypoxia in the lung causes pulmonary vasoconstriction that may lead to right heart failure, bronchospasm and weakened respiratory muscles. Lowering in gastric pH may be seen in conditions of tissue hypoxia and, although somewhat cumbersome, may be used to monitor the presence of tissue oxygenation.

The consequences of long-term hypoxaemia along with

the impact of LTOT were addressed in two companion, landmark, randomly controlled clinical trials reported in early 1980s [1,2]. The British Medical Research Council (MRC) study randomly assigned hypoxaemic COPD patients to receive oxygen therapy 15 h/day (including the hours of sleep) versus no oxygen [1]. The survival benefit, which became apparent after 4 years, showed that 55% of the oxygen therapy group was alive versus 33% of the control group.

The National Institutes of Health Nocturnal Oxygen Therapy Trial (NOTT), performed at several centres in North America on a similar population of COPD patients, compared patients receiving oxygen 12 h/day (including the hours of sleep) versus 24 h/day [2]. Actually, the 24 h/day group used their oxygen an average of 19 h/day. Survival after 3 years was 70% for the continuous group versus 50% for the nocturnal oxygen therapy group. This survival difference became apparent after 12 months of oxygen use.

The results were more impressive when patients were stratified by the level of CO_2 retention [2]. A significant decrease in haematocrit and pulmonary vascular resistance was seen in the continuous oxygen group. However, these changes were not sufficient to explain the difference in survival. Autopsies on some of the NOTT patients failed to reveal a difference in pathology, which lends support to the conclusion that the observed survival difference may be related to the number of hours per day of oxygen therapy [15].

Because these two studies were performed on similar groups of patients with the common denominators being COPD and hypoxaemia, the results are often combined to present a unified message (Fig. 54.2): survival is positively

Figure 54.2 Combined results of the Medical Research Council (MRC) and National Institutes of Health Nocturnal Oxygen Therapy Trial (NOTT) studies. Survival is determined by the hours per day of oxygen therapy.

correlated with the number of hours per day of oxygen usage. However, several important areas were not specifically addressed. For example, we do not know if these patients benefited from oxygen during exertion or even if they used their oxygen during exertion. Also, even though implied by the MRC study, we do not know whether patients receiving oxygen during sleep improved their survival.

When LTOT was administered to a different group of patients with moderate hypoxaemia (partial pressure of arterial oxygen [P_{aO_2}] 55–65 mmHg) no survival benefit could be demonstrated [3]. Younger age, better lung function as assessed using spirometry and higher body mass index (BMI) have been identified as positive predictors of survival. Certainly, survival is important but it does not relate to the many comorbidities encountered by the patients nor does it impact on the quality of life prior to mortality. Thus, we must also focus our attention toward other important and relevant endpoints. As will be shown in the sections that follow, oxygen has a positive effect on the ability to exert and exercise. Oxygen can improve the patient's ability to function, partly by reducing dyspnoea which discourages attempts to be active. Further, quality of life is improved, hospitalizations are decreased, enhanced neuropsychological performance is realized and there is the suggestion that oxygen may act as a reparative agent for the lung and other organs [16].

Hazards of oxygen therapy

Overall, oxygen therapy is safe. However, it is important to recognize conditions where oxygen, its associated equipment and patient misuse presents either clinical hazards, such as absorptive atelectasis, oxygen toxicity, CO_2 retention, or the risk of accidents relating to oxygen storage and handling.

Absorptive atelectasis

Oxygen administered in high concentrations may cause absorptive atelectasis and attenuation of hypoxic vasoconstriction [17]. Each of these responses may widen V/Q inequality. While some negative potential exists even at moderately low flows, the goal of LTOT is to prevent hypoxaemia. Thus, the benefits for correction of hypoxaemia support the administration of oxygen to a wide array of patients.

Oxygen toxicity

Patients experiencing prolonged exposure to oxygen, in high concentrations above 50%, may be subject to oxygen toxicity [18]. Oxygen toxicity is related to free radical load in the lung. The major end product of normal oxygen meta-

bolism is water. However, some oxygen molecules are not fully reduced and form reactive oxygen metabolites. These include superoxide anions, perhydroxy radicals, hydroxyl radicals and hydrogen peroxide. These free radicals are damaging to alveolar and tracheobronchial cells [19]. Normally, antioxidant enzymes, including metalloproteins (superoxide dismutase), catalase and glutathione peroxidase, protect cells by scavenging oxygen radicals. However, in the face of prolonged exposure to high concentrations of oxygen and/or chronic inflammation, the antioxidant system becomes overwhelmed, thereby permitting oxidative destruction of lung tissue.

Concern for oxygen toxicity generally begins at an F_{iO_2} of more than 50%. In the case of LTOT, pure oxygen is administered at a low flow that is rapidly diluted by a much higher flow of atmospheric air. This results in a F_{iO_2} that is much closer to atmospheric air than pure oxygen. For example, the most common oxygen setting is 2 L/min, which produces an F_{iO_2} of 27–28%. Even at 4 L/min the F_{iO_2} is usually less than 36%.

In considering the hazards of long-term exposure to low-flow LTOT, an uncontrolled autopsy study of COPD patients revealed exudative and proliferative changes consistent with oxygen toxicity [20]; however, there was no indication that these changes altered survival. Animal studies suggest that long-term exposure to 80% F_{iO_2} may stimulate greater levels of protective antioxidant enzymes. In general, the benefits of LTOT far outweigh the risks.

CO_2 retention

Concern that oxygen therapy will depress the respiratory drive and promote retention of CO_2 in COPD patients has led to inadequate oxygen prescriptions. Oxygen-induced hypercapnia does rarely occur, but it does not usually lead to respiratory acidosis. The cause of CO_2 retention in some patients has been the subject of debate. Originally, it was believed that patients with severe disease, particularly with CO_2 retention, possessed a defective CO_2 drive. Adaptively, they would then breathe from their hypoxaemia drive and administering oxygen would depress that drive. Aubier *et al.* [21] and Sassoon *et al.* [22] demonstrated an increase in V_D/V_T (V_D , physiological dead space; V_T , tidal volume) rather than a decrease in ventilation consistent with a widening of \dot{V}_a/\dot{Q} mismatch. Dunn *et al.* [23] found some evidence for depressed respiratory drive. Robinson *et al.* [24] found that a reduction in ventilation does occur in some patients during an exacerbation. Patients with lower room air oxygen saturation (%) (S_{aO_2}) tended to be retainers and that providing high concentrations of oxygen had a specific effect on perfusion. In general, titrating oxygen flow so as to maintain P_{aO_2} between 60 and 65 mmHg can minimize the likelihood of hypercapnia and respiratory

acidosis while providing adequate oxygenation. Initial oxygen delivery settings should be adjusted via arterial blood gas (ABG) rather than oximetry to assess P_{aCO_2} and acid–base changes.

Many patients can tolerate chronic hypercapnia because of renal compensation that maintains their pH in the normal range. In fact, the ability of patients to tolerate hypercapnia may be an adaptive mechanism that minimizes their work of breathing. It is reasonable to accept chronic hypercapnia in this patient cohort. Thus, chronic hypercapnia may not always be a poor prognostic sign [25]. Adverse consequences of hypercapnia are related to acute acidemia that can be detected by serial ABGs and the monitoring of mental status. In summary, correction of hypoxaemia takes precedence over concerns about CO_2 retention for patients with COPD.

Physical hazards

Oxygen therapy is safe and few accidents have been reported. Most major concerns relate to combustion. Some fires have been caused by patients lighting a cigarette as oxygen is flowing into their noses with destructive and sometimes fatal consequences [26]. The plastic cannula does not burn unless oxygen is flowing and a fire is lit. Hence, smoking in the presence of oxygen is to be strictly avoided.

Compressed gas oxygen is stored under pressure. It is possible, albeit rare, that an oxygen cylinder gets knocked over causing an explosive disconnection of the regulator, rendering the cylinder into a dangerous missile. Mishandling liquid oxygen systems can rarely lead to freeze burns during transfilling. Most accidents are completely avoidable by following manufacturers' directions and common sense.

LTOT and optimal medical management

Optimal medical management of a chronic illness with far-reaching systemic manifestations requires that the clinician maximize all aspects of care. COPD is chronic and progressive with episodes of acute exacerbations. However, all parts of the disease are treatable including most comorbidities. V/Q mismatching, a prevalent cause of hypoxaemia, is often worsened by bronchoconstriction, inflammation and hyperinflation, and V/Q mismatch tends to further widen during an exacerbation. Therefore, by addressing these components, the need for oxygen may be reduced. For the already hypoxaemic patient, oxygen appears to have a reparative effect over time – beyond simple therapeutic replacement. By reducing hypoxic vasoconstriction of the pulmonary arteries, V/Q matching is improved [16,27].

Hence, oxygen therapy performs a fundamental role in optimal medical management.

Again, the full route of oxygen transport requires regular clinical attention. Correction of anaemia, control of congestive heart failure and assuring adequate renal function are inherent components of medical management. An exercise programme delivered during the non-acute phase of the disease process will enhance oxygen transport and utilization and improve efficiency for many bodily functions.

Oxygen during sleep

A significant portion of the day is spent sleeping. Healthy persons commonly experience transient mild desaturations during sleep, particularly during rapid eye movement (REM) sleep. For the COPD patient, these desaturations are more common, more pronounced and tend to start from a lower baseline level. COPD patients with no sign of obstructive sleep apnoea (OSA) may undergo desaturations of 9–21% [28]. Thus, saturations dipping below 90% are frequent, with some patients spending more than 30% of the night below 90% [29].

The mechanisms vary but rapid shallow breathing with alveolar hypoventilation seem to be the major cause of sleep oxygen desaturation [11]. Nocturnal oxygen desaturation has also been attributed to suppression of the ventilatory drive that occurs largely during REM sleep, although it can occur in any stage including just after sleep onset. Other mechanisms include an increase in V_D/V_T and an increase in V/Q mismatch. Desaturation at night may not be totally predictable from daytime arterial blood gases, because sleep pattern abnormalities and their consequence on respiration may also contribute independent of the awake state [28].

Most COPD patients with well-corrected daytime saturation require an increase in oxygen flow during sleep in order to maintain an adequate saturation. This was recognized during the 1970s before the advent of modern oximeters. Patients in the NOTT study were prescribed an increase in flow of 1 L/min at night [2]. Patients with both hypercapnia and hypoxaemia are likely to desaturate at night [30]. Patients who desaturate at night have an increased risk of ventricular ectopy, higher pulmonary artery pressure and pulmonary vascular resistance and shortened survival [31]. In patients with nocturnal desaturation, adequate oxygenation during sleep may prevent or reverse those complications [32].

Nocturnal oxygen desaturation with adequate daytime saturations

Chaouat *et al.* [33] studied nocturnal desaturators with mild

daytime hypoxaemia (Sa_{O_2} greater than 88%) and compared them with non-desaturators for a total of 2 years [33]. The desaturators tended to be those with a slightly higher $Paco_2$ and pulmonary artery pressure (PAP), whereas the non-desaturators had no increase in their $Paco_2$ or PAP. This study concluded that nocturnal oxygen desaturation is specifically associated with CO_2 retention [33]. Other studies have concluded that disease severity, CO_2 retention and high BMI are predictive of nocturnal oxygen desaturation [34]. Fletcher *et al.* [35] found that COPD patients with severely impaired pulmonary mechanics along with CO_2 retention were more likely to desaturate during sleep.

Whether LTOT during sleep in this population improves survival or ameliorates the consequences of nocturnal desaturations warrants further study. The risks and concerns as previously described as well as from OSA research are substantial. A large multicentred trial studied patients with mild daytime hypoxaemia and noted that nocturnal oxygen therapy did not modify the evolution of pulmonary hypertension or delay the patient from meeting the criteria for LTOT. They did not detect a survival difference – albeit their population was small and the study did not last long enough to draw a definite conclusion [36]. On the other hand, Fletcher *et al.* [32], in a relatively small group of patients, found that oxygen therapy for nocturnal desaturation reduced pulmonary artery pressure with the suggestion of improved survival.

Overlap syndrome

Some patients have a coexistence of COPD and OSA – called overlap syndrome [37]. It is questionable whether the incidence of OSA is higher in COPD than the general population. Weitzenblum *et al.* [38] reported that 11% of their OSA patients had coexisting COPD. Patients with overlap syndrome may have an abnormally high rise in PAP during exercise [39]. The recommended approach for these patients is to perform a polysomnography and to address the OSA component [40] independent of the COPD.

Prescribing nocturnal oxygen

Patients who require LTOT because of daytime hypoxaemia will require nocturnal oxygen as well. If there are no symptoms of nocturnal desaturation, it is usually adequate to increase daytime setting by 1 L/m equivalent. Alternatively, a nocturnal saturation study can be utilized to establish the setting. In COPD patients with mild daytime hypoxaemia, who have cor pulmonale, right heart failure or erythrocytosis, nocturnal oxygen therapy may be warranted. Patients with mild daytime hypoxaemia in whom nocturnal desaturation has been documented can benefit from nocturnal oxygen therapy depending on the degree of

desaturation, percentage of the night below Sa_{O_2} of 90% and tendency for hypercarbia. The supplementation of oxygen to patients with these characteristics remains a clinical judgement. Screening asymptomatic non-hypoxaemic patients for nocturnal oxygen desaturation is not warranted based on our present understanding.

Oxygen during exercise

Exercise hypoxaemia

Exercise training improves strength, endurance and confidence and lessens exertional dyspnoea – enabling an active lifestyle. In healthy individuals, the lungs easily meet oxygen uptake demands of exercising muscle by delivering adequate amounts of oxygen to the alveoli to participate in gas exchange thereby maintaining arterial oxygenation [41]. Red cell transit time can decrease from 0.75–1.0 s at rest to less than 0.5 s during exercise. D_L/Q as well as V/Q matching is maintained by recruiting previously non-communicating alveolar units to meet the oxygen delivery demands for cellular respiration/metabolism of active muscle tissues during exercise.

The pathophysiological progression of COPD eventually leads to hypoxaemia during exertion. During rest patients are generally not limited by lung diffusion or red cell transit time [42]. During exercise these factors come into play [43] along with a widening of the V/Q mismatch, progressive hyperinflation [44], an increase in oxygen cost and work of breathing [45], and suboptimal length–tension positioning of foreshortened ventilatory muscles. Otherwise stated, increasing oxygen uptake demands are met by inefficient lungs powered by a weakened ventilatory pump that drains a disproportionate share of the inspired oxygen.

Healthy individuals living at high altitude and exercising at low altitudes have improved performance and greater $\dot{V}O_{2max}$, whereas persons living at low altitude and exercising at high altitude had the opposite effect [46]. Thus, exercising in hypoxaemic conditions impairs performance and the resultant tissue hypoxia may be harmful. In COPD patients, exercise-induced hypoxaemia over the long term portends poor survival [47]. What remains to be determined is whether administering oxygen during exercise improves survival.

Short-term benefits of oxygen during exercise

Early studies demonstrated substantial short-term benefits of oxygen supplementation during exercise. Oxygen enables patients to exercise at higher workloads for longer periods, more intensely and with less dyspnoea [48–50]. There is less hyperinflation, which places the tidal loop in a

more advantageous position along the flow–volume loop, decreasing the overall work of breathing thereby providing some relief to the compromised ventilatory muscles [44,51].

To some degree, higher exercise tolerance is made possible by depressing the carotid and aortic body chemosensors [52]. Oxygen can increase exercise tolerance by reducing minute ventilation at similar workloads [53]. A reduction in minute ventilation, which tolerates mild CO₂ retention, further eases the ventilatory burden. Oxygen administered during exercise may prevent transient increases in pulmonary artery pressure and pulmonary vascular resistance [54]. Oxygen therapy improves indices of oxidative metabolism in peripheral muscles. Some of the exercise metabolic indices remain abnormal, possibly indicating persistent cellular damage from chronic hypoxaemia [55]. Eaton *et al.* [56], in a randomized trial, showed that ambulatory oxygen can improve quality of life.

Oxygen to prevent exercise oxygen desaturation

McDonald *et al.* [57] compared delivery of oxygen versus compressed air using a portable cylinder with an oxygen-conserving device. They demonstrated immediate improvements in exercise performance, but failed to demonstrate longer term effects on exercise performance or quality of life. Survival benefits have not been demonstrated nor have functional improvements in rehabilitation performance over the long term [57–60]. Rooyackers *et al.* [59] compared training with oxygen versus room air. Sao₂ was never below 90%. Both groups improved exercise capacity and quality of life indices, but oxygen did not add to the benefits of training on room air [59]. Garrod *et al.* [60] showed a reduction of dyspnoea during exercise but no training effect from ambulatory oxygen therapy in a rehabilitation programme. Definitive studies combining pulmonary rehabilitation and disease management with oxygen therapy to prevent exercise desaturation are needed. Definitive research is required to fully understand the long-term benefits of preventing exercise desaturation. Clinical judgement suggests that exercise oxygen, delivered at the correct flow rate, is an important and essential component COPD disease management.

Oxygen to enhance exercise benefits

Exercise training in COPD patients is able to achieve a physiological training effect [61]. Previous investigations that studied the ability of hyperoxic mixtures to improve exercise and functional performance and boost $\dot{V}O_2$ to peripheral muscle have led to mixed results [52]. Early studies by Cotes and Gilson [48] in 1956 found progressive improvement in exercise performance up to Fio₂ of 0.5. Somfay *et al.*

[51] later demonstrated a dose-dependent reduction in hyperinflation and improvement in endurance with Fio₂ up to 0.5, with no further benefit at higher Fio₂. O'Donnell *et al.* [44] determined that exercise dyspnoea was ameliorated by lowering the ventilatory demand, reducing hyperinflation and decreasing lactate levels. Dean *et al.* [62] found a positive relationship between exercise performance and decreased dyspnoea, but minute ventilation, heart rate or right ventricular pressure remained unchanged. Mannix *et al.* [63] found that 30% oxygen lowered the oxygen cost of ventilation. Jolly *et al.* [49] observed no increase in exercise performance in non-debilitated patients in spite of the fact oxygen led to a substantial reduction in dyspnoea.

Muscle performance is improved with oxygen supplementation with no alteration in muscle kinetics [55,64]. The immediate effect of exercise oxygen is to reduce minute ventilation by slowing breath rate and reducing tidal volume. The net effect is to decrease the work of breathing by lowering minute ventilation at the cost of minimal CO₂ retention. The reduction in respiratory rate decreases hyperinflation, thereby alleviating dyspnoea [44]. The mechanism appears to be a blunting of the chemoreceptor response [55]. Maltais *et al.* [65], utilizing an Fio₂ of 0.75, demonstrated improvement in blood flow to the lower limb muscles.

Emtner *et al.* [66], in a randomized double-blinded trial, administered oxygen versus compressed room air to COPD patients ($FEV_1 = 36\%$ predicted), who were non-hypoxaemic at rest and did not desaturate below 89% during exercise. Patients participated in high-intensity training to 75% of maximum workload. Both groups benefited from exercise training, achieving greater endurance, higher exercise tolerance and lower respiratory rate, with the oxygen trained group performing significantly better. After training, the oxygen group performed better on constant work rate tests with lower breath rates, while breathing both room air and oxygen. Thus, oxygen is considered to be a therapeutic enabler for exercise training beyond simple protection against hypoxaemia.

Prescribing exercise oxygen

Patients should be evaluated using the same delivery devices they expect to use at home (e.g. nasal cannula or oxygen conserving device). Exercise testing is best carried out using muscle groups where dyspnoea is most pronounced (e.g. legs versus arms). The American Thoracic Society and European Respiratory Society (ATS-ERS) standards [67] recommend that exercise oxygen setting be titrated during a typical exercise such as a hallway walk. In daily life, most people tend to be inactive, interspersed with short bursts of activity approaching peak limits given the underlying impairment. In such circumstances, patients have little time to achieve a steady state. The resulting

desaturation and ensuing dyspnoea discourages an active lifestyle. It is known that hypoxaemic COPD patients undergo many short periods of oxygen desaturation daily while complying with their oxygen prescription [68–71]. As such, a hallway walk at a steady pace may be inadequate to prevent these saturation dips. Also, many patients tend to forget to increase their oxygen setting during exertion – particularly for short intervals. Either the exercise setting must be increased or the setting adjustment needs to be automated. Recently, such a device has been announced, but studies in the home setting are recommended to determine its applicability.

Physiological qualification for LTOT

Guidelines for determining which patients will qualify for LTOT are based on the physiology and survival benefits as revealed in the MRC and NOTT studies [1,2]. Determination as to which patients will actually receive LTOT is heavily influenced by reimbursement, which varies by country. On the basis of both the MRC and NOTT studies, patients who meet the qualification criteria for home oxygen should use it continuously – at least 15 h/day [1,2].

Both ATS-ERS Standards and the Global initiative for Obstructive Lung Disease (GOLD) Guidelines qualify COPD patients for LTOT with P_{aO_2} less than 55 mmHg (7.3 kPa) or S_{aO_2} less than 88%. Patients may also qualify with P_{aO_2} between 55 and 60 mmHg (7.3–8.0 kPa) or S_{aO_2} of 89% with evidence of pulmonary hypertension, peripheral oedema indicating right heart failure, or polycythaemia [67,72].

Arterial blood gases

Initial qualification for LTOT should be based on arterial blood gases (ABG) measurement. It is more accurate than non-invasive oximetry and includes P_{aCO_2} , pH and S_{aO_2} . GOLD recommends an ABG when the forced expiratory volume in 1 s (FEV_1) is less than 40% predicted or if there are signs of respiratory failure or right heart failure [72]. An early indicator of respiratory distress is dyspnoea; a late clinical sign of respiratory failure is cyanosis. Right heart failure is indicated by pedal oedema or an increase in jugular venous pressure. An added benefit is the ability to detect carboxyhaemoglobin in arterial blood through co-oximetry. This clinical knowledge may be used to reinforce smoking cessation or compliance.

Pulse oximetry

The Sp_{O_2} represents the arterial oxygen saturation (S_{aO_2}) measured by pulse oximetry. Oximetry Sp_{O_2} closely tracks arterial S_{aO_2} under most conditions and is non-invasive.

With its continuous readout, oximetry has the advantage in being able to track changes over time. Sp_{O_2} during exercise helps to determine the speed and extent of the desaturation response. Unfortunately, absolute values may not be accurate during exercise, particularly in patients with poor peripheral perfusion. Also, there is a time lag between desaturation and detection at the fingertip [73]. Verification of oximetry accuracy can be accomplished by obtaining ABG before and after exercise. A therapeutic use for pulse oximetry is as a biofeedback guide in conjunction with pursed lips breathing. The patient guided by the oximetry Sp_{O_2} readout can learn to alter breathing patterns to increase Sp_{O_2} and lessen dyspnoea [74].

Determining the LTOT prescription

An ABG drawn, while breathing room air, is used to determine whether the patient qualifies for LTOT. Concomitant oximetry provides a corresponding Sp_{O_2} useful for flow adjustments. The ATS-ERS standards algorithm (Fig. 54.3) is a guide to adjusting oxygen settings. The resting flow rate can be adjusted via oximetry to Sp_{O_2} of 92% or greater. Full equilibration may require 15 min or more. Concerns about hypercarbia may be addressed by drawing an ABG after the Sp_{O_2} reaches 92%. If there is greater CO_2 retention, check the pH for acidosis. If the pH is balanced, that patient is chronically hypercapnic and no further adjustment is necessary.

COPD patients are encouraged live an active life and maintain an exercise programme. Accordingly, there should be a highly portable component to the oxygen system. The patient should be tested on the system being prescribed – particularly if an oxygen conserving device is included – during a typical or higher level of exertion than commonly experienced, such as walking with the oxygen flow setting titrated to achieve an Sp_{O_2} of more than 92%. If dyspnoea is especially prevalent during arm exertion, the patient may also be tested while performing arm tasks. If an autoadjusting conserving device is prescribed, the setting should also be determined with the patient alternately sitting and walking.

Oxygen therapy during sleep is often set 1 L/min higher than daytime resting setting. If there are signs of cor pulmonale despite adequate daytime Sp_{O_2} , a sleep oximetry may be performed to establish fluctuations in Sp_{O_2} and provide titration feedback to achieve an Sp_{O_2} of more than 90%.

Oxygen systems

Oxygen is supplied and packaged as either compressed gas, liquid or oxygen concentrator. There are advantages and

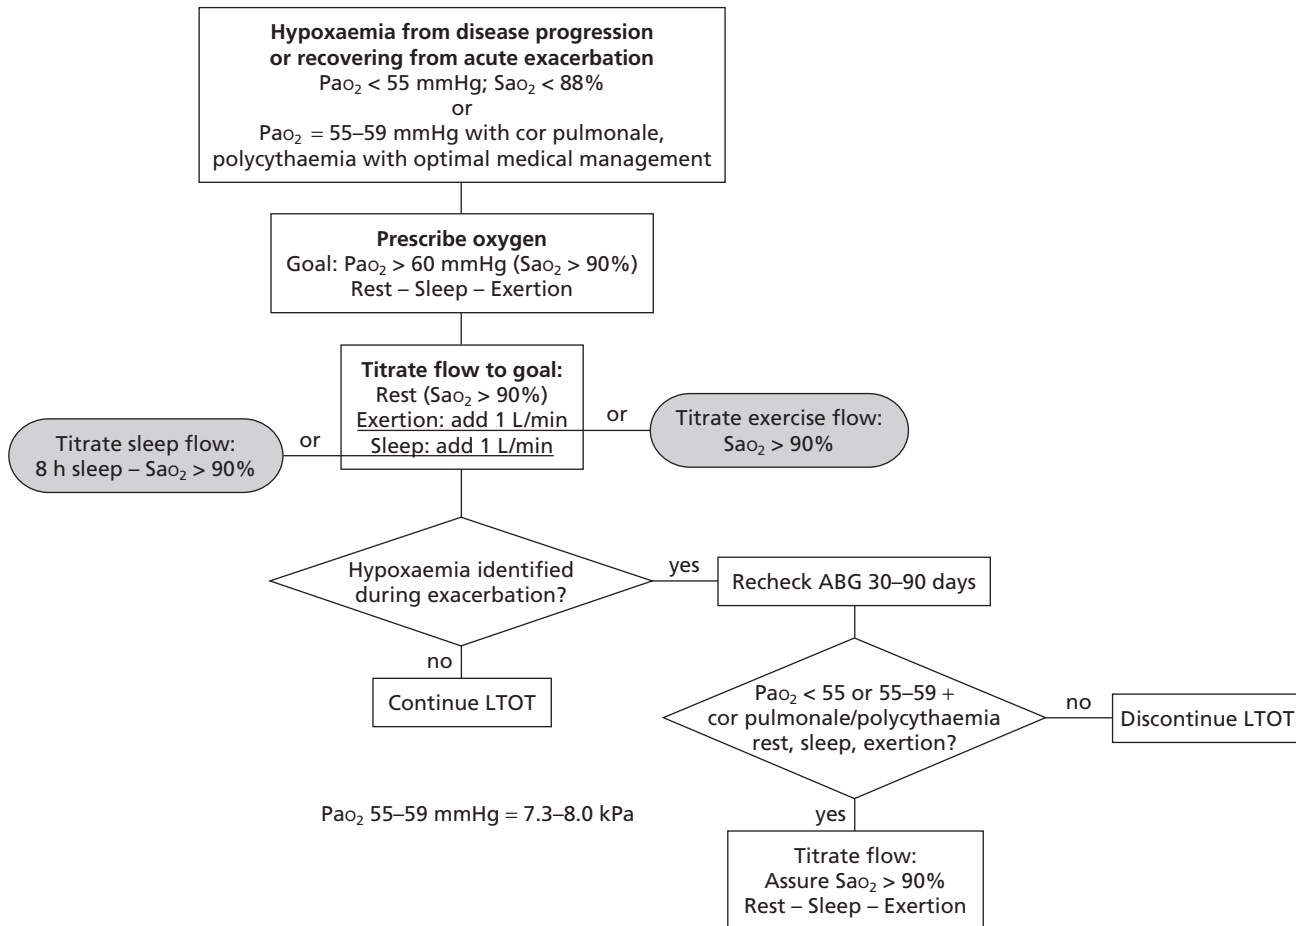

Figure 54.3 An algorithm for long-term oxygen therapy from the American Thoracic Society and European Respiratory Society (ATS-ERS) standards for the diagnosis and management of COPD. ABG, arterial blood gas; LTOT, long-term oxygen therapy; PaO₂, partial pressure arterial oxygen; Sao₂, arterial oxygen saturation.

disadvantages to each system depending on the needs of the individual patient, clinical application, and practical considerations such as availability, cost, ease of use, delivery to the home, and maintenance.

Compressed gas oxygen

Compressed gas oxygen is typically pressurized to 2200 psi and stored in steel or aluminum cylinders. The H cylinder is large, weighs over 200 lb (91 kg), stores 6900 L and lasts for 2.4 days set at 2 L/min. The E cylinder is a commonly used portable system; however, it is heavy and requires a cart. An aluminum E cylinder weighs 16-18 lb (7.3-8.2 kg) stores, 523 L, and lasts 5 h at 2 L/min. It must be wheeled on a cart that may add as much as 1 kg (2.2 lb) to the total weight. The M-6 aluminum cylinder weighs 4 lb (1.8 kg) and lasts about 1.2 h at 2 L/min. These cylinders are designed for use with an oxygen-conserving device that extends the cylinder life threefold or more. Transfillable

cylinders, which fill from an oxygen concentrator, enable patients to be free from home deliveries.

Oxygen concentrator

Oxygen concentrators extract oxygen directly from room air. Using a molecular sieve constructed of zeolite, oxygen is separated from nitrogen, which is returned to the room air. The purity at low flows is about 97% oxygen and drops to 94% at higher flows largely due to the presence of argon. Most oxygen concentrators are large consoles that operate on wall current. However, battery powered concentrators are now available - some weighing less than 10 lb with a battery that lasts approximately 50 min on a charge. The biggest advantages of standard concentrators are their low cost and high availability. Accordingly, concentrators are used as a stationary system in the home. Specialized concentrators are now available that refill small 4 lb portable cylinders that, combined with an oxygen conserving device,

last up to 10 h at 2 L/min. Such systems are fully self-contained as they free the patient from home deliveries. These systems have demonstrated that they are easy for the patient to operate, are safe and reliable.

Liquid oxygen

Liquid oxygen is supercooled to convert it to its liquid state. It is stored in a special thermos called a Dewar flask. Because it is in its liquid state, a large volume of oxygen can be stored in a small, lightweight container. One liquid litre expands to nearly 1000 gaseous litres of oxygen. Liquid oxygen is easily transfilled by the patient from a larger stationary unit to a portable unit that patients can easily carry. Several manufacturers now supply liquid portable oxygen systems with a built-in oxygen-conserving device. This further reduces the size and weight so that a unit that weighs 3.5 lb (1.6 kg) can provide up to 10 h of oxygen at a 2 L/min setting.

Oxygen delivery methods

Continuous-flow nasal cannulas

Continuous flow delivery via a standard dual prong nasal cannula provides a small flow of oxygen entrained in a much larger flow of inspired air. Each increase in litre flow of 1.0 L/min adds approximately 3–4% to the F_{iO_2} (Table 54.1). One model of delivery is based on a breath cycle of 3 s for a patient breathing 20 breaths/min [75]. COPD patients tend to have inspiratory–expiratory ratios of 1 : 2. This means that 1 s is devoted to inspiration and 2 s is devoted to exhalation. The last one-third of the inspiratory volume fills the dead space, which does not participate in gas exchange. Given that the breath slows at end-inspiration, approximately 0.5 s will be spent in filling the dead space. This leaves 0.5 s for early inhalation where filling of the alveolus and gas exchange takes place. That is the gas exchange window of opportunity [75].

Table 54.1 Approximate fraction of inspired oxygen (F_{iO_2}) from continuous flow and reservoir cannula.

Oxygen setting	F_{iO_2} continuous flow (%)	F_{iO_2} reservoir cannula (%)
Room air	21	21
1 L/min	24	32
2 L/min	28	36
3 L/min	32	40
4 L/min	36	44
5 L/min	40	46

A patient delivered oxygen at 2 L/min using standard flow delivery will receive approximately 16.7 mL of oxygen in the first 0.5 s of inhalation. If mixed into the first 200 mL of inspired gas, this calculates to a F_{iO_2} of 27.6%. At 20 breaths/min the patient receives 333.3 mL (20×16.7 mL) of oxygen per minute. Thus, only 17% (333.3 mL/2000 mL) of the oxygen flow arrives during the gas exchange window of opportunity. The rest is largely wasted.

Reservoir cannulas

Reservoir cannulas function by storing oxygen during exhalation for delivery during the next inhalation [75]. A thin, compliant membrane creates the 20-mL chamber that expands and contracts in response to nasal airflow. Reservoir cannulas are supplied with continuous flow oxygen. The reservoir adds approximately 18 mL of oxygen to the inspiratory mixture, which is the equivalent of adding approximately 2 L/min to the F_{iO_2} (see Table 54.1).

Reservoir cannulas are available as an Oxymizer and Pendant [76,77]. In the Oxymizer, the reservoir is located immediately beneath the nose, whereas the Pendant stores oxygen in a chamber located at the anterior chest wall, as well as the tubing leading to the nasal prongs. Both the Oxymizer and the Pendant maintain the same efficacy. The Oxymizer is more noticeable but more comfortable than the Pendant. Reservoir cannulas are inexpensive and reliable, but do not support pursed lips breathing at low flows. Both reservoir cannulas have been utilized with success for high-flow oxygen delivery [78,79].

Transtracheal catheters

Transtracheal oxygen (TTO) is delivered through a small stoma placed surgically through the neck into the trachea. The objective is to deliver oxygen to the upper airway thereby reducing some dead space ventilation, improving V/Q and lessening the work of breathing [80]. This conserves oxygen and reduces inspired flow to achieve equivalent oxygenation to continuous flow nasal cannulas. The flow setting can be reduced by 50% at rest and 30% during exercise [81–84].

TTO has a cosmetic advantage because oxygen and its paraphernalia are removed from the face. Because oxygen flows directly into the trachea, TTO is able to reduce dyspnoea, minute ventilation, dead space and tension–time index of the diaphragm [84]. TTO candidates are usually active people who are both willing and able to follow a strict care protocol. A trained team of clinicians evaluates, educate and monitor patients [82,83]. TTO patients should not be heavy sputum producers nor experience frequent exacerbations. They should live within 2 h of the institution or have similar follow-up in their home community.

Demand delivery devices

Pulse demand oxygen delivery devices sense the beginning of inhalation – at which point they deliver a small oxygen pulse [85–89]. By delivering during the early part of inhalation, they conserve oxygen that would be otherwise wasted during late inhalation and exhalation. Demand pulsing devices vary in efficiency from 2 : 1 to 7 : 1 as compared with continuous flow. The more rapidly these devices respond while confining the pulse to the first 0.5 s of inhalation, the more efficacious the delivery [85].

Pulse demand oxygen delivery devices operate using several different technologies. The most efficient and effective devices sense the onset of inhalation electronically and deliver via a solenoid-controlled pulse. Pneumatic devices both sense and deliver pneumatically and thus do not require a battery. Newer devices now combine the low volume storage of liquid oxygen with oxygen conservation to create systems that are very small, portable and long-lasting. An oxygen-conserving device that automatically tracks activity and adjusts for exertion is under evaluation. As such, oxygen becomes utilized as a therapeutic tool to assure better oxygenation during usual daily activities.

Many demand oxygen delivery devices are available. Some have undergone clinical studies but most have not. Some devices are relatively insensitive and slow to respond to the beginning of inhalation. Late delivery undoubtedly results in desaturation, particularly during exercise. Since patients vary in their breath pattern, pathology and how much airflow is parcelled to the nose versus mouth, Sp_{O_2} testing using the device being contemplated during rest and exercise is essential to assure adequate oxygenation. It is important to select a device that is easy to use and has demonstrated reliability over the long haul because the typical patient breathes 16 breaths/min; 23 040 breaths/day; 8 409 600 breaths/year.

Humidification

There has been some concern that delivering oxygen will dry the nasal passages and the lungs. However, oxygen is provided at low flows relative to inhalation of atmospheric gas. As demonstrated in Table 54.1, oxygen represents a minor portion of inhalation. Moreover, oxygen flowing through the bubble humidifier is at room temperature; when it is raised to body temperature, the relative humidity falls. Finally, the nose is a very efficient and effective humidifier.

There is no evidence that humidification is necessary when oxygen is given by nasal cannula at flows less than 5 L/min [90]. There are no differences in subjective complaints or in severity of symptoms over time. This does

not apply to patients receiving oxygen by tracheostomy or TTO therapy, in whom the upper airway has been bypassed by the catheter; for these patients, humidification of inspired gas is essential even at low flow rates (1 L/min). TTO patients at high risk for mucus ball formation, including those with oxygen flows more than 5 L/min, large amounts of mucus, or weak cough, may benefit from a servo-controlled heated humidifier because this device more efficiently humidifies inspired gas.

Patient education and training

Education and training is a continuous process that is central to oxygen supplementation, disease management and rehabilitation. One educational goal is help the patient understand their disease and how it impacts their life. Patients must be provided with an optimistic assessment of the enabling benefits of utilizing oxygen, as prescribed. They must be trained, and regularly evaluated, and reinforced with respect to the use of their equipment. The care and cleaning of equipment for proper functioning and prevention of infection is an essential component. It is especially important that patients and caregivers learn and develop the habits of appropriately adjusting oxygen delivery to rest, exertion and sleep. It is also imperative that patients and their caregivers received education regarding signs and symptoms of infection or other medical changes indicating worsening of their condition and to seek medical assistance at the first opportunity.

Conclusions

Human life depends on the adequate delivery of oxygen to the peripheral tissues. The process requires the efficient function of the respiratory pump, finely tuned matching of ventilation and circulation, and a fluid and efficient method of uptake, transport and delivery. The disruption of these steps with progressive COPD has dire consequences to the patient. The supplementation of oxygen is an important, essential and often misunderstood therapy in the management of hypoxaemic COPD patients. Oxygen is prescribed to prevent cellular hypoxia and end-organ destruction. It is a kind of replacement therapy – providing supplementation where the lungs have failed. Excellent studies have lent support to its life-saving benefits, as well as its ability to reduce mortality, improve psychomotor performance and prevent hospitalizations. A recent and exciting area of research is the use of oxygen as a tool to improve exercise performance and rehabilitation. Thus, oxygen also becomes a therapeutic tool. Technology has come through with the development of highly portable delivery devices, a portable

oxygen concentrator, a concentrator that refills portable cylinders and an oxygen-conserving device that automatically adjusts to assure higher flows during usual exertion. For patients requiring oxygen supplementation, technological innovation, coupled with a better understanding of the patient, has provided realistic, reliable and cost-effective options for delivering oxygen and maintaining function.

CHAPTER 55

Surgical therapy for COPD

Fernando J. Martinez

COPD is a category of diseases with a varying pathophysiological basis but with a common picture of chronic airflow obstruction and hyperinflation [1]. Despite advances in medical therapy [2,3], many patients continue to experience incapacitating breathlessness and exercise limitation. Over the past several decades this has led to numerous surgical approaches to ameliorate symptoms in these patients.

History of surgical therapy for emphysema

Detailed discussions of the surgical history of emphysema management have been provided by several authors [4–6], with the surgical approaches reflecting the state of knowledge for their era. Early studies attempted to improve thoracic mobility, with procedures including costochondrectomy and transverse sternotomy [4,5], with unpredictable results. Later on, surgeons utilized techniques to decrease the size of the thoracic cage, including thoracoplasty and phrenicectomy, or to improve diaphragmatic architecture and function [4,5]. Although transient relief was noted, practical considerations limited widespread use [4,5]. Denervation was used to treat the chronic airflow obstruction, while various prosthetic devices supported the membranous trachea [5]. Significant morbidity and unpredictable results dampened the initial enthusiasm.

Brantigan *et al.* [7,8] hypothesized that by surgically removing lung volume one could restore radial traction on the terminal bronchioles, thereby improving airflow obstruction and improving diaphragmatic position and function. Although symptomatic improvement was reported in many patients, operative mortality was significant (18%) [7]. Widespread application of this technique never materialized. Over the subsequent 40 years various groups applied similar principles in small case series using various surgical techniques [9–14]. The current era of surgical lung volume reduc-

tion was ushered by Cooper *et al.* [15] who reported dramatic improvement with bilateral procedure performed via median sternotomy. Multiple investigators subsequently reported more limited improvements [16–19]. The results of the National Emphysema Treatment Trial (NETT) [21,22] have provided more definitive recommendations regarding the role of lung volume reduction surgery (LVRS) in patients with advanced emphysema.

Lung transplantation dates to the early 1960s, with 36 transplants performed between 1963 and 1974, 14 in patients with emphysema [22]. Uniformly poor results were described, with only three patients living more than 1 month. The major causes of death among the COPD patients were respiratory failure resulting from rejection, infection or bronchial disruption [23–25]. The first successful lung transplantation was performed as a heart–lung block for pulmonary vascular disease in 1981 [26]. The first successful single lung transplant (SLT) was reported in 1986 in patients with idiopathic pulmonary fibrosis. Because of differences in lung compliance, SLT was felt inappropriate for COPD patients [27,28]. Patterson *et al.* [29–31] reported successful double lung transplantation (DLT) in COPD patients, with Mal *et al.* [32] reporting successful SLT in COPD patients. SLT has become the predominant surgical therapy for advanced COPD [6,22].

Surgical techniques

An exhaustive description of the surgical techniques is outside the scope of this chapter. The important concepts are briefly reviewed here.

Bullectomy

Multiple techniques have been utilized to achieve resection of localized bullae, including standard lateral thoracotomy

[4], bilateral resection via median sternotomy (MS) [33], and video-assisted thoracoscopy (VATS) with stapling [34] or VATS with endoloop ligation [35].

LVRS without giant bullae

The approach to LVRS has included MS [36], standard thoracotomy and VATS [37]. Laser ablation has fallen out of favour as postoperative improvements were shown to be similar to stapled unilateral LVRS but with a higher complication rate [38]. Comparative studies have confirmed greater improvement with bilateral procedures [39,40], although not all investigators concur with this impression [41]. Results from the recently completed NETT study prospectively compared bilateral VATS with MS [21]. Similar morbidity and mortality were noted with both surgical techniques although the overall length of stay was longer for MS (10 days vs 9 days; $P = 0.01$). By 30 days after surgery, 70.5% of MS patients and 80.9% of VATS patients were living independently.

Lung transplantation

The current surgical approaches and principles of postoperative management are outside the scope of this chapter [22, 42–44]. Although controversy continues to revolve around the optimal transplant procedure in patients with COPD [45], increasing data have suggested improved long-term outcomes in COPD patients treated with DLT versus SLT [46–49]. These data are limited by the lack of prospective data collection and randomization to ensure comparable treatment groups. As such, clear recommendations require further data collection.

What are the results of surgery?

Short-term results

Bullectomy

Bullectomy appears to result in short-term benefit in highly selected patients [50–56]. Snider [57], in providing an elegant review of case series published from 1950 to the early 1990s, noted that none of the 22 studies included a control group and the majority were retrospective in nature, such that firm conclusions were difficult to reach. Nevertheless, improvement in hypoxaemia and hypercapnia were most frequently reported, with improvement in airflow being more heterogeneous. When measured, total lung capacity, residual volume and trapped gas generally decreased. In highly selected patients, cor pulmonale reversed if hypoxaemia and hypercapnia were present. Most authors described improvement in dyspnoea, with

several investigative groups reporting quantitative improvement in breathlessness. For example, the most recent series confirmed significant improvement in spirometry, residual volume (RV) and 6-minute walk distance [58].

LVRS without giant bullae

Since the early report of Cooper *et al.* in 1995 [15] numerous investigators have reported results of LVRS. Summaries of these studies have been reviewed by several authors [18,19]. Although several of these studies likely suffered from duplicate reporting of patient data, it is evident that major problems are consistently noted in the literature. These include:

- 1 Variable surgical techniques and selection criteria;
- 2 Short and often incomplete postoperative follow-up;
- 3 Retrospective data collection in most series; and
- 4 The absence of a control group in all but a few published reports.

Recently, however, results of several randomized controlled trials have clarified expectations [20,59–61].

Pulmonary function

Although Cooper *et al.* [15] initially documented an 82% improvement in forced expiratory volume in 1 s (FEV_1) after bilateral LVRS via MS, subsequent studies by this group and those of subsequent case series by others confirmed significant mean improvements in spirometry although to a lesser extent than initially suggested [18]. The NETT clearly demonstrated a modest improvement in FEV_1 for patients treated surgically compared with a modest decrement in medically treated patients (Fig. 55.1).

In general, bilateral surgical procedures have been associated with greater short-term improvement, although direct comparisons between unilateral and bilateral reduction are rare [39–41,62–66]. A multicentre prospective study comparing unilateral VATS LVRS ($n = 338$) with bilateral VATS LVRS ($n = 344$) noted greater pulmonary function improvement with the bilateral approach [66]. Unfortunately, no prospective randomized comparison exists although a strong suggestion is apparent of improved spirometric results in patients undergoing bilateral procedures. The results of laser procedures appear to be worse than those with stapling techniques. McKenna *et al.* [38] confirmed a greater short-term improvement in FEV_1 (32.9%) for those patients treated with staple resection than those undergoing laser reduction (13.4%). In addition, Keenan *et al.* [67] noted higher morbidity in a limited number of patients undergoing unilateral laser reduction ($n = 10$) compared with a group undergoing predominantly stapled resections ($n = 57$). As such, current laser technology has a limited role in LVRS.

Several investigators have compared the short-term physiological results of bilateral LVRS performed via VATS

Figure 55.1 Box plots of changes from post-rehabilitation baseline in percentage of the predicted value for FEV_1 among National Emphysema Treatment Trial (NETT) patients who provided data after 6, 12 or 24 months of follow-up. High-risk patients were excluded. Solid boxes represent patients assigned to lung volume reduction surgery (LVRS); open boxes represent patients assigned to medical therapy. The line inside each box indicates the median value, the top and bottom of each box indicate the first and third quartiles, and the tails of the boxes extend to the most extreme values not considered to be outliers. Values outside the tails of the box plot are considered to be outliers. FEV_1 , forced expiratory volume in 1 s; SD, standard deviation. (From the National Emphysema Treatment Trial Research Group [20], with permission.)

or MS. Kotloff *et al.* [63] noted no difference in short-term spirometric outcomes although the total in-hospital mortality was higher in the MS group (13.8 vs 2.5%). Wisser *et al.* [68] noted little difference in all outcomes between 15 patients treated with bilateral LVRS via MS compared with 15 undergoing bilateral thoracoscopic LVRS. These data corroborate the retrospective findings of other investigators [64,69]. In contrast, Ko and Waters [70] noted a higher total mortality (25%) in 19 patients undergoing bilateral LVRS via MS compared with 23 patients treated thoracoscopically (8%); the improvement in FEV_1 was higher in the VATS group (62 vs 28%). Data from the NETT have recently confirmed similar functional benefits between bilateral LVRS performed using MS or VATS [21].

The variance around the mean improvement in FEV_1 is demonstrated in remarkably few studies [63,71,72]. Figure 55.2 demonstrates the heterogeneity in spirometric response for the NETT. These data support the contention of others that 20–50% of patients show little short-term spirometric improvement after LVRS [73]. Interestingly, many patients who experience little spirometric improvement experience significant improvement in breathless-

ness, highlighting the limitation of FEV_1 as the sole measure of improvement [74].

Although published data are limited, lung volumes have generally decreased during short-term follow-up while the diffusing capacity of lung for carbon monoxide (DLCO) changes modestly [18]. Changes in resting arterial blood gases (ABGs) have also been heterogeneous [18]. For example, Albert *et al.* [75] noted minimal changes in ABGs for a group of patients as whole; some patients experienced significant improvement while others experienced worsening. In addition, no correlation was seen between ABG changes and the change in spirometry, lung volumes or DLCO.

Exercise capacity

The majority of investigators have confirmed improvements in simple measures of exercise capacity such as timed measures of walk distance [18]. Unfortunately, limited descriptions of the methodology utilized have been provided, which is particularly important for the 6-minute walk distance [76]. For example, NETT investigators have confirmed the effect of repeated testing and varying exercise format on outcomes in a large cohort of patients with severe emphysema [77]. Similarly, these investigators confirmed a modest improvement in 6-minute walk distance for the surgically treated patients compared with a consistent decrease in medically treated patients [20].

Similarly, numerous groups have reported results of cardiopulmonary exercise testing (CPET) [18], with consistent short-term increases in maximal work load, $\dot{V}O_2$ and \dot{V}_E generally reported [71,74,78–82]. The improved maximal ventilation appears to be achieved through increased tidal volume, V_T , with little change in respiratory rate, f_b [71]; mean inspiratory and expiratory flows increased significantly while Pao_2 improved in 20 [71]. Benditt *et al.* [78] confirmed an improved exercise capacity after bilateral LVRS while noting decreased heart rate at similar work loads; the primary limitation to exercise was felt to be ventilatory. An improved V_T and physiological dead space at submaximal work loads during steady-state testing was associated with a decreased $Paco_2$ during exercise in one series [80]. The NETT investigators confirmed an increase in maximal achieved wattage during oxygen supplemented cycle ergometry in surgical patients, while lesser improvement was noted in patients that continued aggressive medical management (Fig. 55.3) [20]. Additional results from another randomized trial have been recently published by Dolmage *et al.* [82]. These investigators documented an improved $\dot{V}O_{2\text{ peak}}$ and power with a greater minute ventilation and tidal volume [82]. Importantly, an improvement in operational lung volumes was confirmed with LVRS. Importantly, the improvement in dyspnoea after surgery has been demonstrated to correlate best with decreased dynamic hyperinflation [74].

Figure 55.2 Histograms of changes from baseline in FEV_1 after 6, 12 and 24 months of follow-up. (a) Percentage of patients experiencing a change in FEV_1 per cent predicted 6 months after randomization to lung volume reduction surgery (LVRS) or medical therapy. (b) Percentage of patients experiencing a change in FEV_1 per cent predicted 12 months after randomization to LVRS or medical therapy. (c) Percentage of patients experiencing a change in FEV_1 per cent predicted 24 months after randomization to LVRS or medical therapy. Baseline measurements were performed after pulmonary rehabilitation. Patients previously identified as high risk were excluded. Patients who were too ill to complete the procedure or who declined to complete the procedure but did not explain why were included in the ‘missing’ category. P values were determined by the Wilcoxon rank-sum test. The degree to which the bars are shifted to the upper left of the chart indicates the degree of relative benefit of LVRS over medical treatment. The percentage shown in each quadrant is the percentage of patients in the specified treatment group with a change in the outcome falling into that quadrant. This was an intention-to-treat analysis. FEV_1 , forced expiratory volume in 1 s. (From the National Emphysema Treatment Trial Research Group [20], with permission.)

Figure 55.3 Histograms of changes from baseline in maximal achieved workload after 6, 12 and 24 months of follow-up. (a) Percentage of patients experiencing a change in maximal achieved work load predicted 6 months after randomization to lung volume reduction surgery (LVRS) or medical therapy. (b) Percentage of patients experiencing a change in maximum achieved work load 12 months after randomization to LVRS or medical therapy. (c) Percentage of patients experiencing a change in maximum achieved work load 24 months after randomization to LVRS or medical therapy. Baseline measurements were performed after pulmonary rehabilitation. Patients previously identified as high risk were excluded. Patients who were too ill to complete the procedure or who declined to complete the procedure but did not explain why were included in the ‘missing’ category. P values were determined by the Wilcoxon rank-sum test. The degree to which the bars are shifted to the upper left of the chart indicates the degree of relative benefit of LVRS over medical treatment. The percentage shown in each quadrant is the percentage of patients in the specified treatment group with a change in the outcome falling into that quadrant. This was an intention-to-treat analysis. P values were determined by the Wilcoxon rank-sum test. The degree to which the bars are shifted to the upper left of the chart indicates the degree of relative benefit of LVRS over medical treatment. The percentage shown in each quadrant is the percentage of patients in the specified treatment group with a change in the outcome falling into that quadrant. This was an intention-to-treat analysis. (From the National Emphysema Treatment Trial Research Group [20], with permission.)

The short-term effects of LVRS on the pulmonary vascular response to exercise have been described by several investigative groups [83–85]. Most groups noted little change in pulmonary haemodynamics at rest or during exercise, although improvement in right heart function during exercise has been reported [86]. In contrast, Weg *et al.* [87] reported an elevation of resting pulmonary artery pressures 3 months after bilateral LVRS. Further prospective data are required to better define these changes and their clinical significance.

Medication and oxygen requirements

Several groups have described improvements in oxygen requirement after surgery [18,39,62,67,88–91]. For example, Cooper *et al.* [92] reported that of the 52% of patients using O_2 continuously before surgery, only 16% were using O_2 continuously 6 months after bilateral LVRS. Of the 92% who were using O_2 with exertion preoperatively, only 44% were doing so postoperatively. Similar data have been reported by others [38,68–70,91,93–95]. Several groups have noted discontinuation of oral steroid requirement after LVRS [15,62,69,88,89,92,96,97], although the majority of studies provided limited detail regarding specific steroid reduction protocols.

Health status

Several groups have demonstrated short-term improvement in the Medical Research Council (MRC) dyspnoea scoring system [15,38–40,62,92,98–102]. Others have confirmed similar improvement using the transitional dyspnoea index (TDI) of Mahler *et al.* [103]; the range of improvement has varied widely [15,67,71,74,88,90,92,95,97,104–106]. The NETT investigators presented detailed assessment of breathlessness using the University of California Shortness of Breath Questionnaire (UCSD SOBQ), a symptom-based instrument validated in COPD [107]. Figure 55.4 demonstrates the heterogeneity of response noted, although a clear benefit is noted in the surgically treated group compared with medically managed patients. Some have suggested little difference in dyspnoea improvement between unilateral or bilateral LVRS [40], or between bilateral compared with unilateral LVRS [68], while others have reported better improvement with bilateral procedures [39].

The improvement in health status has been extensively reviewed [108]. Cooper *et al.* [15,92] confirmed short-term improvements using two generic instruments, the Medical Outcomes Survey-Short Form 36 (SF-36) and the Nottingham Health Profile (NHP), which have been

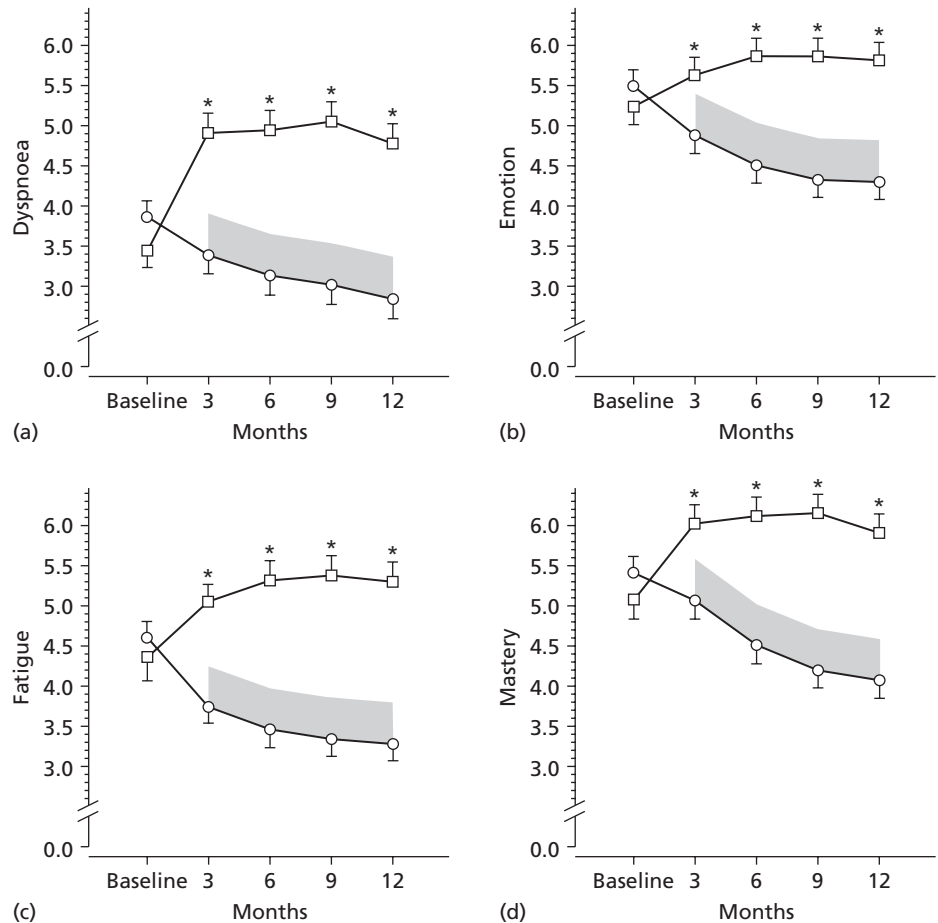

Figure 55.5 Panels (a–d) reflect the effect of surgery (□) and medical control treatment (○) on each of the four domains of the Chronic Respiratory Questionnaire (dyspnoea, emotional function, fatigue and mastery) at baseline and 3, 6, 9 and 12 months after randomization. Values at follow-up are adjusted least square mean (SE). The shaded area shows the minimum clinically important difference for each measure. (From Goldstein *et al.* [61], with permission.)

validated in COPD patients [109–111]. Similar results have been reported by other groups [69,80,112]. Several groups have described detailed analyses of health status as measured with the SF-36. Moy *et al.* [113] measured health-related quality of life (HRQL) with the SF-36 before and after comprehensive pulmonary rehabilitation and again after bilateral LVRS via VATS in 19 patients [114]. No significant change in any of the domains was noted after pulmonary rehabilitation although significant improvement was noted in vitality after LVRS. When compared with baseline, the combination of rehabilitation and bilateral LVRS resulted in significant improvement in four of the eight domains (physical functioning, role limitations because of physical problems, social functioning and vitality). Importantly, pulmonary rehabilitation accounted for most of the improvement in role limitations while LVRS accounted for most of the improvement in physical functioning, vitality and social functioning.

Change in health status measured with disease-specific instruments has been reported. Bagley *et al.* [91] described improvement in the Chronic Respiratory Questionnaire (CRQ) while Norman *et al.* [115] reported improvement

using the St. George's Respiratory Questionnaire (SGRQ). Canadian investigators noted clear improvement in the CRQ in patients treated surgically compared with a matched group randomized to medical therapy (Fig. 55.5) [61]. The NETT investigators noted significant improvement in the SGRQ of surgically treated patients compared with more modest effects [20]. Importantly, clinically significant improvement in SGRQ scores was seen in a minority of medically treated patients.

Lung transplantation

Pulmonary function

Spirometric improvement after both SLT and DLT has been consistently reported with lesser improvement generally reported in SLT recipients [46,94,116–125]. For example, Levine *et al.* [116] described functional results in 28 patients undergoing 29 SLT procedures; a rise in FEV_1 from a baseline of 16% predicted to 57% predicted at 3 months and 60% predicted at 6 months after SLT. Brunsting *et al.* [125] suggested that recipient chest wall factors determined post-operative pulmonary function, while Cheriyan *et al.* [126]

confirmed the importance of recipient factors by noting that pulmonary function after SLT reflected restriction of the transplanted lung and obstruction in the native lung with a decreased transpulmonary pressure. In an elegant study, Estenne *et al.* [127] confirmed hyperinflation of the native lung in all patients with a lower, yet stable, total lung capacity (TLC) in the allograft. The graft exhibited a normal functional residual capacity (FRC) suggesting the expansion of the rib cage allows preservation of the FRC in the transplanted lung. In contrast to SLT, DLT recipients experience a significantly higher FEV_1 with most series reporting values near normal [94,118,119].

Exercise capacity

Several early reports noted rising distance walked after SLT [117,121]. Early comparisons suggested a greater improvement in walk distance in emphysema patients undergoing SLT compared with DLT [46,118,124]. In contrast, others described similar 6-minute walk distance in patients after both types of transplantation for COPD [94,119].

Numerous investigators have confirmed persistent aerobic limitation after SLT or DLT with little evidence for ventilatory limitation [128,129]. In fact, short-term data reported by other investigators have been remarkably consistent [130–132]. Schwaiblmair *et al.* [133] demonstrated a severe aerobic limitation before transplantation which improved significantly after surgery. Importantly, no evidence of ventilatory limitation was noted after transplantation with a significant decrease in physiological dead space and $P(A-a)O_2$ at peak exercise.

Persistent aerobic limitation after transplantation has been consistently noted, with most reports supporting peripheral muscle dysfunction as the predominant cause of exercise limitation [134,135]. Pantoja *et al.* [136] examined nine lung transplant recipients (eight SLT, one DLT) 5–102 months after transplantation. In a subset, maximal voluntary contraction of the tibialis anterior muscle was decreased. Although maximal inspiratory pressures did not differ from control values, the maximal expiratory pressures were diminished by 30% relative to control ($P < 0.05$). The authors concluded that peripheral and expiratory muscle weakness, atrophy and reduction in muscular function with exercise was present in patients up to 3 years post-transplant [136]. Evans *et al.* [137] noted that quadriceps muscle intracellular pH was more acidic at rest and fell during exercise at a lower metabolic rate in transplant recipients versus healthy controls. In fact, the persistent decrease in $\dot{V}O_{2max}$ correlated closely with the metabolic rate at which muscle pH fell. Using non-invasive optical techniques, Tirdel *et al.* [138] reported that lung transplant recipients had a reduced maximum $\dot{V}O_2$ and an earlier onset of anaerobic threshold compared with matched healthy controls, suggesting an alteration in peripheral oxygen

utilization by the myocyte. Wang *et al.* [139] extended these findings by analysing vastus lateralis muscle biopsies in lung transplant recipients following exercise. These biopsies demonstrated a lower mitochondrial adenosine triphosphate (ATP) production rate, lower activity of mitochondrial enzymes, a lower proportion of type I fibres and a higher lactate and inosine monophosphate content in the transplant recipients compared with controls. These findings were concordant with previous reports that reduced muscle calcium regulation and impaired potassium regulation after lung transplantation contributed to impaired muscle performance during exercise [140,141]. The cause of this peripheral muscle dysfunction post-transplantation remains unclear, although chronic disease, drug therapy, disuse and poor nutrition have all been suggested as contributing factors. For example, ciclosporin inhibits maximal coupled and uncoupled skeletal muscle mitochondrial respiration *in vitro* [142–144].

Health status

Gross *et al.* [145] administered to lung transplant candidates and recipients the Medical Outcome Study Health Survey (MOS 20), the Index of Well-Being, the Karnofsky Performance Status Index and questions assessing work history. Lung transplant candidates, most of who suffered from obstructive diseases, demonstrated significant impairment in health status. In those with sequential measurements, significant improvement was noted 6–12 months after transplantation. In a rare, prospective longitudinal study, TenVergert *et al.* [146] noted improvement in NHP 1 month after transplantation (13/24 patients with emphysema). Further improvement was noted during the first 4 post-operative months such that NHP scores were comparable to those of the general population. Cohen *et al.* [147] extended these findings by noting that pretransplant anxiety and psychopathology predicted post-transplant adjustment with greater anxiety predicting worse post-transplant quality of life.

Long-term results

Bullectomy

Fitzgerald *et al.* [51] reported results in 84 patients who underwent 95 surgical procedures performed over a greater than 20 year period. The mean follow-up was 7.3 years [51], with long-term follow-up available in 47 patients. Inconsistent maintenance of improvement was noted although some patients demonstrated improvement for 3–5 years. Pearson and Ogilvie [148] noted short-term improvement in 11 patients during a mean follow-up of 7.3 years, although a gradual decrement in physiological improvement was noted in most patients. During a mean follow-up of 4.5 years in 43 patients, Schipper *et al.* [58]

noted initial improvement in spirometry, residual volume and 6-minute walk distance, although a gradual worsening was noted over the years. Most authors have reported poorest long-term outcome in those individuals with greater degrees of emphysema in the remaining lung and greater underlying chronic bronchitis.

LVRS without giant bullae

Roue *et al.* [149] reported symptomatic improvement in 12/13 patients 6 months after LVRS (unilateral in 11). Although collection was incomplete, four of six patients with available data maintained a greater than 20% improvement in FEV_1 at 2 years, but neither of two patients maintained improvement at 4 years. Brenner *et al.* [150] noted a higher rate of drop in FEV_1 (0.255 ± 0.057 L/year) in those patients experiencing the greatest improvement in the initial 6 months after surgery (those treated with bilateral stapling). The lowest rate of drop was noted in those with the least initial improvement. Flaherty *et al.* [106] documented a gradual decrement in FEV_1 over the course of 3 years after bilateral LVRS, while the Washington University group has recently reported that the majority of 200 consecutive patients exhibited spirometric improvement 3 and 5 years after surgery [151].

Cordova *et al.* [152] noted a higher 6-minute walk distance in six patients 18 months after surgery compared with preoperative values; improvement in cardiopulmonary performance tended to be maintained 12 months after surgery. Flaherty *et al.* [106] also described maintenance of improvement in 6-minute walk distance despite spirometric decrement over 3 years after bilateral surgery. The NETT investigative group noted that surgical patients, in contrast to medically treated patients, were more likely to maintain improved maximal wattage during oxygen supplemented cardiopulmonary exercise testing up to 2 years after surgery [20].

Data regarding improved dyspnoea or health status have been limited. Appleton *et al.* [153] noted a sustained improvement in MRC scale and transitional dyspnoea scores during a mean of 51 months of follow-up. Cordova *et al.* [152] reported maintenance of improvement in sickness impact profile (SIP) in five of six patients with 18 months follow-up. Yusen *et al.* [151] reported improvement in MRC scores in 52% and 40% of patients 3 and 5 years after bilateral LVRS, respectively. Sixty nine per cent and 57% reported clinically significant improvement in the pulmonary function component and 65% and 54% in the dyspnoea component, 3 and 5 years after surgery, respectively. Similarly, the NETT investigators reported that surgical patients compared with medically treated patients were more likely to demonstrated clinically significant improvements in the SGRQ up to 2 years after surgery [20].

Lung transplantation

Clinical results

Data from the Registry of the International Society for Heart and Lung Transplantation suggests an approximately 80% 1 year, 50% 5 year and 35% 10 year survival for emphysema patients [48]. Long-term mortality seems positively related to increasing recipient age but appears less in patients with underlying emphysema [48]. The most frequent causes of late death include obliterative bronchiolitis, infection and malignancy [48,154].

Pulmonary function

Early reports noted that some patients demonstrated stability in FEV_1 improvement while others experienced a decline in pulmonary function after several months [116,121]. The importance of obliterative bronchiolitis on this loss of lung function has been reviewed recently [155,156]. Bjortuft *et al.* [123] compared pulmonary function in stable SLT recipients to recipients who developed histological obliterative bronchiolitis or obliterative bronchiolitis syndrome (BOS). Several groups have suggested that decrease in pulmonary function with BOS is particularly likely in SLT recipients [46,157]. Given the difficulty in histological confirmation of obliterative bronchiolitis, BOS has been defined physiologically as a persistent, greater than 20% drop in FEV_1 from the post-transplant baseline, in the absence of other acute conditions (airway complications, infection, congestive heart failure, reversible airway reactivity and systemic disease) [158]. Furthermore, BOS can be staged according to the drop in FEV_1 from the peak post-transplant value. Obliterative bronchiolitis is associated not only with a drop in pulmonary function but also by increased mortality [154,156].

Exercise capacity

Sundaresan *et al.* [46] noted persistent improvement in 6-minute walk distance after both SLT and DLT for COPD up to 4 years after transplantation. The same group has recently noted a mild decrease in 6-minute walk distance 5 years after transplantation [49]. Maximal achieved \dot{V}_{O_2} has been documented to change little in SLT or DLT recipients from 3 months to 1–2 years after transplantation [116,130]. As such, a significant limitation to exercise remains for patients after lung transplantation, although the effect of long-term aerobic training has not been described in this patient population.

Health status

Gross *et al.* [145] noted a similar result on the MOS 20 questionnaire in 17 recipients tested 19–36 months and 16 recipients tested greater than 36 months after transplantation when compared with responses 11 months after surgery. Importantly, recipients with BOS showed

decrements in health status, particularly in the physical and social functioning and bodily pain. Similar results have been demonstrated by others [146,159,160].

Which patients should and which should not be considered for surgery?

Bullectomy

Most investigators have attempted to identify optimal surgical candidates using physiological tests and radiographical studies to identify compressed normal lung that is most likely to respond to bullectomy. These are summarized in Tables 55.1 and 55.2.

Clinical features

In general, optimal candidates suffer from persistent exertional limitation despite optimal medical therapy and pulmonary rehabilitation. A worse surgical result has been associated with older age in some series [51,52]. Some investigators have suggested a higher morbidity and worse long-term results in the presence of superimposed chronic bronchitis [51,52,56]. Although imperfect, a history of chronic sputum production and recurrent respiratory infections may provide a suggestion of such primary airway disease [1].

Physiological features

In general, ideal patients exhibit a 'restrictive' spirometric pattern with simultaneous elevation of the FRC and TLC

Table 55.1 Potential indications for classical bullectomy and lung volume reduction surgery (LVRS) in the absence of giant bullae. (Adapted from www.thoracic.org/copd/)

Parameter	Bullectomy	LVRS without giant bullae
Clinical	Young age (< 50 years) Rapid progressive dyspnoea despite maximal medical therapy Ex smoker	Age < 75 years Clinical picture consistent with emphysema Dyspnoea despite maximal medical treatment pulmonary rehabilitation Ex-smoker (> 6 months) Requiring < 20 mg prednisone/day
Physiological	Normal or slightly ↓ FVC FEV ₁ > 40% prednisone Little bronchoreversibility 'High' trapped lung volume Normal or near normal DLCO Normal Pao ₂ and Paco ₂	FEV ₁ after bronchodilator < 45% prednisone Hyperinflation: TLC > 100% prednisone RV > 150% Pao ₂ > 45 mmHg Paco ₂ < 60 mmHg Post-rehabilitation 6-min walk distance > 140 m Low post-rehabilitation maximal achieved cycle ergometry watts
Imaging	CXR Bulla > 1/3 hemithorax CT Large and localized bulla with vascular crowding and normal, compressed pulmonary parenchyma around bulla Angiography Vascular crowding with preserved distal vascular branching Isotope scan Well-localized matching defect with normal uptake and washout for underlying lung	CXR Hyperinflation CT High-resolution CT confirming severe emphysema, ideally with upper lobe predominance

Table 55.2 Potential contraindications for classical bullectomy and lung volume reduction surgery (LVRS) in the absence of giant bullae. (Adapted from www.thoracic.org/copd/)

Parameter	Bullectomy	LVRS without giant bullae
Clinical	Age > 50 years Comorbid illness Cardiac disease Pulmonary hypertension > 10% weight loss Frequent respiratory infections Chronic bronchitis	Age > 75–80 years Comorbid illness that increases surgical mortality Clinically significant coronary artery disease Pulmonary hypertension (PA systolic > 45, PA mean > 35 mmHg) Surgical constraints: Previous thoracic procedure Pleuradesis Chest wall deformity
Physiologic	$FEV_1 < 35\%$ prednisone 'Low' trapped gas volume Decreased DLCO	$FEV_1 \leq 20\%$ predicted and DLCO $\leq 20\%$ prednisone \uparrow inspiratory resistance
Imaging	<i>CXR</i> Vanishing lung syndrome Poorly defined bullae <i>CT</i> Multiple ill-defined bullae in underlying lung <i>Angiography</i> Vague bullae; disrupted vasculature elsewhere <i>Isotope scan</i> Absence of target zones, poor washout in remaining lung	Homogeneous emphysema and $FEV_1 \leq 20\%$ predicted Non-upper lobe predominant emphysema and high post-rehabilitation cycle ergometry maximal achieved wattage

CT, computed tomography; CXR, chest X-ray; DLCO, diffusing capacity of lung for carbon monoxide; FEV_1 , forced expiratory volume in 1 s; PA, pulmonary artery.

[161]; severe obstruction, particularly when associated with smaller bullae, have been associated with poor long-term results [161]. One group noted the best improvement in patients with an FEV_1 of more than 40% predicted [162]. Significant bronchoreversibility has been proposed as an additional relative contraindication (see Table 55.2) [4,161]. Baseline elevation of the trapped gas volume has been noted in groups demonstrating better responses to classic bullectomy [51,161]. Some have utilized the DLCO as a marker of greater underlying emphysema; two groups have suggested a better response in those patients with higher DLCO and lack of exertional desaturation [50,162]. However, absolute thresholds are not available.

Imaging

Multiple groups have noted inferior surgical results in patients with bullae occupying less than one-third of the hemithorax, particularly for the long-term maintenance of functional improvement [51–53,163]. Angiography was a popular method used to identify crowded vasculature in compressed lung [161], although computed tomography (CT) has demonstrated a clear advantage. CT allows an

assessment of the volume of air in bullae, the presence of compressed lung and an examination of the structure of the remaining lung tissue [53,161,164,165]. Some authors have advocated the use of radionuclide scans to assess the relative function of bullous and non-bullous areas, which may be particularly useful in identifying lung zones that appear normal or minimally involved on CT or chest radiograph [166].

Lung volume reduction without giant bullae

Clinical features

The clinical evaluation aims to identify patients with emphysema. As such, the presence of frequent respiratory infections and chronic copious sputum production may be useful in identifying patients with primary airway disease [167]. In addition, the clinical assessment should attempt to identify features predicting a higher mortality or likelihood of poor functional result (see Tables 55.1 and 55.2). Significant comorbidity, such as advanced cancer or multiorgan disease, is a reasonable contraindication (see Table 55.2). Coronary artery disease is frequently seen in this patient

population [168], although it is not an absolute contraindication to surgery. Successful combined LVRS and cardiac surgery has been well documented [169,170]. Similarly, pulmonary hypertension has been described as a relative contraindication for LVRS [171], although prohibitive pulmonary hypertension is infrequent in this patient population [172–174]. The effect of milder pulmonary hypertension has not been prospectively studied [16]. Several groups have reported either no consistent change or a mild improvement in pulmonary artery pressure early after bilateral LVRS [84,85,175,176] or improved right ventricular function early after LVRS [83,86,177]. In contrast, some have reported worsening resting pulmonary hypertension after LVRS [87].

Less favourable outcomes have been reported in the presence of α_1 -antitrypsin deficiency by some groups [36,178]. Cassina *et al.* [99] noted similar short-term clinical and physiological responses in 12 patients with α_1 -antitrypsin deficiency compared with 18 patients with typical smoker's related emphysema; long-term response (12–24 months) was clearly poorer in those with α_1 -antitrypsin deficiency [99]. Similarly, Gelb *et al.* [179] described only modest spirometric improvement after lower lobe LVRS via VATS in six patients with α_1 -antitrypsin deficiency [179]. In contrast, one group has recently reported good long-term results in a group of emphysema patients with α_1 -antitrypsin deficiency who were followed up to 5 years after thoracoscopic LVRS [180].

An impaired nutritional status, as measured by a lower body mass index or by decreased percentage of ideal body weight or fat-free mass index, has been associated with increased perioperative complications [181,182]. Importantly, clinical severity of disease has not proven a consistent contraindication [91,97,183,184].

Physiological features

Pulmonary function testing has proven instrumental in identifying optimal candidates for surgery (see Table 55.1). A lower limit of FEV_1 that identifies individuals at prohibitive risk has not been agreed upon, with some investigators reporting acceptable outcomes in patients with very severely decreased FEV_1 less than 500 mL [62,97,183,185]. As the mechanism of improvement in spirometry relates to improvement in elastic recoil [186], patients with airflow obstruction from structural emphysema appear to be the ones who benefit most from LVRS. Ingenito *et al.* [187] reported a relationship between low inspiratory resistance (as a measure of primarily airway disease) and short-term improvements in FEV_1 . These same investigators have confirmed that measurement of inspiratory resistance provides additional information to emphysema distribution as defined by perfusion scintigraphy [188]. One group has recently confirmed that greater histopathological

abnormalities of the smaller airways are associated with poorer short-term response to LVRS [189].

Although some have advocated LVRS only in those patients with a significant elevation of TLC [171], the RV and RV : TLC ratio may be better predictors of response [190]. Preliminary data have suggested that an elevated RV : TLC ratio may be the best physiological parameter to identify patients demonstrating improved quality of life, pulmonary function and exercise capacity after bilateral LVRS [191]. Importantly, the NETT did not identify lung volume as a predictor of mortality or functional improvement after bilateral LVRS [20].

Several investigators have suggested that a very low DLCO increases risk [67,90,192], but others have not confirmed these findings [185]. The NETT identified two subgroups of patients at particularly high risk of surgical mortality after bilateral LVRS [193]. One subgroup, composed of patients with a post-bronchodilator $FEV_1 \leq 20\%$ predicted and a DLCO $\leq 20\%$ predicted, experienced a much higher mortality with LVRS than with medical management (odds ratio [OR] 2.98; 95% confidence interval [CI], 1.3–7.7).

ABG abnormalities have been suggested to predict a bad outcome. Several investigators have suggested higher mortality in patients with hypercapnia [38,80,90,194], while others have not confirmed this finding [97,195–198]. The most definitive data come from the NETT where baseline $Paco_2$ was not associated with impaired outcome despite over 30% of randomized patients exhibiting baseline hypercapnia [20].

Preoperative exercise capacity has been documented to be a predictor of outcome by numerous investigators [90,183,194]. The most compelling data comes from the NETT, where one of the primary endpoints was maximal achieved work load achieved on a cycle ergometer while breathing supplemental oxygen [20]. A threshold of 40% of the baseline workload demonstrated a clear breakpoint in mortality for the overall study group; this corresponded to a work load of 25 watts (W) for females and 40 W for male patients [20]. These thresholds, in conjunction with computed tomography data, allowed a clear separation of non-high risk patients into four distinct categories (Fig. 55.6 and Table 55.3).

Imaging

Thoracic imaging is vital in the evaluation for LVRS [199], with most authorities considering topographical heterogeneity an important predictor of an optimal response from LVRS [16,18]. Some investigative groups have utilized chest radiographs to identify a favourable distribution of emphysema [200]. CT has proven particularly useful in this regard [201–203]. The severity of emphysema on CT may be associated with outcome after LVRS [204–206]. The

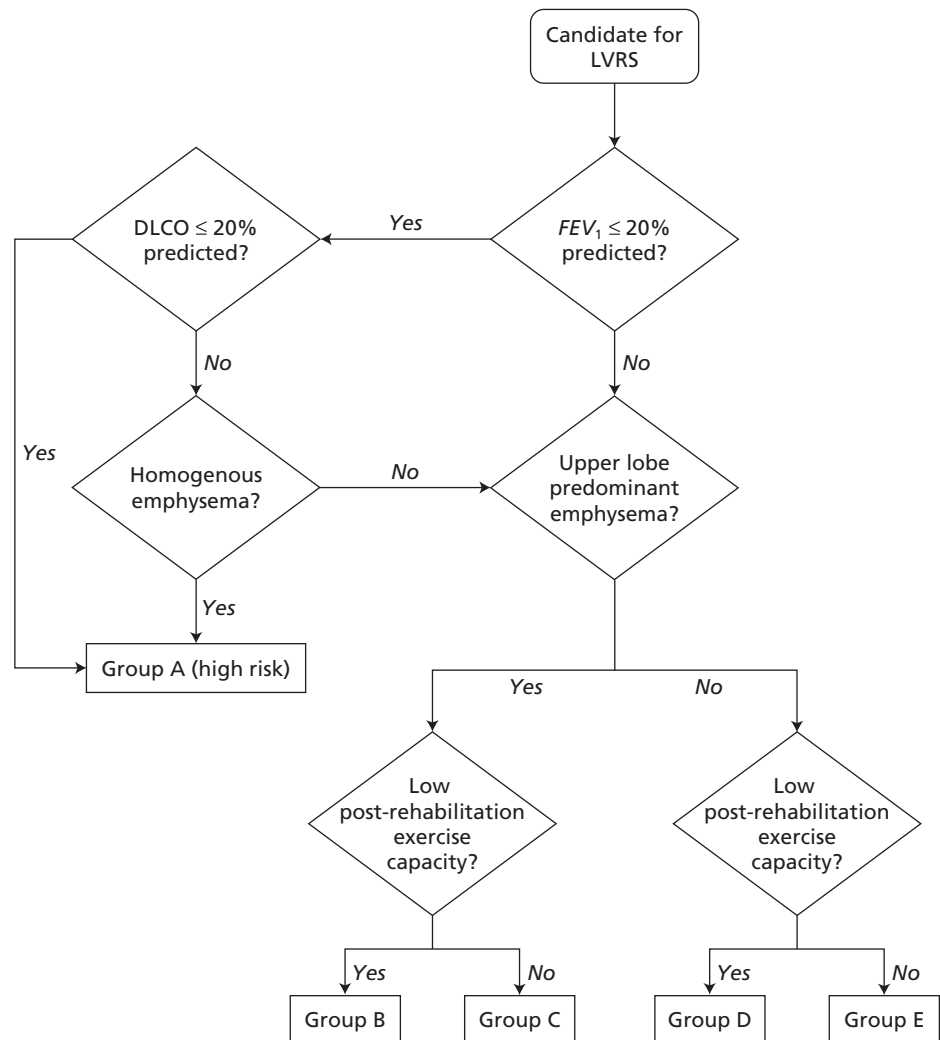

Figure 55.6 Diagnostic algorithm for patients being considered for lung volume reduction surgery (LVRS) based on data from the National Emphysema Treatment Trial (NETT) [20]. FEV_1 , forced expiratory volume in 1 s; DLCO, diffusing capacity of lung for carbon monoxide. (From Martinez *et al.* [244], with permission.)

importance of emphysema heterogeneity has been consistently identified by many investigative groups [185,192, 206–212]. The most compelling data supporting the value of visual grading of emphysema distribution have been provided by NETT investigators [20]. Radiologists at 17 participating clinical centres classified HRCT scans as exhibiting predominantly upper lobe or non-upper lobe emphysema based on visual scoring of disproportionate disease between non-anatomical thirds divided equally from apex to base [213]. Using this method, in conjunction with the maximal achieved workload during oxygen supplemented maximal cycle ergometry, NETT investigators published two sentinel studies that clarified the role of CT imaging in the evaluation of patients for LVRS. An early manuscript identified an increased risk of surgical mortality in patients with severe obstruction ($FEV_1 \leq 20\%$ predicted) and either diffuse emphysema on HRCT or a $DLCO \leq 20\%$ predicted (relative risk [RR] 3.9; 95% CI, 1.9–9.0) [193]. Patients

with upper-lobe predominant emphysema and a low post-rehabilitation exercise tolerance exhibited a decreased risk of mortality (RR 0.47; $P = 0.005$) after LVRS compared with medical therapy [20]. Patients with non-upper lobe predominant emphysema and a high post-rehabilitation exercise capacity exhibited an increased risk of death during follow-up after LVRS (RR 2.06; $P = 0.02$) (see Table 55.3). Patients with upper lobe predominant emphysema and a high post-rehabilitation exercise capacity or patients with non-upper lobe predominant emphysema and a low post-rehabilitation exercise capacity did not have a survival advantage or disadvantage [20]. In addition, patients with upper lobe predominant emphysema treated surgically were more likely to improve their exercise capacity compared with medically treated patients (see Table 55.3). Figure 55.6 and Table 55.3 illustrate an approach to the evaluation of patients based on NETT data.

Unfortunately, the definition of emphysema heterogeneity

Table 55.3 Results of bilateral lung volume reduction surgery (LVRS) compared with medical therapy in patients with severe emphysema. Values in parentheses indicates percentage. Groups A–E refer to the patients as defined in Figure 55.6. (Adapted from National Emphysema Treatment Trial Research Group [20] and Martinez *et al.* [240], with permission.)

Patients	90-day mortality			Total mortality			
	LVRS	Medical therapy	<i>P</i> value	LVRS	Medical therapy	Risk ratio*	<i>P</i> value

* Risk ratio for total mortality in surgically versus medically treated patients during a mean follow-up of 29.2 months.
[†] Increase in the maximal workload of more than 10 W from the patient's post-rehabilitation base-line value (24 months after randomization).
[‡] Improvement in the health-related quality of life was defined as a decrease in the score on the St. George's Respiratory Questionnaire of more than 8 points (on a 100-point scale) from the patient's post-rehabilitation baseline score (24 months after randomization).

has varied widely [213]. As such, many investigators have utilized quantitative CT methodology to define disease heterogeneity. Several groups have confirmed moderately strong correlations between several quantitative CT values and outcome measures [106,214]. Nakano *et al.* [215] reported a positive correlation between the amount of amount of severe emphysema in the peripheral 50% of the lung and improvement in maximal achieved watts during cycle ergometry after LVRS [215]. This same group examined the relationship between the number and size of emphysematous lesions and the short-term response to LVRS [216]. The power law exponent (D) represents the slope of the relationship between the log of the cumulative number of emphysematous lesions and the log of the emphysema lesion size. As such, a steep slope and thus large D represents lungs with predominantly small lesions, while a shallow slope and small D suggests lungs with larger emphysematous lesions. A positive correlation was noted between the change in D and the change in maximal wattage achieved during cycle ergometry after surgery. As such, the authors suggested that patients with larger upper lobe lesions respond better to surgery than patients with small, uniformly distributed lesions [216].

Several groups have suggested that identifying heterogeneous perfusion during perfusion scanning may predict outcome after LVRS [217–219]. Thurnheer *et al.* [101] reported that functional improvement after surgery correlated better with physiological hyperinflation and emphysema heterogeneity as assessed by CT compared with perfusion heterogeneity assessed by scintigraphy. Hunsaker *et al.* [205] noted that patients with more heterogeneous emphysema, as determined by CT or V/Q imaging, tended to show a greater magnitude and likelihood for improved FEV₁. Cederlund *et al.* [220] noted little difference in emphysema heterogeneity classification based on CT or scintigraphy alone; the combination of the two was superior when contrasted with quantitative methodology as the 'gold standard'. It is likely that CT and scintigraphy demonstrate similar predictive ability in suggesting outcome after LVRS.

Lung transplantation

Given the significant morbidity and mortality associated with lung transplantation, careful patient selection is crucial. This is particularly relevant in COPD, as controversy

Table 55.4 General selection guidelines for candidate selection for lung transplantation in COPD patients. (Adapted from [225,227–229,241,242] and www.thoracic.org/copd/)

Relative contraindications

Age limits

- Heart-lung transplants ~ 55 years
- Double lung transplant ~ 60 years
- Single lung transplant ~ 65 years

Poorly or untreated, symptomatic osteoporosis

Oral corticosteroids > 20 mg/day prednisone

Ideal body weight < 70% or > 130%

Psychosocial problems

Requirement for invasive mechanical ventilation

Colonization with fungi or atypical mycobacteria

Absolute contraindications

Severe musculoskeletal disease affecting the thorax

Substance addiction within previous 6 months

Dysfunction of extrathoracic organ, particularly renal dysfunction

Human immunodeficiency virus infection

Active malignancy within 2 years except basal or squamous cell carcinoma of skin

Hepatitis B antigen positivity

Hepatitis C with biopsy-proven evidence of liver disease

exists regarding whether a survival benefit is noted after lung transplantation in this condition [154,221–224]. A summary of potential selection criteria is contrasted with bullectomy and LVRS in Tables 55.4 and 55.5.

Clinical features

The initial evaluation should include an assessment of the general surgical risks associated with age, as older recipients have a significantly worse survival rate [48]. The Joint Statement of the American Society for Transplant Physicians, the American Thoracic Society, the European Respiratory Society and the International Society for Heart and Lung Transplantation suggests that potential age limits included approximately 55 years for HLT, 65 years for SLT and 60 years for DLT [225]. Several clinical characteristics are felt to represent absolute or relative contraindications as enumerated in Table 55.3 [22,225–230].

Physiological features

Physiological testing has been the most frequently used modality to assess prognosis in patients with COPD [231]. Numerous investigators have documented that the FEV_1 after bronchodilator administration is an important predictor of mortality in COPD [232–236]. An emphysema patient can be considered an appropriate candidate for transplantation when the FEV_1 is below 25% predicted

Table 55.5 Disease-specific guidelines for candidate referral for lung transplantation in COPD patients. (Modified from [227,242,243].)

$FEV_1 < 20\text{--}25\%$ prednisone

$P_{CO_2} > 7.3$ kPa (55 mmHg)

Homogeneous emphysema distribution

Pulmonary hypertension

FEV_1 , forced expiratory volume in 1 s; P_{CO_2} , arterial carbon dioxide tension.

and/or the $P_{aCO_2} \geq 55$ mmHg [225]. A recent study has suggested that a multidimensional index incorporating FEV_1 , 6-minute walk distance, measurement of dyspnoea and body mass index predicts survival better in COPD than spirometry alone [237]. How this index will impact transplant listing decision making requires further investigation. Similarly, the presence of pulmonary hypertension with progressive deterioration should be considered an additional feature suggesting that transplantation should be considered an appropriate surgical intervention.

Imaging

Imaging techniques have a less defined role in the preoperative evaluation for lung transplantation. CT appears to alter the surgical approach to lung transplantation. Kazerooni *et al.* [238] noted a change in the determination of which lung was more severely diseased in 27/169 patients examined with preoperative chest radiography and CT. Of the 45 patients who subsequently underwent transplantation, CT prompted a change in the determination of which side to perform SLT in four. This same group has identified pulmonary nodules, suspicious for malignancy, in eight of 190 patients evaluated for lung transplantation [239]. As an active malignancy precludes transplantation, such a finding would clearly alter the candidacy of a patient for lung transplantation. Finally, the presence of unsuspected bronchiectasis could alter the decision to perform DLT in contrast to SLT.

Conclusions

Extensive literature has been published regarding surgical therapies for advanced COPD, with the most widely accepted directed at surgical relief of hyperinflation. Bullectomy and LVRS are established surgical techniques for a very limited number of patients. The patients with the poorest long-term outcomes appear to be those with the most abnormal respiratory function or greater extent of emphysema on imaging studies. Lung transplantation may

serve as a viable therapeutic option for some of these COPD patients.

CHAPTER 56

Anticholinergics in COPD

Theodore J. Witek, Jr

Bronchodilators are regarded as the mainstay of COPD pharmacotherapy [1–4] and the anticholinergic class of agents has proven over several decades to provide effective maintenance therapy [5]. This recognition of the value of anticholinergic therapy in COPD is anchored by the fascinating centuries of history of the medicinal properties of plants containing belladonna alkaloids and the present-day introduction of the new generation agent tiotropium. The recent introduction of tiotropium represents a significant advance in therapy, not only being the first inhaled once-daily agent, but also by its consistently better bronchodilatory effects relative to existing therapy as demonstrated in clinical trials [6–10].

This chapter briefly reviews the history and basic pharmacology of anticholinergics followed by a summary of the major clinical trials that have characterized the efficacy and safety of this class of agents in the treatment of COPD.

History

Uses of medicinal properties

The medicinal uses of inhaled antimuscarinics have been documented for centuries [11,12] and this history is made more fascinating by the fact that new generations of this class are being developed and introduced as innovative therapy at the present day.

In the time of Hippocrates, vapour inhalation was recorded and the use of the alkaloid in the treatment of asthma was cited in the 17th century. This practice was transferred from India to Great Britain where a more widespread use was observed in the 1800s. An interesting paper by Herxheimer in 1959 [13] described spirometric results following inhalation of asthma cigarettes containing atropine. Not only was his work among the first known to this author to evaluate spirometric therapeutic responses, it should not be overlooked that his insights to combine both

atropine and ephedrine was also novel in combination bronchodilator therapy.

Clearly, the ability of atropine as a bronchodilator was known, but its therapeutic utility was limited by systematic antimuscarinic side-effects. The first major advance was the discovery and development of ipratropium bromide, whose structure allowed preservation of bronchodilatation, but minimized absorption and side-effects [14,15]. Ipratropium bromide evolved to first-line maintenance treatment in COPD [16], and has been established as an effective and safe agent over decades of use. Its main disadvantage of four times daily dosing has recently been overcome with the latest generation compound tiotropium [17]. Tiotropium has significantly longer binding to muscarinic receptors than both atropine and ipratropium [18,19] with resultant functional consequences *in vitro* (Fig. 56.1) [20]. The clinical profile of these agents are detailed subsequently in this chapter.

Figure 56.1 Time course of effects of BA679 BR (10^{-9} mol) (circles), ipratropium bromide (10^{-8} mol) (squares) and atropine (10^{-8} mol) (triangles) after washout of the test drugs in guinea pig trachea. Each value is the mean \pm SEM of five animals. (From Takahashi *et al.* [20], with permission.)

Table 56.1 Muscarinic receptor subtypes nomenclature and characterization. (Derived from Roux *et al.* [101].)

Subtype	M ₁	M ₂	M ₃
Selective antagonists (Range of affinity)	Pirenzepine (M ₁ > M ₄ > M ₃ ≥ M ₂) Telenzepine (M ₁ > M ₄ > M ₃ ≥ M ₂)	Methoctramine (M ₂ ≥ M ₄ > M ₁ ≥ M ₃) AF-DX 116 (M ₂ ≥ M ₄ > M ₁ ≥ M ₃) Himbacine (M ₂ ≥ M ₄ > M ₁ ≥ M ₃)	4-DAMP (M ₃ ≥ M ₁ ≥ M ₄ > M ₂) p-F-HHSiD (M ₃ ≥ M ₁ ≥ M ₄ > M ₂)
Genes	m ₁	m ₂	m ₃
Localization in airway tissue	Parasympathetic ganglia Submucosal glands Alveolar walls	Postganglionic nerves Airway smooth muscle	Airway smooth muscle Submucosal glands Epithelial cells Endothelial cells
4-DAMP, 4-diphenylacetoxo- <i>N</i> -methylpiperidine.			

Box 56.1 Excerpts from H. H. Dales' 1933 letter to American Physiologic Society on Anatomic Nervous System Nomenclature [22].

'Evidence has been rapidly accumulating in favour of the view that the effects of nervous impulses in the postganglionic fibres of the autonomic system are chemically transmitted, by substances liberated in relation to their endings, and directly acting on the effector cells'.

'My own earlier observations [1914] on acetylcholine had indicated a substance of this kind as a likely candidate for the function of transmitting the effects of impulses in peripheral parasympathetic fibres; and the evidence in recent years has all tended to increase the probability that this choline ester is the actual parasympathetic transmitter'.

'Chemical transmission occurs at synapses in a sympathetic ganglion, and that the transmitter, even though the preganglionic fibres are anatomically sympathetic, is a substance indistinguishable from that which transmits the effects of postganglionic parasympathetic impulses'.

'These observations bring into the physiological picture the other aspect of the action of acetylcholine, which I called "nicotine like". To avoid elaborate periphrasis, and to promote clear ideas, we seem to need words which will briefly indicate action by two kinds of chemical transmission, due in one case to some substance like adrenaline, in the other case to a substance like acetylcholine, so that we may distinguish between chemical function and anatomical origin. I suggest the words "adrenergic" and "cholinergic", respectively for use in this sense'.

Evolution of pharmacology

Muscarinic pharmacology had its modern foundation in 1914 when Sir Henry Dale [21] classified receptors for acetylcholine as nicotinic and muscarinic. Receptor subtyping was reported in 1980 and was rooted in the establishment of high (M₁) or low (M₂) affinity for the antagonist pirenzepine. This basis of using selective antagonists to classify subtypes was expanded with further division of the M₂ receptor into M₂, M₃ and M₄ (Table 56.1).

The description of the autonomic nervous system that has evolved over the past century encompasses many terms as one describes cholinergic nerves travelling down to the vagus nerve into parasympathetic ganglia within the airway. Its principal neurotransmitter, acetylcholine, is released at ganglionic synapses and postganglionic neuroeffector junctions. Acetylcholine acts at both nicotinic and muscarinic cholinergic receptors – the former located at

parasympathetic ganglia and mediating ganglionic neurotransmission and the later located on postganglionic nerve fibres and on target cells such as epithelium, submucosal glands and airway smooth muscle. Nicotinic transmission at ganglia can be provoked by either acetylcholine or nicotine – transmission here can be interrupted by cholinergic blockers such as hexamethonium or *D*-tubocurarine. The acetylcholine released at postganglionic fibres has been termed muscarinic because transmission can be mimicked by muscarine. Effects resulting from muscarinic activity are blocked by antimuscarinics such as atropine; they are not blocked by curare. Thus, the evolution to the clinical referral of atropine and atropine-derived agents such as ipratropium and tiotropium as anticholinergics is correct; however, their description as antimuscarinics is more accurate. Box 56.1 lists excerpts from Dale's suggestions on such nomenclature in a 1933 note to the American Physiologic Society [22].

Basic pharmacology overview

Muscarinic receptors

The function of the various muscarinic receptor subtypes comes from observations in many species with the general understanding that M_1 receptors found in parasympathetic ganglia facilitate neurotransmission, M_2 receptors are localized to postganglionic cholinergic nerve terminals and provide a negative feedback modulation of acetylcholine release, and M_3 receptors are present on airway smooth muscle cells and mucosal glands with functional mediation of bronchoconstriction and glandular secretion (see Table 56.1). Several reviews describe investigations leading to this understanding [23–25].

Signal transduction

Ligand–receptor interaction of the muscarinic nature involves a biochemical pathway leading to an ultimate

Figure 56.2 Guanosine triphosphate (GTP)-binding protein-coupled muscarinic cholinergic receptor. This superfamily of receptors features seven transmembrane domains (TM_{1–7}). Acetylcholine binds to a cleft formed by the extracellular part of each of the seven TM domains and in particular to amino acid residues located in the third, fifth, sixth and seventh TM regions. Among the three intracellular loops (i₁–i₃), i₂ and i₃ as well as the membrane proximal part of the intracellular tail of the receptor are implicated in G-protein coupling. Critical determinants for G-coupling selectivity are in i₃. M_2 cholinergic receptors are coupled to G_i protein, leading to adenylyl cyclase inhibition and a decrease in cyclic adenosine monophosphate (cAMP). M_3 cholinergic receptors are coupled to G_{q-11} protein, leading to phospholipase C activation and an increase in Ca^{2+} . (From Roux *et al.* [101], with permission from Elsevier.)

tissue response (e.g. contraction of airway smooth muscle; Fig. 56.2). While these events are complex, with several investigations advancing fundamental concepts, it is accepted that the neurotransmitter acetylcholine interacts with G proteins, stimulating phospholipase C (PLC) and the breakdown of membrane lipids (e.g. phosphatidylinositol polyphosphates → inositol phosphates [IP]) resulting in the release of intracellular calcium from the endoplasmic reticulum. These collective events lead to the end organ effect. Of most relevance in COPD are the airway smooth muscle contraction and possibly glandular secretion. Diacylglycerol is another second messenger which is associated with protein kinase C (PKC) activation. There have been some theories put forth that PKC could be involved in a slow, sustained contractile response where as IP may be more related to initiation of contraction [26–28].

The number, distribution and special function of these receptor subtypes in human lung tissue is not fully understood. In the human trachea, muscarinic receptors are likely of the M_2 and M_3 receptor subtype as they have low affinity for the M_1 specific antagonist pirenzepine [29]. Furthermore, mRNA for M_2 and M_3 receptors have been detected in human bronchi [30].

Potential cellular effects of relevance

While the focus of the role of bronchodilators in COPD has for decades been based on their ability to dilate airways via smooth muscle contraction, there has been a recent surge in interest in the role of inflammation in this disease, particularly in those with more severe illness and prone to frequent exacerbations. In fact, the consistent findings of reduced exacerbations evaluated as secondary endpoints in clinical trials of antimuscarinic bronchodilators have sparked interest. A potential effect can be both indirect and direct. First, prolonged maintenance of bronchial opening from the long-acting agent tiotropium may minimize physical forces that could lead to effects potentially associated with exacerbations [31]. Secondly, while acetylcholine has long been viewed solely as a neurotransmitter, it may have non-neuronal roles that may offer explanations for some of the favourable outcomes observed in clinical trials [32].

Disse [32] first raised the possible anti-inflammatory potential of antimuscarinics in this light, based on observations on the influence of acetylcholine on mast cells, epithelial mediator release and alveolar macrophage chemotactic activity release. Additionally, recent evidence suggests a synergistic role of methylcholine with platelet-derived growth factor (PDGF) in potentiating mitogenesis in bovine tracheal smooth muscle cells [33].

While the clinical relevance of the role of antimuscarinics in the inflammatory arena is not clear, current observations prompt need for further characterization. For example, incubation of human lung tissue with acetylcholine (10^{-7} mol

showed increased histamine release with antigen exposure [34,35]. Furthermore, acetylcholine (10^{-7} to 10^{-4} mol) potentiated the release of 15-hydroxyeicosatetraenoic acid (15-HETE) and, to a lesser extent, prostaglandin E_2 (PGE_2), in the presence of $10 \mu\text{mol}$ arachidonic acid [36]. Perhaps of more relevance to COPD is the cholinergic influence on the release of chemotactic activity by alveolar macrophages. Sato *et al.* [37] reported that chemotactic activity more than doubled in the presence of acetylcholine (10^{-7} to 10^{-5} mol). This stimulation of release was blunted by the M_3 -selective antagonist 4-diphenylacetoxy-*N*-methylpiperidine (4-DAMP). As pointed out by Disse [32], acetylcholine concentrations in the range of 10^{-5} mol can be reached locally; therefore, a potential 'non-neuronal' therapeutic role of muscarinic blockade in the airways may be operating.

Clinical pharmacology overview

Pharmacodynamic effects in humans

The primary intended role of antimuscarinics in respiratory care is bronchodilatation. The basis for this effect rests on the role of the parasympathetic nervous system in regulating bronchomotor tone. In healthy individuals, indirect evidence for the presence of cholinergic airway tone can be seen in spirometric improvements following inhalation of atropine or ipratropium [38–40]. Dose-ordered reductions in airway resistance have also been observed in early human pharmacological studies with tiotropium [41]. The blunting of the response of the cholinergic agonist methacholine with tiotropium (Fig. 56.3) also provides a clinical demonstration of the pharmacological concept and agonist–antagonist interactions at the receptor level [42].

Figure 56.3 Change in PC_{20} from placebo, for each dose of tiotropium at each time point after treatment, expressed in terms of doubling dose protection. (From O'Connor *et al.* [42], with permission.)

β -Adrenergic agonists dilate airways through functional antagonism (i.e. they functionally reverse or inhibit the action of another agonist). By way of this unspecific mechanism they can cover a broad range of bronchoconstrictive effects. In COPD, the agonist acetylcholine causes bronchoconstriction which can be functionally antagonized by giving an adrenergic agonist (Fig. 56.4). Competitive antagonism invokes competing of an agonist (e.g. acetylcholine) directly with an antagonist (e.g. tiotropium). The fact that anticholinergics provide equal or greater bronchodilatation than β -agonists is the basis for cholinergic tone being the major reversible component in COPD. Such is not the case in asthma.

The heightened cholinergic tone in COPD has been proposed based on greater bronchodilator responses in COPD versus healthy subjects, with the amount of bronchodilatation being directly proportional to severity of airflow limitation [38]. Other indirect support for a prominent role of the cholinergic system in COPD comes from the greater bronchodilatation most often observed with antimuscarinics versus β -adrenergic agonists [6,7,10].

Muscarinic receptors are located throughout the body and end-organ-driven pharmacodynamic effects can be anticipated based on concentrations at these sites which will be indirectly driven by the agent administered (e.g. potency) and the route of administration (e.g. inhalation). As there is not equal sensitivity to muscarinic receptor antagonists at the parasympathetic neuroeffector junctions in different end organs [43], dose–response effects can be observed clinically – as long described for atropine. The unintended pharmacodynamic effects that can be observed with inhaled therapeutic doses of ipratropium and tiotropium are minimized by their quaternary structure

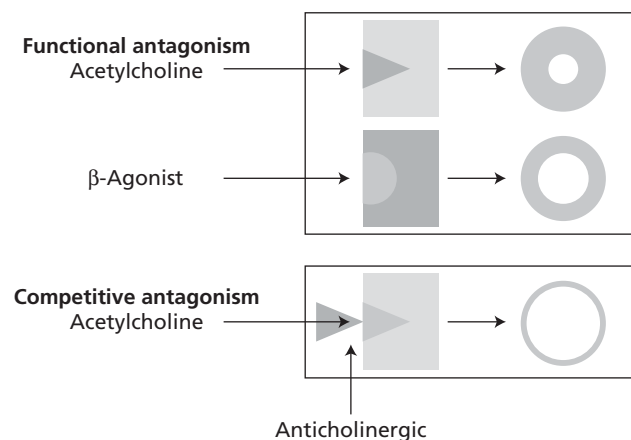

Figure 56.4 A schematic simplification of functional and competitive antagonism. The greater bronchodilatation with competitive antagonism of acetylcholine with anticholinergics versus that seen with functional antagonism via stimulation of β -receptors gives evidence that cholinergic tone is the major reversible competitor in COPD.

and less absorption, with the most commonly observed unintended pharmacodynamic effect being dry mouth [8]. The manifestation of dry mouth and the observation of reduced salivary secretion as the most sensitive antimuscarinic effect is supported by early clinical studies with tiotropium [41], where these effects were the first to manifest at high inhaled doses in the absence of heart rate or pupillary diameter changes.

The cholinergic system is involved in airway mucociliary system control [43], but a clear picture of clinical relevance does not emerge when considering endpoints such as sputum volume. For example, no reduction in sputum volume was observed after three times daily inhalation of 200 µg of either ipratropium [44] or oxitropium [45], while Ghafouri *et al.* [46] noted a significant reduction after 7 weeks of inhaled ipratropium (40 mg, q.i.d.). A reduction in sputum volume after 7 weeks' treatment with 200 µg oxitropium was also observed [47]. As the first two trials were of 4 weeks' duration, it may be that the duration of therapy is an important feature of any possible effect. Untoward effects of antimuscarinic therapy on mucociliary clearance have not been observed with quaternary agents such as ipratropium [45,48] and tiotropium [49].

The antimuscarinic effects of constipation (from decreased gastrointestinal tone and motility) and difficult urination (from decreased tone and contraction of urinary bladder) have been observed in small numbers in clinical trials with both ipratropium and tiotropium. Antimuscarinic action in the eye results in dilatation of pupils (mydriasis) and accommodation paralysis (cycloplegia). While these effects are uncommon in respiratory therapy, care should always be taken to avoid exposure of drug in the eye. Tachycardia and supraventricular tachycardia have been observed in small numbers in controlled clinical trials.

Clinical observations

There are case reports and small-scale clinical trials on the response to atropine of healthy subjects and those with COPD [38,40,50]. These observations confirm the intended pharmacodynamic effect of bronchodilatation as measured by lung function tests as well as the fact that antimuscarinic side-effects manifest more commonly with the tertiary amine atropine. The clinical development programmes leading to regulatory reviews and approvals of ipratropium, alone and in combination with albuterol as well as tiotropium, have provided the largest body of evidence of the beneficial therapeutic window of this class of agents in COPD. Also, given the decades of experience with antimuscarinics such as ipratropium, observational studies and evaluation of patient databases have contributed further to our knowledge of the utility of these agents in COPD. While some observational and retrospective cohort analyses

have reported possible associations of antimuscarinics with increased risk of cardiovascular morbidity and mortality [51–53], no effects have been consistently shown [54], particularly after controlling for confounders such as disease severity [55,56].

Ipratropium

Among the early large-scale studies with ipratropium in COPD were the comparative studies with metaproterenol where its bronchodilator effect and safety were demonstrated [57,58] and the anticholinergic class of bronchodilators as foundation therapy was grounded. The largest controlled observation with ipratropium comes with the original Lung Health Study [59] where it was concluded that ipratropium bromide sustained its maintenance bronchodilatation over 5 years; however, there was no impact of ipratropium treatment on the longer term decline in forced expiratory volume in 1 s (FEV_1). A retrospective analysis of seven clinical trials comparing ipratropium with short-acting β -agonists in COPD found that baseline lung function improved with the anticholinergic over 90 days – an effect that was not seen with the β -agonist [60]. Additional present day studies with ipratropium come in the form of it being a gold standard comparator during the development of alternative delivery systems and long-acting β -agonists. For example, comparable efficacy and safety of chlorofluorocarbon (CFC) and hydrofluoroalkane (HFA) driven metered dose inhaler (MDI) ipratropium has been demonstrated [61,62]. The efficacy and safety of ipratropium have been confirmed in trials evaluating salmeterol [63,64] and formoterol [65]. In the salmeterol trials, the efficacy of ipratropium four times daily was reconfirmed and was similar to salmeterol twice daily. The effects of ipratropium on dyspnoea relief were more consistent than observed with salmeterol. In the formoterol trial [65], ipratropium (40 µg q.i.d.) significantly increased the area-under-the-curve over placebo for FEV_1 ; significantly greater responses were seen in the formoterol-treated patients, which can be caused, in part, by the fact that patients treated regularly with anticholinergic therapy were not allowed to participate in the study [66].

Short-acting anticholinergic- β -agonist combinations

Ipratropium was the first bronchodilator to focus its clinical development in COPD. Additionally, it was realized that with the polypharmacy common in COPD, many patients were co-prescribed a β -agonist with ipratropium. This was the basis for the development of the fixed combination of ipratropium bromide and albuterol, ultimately marketed as Combivent® [67]. The pharmacological basis for this therapy rested on the distinct mechanisms of action of

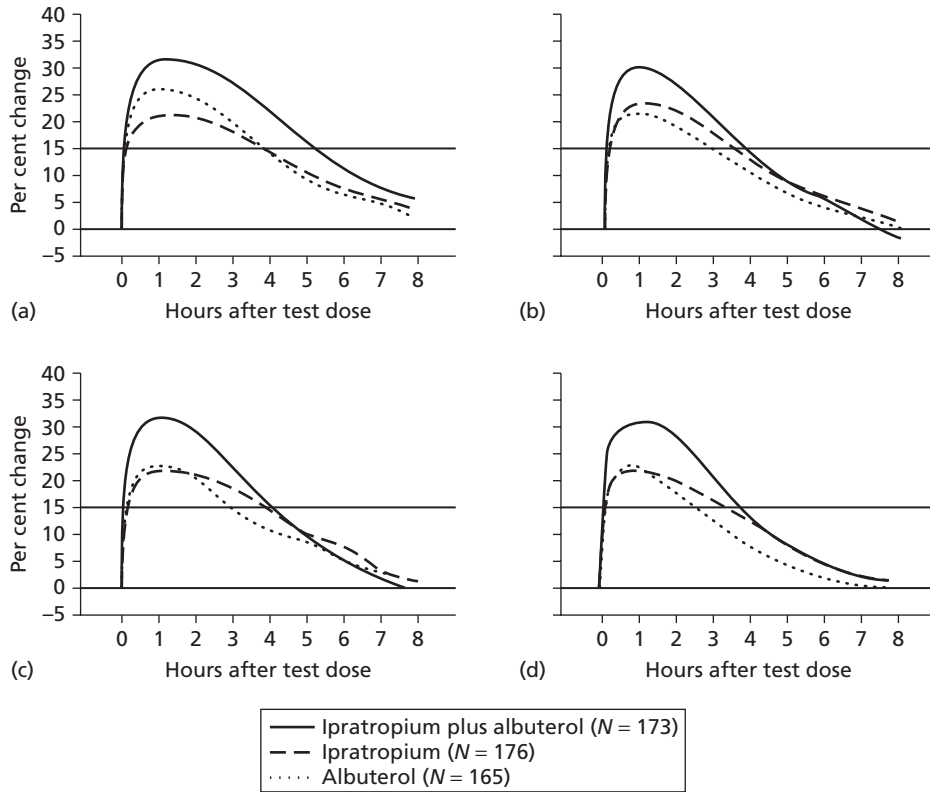

Figure 56.5 Percentage changes in mean forced expiratory volume in 1 s (FEV_1) from test day baselines. (a) Test day 1. (b) Test day 29. (c) Test day 57. (d) Test day 85. (From the Combivent Inhalation Study Group [70], with permission.)

antimuscarinics and sympathomimetics which supported the clinical research hypothesis that the combination would provide superior bronchodilatation than either agent administered alone. This was established in adequate and well-controlled clinical trials where the fixed combination provided significant increases in spirometric endpoints over the individual agents [68–70]. As illustrated in Figure 56.5, the additive benefit of the combination was consistent and maintained over the 3-month study period. In a retrospective analysis of these data, we also reported that more than 80% of patients receiving the combination of ipratropium bromide and albuterol had a 15% or greater increase in FEV_1 , providing support for the concept of ‘reversibility’ in COPD [71].

Tiotropium

The functional and therapeutically relevant consequence of the prolonged receptor binding of tiotropium was first demonstrated in the form of sustained improvement in the FEV_1 of stable COPD patients, thus forming the basis for once daily therapy [72,73]. This effect observed from single-dose studies was confirmed in a 4-week dose–response trial [74] that set the stage for development of 18 μ g tiotropium once daily for long-term maintenance therapy. One unique trial provided the first around-the-clock (every 3 h) assessment of spirometry in COPD [75]. This study pro-

Figure 56.6 Mean forced expiratory volume in 1 s (FEV_1) in litres over 24 h after 6 weeks (steady state) of tiotropium in the evening (p.m.), tiotropium in the morning (a.m.) or placebo. (From Calverley *et al.* [102], with permission.)

vided evidence for the effectiveness of tiotropium throughout its dosing interval as well as interesting insights into the circadian spirometric response in this patient group (Fig. 56.6).

The major development studies for tiotropium consisted of two replicate trials for each of the major comparators

including usual care (placebo), ipratropium and salmeterol. In the individual and reported integrated analysis of these studies, tiotropium provided consistently better bronchodilatation than all comparators (Fig. 56.7) [7–9]. Spirometric responses were consistent in all trials, with the exception of

one sister study versus salmeterol where the primary endpoint (trough FEV_1) was directionally, but not statistically significantly greater. Statistical significance favouring tiotropium over placebo and salmeterol was seen in all other spirometric endpoints (Fig. 56.8). The response

Figure 56.7 Spirometric response of tiotropium (TIO) compared with: (a) usual care (placebo [PBO]); (b) ipratropium (IPR); and (c) salmeterol (SAL). Figure derived from data in [7–9]. Data represents integrated data from two sister trials.

Figure 56.8 The spirometric results from three head-to-head trials of tiotropium versus salmeterol. * Peak represents maximum response over 3 h post-treatment administration; at 6 months for studies 1 and 2 and at 3 months for study 3. † Average is defined as normalized area-under-the-response curve post-treatment administration; for 12 h at 6 months for study 1, for 3 h at 6 months for study 2 and for 12 h at 3 months for study 3. ‡ Trough is the response value at the end of dosing interval – 12 h post-treatment for salmeterol and 24 h post-treatment for tiotropium; at 6 months for studies 1 and 2 and at 3 months for study 3. Further details provided in references [6,7,77]. * $P < 0.05$ tiotropium greater than salmeterol. Study 1 was a 6-month study with 12-h spirometry. Study 2 was a 6-month study with 3-h spirometry. Study 3 was a 3-month study with 12-h spirometry.

Figure 56.9 Changes in constant-load exercise endurance time are shown from baseline (day -5) for placebo and tiotropium. Data are presented as mean \pm SEM. * $P < 0.05$ between groups. (From O'Donnell *et al.* [79] with permission.)

to tiotropium was maintained over 6 months, while the effects with salmeterol decreased over time [76]. A recent report from a completed third comparator trial once again showed significantly greater bronchodilatation of tiotropium over salmeterol, including the primary endpoint of the 12-h spirometric response [77].

In addition to the improved spirometry, tiotropium has been demonstrated to reduce hyperinflation as evidenced by a marked reduction in static lung volumes [78–80]. These mechanical changes are likely associated with the reduced dyspnoea observed in both the shorter term [79] and longer term trials [7–9], as measured by the validated Transition Dyspnea Index (TDI) [81–83]. Relief of hyperinflation at rest has also been accompanied by evidence from two independent clinical studies [79,84] that operating

lung volume is reduced and exercise tolerance, as assessed by endurance time, is improved (Fig. 56.9) [79,84]. Preliminary data have also revealed that tiotropium augments the effect of pulmonary rehabilitation [85]. The relationship between the mechanical and functional response has been advanced in the past decade by O'Donnell *et al.* [86], and the investigations with tiotropium now provide substantial evidence of the impact that sustained bronchodilatation can have.

Furthermore, the sustained bronchodilatation and its mechanical consequences are likely to be the basis for the observed improvements in health status. Here, tiotropium has been associated with improvements in all trials [6–8]. Understanding the improvements in health status with tiotropium, which is the ultimate goal of therapy, must consider both the mechanical benefits and the associated improvements in endpoints, reflecting the number and severity of exacerbations. Parameters associated with the worsening of disease have been evaluated as secondary endpoints in all of the major trials and consistent benefits have been observed (Table 56.2). Importantly, when exacerbations were evaluated as the primary endpoint in a cohort of US Veteran's Administration patients, tiotropium has shown to again be associated with a reduction [87]. Additionally, a report from over 1000 patients in France noted that tiotropium was significantly more effective than placebo in reducing the incidence, severity and duration of COPD exacerbations [88]. These effects can have their genesis in both the mechanical benefits (i.e. sustained 24-h bronchodilatation) as well as the potential anti-inflammatory effects that can accompany blockade of acetylcholine (see above). It is well known that exacerbations impact quality of life [89] and a retrospective analysis has shown that tiotropium blunts the impaired health status associated with frequent exacerbations [90].

Table 56.2 The balance of evidence in clinical endpoints associated with exacerbation of disease and the impact of tiotropium.

Study/variable	Trial duration (weeks)			
	49	52	26	26
Percentage of patients with at least one exacerbation	+ (0.03)	+ (0.01)	+ (0.064)	+ (0.0368)
Time to first exacerbation	+ (0.011)	+ (0.008)	+ (0.005)	+ (0.0337)
Number of exacerbations	+ (0.04)	+ (0.005)	+ (0.025)	+ (0.0028)
Percentage of patients with hospitalizations	+ (0.02)	+ (0.108)	+ (0.37)	+ (0.0557)
Time to first hospitalization	+ (0.007)	+ (0.048)	+ (0.137)	+ (0.0493)
Number of hospitalizations	+ (0.02)	+ (0.08)	+ (0.25)	+ (0.0131)

Numbers indicate the nominal P value associated with the comparison of tiotropium with the control (placebo or ipratropium). Plus (+) indicates that tiotropium was numerically superior to the control. Table based on trials reported in [7,9,10,87].

Long-acting anticholinergic- β -agonist combinations

Given the pharmacological premise that different modes of actions of anticholinergics and β -agonists on airway smooth muscle would result in additive bronchodilator response, there is no reason not to conclude that such effects would operate with agents with longer durations of effect. In a report describing the effects of ipratropium bromide administered concurrently with salmeterol, it was reported that significant increases in FEV_1 and reduced exacerbations only manifested with this combination and not with salmeterol alone [91]. A report evaluating the effects of tiotropium alone and in combination with formoterol [10] noted the greatest increase in FEV_1 with tiotropium and a significant added benefit when formoterol was added. Further studies characterizing this effect, along with expected growing clinical experience, will likely establish the roles of the bronchodilator combinations more firmly.

Therapeutic role in COPD

Inhaled anticholinergic therapy has gained wide acceptance as a foundation treatment in COPD, based in large part by the important role of the cholinergic nervous system in COPD. Treatment guidelines [92–95] and therapeutic reviews [13,96–100] published in the past decade have acknowledged this established role (Fig. 56.10). According to these reviews [1,2,4], bronchodilators are the primary intervention and mainstay of therapy, while other interventions such as inhaled steroids have restricted indication

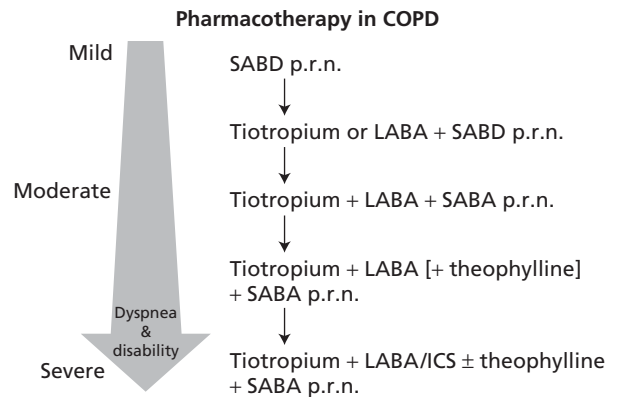

Figure 56.10 Pharmacological treatment of chronic obstructive pulmonary disease (COPD) based on increasing symptoms and disability. [+ theophylline] Add if tolerated: long-acting β_2 -agonist (LABA) (i.e. formoterol or salmeterol); LABA combined with an inhaled corticosteroid in one preparation (LABA/ICS); short-acting β_2 -agonist (SABA) (i.e. salbutamol); short-acting bronchodilator (SABD) (β_2 -agonists or anticholinergics). p.r.n., as needed. (From O'Donnell *et al.* [95] with permission.)

(i.e. when additional treatment is required in severe disease). The recent introduction of tiotropium is an advance as its stable, long-lasting and sustained bronchodilation achieved with a once daily regimen supports its role as foundation therapy and there is substantial and growing evidence of linked symptomatic and health status benefits (Fig. 56.11). Finally, its comparative efficacy versus salmeterol has been addressed in three trials (see Fig. 56.8) where tiotropium has provided consistently better bronchodilation, with significantly greater spirometric responses during

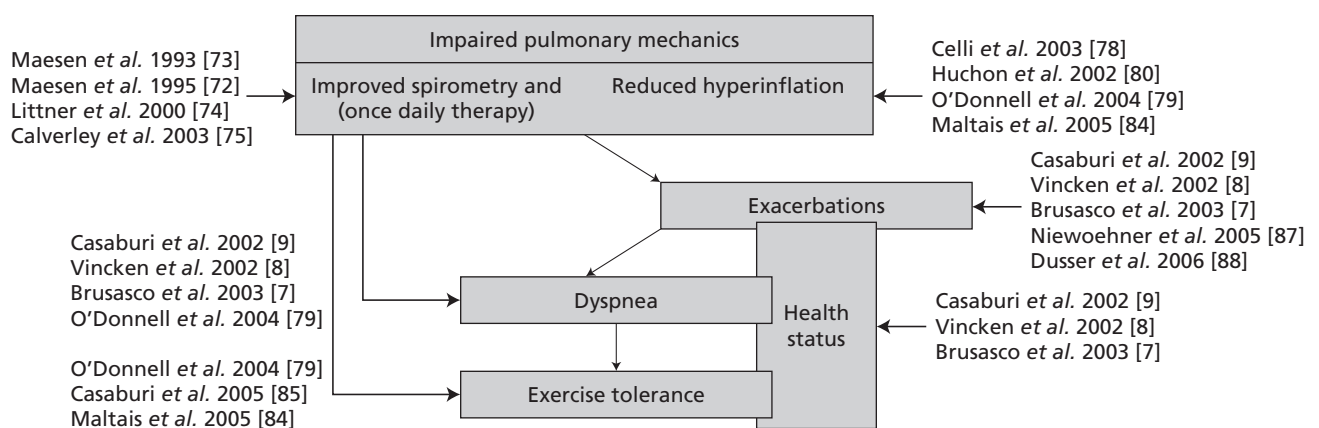

Figure 56.11 A simplified representation of the impairment, disability and involvement associated with COPD and the impact of tiotropium on relevant endpoints. The sustained bronchodilation with tiotropium via inhibitor of cholinergic tone improves the altered pulmonary mechanisms as assessed by spirometry and static lung volume measures is supported by substantial and growing evidence. Reduced breathlessness and improved exercise tolerance as well as the reduction in the interrelation with improvements in health status are now established in the literature.

the day for peak and average, and significant or directional benefits in the trough value 24 h after tiotropium versus 12 h after salmeterol.

CHAPTER 57

β_2 -Agonists

Malcolm Johnson

The pathophysiology of COPD may be considered as multi-component in nature [1]. It involves the large airways, small airways and lung parenchyma and comprises airway inflammation, structural changes, mucociliary dysfunction and a systemic component, all of which contribute to the airflow limitation characteristic of the disease.

Airway inflammation in stable COPD is characterized by increased numbers of inflammatory cells such as neutrophils, CD8⁺ T lymphocytes, monocytes–macrophages and mast cells, and elevated levels of inflammatory mediators such as interleukin 8 (IL-8), tumour necrosis factor α (TNF- α), leukotriene B₄ (LTB₄), RANTES, oxidants and proteases [1]. Exacerbations of COPD are associated with increased airway inflammation over stable disease and the increased presence of other cells such as eosinophils [2]. Inflammation in COPD is associated with many structural changes such as mural oedema, goblet cell hyperplasia and mucosal glandular hypertrophy in the large airways, fibrosis with collagen deposition and thickening of airway smooth muscle in the small airways and alveolar destruction in the parenchyma [3]. Airway inflammation is also associated with mucociliary dysfunction, including mucus hypersecretion, increased mucus viscosity and reduced mucociliary transport promoting bacterial colonization and mucosal damage [4]. COPD also has a number of systemic manifestations: weight loss, muscle weakness and reduced muscle mass [5] and a high incidence of disease co-morbidity [1].

Several pathophysiological mechanisms may therefore be responsible for airflow limitation in COPD. Because of this complexity of the disease, pharmacological agents that address more than one component of the underlying pathophysiology may have greater clinical efficacy.

Salbutamol, a short-acting β_2 -agonist (SABA), has been used by patients with COPD over the past three decades to treat and prevent symptoms. It remains the standard bronchodilator for use in COPD-related acute bronchospasm and bronchitis. The major drawback with the first genera-

tion of β_2 -agonists is in their short duration of action (4–6 h). The need for a drug with more prolonged bronchodilator activity for use in COPD has been met with the development of the long-acting β_2 -agonists (LABAs), salmeterol [6] and formoterol [7]. The aim of this chapter is to review the scientific and clinical evidence for the benefit of β_2 -agonists in the treatment of COPD.

Mechanisms of action of β_2 -agonists

β_2 -Agonists exert their biological and therapeutic effects through β_2 -adrenoceptors, members of the seven-transmembrane family of receptors, which are coupled to adenylate cyclase through a trimeric Gs-protein, consisting of α , β and γ subunits [8].

There is now good evidence that β_2 -adrenoceptors exist in two forms, activated and inactivated, and that under resting conditions these two forms are in equilibrium [9]. The β_2 -receptor is in the activated form when it is associated with the α -subunit of the G protein and guanosine triphosphate (GTP), and it is through this α -subunit that the receptor is coupled to adenylate cyclase (Fig. 57.1) to stimulate the conversion of adenosine triphosphate (ATP) to cyclic adenosine monophosphate (cAMP). It is probable that β_2 -agonists have their effects by binding to and temporarily stabilizing receptors in their activated state [9]. cAMP catalyses the activation of protein kinase A (PKA), which in turn phosphorylates key regulatory proteins involved in the control of cell function [10]. cAMP also modulates intracellular calcium ion (Ca²⁺) concentrations [11].

Salbutamol interacts directly with the active site of the β_2 -adrenoceptor. Salmeterol, because of its lipophilic properties, partitions into the phospholipid membrane and diffuses laterally to approach the receptor through the cell membrane (see Fig. 57.1). The side-chain of salmeterol then binds to a discrete hydrophobic domain within the

Figure 57.1 Interactions of salbutamol (short-acting β_2 -agonist, SABA) and salmeterol and formoterol (long-acting β_2 -agonists, LABAs) with the β_2 -receptor. ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate.

fourth transmembrane region of the β_2 -adrenoceptor, called the exosite [12]. Binding to the exosite prevents the molecule from dissociating from the receptor and the saligenin head of salmeterol is then free to engage and disengage with the active site of the receptor, leading to a long concentration-independent duration of action [13]. Formoterol, which is moderately lipophilic, enters the membrane lipid bilayer and is retained as a depot (see Fig. 57.1). Subsequently, it gradually leaches out from the membrane to activate the receptor, imparting a prolonged concentration-dependent effect [14].

Effects of β_2 -agonists on airway inflammation

Inflammatory cells

β_2 -Receptors are present on a range of inflammatory cells that have been implicated in the pathophysiology of COPD (Table 57.1).

Fibroblasts

Anti-neutrophil effects of β_2 -agonists

Neutrophils have relatively low β_2 -receptor density [15]. Nevertheless, LABAs have been shown to reduce the number of neutrophils in the airway by inhibiting adhesion [16], accumulation [17], chemoattractant release [18] and by inducing apoptosis [19].

Adhesion of human neutrophils is attenuated by agents that elevate cAMP through inhibition of neutrophil Mac-1 cell surface expression. Salmeterol increased human neutrophil cAMP levels in a concentration-dependent manner [20]. Bloemen *et al.* [16] showed that salmeterol inhibited *N*-formyl-methionyl-leucyl-phenylalanine (fMLP) stimulated human neutrophil adhesion to human airway epithelial cells. The relevance of these findings to COPD patients is unclear.

In addition to their effects on adhesion, β_2 -agonists also affect neutrophil accumulation [17]. In a clinical study of patients with mild asthma, salmeterol (50 μg b.i.d. for 6 weeks) treatment significantly reduced the number of neutrophils in bronchial biopsies [17]. The addition of salmeterol (50 μg b.i.d.) to low-dose inhaled corticosteroids (ICS) also reduced neutrophils in bronchoalveolar lavage (BAL; $P < 0.02$) from asthmatic patients with mild to moderate disease over 3 months [21]. Whether LABAs alone exhibit inhibitory effects on neutrophil accumulation in COPD has yet to be established.

IL-8 may be important in COPD pathophysiology because it is a chemoattractant and an activator for neutrophils. Three months' treatment with salmeterol (50 μg b.i.d.) reduced BAL IL-8 concentrations in asthmatics' ICS [21]. Compared with placebo, salmeterol also reduced the

IL-8, interleukin 8; PAF, platelet-activating factor.

concentrations of myeloperoxidase and lipocalin (indicators of neutrophil activation) in bronchoalveolar lavage fluid (BALF) [17]. Formoterol and salmeterol [20,22,23] caused down-regulation of neutrophil respiratory burst (oxygen production) in response to fMLP, while salbutamol was without effect. Salmeterol also inhibited fMLP-induced intracellular calcium flux, phospholipase A₂ activity and synthesis of platelet-activating factor (PAF) [24]. This may be relevant because PAF has been associated with ciliary dysfunction, cytotoxicity and impaired mucociliary clearance [25]. Therefore, LABAs have the potential to decrease neutrophil activation in patients with COPD and may be useful in reducing the cytotoxic effects of neutrophil-derived oxidants at sites of inflammation within the airways (Table 57.2).

When neutrophils fail to undergo apoptosis, or programmed cell death, they die by lysis releasing their cellular components into the airways. In contrast to corticosteroids, LABAs can induce apoptosis in human neutrophils [19]. Salmeterol has been shown to increase apoptosis in human neutrophils via activation of the β₂-adrenoceptor and elevation of intracellular cAMP [19]. Although at present there are no published studies investigating the effect of formoterol on neutrophil apoptosis, it is likely to have similar activity to salmeterol.

A possible reduction by LABAs in the number of neutrophils in airway tissue and in the airway lumen may contribute to clinical efficacy in COPD.

Effects of β₂-agonists on monocytes–macrophages

Peripheral blood monocytes express high numbers of β₂-receptors, and there have been a number of reports of β₂-agonist inhibition of cytokine release from human monocytes *in vitro* [26]. For example, LABAs have been shown to inhibit TNF-α and IL-8 release from monocytes predominantly via the β₂-receptor through the generation of cAMP and activation of PKA. Maximum inhibition occurred at 10⁻⁸ mol/L [27]. Both salmeterol and formoterol also inhibited LTB₄ and IL-1β secretion from human blood monocytes by a β₂-receptor-independent mechanism, but only salmeterol lowered the secretion of prostaglandin E₂ (PGE₂) [28]. In contrast, the differentiated macrophage, with lower β₂-receptor density, exhibits reduced sensitivity to β₂-agonists. Concentrations of formoterol and salmeterol in excess of 10⁻⁶ mol/L were required to inhibit superoxide, protease and thromboxane B₂ release from alveolar macrophages *in vitro* [29].

Mucosal oedema

Many of the mediators released by inflammatory cells have the potential to induce tissue oedema, which is initiated by increased microvascular permeability to plasma proteins in the airway. Hill *et al.* [30] showed an inverse relationship between protein concentrations in BALF from COPD patients and lung function. A recent study has suggested that β₂-agonists may have a beneficial effect on pulmonary

oedema [31]. Inhaled salmeterol (100 µg) decreased the incidence of high-altitude pulmonary oedema (assessed radiologically) by more than 50% compared with placebo, at the same time as arterial O₂ saturation increased. The relevance of this observation to mural oedema in COPD remains to be established.

Effects of β₂-agonists on the airway epithelium

Airway inflammation in COPD is associated with both epithelial and mucociliary dysfunction [1].

Mucociliary dysfunction

During exacerbations of COPD, the airways can be obstructed by mucus as a result of increased production, altered rheology, as well as by defective mucociliary clearance.

Mucociliary clearance

Stimulation of epithelial β₂-receptors by β₂-agonists increases ciliary beat frequency (CBF) and mucociliary transport (MCT). Salbutamol and salmeterol increased CBF in human nasal epithelial cells, with salmeterol being active at 100-fold lower concentrations than salbutamol [32]. A similar study with human bronchial epithelium revealed that, while salbutamol induced a transient increase in CBF, salmeterol caused a significant increase for 24 h [33]. Salmeterol (10⁻⁷ M) increased CBF from 8.6 Hz to 10.0 Hz in epithelial cells taken from COPD patients [34]. At lower concentrations, salmeterol, while having no effect itself, inhibited *Pseudomonas aeruginosa* (PA) pyocyanin-induced reduction in CBF [35]. At present, there are no published accounts on the effect of formoterol on CBF.

Short-acting β₂-agonists such as salbutamol and terbutaline have been reported to increase MCT *in vivo* [36]. This has also been shown with salmeterol and formoterol. Studies in healthy subjects showed that salmeterol (50 µg) significantly increased mucociliary transport compared with placebo [37,38]. A clinical study with salmeterol in asthmatic patients indicated a modest enhancement of mucociliary function [39]. Formoterol (24 µg b.i.d. for 7 days) has also been shown to significantly increase mucociliary clearance in bronchitic patients [40]. In contrast, the long-acting anticholinergic, tiotropium, had no significant effect on mucociliary clearance in COPD [41].

Airway secretions

The efficiency of mucociliary clearance is also affected by the amount and physical properties of airway secretions. Both α-adrenergic and β₂-receptors are present on submucosal gland mucous cells [42], but earlier studies did not report consistent effects of β₂-agonists on mucus viscosity

and glycoprotein secretion [43]. However, a recent study [44] has shown that the LABA, salmeterol, but not the SABA, salbutamol, potentiates the inhibitory effect of corticosteroids on mucin secretion by airway epithelial cells. This effect of salmeterol was synergistic in nature, decreasing the IC₅₀ for fluticasone propionate (FP) from 1.8 nM to 0.3 nM [44]. There is a growing body of literature [45] that supports the role of β₂-agonists in increasing mucus hydration, thereby possibly reducing viscosity and thus aiding effective mucociliary transport.

Cigarette smoke is known to adversely affect surfactant [46] and Anzueto *et al.* [47] showed that aerosolized surfactant resulted in an improvement in mucociliary transport in patients with stable chronic bronchitis. Surfactant may also modulate the function of respiratory inflammatory cells [48]. β₂-Agonists enhance secretion of surfactant (phosphatidylcholine, PC) by type II epithelial cells. Salmeterol stimulated PC secretion by up to 60% with a duration of action of more than 6 h [49]. More investigations evaluating the potential benefits of β₂-agonists in modulating surfactant secretion are needed.

Finally, β₂-agonists increase fluid clearance (reabsorption) by stimulating apical sodium uptake and sodium/potassium-adenosine triphosphatase activity in type II cells [50]. Terbutaline stimulated clearance of alveolar fluid through amiloride-sensitive and amiloride-insensitive pathways [51] and salmeterol increased alveolar fluid clearance in human lung explants instilled with iso-osmolar albumin solution [52]. Augmented fluid clearance with LABAs could contribute to a reduction in exacerbations of COPD.

Mucosal damage

Recurrent bacterial infection is a hallmark of COPD. With increased mucus accumulation in the airways and compromised mucociliary clearance, patients with stable COPD are frequently colonized by bacteria such as unencapsulated *Haemophilus influenzae* (HI), *Streptococcus pneumoniae* (SP) and *Moraxella catarrhalis* [52]. Bacteria damage the respiratory epithelium by releasing toxins, proteases, oxidants and other mediators, and by stimulating recruitment of inflammatory cells, which release pro-inflammatory mediators.

LABAs have a cytoprotective effect on the respiratory epithelium against microorganisms [54,55]. Salmeterol inhibited the invasiveness of SP and HI into airway epithelial cells, partly due to decreased expression of PAF receptors on the cell surface [53]. Salmeterol protected the respiratory epithelium against ultrastructural damage (cytoplasmic blebbing, mitochondrial damage) induced by the PA-derived toxin, pyocyanin and elastase [54]. This effect, which was mediated via β₂-receptors, was not apparent with SABAs or the anticholinergic, ipratropium bromide [54]. Salmeterol also protected the respiratory epithelium against HI-induced damage [55], with preservation of the number of both ciliated and unciliated cells and a

concomitant reduction in epithelial stripping, as well as inhibition of the number of bacteria adhering to the respiratory mucosa [55]. A cytoprotective effect of formoterol has not been reported but, if used in sufficient concentrations to increase cAMP over time, is likely to have the same activity. It is encouraging that the concentration range of salmeterol for epithelial cytoprotective activity is similar to that observed in human peripheral lung tissue *in vivo*, following an inhaled dose of 50 μg [56].

De Bentzmann *et al.* [57] showed that salmeterol significantly reduced transepithelial permeability, as assessed by transepithelial resistance, mannitol flux and diffusion of a low molecular weight tracer, and prevented degradation of epithelial cell tight junctional proteins such as ZO1 and vinculin. Maintenance of tight junction integrity by salmeterol may be caused by prevention of bacterial-induced reductions in intracellular cAMP or, more importantly, by up-regulation of junctional protein expression [55]. Preservation of the number of ciliated cells and stimulation of ciliary beating by salmeterol may protect the respiratory epithelium against bacterial-induced damage by preventing bacterial adherence and by reducing the concentration of bacterial toxins in the microenvironment of the mucosal surface.

A reduction by LABA in the number of bacteria adhering to the epithelium may render patients less prone to acute bacterial infections. The incidence of respiratory infections in a 16-week study [58] in COPD patients was 15% with placebo, compared with 8% with salmeterol ($P < 0.005$). This was confirmed in a second study of salmeterol in COPD [59], where the incidence of bronchitis was 1%, compared with 8% in the placebo group ($P < 0.001$). Thus, it appears that salmeterol offers some protection against respiratory infections, perhaps by having a cytoprotective effect on the airway epithelium [60].

Potential effects of β_2 -agonists on structural changes in COPD

The clinical relevance of airway smooth-muscle and fibroblast proliferation in patients with COPD remains to be determined. Salbutamol and salmeterol-inhibited human airway smooth-muscle cell proliferation *in vitro* induced by mitogens, such as thrombin, an effect that was mediated by an increase in cAMP and an action on cyclin D₁ [61]. Similarly, β_2 -agonists also attenuated fibroblast contraction *in vitro* [62] and the differentiation of fibroblasts to myofibroblasts [63], suggesting a potential antifibrotic activity (see Table 57.2). Again, it is encouraging that human peripheral lung tissue concentrations of salmeterol [56] exceed that shown to have antiproliferative activity *in vitro* [61]. Furthermore, although carried out in asthmatic patients, a recent study has shown that salmeterol, when

added to ICS, reduces the degree of ongoing angiogenesis [64], a recognized component of airway remodelling.

Effects of β_2 -agonists on the systemic component of COPD

Recent evidence suggests that β_2 -agonists may have beneficial effects on respiratory muscle contractility and therefore improve the mechanics of breathing in COPD [65,66]. In healthy subjects, salbutamol (10–20 μg i.v.) was shown to increase minute ventilation, tidal volume and respiratory flow, both at rest and under conditions of CO₂ stimulation [65]. This was associated with enhanced contractility of parasternal muscles, a surrogate for the diaphragm. Importantly, this effect was also observed with inhaled salmeterol (50 and 100 μg) where increases in minute ventilation were paralleled by enhanced parasternal contractility, independent of changes in pulmonary mechanics and heart rate [66].

The clinical relevance of these findings has now been investigated in COPD patients. Salmeterol/FP combination produced a significant increase in both ventilation and parasternal muscle contractility in severe COPD patients who were bronchodilator unresponsive and had minimal improvement in gas trapping [67]. It is an interesting possibility that the action of salmeterol may be similar to the recognized 'theophylline effect' on the diaphragm and other respiratory muscles [68], and may be particularly crucial at later stages of the disease.

Clinical efficacy of β_2 -agonists in patients with COPD

β_2 -Agonists are recommended in treatment guidelines for COPD [66] as they improve lung function, reduce symptoms and protect against exercise-induced dyspnoea. Several clinical studies have investigated the effect of LABAs in COPD and have shown them to provide important benefits in symptomatic patients (Table 57.3). Both salmeterol [70] and formoterol [71] significantly improve lung function (forced expiratory volume in 1 s [FEV_1], forced vital capacity [FVC] and peak expiratory flow rate [$PEFR$]) and appear to be more effective than SABAs. Other improvements include a reduction in breathlessness, hyperinflation, night-time awakenings, rescue medication usage and respiratory tract infections, an increase in health status and a decrease in exacerbations and hospitalizations [72–74].

LABAs versus placebo

A 12-week study examined the onset and duration of action of salmeterol in COPD [75]. Clinically significant bronchodilator activity (≥ 0.1 L increase in FEV_1) occurred

Table 57.3 Clinical efficacy and safety of long-acting β_2 -agonists (LABAs) in COPD.

Figure 57.2 Effects of salmeterol (50 μ g b.i.d. for 12 weeks) on forced expiratory volume in 1 s (FEV_1) in patients with COPD. FEV_1 (L) as change from baseline following a dose of salmeterol (50 μ g) was measured over 12 h at week 0 (solid line) and week 12 (dashed line) of treatment. (From Rennard *et al.* [85] with permission.)

on day 1 after 24 min. This was maintained throughout the study. The duration of action was 10.9 and 11.7 h on day 1 and day 84, respectively. The bronchodilator response to LABAs in COPD therefore shows no evidence of tolerance (Fig. 57.2).

The efficacy and safety of 50 and 100 μ g salmeterol b.i.d. was studied in COPD patients over 16 weeks [70]. FEV_1

improved significantly in the salmeterol group compared with placebo ($P < 0.001$), and significant reversibility to salmeterol was present in patients classified as not reversible to salbutamol at baseline. Maesen *et al.* [76] also demonstrated that inhaled formoterol caused long-lasting dose-dependent lung function improvement in COPD patients poorly reversible to terbutaline.

Treatment with LABAs significantly decreased daytime and night-time symptom scores, improved dyspnoea and reduced hyperinflation. In a randomised, double-blind crossover study over 2 weeks, salmeterol (50 μ g b.i.d.) increased inspiratory capacity, tidal volume, mean inspiratory and expiratory flow, ventilation, oxygen uptake and carbon dioxide output [77]. These improvements were accompanied by increased peak exercise endurance [77]. These effects were associated with a clinically significant improvement in health status (quality of life) with salmeterol and formoterol, which correlated with patient and physician assessments of treatment efficacy [73].

In a 12-month randomized double-blind parallel group, placebo-controlled study in COPD [78], end-of-treatment predose FEV_1 was 1323 mL following salmeterol (50 μ g b.i.d.) compared with 1264 mL with placebo ($P < 0.0001$). The rate of exacerbations was 1.04 and 1.30/year in the salmeterol and placebo groups, respectively; a reduction of 20% ($P = 0.003$). Exacerbations that required oral corticosteroids were also reduced by 29% in the salmeterol group [78].

A similar 12-month study [79] in a more severe COPD population (FEV_1 of less than 50%) showed an improvement in post-dose FEV_1 with formoterol (4.5 μg b.i.d.) of 140 mL (14%) compared with placebo. Reductions in severe exacerbations were, however, only 2% and the decrease in oral steroid use was 3% [79].

Salmeterol versus formoterol

Salmeterol and formoterol are both effective in improving airflow limitation in patients with COPD. Cazzola *et al.* [80] showed that salmeterol (50 μg) induced a dose-independent bronchodilator response, which lasted longer than formoterol (12 or 24 μg). However, in another study [81], there was no significant difference in the duration of action of salmeterol and formoterol (both less than 12 h). Disparity in these results may be explained by differences in the severity of disease. In a later dose-ranging study, Cazzola *et al.* [82] showed that both salmeterol (25, 50 and 75 μg) and formoterol (12, 24 and 36 μg) induced an increase in FVC and FEV_1 over 12 h in patients with partially reversible but severe COPD.

In some studies [83], formoterol has been shown to induce bronchodilatation more rapidly than salmeterol. Celik *et al.* [83] showed formoterol and salmeterol induced a clinically and statistically significant improvement in FEV_1 compared with placebo, after 10 and 20 min, respectively. This difference between salmeterol and formoterol is, however, lost on chronic dosing because bronchodilatation is still evident 12 h after the last dose [80,82].

LABAs: comparison with other therapies

In patients with stable COPD, LABAs have been shown to be more effective than short-acting anticholinergic agents or theophylline.

LABAs versus anticholinergics

Several studies have compared salmeterol with ipratropium bromide in terms of safety and efficacy in COPD patients [59,84,85]. Salmeterol showed a greater improvement in FEV_1 compared with ipratropium bromide or placebo [59]. Patients treated with ipratropium bromide experienced a trough in FEV_1 after 6 h because of its shorter duration of action, whereas those receiving salmeterol had a sustained improvement in FEV_1 over 12 h. Salmeterol also improved morning peak expiratory flow (PEF), evening PEF and nighttime shortness of breath ($P = 0.04$) compared with ipratropium bromide. These beneficial effects were apparent in those patients who were responsive as well as those unresponsive to salbutamol at baseline. Patients with partially reversible COPD, pretreated with salmeterol, responded normally to salbutamol when required for rescue therapy [84].

While one study demonstrated that salmeterol extended the time to first exacerbation [59], this was not confirmed in a second study [85], where the percentage of patients experiencing one or more COPD exacerbations over the 12-week treatment period were 30.4, 28.8 and 26.8% for the placebo, salmeterol and ipratropium groups, respectively. However, 20 patients (14.8%) in the placebo group experienced their first exacerbation during week 1, compared with six patients (4.6%) in the salmeterol group. Interestingly, the trend for salmeterol to reduce exacerbations does not appear to be an effect associated with SABA.

A number of studies have also compared formoterol with ipratropium bromide. Dahl *et al.* [86] studied the efficacy and safety of 12 weeks of treatment with formoterol (12 and 24 μg b.i.d.) or ipratropium bromide (40 μg q.i.d.) in patients with COPD. In terms of improving FEV_1 , both doses of formoterol were significantly superior to ipratropium bromide. In addition, the onset of action of formoterol (less than 5 min), was faster than that of ipratropium bromide, and the duration of action was at least 12 h [86]. Formoterol also significantly improved quality of life and reduced the number of 'bad' days (more than 20% reduction in PEF and/or at least double symptom score) compared with ipratropium bromide [86].

Inhaled SABAs have been shown to reduce dynamic hyperinflation during exercise, thus improving breathlessness on exertion [87,88]. This may be an effect of β_2 -agonists in improving lung emptying, resulting in reduced lung volumes. In this context, reduction in end-expiratory lung volume following β -agonist bronchodilators is better correlated with improved dyspnoea than FEV_1 [84]. In a recent study [89], the effect of 1 week of treatment with 4.5, 9.0 or 18.0 μg formoterol b.i.d. on exercise capacity was compared with that of 80 μg ipratropium bromide t.i.d. or placebo, using a bicycle ergometer test. All three doses of formoterol significantly prolonged the time to exhaustion, which was comparable to the effect of 80 μg ipratropium t.i.d. The maximum Borg dyspnoea scale was unaffected. Similar data were reported by Ayers *et al.* [90] and Patakas *et al.* [91], who evaluated the effect of salmeterol in an ergometry and a treadmill exercise test, respectively. The mean distance walked did not increase by more than 9.1 m (10 yards) during the 12-week treatment period [91]. However, salmeterol significantly reduced the prewalk dyspnoea score, but there were no significant differences in postwalk Borg scores at the end of the study period.

A 6-month study has compared the effects of salmeterol (50 μg b.i.d.) with tiotropium (18 μg o.d.) in COPD [92]. In terms of lung function, mean trough FEV_1 responses were approximately 50 mL higher with tiotropium than salmeterol, increases in morning PEF were 11% and 9% in the tiotropium and salmeterol groups, respectively, and there were equal reductions in lung hyperinflation [92]. Both

groups reduced the need for rescue medication to the same extent, and there were fewer exacerbations (36.8%, tiotropium; 38.5%, salmeterol) compared with placebo (45.8%).

LABAs versus theophylline

In the long-term treatment of patients with COPD, LABAs were shown to be more effective than oral (dose-titrated) theophylline. Salmeterol (50 µg b.i.d.) was statistically more effective than theophylline in improving FEV_1 and morning PEF, and in increasing the percentage of days and nights without symptoms [93]. Salmeterol was also significantly superior to theophylline in reducing the need for additional salbutamol during the day and night and increasing patient quality of life [93]. Similar findings have been reported for formoterol over 12 months [94]. Treatment-related adverse events were more frequent among patients receiving theophylline.

Combination therapy with LABAs and corticosteroids

Interactions between β_2 -agonists and corticosteroids

A complementary effect occurs when the response of two or more drugs combined produces a greater effect than either drug alone. An additive effect is where the combined response of two or more drugs equals the sum of the response of the individual drugs. A synergistic effect occurs when the combined response of two or more drugs is greater than the sum of the response of the individual drugs.

Complementary interactions at the molecular and receptor levels

Corticosteroids (CS) increase the synthesis of β_2 -receptors and reduce receptor desensitization [95]. β_2 -Agonists, particularly LABAs, modulate glucocorticoid receptors (GRs) by priming the GR for subsequent corticosteroid binding and by increasing the translocation of the GR from the cell cytosol to the nucleus [96,97]. GRs are modulated by phosphorylation which leads to activation, and dephosphorylation which leads to inactivation [98]. LABA-induced GR priming is achieved by mitogen-activated protein kinase (MAPK) dependent phosphorylation [99]. When salmeterol or formoterol stimulate the β_2 -receptor, the G- α_s subunit disassociates and the residual $\beta\gamma$ -subunit of the G-protein initiates an intracellular signalling cascade, culminating in the activation of MAPK [100]. This has been demonstrated with salmeterol in cells transfected with a MAPK-luciferin/luciferase reporter construct and directly, by isolation of phospho-MAPK [101].

Activation of the MAPK pathway by the LABA requires that the β_2 -receptor is phosphorylated, probably by PKA. MAPK then phosphorylates the GR at a number of proline-directed serine residues in the N-terminus region of the receptor [102]. Phosphorylated GR has been detected in cells, containing both β_2 -receptors and GRs, when stimulated with salmeterol in the presence of radiolabelled phosphate [103]. An increase in negative charge at the N-terminal domain of the receptor resulting from phosphorylation may lead to a conformational change in the GR protein, leading to the 'priming' event and rendering the receptor more sensitive to steroid-dependent activation.

Translocation of the GR from the cell cytosol to the nucleus is a fundamental step in the anti-inflammatory activity of ICS. GR translocation has been shown to be increased by the addition of a LABA *in vitro* [96,97] and in some cases *in vivo* [104]. The mechanism of this effect has been further investigated. Salmeterol and formoterol have been shown to activate a CCAAT enhancer binding protein (C/EBP- α) in airway smooth muscle cells [105] and in epithelial cells). The synchronous activation of GR by CS and of C/EBP- α by LABA allows a heterodimer between GR and C/EBP- α to form, increasing the activation of the receptor and nuclear translocation [105]. Haque *et al.* [106] showed that the combined inhalation of salmeterol (50 µg) and FP (100 µg) by COPD patients increased the nuclear translocation of GR in sputum macrophages significantly more than the same dose of FP alone and equivalent to a fivefold higher dose of steroid [106]. Whereas budesonide (BUD) (800 µg) also significantly increased the translocation of the GR from the cytosol into the nuclei of peripheral blood leucocytes, the combination with formoterol (24 µg) did not enhance this effect versus BUD alone.

Complementary anti-inflammatory effects of LABAs and corticosteroids

Complementary cellular effects of LABAs and CS that may be of relevance in COPD have been demonstrated *in vitro* in terms of inhibition of inflammatory mediator release [107–109], protection of the respiratory mucosa against bacterial-induced damage [110], inhibition of neutrophil chemoattractant release [107–109], eosinophilic oxidative burst [111] and myofibroblast differentiation [63], and stimulation of T-lymphocyte apoptosis [112].

Dowling *et al.* [110] reported that incubation of human respiratory mucosa with either salmeterol or FP alone, significantly inhibited PA-induced epithelial damage and loss of ciliated cells in a concentration-dependent manner. However, when a combination of salmeterol and FP was used, the loss of cilia from the epithelial surface was synergistically reduced [110].

IL-8 is a major neutrophil chemoattractant involved in the pathogenesis of COPD. Pang and Knox [107] showed

that TNF- α -induced IL-8 release from human airway smooth-muscle cells was markedly inhibited by FP, but unaffected by salmeterol. However, a combination of salmeterol with FP synergistically enhanced the inhibition induced by the CS. Cigarette smoke-induced release of IL-8 from human monocyte-derived macrophages was synergistically inhibited by a combination of FP and salmeterol. Similar results were reported in human alveolar macrophages isolated from the BALF of COPD patients. FP (10^{-8} – 10^{-12} mol/L) inhibited IL-8 and TNF- α production in a dose-dependent manner, while salmeterol was without effect [108]. Combining both drugs resulted in a greater inhibition of cytokine production than FP alone [108]. Combination therapy with FP (10^{-9} or 10^{-10} mol/L) and salmeterol (10^{-9} mol/L) also synergistically inhibited rhinovirus-induced IL-8 and RANTES release from bronchial epithelial cells [109].

Inhibition of cytokine release by CS is thought to be caused by reduced activation of transcription factors such as GATA-3 and nuclear factor κ B (NF- κ B) (via IKK β). Maneechotesuwan *et al.* [113] showed that GATA-3 nuclear localization in peripheral blood mononuclear cells was decreased by inhaled FP (both 100 and 500 μ g) but unaffected by salmeterol (50 μ g). However, a combination of salmeterol (50 μ g) with the lower dose of FP (100 μ g) synergistically reduced GATA-3 nuclear expression [113]. Similarly, in human bronchial epithelial cells FP caused a dose-dependent inhibition of IKK β phosphorylation [114]. The combination of FP and salmeterol caused an inhibition of IKK β phosphorylation which was significantly greater than FP alone (0.01 μ mol/L) and similar to that achieved by a higher concentration of FP (0.1 μ mol/L). A number of studies have now investigated the anti-inflammatory effects of LABA/ICS combinations.

In COPD patients, the combination of salmeterol and FP at a dose of 50/500 μ g b.i.d. significantly ($P < 0.04$) reduced neutrophils in induced sputum over 13 weeks [115]. Similarly, whereas FP (500 μ g b.i.d.) alone increased neutrophil numbers in airway tissue from COPD patients, this was not observed [116] when salmeterol was added to the inhaled corticosteroid.

In a study in COPD, the salmeterol/FP combination (50/500 μ g b.i.d.), but not FP alone, reduced macrophages (CD68 $^+$ cells) in airway tissue over 3 months of treatment [116]. However, a second study [115] failed to show an effect compared with placebo.

There is evidence for a key role for the CD8 $^+$ T-lymphocyte in the pathophysiology of COPD and an elevated CD8/CD4 ratio has been reported [2]. Three studies [115–117] have investigated the effect of salmeterol/FP combination therapy on airway T-lymphocyte populations in COPD patients. Both CD8 $^+$ and CD4 $^+$ cells were significantly reduced over 3 months [115–117] and this

effect was greater than that observed with FP alone [116,117]. In addition, cells staining positive for mRNA for TNF- α and IFN- γ were also suppressed [115]. These broad spectrum anti-inflammatory effects observed when a LABA is added to an ICS may have relevance to the enhanced clinical benefit in COPD.

Elevated numbers of eosinophils have been found in the induced sputum, bronchial biopsies and lamina propria of COPD patients, particularly during an exacerbation [2]. Both formoterol (1–10 nmol/L) and BUD (1–100 nmol/L) when administered separately inhibit superoxide generation from peripheral blood eosinophils. Combination of a low concentration of BUD (0.1 nmol/L) with formoterol (1 nmol/L) inhibited eosinophilic oxidative burst with an effect that was more than additive [111]. Another key element in the anti-inflammatory effects of ICS is their ability to shorten the survival of inflammatory cells in airway tissue. In T lymphocytes, apoptosis in response to FP, at both low and higher concentrations, was enhanced by the addition of salmeterol [112].

Airway remodelling occurs in both asthma and COPD [1,2] and has been shown to be associated with increased numbers of activated fibroblasts, many of which have the phenotypic characteristics of myofibroblasts (i.e. express α -smooth muscle actin [SMA]). Giuliani *et al.* [63] showed that transforming growth factor β_1 (TGF- β_1), a cytokine present in increased quantities in COPD, induced a dose-dependent increase in the number of SMA-positive cells in primary human airway fibroblast culture. This TGF- β_1 -induced myofibroblast differentiation was effectively down-regulated by salmeterol and FP. Both agents administered together produced a synergistic inhibitory effect [63].

Clinical efficacy of LABA/ICS combination therapy

What is the clinical rationale for combining LABAs with ICS in the treatment of COPD? First, LABAs are potent bronchodilators and have non-bronchodilator activity [18], which may be relevant to their efficacy in COPD. Secondly, LABAs and ICS influence different aspects of COPD pathophysiology, so together they may provide an additive therapeutic effect. Finally, there is some evidence of synergy between LABAs and ICS in COPD which may be important in improving the overall clinical efficacy of the combination.

The efficacy of inhaled salmeterol/fluticasone propionate 50/250 or 50/500 μ g b.i.d. compared with its components or placebo in the treatment of patients with COPD was initially evaluated in three randomized double-blind placebo-controlled 24-week multicentre trials [118–120].

In the first study [118], a significantly greater increase in predose FEV $_1$ at endpoint was observed after combination therapy (15%) compared with salmeterol (10%; $P = 0.012$)

and placebo (2%; $P < 0.0001$). An increase in 2-h postdose FEV_1 was also observed after treatment with the combination (261 mL) compared with FP (138 mL; $P < 0.001$) and placebo (28 mL; $P < 0.001$). There were greater improvements in the Transitional Dyspnoea Index (TDI) with salmeterol/FP (2.1) compared with FP (1.3; $P = 0.033$), salmeterol (0.9; $P < 0.001$), and placebo (0.4; $P < 0.0001$). There was an associated reduction in the need for rescue salbutamol use (1.2 puffs/day) and an increase of 16.3% in rescue-free days compared with placebo [118]. Health status (Chronic Respiratory Disease Questionnaire, CRDQ) also improved significantly (score 10.0).

Similar findings were obtained in a second study [119], where PEFr increased by 30.7 L/min over baseline, compared with 0.8, 14.4 and 11.3 L/min for placebo, salmeterol and FP, respectively. This was associated with a change in TDI of 1.7 [119].

The trial of inhaled steroids and long-acting β_2 -agonists (TRISTAN) [78] was the first long-term study to investigate the efficacy and safety of LABA/ICS combination therapy for the treatment of COPD patients. COPD patients were randomized to treatment with either salmeterol (50 μg b.i.d.), FP (500 μg b.i.d.), salmeterol/FP (50/500 μg b.i.d.) or placebo for 12 months in a double-blind parallel-group placebo-controlled design.

There was good evidence of the beneficial effects of combining a LABA with an ICS in this COPD patient population. Combination therapy improved pretreatment FEV_1 significantly ($P < 0.001$) more than placebo (treatment difference 133 mL), salmeterol (73 mL) or FP (95 mL) alone [78]. This was also seen with FVC and PEF. The improvement in PEF was evident within 1 week of treatment and was sustained throughout the year. The improvement in FVC observed for combination therapy may be indicative of improved exercise performance. Combination treatment was also the only treatment to produce a clinically significant improvement in health status (St. George's Respiratory Questionnaire, SGRQ), and produced the greatest reduction in daily symptoms, particularly breathlessness, and this was evident within 1 week of treatment. The exacerbation rate significantly fell by 25% ($P < 0.001$) in the combination group and by 20% and 19% in the salmeterol and FP group, respectively, compared with placebo (Fig. 57.3). The treatment effect was more pronounced in the more severe patients (baseline FEV_1 less than 50% predicted), where exacerbations requiring oral corticosteroids were reduced by 39% ($P < 0.001$) in the combination group [78]. The absence of a statistical, significant gender interaction in this study indicates that the salmeterol/fluticasone combination therapy was equally effective in both women and men with COPD [121].

Possible evidence of clinical synergy was obtained from predose FEV_1 and rescue medication use in the more severe patient subgroup [78]. By week 52, predose FEV_1 in the

Figure 57.3 Effect of long-acting β_2 -agonists (LABAs) on exacerbations in COPD. COPD patients were treated for 1 year with: (a) salmeterol (50 μg b.i.d.) or placebo; or (b) formoterol (4.5 μg b.i.d.) or placebo. The rate of severe exacerbations (requiring use of oral steroids and/or antibiotics and/or hospitalizations resulting from respiratory symptoms) was calculated as differences (%) from placebo. (Data from Calverley *et al.* [78] and Szafranski *et al.* [79].)

combination group had increased by 10% ($P < 0.001$) compared with 2% in both the salmeterol and FP groups, and had decreased by 3% in the placebo group [78]. Similarly, median percentage of days without reliever medication were 0% for placebo, 3% for salmeterol, 2% for FP and 14% for combination therapy ($P < 0.004$).

The efficacy and safety of BUD/formoterol in a single inhaler compared with either agent alone has also recently been evaluated in patients with moderate to severe COPD [79]. COPD patients were randomized to treatment with either formoterol (4.5 μg b.i.d.), BUD (400 μg b.i.d.), formoterol/BUD (4.5/400 μg b.i.d.) or placebo for 12 months in a double-blind parallel-group placebo-controlled study. The results of this study showed BUD/formoterol improved FEV_1 versus placebo (15%) and versus ICS (9%), but not compared with formoterol, and reduced symptom scores and use of relief medication versus BUD alone [79]. Improvements in morning and evening PEF were maintained over the 12 months of the study. The mean number of severe exacerbations (see Fig. 57.3) was equally reduced by BUD (23%) and BUD/formoterol (24%), but unchanged by formoterol alone (2%). Mild exacerbations were reduced by 62% with combination therapy compared with 55% for formoterol and 41% for budesonide [79].

These findings suggest that treatment of the underlying

multicomponent pathophysiology of COPD with both LABAs and ICS is necessary for improved control of the disease in many patients. Support for this approach was provided by a retrospective cohort study of COPD patients [122], which revealed that regular use of salmeterol/FP combination therapy was associated with significantly greater 3-year survival than those patients taking short-acting bronchodilators. A landmark study, Towards a revolution in COPD Health (TORCH) is underway to assess the impact of salmeterol/FP combination therapy on all-cause mortality over 3 years in COPD [123].

Combination of β_2 -agonists and anticholinergics

Beneficial effects have been reported previously when salbutamol is added to anticholinergic therapy in COPD [124]. Van Noord *et al.* [125] more recently examined the effect of the combination of 50 μg salmeterol b.i.d. and 40 μg ipratropium bromide q.i.d. They showed that ipratropium bromide and salmeterol improved FEV_1 to a significantly greater extent than salmeterol alone. This has been confirmed in another study over 24 weeks [126]. However, patients did not experience any additional benefit in symptom control when salmeterol and ipratropium bromide were administered together [126]. The combination of 12 μg formoterol b.i.d. and 40 μg ipratropium bromide q.i.d. has also been shown to be superior to formoterol alone in improving morning PEF and FEV_1 in patients with COPD [127]. A second study showed that the effects of formoterol/ipratropium over 3 weeks were significantly superior to salbutamol/ipratropium [128]. The effect of tiotropium in combination with LABAs has also been evaluated. The acute effects of adding salmeterol (50 μg) and tiotropium (18 μg) has been studied in patients with stable COPD [129,130]. At 12 h, the mean increase in FEV_1 for the salmeterol/tiotropium combination was significantly ($P = 0.009$) greater than for salmeterol alone [129]. Salmeterol and tiotropium produced a further increase in FEV_1 and FVC over that observed with either alone [130]. Combination therapy of salmeterol and tiotropium also resulted in the greatest reduction in dynamic hyper-inflation compared with single agent therapy [131]. Finally, one study has shown that the triple combination of salmeterol/FP/tiotropium was superior to the dual combinations in improving lung function in COPD patients [132].

Combination of β_2 -agonists and theophylline

Both SABAs [133] and LABAs [134,135] have been studied in combination with theophylline. The beneficial effects of

the combination of 50 μg salmeterol b.i.d. and theophylline (titrated to 10–20 $\mu\text{g}/\text{mL}$) over 12 weeks of treatment has recently been shown in two large multicentre studies [134,135]. By week 4, the combination of salmeterol and theophylline was significantly superior in improving FEV_1 than either salmeterol or theophylline alone, and this benefit was maintained over the 12 weeks. In addition, significantly fewer patients in the combination group had exacerbations, and the TDI was also significantly improved [134]. At each 4-week period, salbutamol use was significantly decreased in both the combination and salmeterol-alone groups. Although no studies examining the combination of formoterol and theophylline have been published, it is likely that formoterol would have similar activity to salmeterol. One study has evaluated salbutamol and theophylline in combination with ipratropium bromide or placebo and has demonstrated benefit of the triple combination in some patients [136].

Safety of β_2 -agonists in COPD

Patients with COPD are known to be at increased risk of cardiovascular disease [137]. Pharmacologically predictable cardiovascular adverse effects of β_2 -agonists include tachycardia, hypokalaemia and worsening ventilation–perfusion (V/Q) matching [138].

The systemic effects of a single dose of salmeterol (50 μg) and formoterol (12–24 μg) have been studied in patients with a history of ‘mild to moderate’ cardiac arrhythmias and hypoxaemia ($P_{aO_2} < 60$ mmHg). Mean maximum heart rate increased by approximately 6 beats/min and mean plasma potassium concentrations decreased by 0.45 mmol/L after inhalation of salmeterol [139]. The effects of formoterol (12 μg) on these parameters were generally similar to those of salmeterol; however, the effects of a higher dose of formoterol (24 μg) were more marked. The number of patients experiencing supraventricular premature beats or isolated ventricular premature beats (VPB) was similar after inhalation of placebo or salmeterol. Complex ventricular arrhythmias (multiform or paired VPBs) were reported only after inhalation of formoterol. The authors concluded that 50 μg salmeterol and 12 μg formoterol had a higher ‘safety margin’ than 24 μg formoterol in COPD patients with pre-existing cardiac arrhythmias and hypoxaemia [139]. A pooled analysis of salmeterol treatment in COPD for 12 weeks to 1 year showed no clinically significant differences from placebo in electrocardiogram (ECG), QTC interval or 24-h heart rate [140].

The concern that LABA bronchodilators may induce a mismatch between ventilation and perfusion, resulting in a degree of oxygen desaturation was examined in a three-way cross-over study [141], which showed that salmeterol, ipratropium bromide and salbutamol all induced an equally

small and transient fall in P_{aO_2} . The nadir in P_{aO_2} was greatest (3.5 mmHg; $P < 0.05$ vs baseline) after inhalation of salbutamol (200 µg), lowest after ipratropium bromide (1.4 mmHg) and intermediate (2.8 mmHg; $P < 0.05$ vs baseline) after salmeterol (50 µg). Compared with baseline, P_{aCO_2} and arterial pH values did not change significantly [141]. The observed effects of salmeterol and salbutamol on P_{aO_2} are therefore unlikely to be of clinical significance. Similarly, there was no evidence that LABAs used in combination therapy increased the risk of hypokalaemia in COPD patients [78].

Conclusions

The pathophysiology of COPD is complex and multi-component in nature. Pharmacological intervention, which addresses a number of elements of the underlying processes, may have greater clinical impact on the disease. β_2 -Agonists, particularly LABAs, have both bronchodilator and non-bronchodilator activity (see Table 57.2) that may be relevant to their efficacy in COPD (see Table 57.3). They have been shown to increase lung function, decrease symptoms, reduce exacerbations, increase health status, decrease hospitalizations and prolong survival. Combinations of LABAs and ICS have superior efficacy than either LABAs alone or other LABA combined therapies, and this may be the result of their effects being additive or, in some cases, synergistic in nature.

Acknowledgement

The author would like to thank Cathy Henderson for her assistance in preparing this manuscript.

CHAPTER 58

Corticosteroids

Olof Selroos

More than 50 years have passed since cortisone and adrenocorticotropic hormone (ACTH) were first administered to patients with asthma [1], obstructive emphysema [2] and chronic pulmonary disease [3]. Subsequently, these agents were found to be an effective treatment for acute exacerbations of asthma. Clinical experience, in addition to results from a few controlled clinical trials, also indicated a possible role for systemic and oral corticosteroids in the treatment of acute exacerbations of chronic obstructive pulmonary disease (COPD) [4]. Indeed, these drugs are now widely used in patients with COPD experiencing an acute exacerbation (in addition to bronchodilators, oxygen supplementation and antibacterial therapy) – clinical routine that is supported by the results of controlled clinical trials [4,5].

The role of inhaled corticosteroids in COPD has for some time been unclear. Debates have taken place [6,7] but no consensus agreement has yet been reached [8]. New studies evaluating the efficacy of the combination of inhaled corticosteroids and long-acting inhaled β_2 -agonists in patients with COPD (GOLD stage III–IV) are of great interest as they show significant effects not only on airway function variables, but also on important outcome measures such as prevention of COPD exacerbations and health-related quality of life [9–11].

This chapter reviews some of the established studies in this field, with a particular focus on more recent clinical trials of inhaled corticosteroids and their combinations with long-acting inhaled β_2 -agonists in the treatment of COPD.

Acute exacerbations of COPD

Systemic corticosteroids

The first double-blind placebo-controlled clinical study evaluated the efficacy of methylprednisolone in 44

consecutive hospitalized patients with chronic bronchitis and acute respiratory insufficiency defined as an arterial $\text{Po}_2 \leq 60$ mmHg [12]. Treatment consisted of either 0.5 mg/kg body weight intravenous methylprednisolone ($n = 22$) or placebo ($n = 22$) every 6 h for 72 h, in addition to ampicillin, oxygen, intravenous aminophylline and inhaled isoprenaline. Pre- and postbronchodilator forced expiratory volume in 1 s (FEV_1) were measured three times daily. Methylprednisolone improved airflow more than placebo; the improvements in both pre- and postbronchodilator FEV_1 were greater in the corticosteroid-treated group ($P < 0.001$ for both). Twelve patients in the corticosteroid group had improvements in $FEV_1 \geq 40\%$ by 72 h compared with three patients in the placebo group ($P < 0.01$).

Thompson *et al.* [13] performed a 10-day double-blind placebo-controlled study in 27 outpatients with an acute exacerbation of COPD. An exacerbation was defined as subjective worsening of chronic baseline dyspnoea or cough for more than 24 h and necessitating a hospital visit. An at least 25% increase in inhaled β_2 -agonist use for more than 24 h was also required, or an increase in sputum production and/or purulence. Postbronchodilator FEV_1 should be less than 60% of predicted normal. Treatment consisted of a 9-day course of prednisone – 60, 40 and 20 mg/day for 3 days each – or placebo, in addition to the patient's previous medication and increased doses of inhaled β_2 -agonists. Assessments of treatment were made at baseline and on days 3 and 10. The primary endpoint was a treatment failure defined as hospitalization or prescription of oral corticosteroids because of dyspnoea. The failure rate was 0/13 in the prednisone group and 8/14 in the placebo group ($P = 0.002$). Treatment with prednisone also resulted in a more rapid improvement in arterial Po_2 ($P = 0.002$), alveolar–arterial oxygen gradient ($P = 0.04$), FEV_1 ($P = 0.006$) and peak expiratory flow (PEF) ($P = 0.009$) and in a trend towards more rapid improvement in dyspnoea scale scores.

A large double-blind randomized study evaluated the efficacy of intravenous hydrocortisone versus placebo in 113 patients attending the emergency room because of an acute COPD exacerbation [14]. FEV_1 and $FEV_1 : FVC$ (forced vital capacity) ratio should be less than 60% of predicted normal. In addition to identical high-dose bronchodilator therapy, the patients received 100 mg hydrocortisone every 4 h for 4 days, or placebo. Of those patients receiving steroids, 22 achieved a more than 40% improvement in PEF by 6 h and 17 achieved similar results in FEV_1 . In the placebo-treated group the corresponding figures were 13 and 8, respectively. More patients in the hydrocortisone group could be discharged within 24 h (16 vs 10) and fewer patients relapsed within 2 weeks requiring hospitalization (0 vs 3).

Davies *et al.* [5] recruited patients with non-acidotic exacerbations of COPD to a double-blind placebo-controlled study. Patients were randomized to treatment with 30 mg oral prednisolone once daily ($n = 29$) or placebo ($n = 27$) for 14 days in addition to standard treatment with nebulized bronchodilators, antibiotics and oxygen. Daily assessments of lung function and symptoms were performed and patients were recalled at 6 weeks for a follow-up examination. Postbronchodilator FEV_1 increased more rapidly and to a greater extent in the steroid-treated group (Fig. 58.1), with percentage predicted FEV_1 rising from 26% to 32% in the placebo group, and from 28% to 42% in the prednisolone

Figure 58.1 Change in absolute postbronchodilator forced expiratory volume in 1 s (FEV_1) from admission by day of study in active and placebo groups. Means (95% confidence interval) are shown. (From Davies *et al.* [15] with permission.)

group ($P < 0.0001$). Up to day 5 of hospital stay, postbronchodilator FEV_1 increased by 90 mL/day in the prednisolone group compared with 30 mL/day in the placebo group. Hospital stays were shorter in the steroid-treated group (9 days vs 7 days; $P = 0.027$). Groups did not differ at 6-week follow-up.

The largest study has been reported by Niewoehner *et al.* [15]. This double-blind 6-month multicentre study conducted at 25 Veterans Affairs medical centres in the USA included 271 eligible patients of 1840 potential study candidates. The main inclusion criteria were age over 50 years, a smoking history of ≥ 30 pack-years, a history of COPD exacerbations and an $FEV_1 \leq 1.5$ L or inability to perform spirometry because of dyspnoea. The main exclusion criterion was use of systemic steroids in the previous 30 days. Patients were randomized to treatment with 125 mg intravenous methylprednisolone every 6 h for 3 days followed by oral prednisone in decreasing doses (60 to 20 mg) for 2 weeks ($n = 80$) or 8 weeks ($n = 80$), or to placebo ($n = 111$). The primary variable of efficacy was the rate of treatment failures, which was significantly higher in the placebo group than in the combined steroid group (at 30 days 33% vs 23%; $P = 0.04$; at 90 days 48% vs 37%; $P = 0.04$). Steroid treatment was also associated with a shorter stay in hospital (8.5 days vs 9.7 days for placebo; $P = 0.03$) and with a greater improvement in FEV_1 of approximately 100 mL by the first day after enrolment. No differences were found between the two steroid treatments for any of the variables. Significant treatment effects were not seen at 6 months' follow-up. Patients receiving steroid treatment were more likely to have hyperglycaemia than placebo-treated patients (15% vs 4%; $P = 0.002$).

Sayiner *et al.* [16] performed a single-blind randomized study in 36 patients with severe COPD exacerbations. Their mean FEV_1 was 0.6 L and Pao_2 46 mmHg. They were randomized to treatment with 0.5 mg/kg body weight intravenous methylprednisolone every 6 h for 3 days followed by 0.5 mg/kg every 12 h for 3 days and 0.5 mg/kg once daily for 4 days, or to the same treatment for the first 3 days and thereafter placebo (saline) injections. Both groups showed improvements in Pao_2 and FEV_1 levels, but these were significantly better in the 10-day active treatment group ($P = 0.012$ and 0.019, respectively). Dyspnoea also improved more in the 10-day treatment group. No difference in exacerbation rate was observed during a 6-month follow-up period. The authors conclude that a 10-day course of steroid treatment is more effective than a 3-day course.

A recent meta-analysis on eight studies fulfilling defined criteria found that in five studies significant improvement in FEV_1 (more than 20%) was associated with administration of corticosteroids [17]. The authors concluded that short courses of systemic corticosteroids in acute exacerbations of

COPD have been shown to improve spirometric and clinical outcomes (good quality evidence for both).

Conclusions

Controlled clinical studies and a meta-analysis show that systemic corticosteroids are beneficial for the treatment of acute exacerbations of COPD in patients not recently treated with corticosteroids. Compared with placebo, systemic corticosteroids improve short-term FEV_1 by approximately 100 mL during acute exacerbations [4]. They can reduce the length of stay in hospitalized patients by 1–2 days and reduce the absolute number of treatment failures by approximately 10% [4]. The importance of treatment duration has been investigated in a few studies which suggest that a 10–14-day course of corticosteroids is most beneficial. A 3-day course was less effective than a 10-day course [16] and no advantage was seen with an 8-week course compared with a 2-week course [15]. Hyperglycaemia has been the most frequently reported adverse event.

Nebulized corticosteroids

The benefits of systemic corticosteroid therapy as described above may be limited by the risk of adverse effects. In addition to hyperglycaemia, adrenal suppression has been reported after short-term use of high doses of systemic corticosteroids [18]. Nebulized therapy has therefore attracted attention. A double-blind randomized placebo-controlled multicentre study investigated the use of a nebulized corticosteroid, budesonide, compared with prednisolone for the treatment of acute exacerbations of COPD [19]. A total of 199 patients were included. They received 2 mg nebulized budesonide every 6 h for 72 h, 30 mg oral prednisolone every 12 h, or placebo in addition to standard treatment with nebulized β_2 -agonists, ipratropium, antibiotics and oxygen. Both active treatments resulted in significant improvements in postbronchodilator FEV_1 compared with placebo and without a significant difference in the change in FEV_1 between the two. However, prednisolone was associated with a higher incidence of hyperglycaemia than budesonide treatment.

In a double-blind study, 40 patients with moderate to severe acute exacerbations of COPD were randomized to treatment with 8 mg/day nebulized budesonide or 40 mg/day intravenous prednisolone for 10 days [20]. Similar improvements were seen in both groups for airway function (PEF), SaO_2 and PaO_2 ($P < 0.001$) and without statistically significant differences between the groups. No adverse events were recorded.

Based on these two studies, it appears that nebulized budesonide may represent an alternative to systemic corticosteroids for the treatment of acute exacerbations of COPD.

Stable COPD

Oral corticosteroids

Short-term studies

A large number of short-term studies (duration of treatment ≤ 3 months) have evaluated the efficacy of oral prednisone or prednisolone in patients with stable COPD. The results have varied greatly as inclusion criteria have differed, the number of patients has usually been small and it has been difficult to determine how well patients with asthma have been excluded. Nevertheless, the results of these early studies suggest that some COPD patients benefit from treatment with corticosteroids. Eosinophilia of blood [21], sputum [22], variability of FEV_1 [21] and response to inhaled β_2 -agonists [22] were cited as criteria for differentiating steroid responders from non-responders.

Callahan *et al.* [23] performed a meta-analysis by selecting 33 studies published since 1951. The quality of the studies was assessed by three investigators using nine selected criteria. Ten studies met all nine criteria. Response to treatment was defined as a 20% or greater increase in FEV_1 from baseline. A calculated mean effect size in the studies was 10% (95% confidence interval [CI], 2–18%) and varied from 0% to 56%. This result suggests that patients treated with oral steroids approximately 10% more often than placebo-treated patients will improve FEV_1 by 20% or more.

Responders and non-responders

Nisar *et al.* [24] showed that approximately 40% of patients with stable, moderate to severe COPD demonstrated a significant increase in FEV_1 when receiving a 2-week course of oral corticosteroids. However, it was not possible to separate responders from non-responders based on baseline characteristics as no clinical differences were found between the groups. A reversibility test with a bronchodilator is neither very sensitive in identifying patients who may respond with a significant change in FEV_1 with a corticosteroid [25].

A further attempt to identify steroid responders was undertaken by Pizzichini *et al.* [26]. In a single-blind crossover study in 18 patients, they investigated whether an increased proportion of sputum eosinophils ($\geq 3\%$) predicts an effect in smokers with severe COPD. The included patients had a mean FEV_1 of less than 30% predicted normal. Treatment consisted of 30 mg/day prednisone for 2 weeks, or placebo. In patients with sputum eosinophilia ($n = 8$), prednisone, as compared with placebo, produced a statistically significant and clinically important mean effect on effort dyspnoea ($P = 0.008$) and health-related quality of life ($P = 0.01$). A mean increase in FEV_1 of 0.11 L was found ($P = 0.05$).

Long-term studies

COPD guidelines published in the 1990s recommended long-term use of oral corticosteroids in patients with COPD who had demonstrated a response in a 2-week test with prednisolone [27–29]. However, there is little scientific support for such a statement. On the contrary, the more recent GOLD and ATS/ERS guidelines clearly state that ‘long-term treatment with oral glucocorticosteroids is not recommended in COPD’ [30,31], mainly because of lack of demonstrated efficacy in prospective controlled clinical trials and the risk of systemic glucocorticoid side-effects.

The available information on long-term therapy with oral corticosteroids comes from retrospective studies. Postma *et al.* [32] reported 14–18 years’ data from a series of 79 patients with severe COPD (FEV_1 less than 1 L). These patients had used 10–15 mg/day prednisolone in the beginning, and later lower doses, if possible. The investigators noticed three patterns of response: no change; initial increase in FEV_1 followed by a decrease; and a linear progression. At an oral dose of 7.5 mg/day or less, FEV_1 decreased, but often after a considerable time-lag (6–32 months). The results indicated that, in doses above 7.5 mg/day, prednisolone may slow down the progression of COPD. However, the treatment was associated with a considerable number of severe side-effects. In a later study, the same authors reported long-term findings in 139 non-allergic patients with less severe disease (FEV_1 more than 1.2 L; FEV_1/VC (vital capacity) 40–55%) [33]. Again they noticed the same three patterns of response as mentioned above, and a further group of patients with an initial decline in FEV_1 followed by an increase. The conclusion was similar: in a dose above 7.5 mg/day, prednisolone may slow down the progression of COPD.

The value of long-term treatment with oral corticosteroids was more recently evaluated in a double-blind prednisolone withdrawal study [34]. A total of 42 steroid-dependent patients out of 164 candidates, who had used prednisolone at least for the last 6 months, agreed to participate in the study. Patients were randomized to continuous treatment with prednisolone ($n = 20$) or to a regimen where the prednisolone dose was reduced by 5 mg/week. Patients were stratified according to baseline prednisolone doses: 5–10 mg/day prednisolone or more than 10 mg. Both groups could receive open label 40 mg/day prednisolone for 10 days for treatment of exacerbations. A total of 33 patients (87%) used an inhaled corticosteroid at baseline and all patients continued treatment with 1600 g/day triamcinolone acetonide throughout the study. No statistically significant differences were found between the groups in number of acute exacerbations, spirometric values, dyspnoea or health-related quality of life. At the end of the study the average daily prednisolone doses (mean \pm standard deviation [SD]) were 10.7 ± 5.2 mg in the continuous

group and 6.3 ± 6.4 mg in the ‘on demand’ group ($P = 0.003$), which also had lost 4.6 ± 2.0 kg (mean \pm SD) of body weight compared with an increase of 0.5 ± 3.5 kg ($P = 0.007$) in the continuous prednisolone group. The results of this study, although in a small number of patients, show that continuous treatment with oral corticosteroids is of minor benefit in patients with COPD, but causes systemic glucocorticoid side-effects.

Conclusions

Few prospective controlled studies have been performed with oral corticosteroids in patients with stable COPD. The effect size has been small. Long-term treatment is not recommended because of the risk of systemic side-effects.

Inhaled corticosteroids

For some time it has been unclear whether inhaled corticosteroids have a role in the treatment of patients with COPD.

Short-term studies

It has been a common understanding that inhaled corticosteroids do not affect the type of inflammation present in patients with COPD [7]. The benefit of systemic corticosteroids in patients with acute exacerbations of COPD has been explained as a consequence of existing eosinophilia in that condition [35].

There are, however, observations that inhaled corticosteroids do affect the cellular findings in bronchial biopsies and in sputum in patients with stable COPD, too. Hattotuwa *et al.* [36] studied the effect of FP 500 μ g b.i.d. over a 3-month period in a randomized, double-blind, placebo-controlled study in 30 patients. The significant finding was a reduction in the CD8 : CD4 ratio in the epithelium and of the numbers of subepithelial mast cells in the FP group.

Gan *et al.* [37] performed a meta-analysis on six inhaled corticosteroid studies with a duration of 2–12 weeks in which sputum analyses had been performed. There were two studies with budesonide, BDP and FP each and with a total of 162 patients. In three studies with a cumulative dose ≥ 60 mg or longer duration (≥ 6 weeks), inhaled corticosteroids were uniformly effective in reducing the total cell, neutrophil, and lymphocyte counts. In contrast, the three studies with lower cumulative doses and of shorter duration of therapy did not demonstrate a favourable effect.

It therefore appears that inhaled corticosteroids may affect cellular components in COPD which are of importance for the pathogenesis and progression of the disease.

In 1998, Barnes *et al.* [38] reviewed the literature on inhaled corticosteroids and COPD and identified more than 100 trials, but only 12 randomized placebo-controlled studies. Most of the studies were short term, varying in duration

from 10 days to 12 weeks. None of the studies measuring bronchial hyperresponsiveness were able to document a change in the provocative concentration of histamine or methacholine causing a 20% decrease in FEV_1 (PC_{20}). All but one failed to show significant improvements in FEV_1 . The exception was a double-blind randomized study with 250 µg beclomethasone dipropionate (BDP) q.i.d. ($n = 20$), or placebo ($n = 10$) for 6 weeks [39]. Bronchoalveolar lavage was performed before and after treatment and showed improvement in epithelial permeability (statistically significant changes in epithelial lining fluid albumin, lactoferrin and lysozyme) and a reduction in sample cell count ($P = 0.048$). A bronchitis index was calculated based on visual inspection during bronchoscopy and this index improved during treatment ($P = 0.02$). Also, the spirometric indices (FEV_1 , FVC and forced expiratory flow during 25 to 75% of VC ($FEF_{25-75\%}$)) improved significantly compared with placebo. A more recent double-blind cross-over study compared the efficacy of 440 µg fluticasone propionate (FP) b.i.d. (delivered dose, corresponding to 500 µg b.i.d. of metered dose) with placebo for 3 months each in 36 patients with COPD (median age 69 years; mean $FEV_1 \pm SD$, 1.10 ± 0.43 L; median pack-years 50) [40]. A total of 52 patients had been included but 16 (12 on placebo) were withdrawn for various reasons. Six (five on placebo) were withdrawn because of acute COPD worsening. FP treatment resulted in higher prebronchodilator FEV_1 (1.17 vs 1.07 L; $P = 0.001$), higher PaO_2 (67 vs 64 mmHg; $P = 0.002$) and better dyspnoea score on the chronic respiratory questionnaire (3.70 vs 3.47; $P = 0.03$). A trend towards fewer exacerbations during FP treatment compared with placebo did not reach a level of statistical significance.

Short-term studies comparing inhaled corticosteroids with oral corticosteroids have usually found the latter to be slightly more effective, although differences have not been statistically significant [38].

Conclusions

Most short-term studies with inhaled corticosteroids in patients with COPD have not shown efficacy compared with placebo. Individual patients have responded to treatment with improved airway function, but as a general rule these patients have exhibited signs of an asthmatic bronchitis (e.g. eosinophilia in blood or sputum, atopy or an increased bronchial hyperresponsiveness).

Medium-term studies

Medium-term studies are defined as clinical trials with a duration of 6–30 months. Eight randomized trials were identified in the literature [41–48]. Of these, three studies [42–44] have been included in a meta-analysis [49]. Baseline characteristics of patients with COPD included in the studies and the main findings are summarized in Table 58.1.

Dompeling *et al.* [41] studied the effect of BDP in a group of 28 COPD (and 28 asthma) patients with a rapid decline in FEV_1 , selected from a previous bronchodilator study [50]. Smoking history and FEV_1 levels had been similar in the two groups and overlaps had probably existed. Both groups showed a mean fall in FEV_1 during the first 2 years of approximately 160 mL/year. After starting treatment with BDP, the patients showed significant improvements in prebronchodilator FEV_1 in the first 6 months, and thereafter the fall in FEV_1 continued over the next 6 months. Treatment with BDP was then extended for a second year [51]. At that time 22 COPD patients had been followed for 4 years. Postbronchodilator FEV_1 was not affected by treatment with BDP (see Table 58.1). Early improvements in symptoms (months 7–12) was not observed later. Some patients discontinued their treatment with BDP and this did not affect the subsequent decline in FEV_1 [52].

The Dutch Chronic Non-Specific Lung Disease Study Group [42] reported the results of a 2.5-year study in which patients with asthma or COPD were included based on degree of airway obstruction and bronchial hyperresponsiveness. Patients were randomized to regular treatment with 0.5 mg terbutaline q.i.d. with the addition of 40 µg ipratropium q.i.d., 200 µg BDP q.i.d. via pressurized metered dose inhaler (pMDI), or placebo. There were equal numbers of smokers, ex-smokers and non-smokers. Approximately half of the patients were skin test positive with common allergens, or had increased levels of immunoglobulin E (IgE). The same proportion had previously been treated with an inhaled corticosteroid. Based on symptoms, the series could be divided into subgroups of 99 patients with asthma, 88 with asthmatic bronchitis, 51 with COPD and 36 with an undefined diagnosis of airway obstruction. The primary variable of efficacy was the withdrawal rate, mainly because of exacerbations, which was significantly lower in the BDP group (see Table 58.1) than in the placebo group. The patients who were withdrawn had a lower mean FEV_1 (61% vs 65% predicted normal) and lower geometric mean PC_{20} (0.19 vs 0.31 mg/mL) than the rest of the patients.

Derenne [43] randomized 194 patients with COPD (mean reversibility with 400 µg salbutamol 3.3% predicted) to treatment for 2 years with BDP or placebo. An intention-to-treat analysis in 170 patients showed a decrease in FEV_1 in the placebo group and an increase in the BDP group (see Table 58.1). The result thus indicated that treatment with BDP could maintain the FEV_1 on a pretreatment level for 2 years.

Renkema *et al.* [44] followed 58 non-allergic patients with COPD and moderate airflow limitation for 2 years in a double-blind randomized study. The patients were treated with budesonide alone, budesonide plus oral prednisolone, or placebo (see Table 58.1). Assessments were performed

Table 58.1 Double-blind randomized 6–24 month studies with inhaled corticosteroids in patients with COPD.

Author [Ref.]	COPD study population Study duration	No. of patients, R/C Mean age Inhaled corticosteroid, daily dose	Per cent smokers Smoking history	Mean FEV_1 (mean \pm SD) and FEV_1 % predicted	Decline in FEV_1 (mL/time)	Exacerbations Symptoms
Dompeling <i>et al.</i> [41]	Selected as a group of rapid decliners (≥ 80 mL/year) from a previous bronchodilator study	28 54 years BDP 800 μ g vs placebo	65% 23 pack-years	70 \pm 16% predicted	0–6 months: BDP –10 mL/year, NS from earlier annual decline of –77 mL/year 7–12 months: BDP –75 mL/year (NS) (postbronchodilator)	7–12 months: sign reduction in symptoms, no reduction in exacerbation rate
Kerstjens <i>et al.</i> [42]	Age 18–60 years Symptom-based diagnosis of COPD PC ₂₀ histamine < 8 mg/mL Dutch multicentre 30 months	274* 39.6 years BDP 800 μ g vs placebo	36% Pack-years not reported	2.33 L 64% (29–115%)	COPD subgroup: 'initial treatment effect maintained', figures not given Median slopes 3–30 months: BDP –33 mL/year, P –64 mL/year (NS) (prebronchodilator)	Sign fewer withdrawals in the BDP group, 0.25/year vs 0.72/year in P group mainly due to exacerbations ($P < 0.001$) 0–3 months: Increase in FEV_1 by 10.3% points in the BDP group vs 1.0% decrease in P ($P < 0.001$) 3–30 months: no difference in FEV_1 slopes

every second month. Eleven patients discontinued the study – seven because of COPD deterioration (five in the placebo group and two in the combined treatment group). The median prebronchodilator decline in FEV_1 in the three groups is shown in Table 58.1, with the lowest mean decline in the budesonide group. However, the variations were large and the differences between the groups were not statistically significant. Symptoms scores calculated at baseline and after treatment for 1 and 2 years decreased significantly in the active treatment groups compared with placebo.

Paggiaro *et al.* [45] conducted a study comparing FP with placebo in patients with moderate COPD (mean bronchodilator reversibility 0.8–1.7% of predicted FEV_1 ; see Table 58.1). Treatment with FP significantly improved FEV_1 , FVC, morning PEF, symptom scores for median cough and sputum volume, prolonged the 6-min walking distance, and reduced the severity of exacerbations but not the exacerbation rate.

Bourbeau *et al.* [46] included patients with moderate to severe COPD, not responding to 40 mg oral prednisolone, into a study comparing the efficacy of budesonide with placebo (see Table 58.1). Only 11 patients in the budesonide group and nine in the placebo group were able to complete the study. No statistically significant difference in the change in FEV_1 over time was seen between the groups up to 6 months. At 12 months there were too few patients left for an evaluation. No changes in the 6-min walking test or in quality of life assessed by the Chronic Respiratory Disease Questionnaire were found.

Weir *et al.* [47] randomized 98 COPD patients into a study where they received BDP 1500 or 2000 $\mu\text{g}/\text{day}$ depending on body weight, or placebo. A total of 59 patients completed the study. The annual decline in FEV_1 was slower in patients treated with BDP but the difference compared with placebo was not significant (see Table 58.1). The exacerbation rate was also lower in the BDP group but again the difference versus placebo was not significant. No difference in dyspnoea scores was found.

Senderovitz *et al.* [48] performed a 6-month study in 40 patients with a mean FEV_1 of 1.49 L and not responding to inhaled β_2 -agonists with a FEV_1 increase of 15%. A total of 26 patients completed the study. Patients were randomized to treatment with budesonide ($n = 14$) or placebo. At the end of the study the median decrease in postbronchodilator FEV_1 was smaller in the budesonide group than in the placebo group (see Table 58.1). There was no difference between the groups in the number of exacerbations or symptoms.

A meta-analysis [49] included data from two studies [42,44], and the otherwise unpublished study by Derenne [43]. The main question of the analysis was whether inhaled corticosteroids were able to slow down the decline

in FEV_1 in patients with COPD. Patients with asthmatic features ($n = 101$) were excluded from the analysis, which was then based on 95 of the initially 140 steroid-treated and on 88 of the placebo-treated patients. The patients in the steroid group had mainly been treated with 1500 $\mu\text{g}/\text{day}$ BDP, and a few with 1600 $\mu\text{g}/\text{day}$ budesonide or 800 $\mu\text{g}/\text{day}$ BDP. The mean age of the patients was 61 years and their mean FEV_1 45% of predicted normal. The estimated 2-year difference in prebronchodilator FEV_1 was 34 mL/year (95% CI, 5–63 mL/year). The postbronchodilator FEV_1 showed a difference of 39 mL/year (95% CI, –6 to 84 mL/year). The number of exacerbations did not differ between the groups.

The effect of FP was furthermore investigated in a placebo-controlled study in 23 COPD patients with increased bronchial hyperresponsiveness [53]. These patients received 500 μg FP b.i.d. or placebo for 6 months. Treatment with FP did not affect the degree of hyperresponsiveness but resulted in an unchanged level of airway function, whereas a decline in FEV_1 was seen in the placebo group. FP treatment resulted in small changes in biopsy indices of airway inflammation.

Conclusions

The individual medium-term studies did not show an effect on the annual decline in FEV_1 with the exception of one study [43], which has been reported only as an abstract. In a meta-analysis of three studies carefully excluding patients with asthma, a statistically significant effect in prebronchodilator FEV_1 was seen between treated and untreated patients, but not in postbronchodilator FEV_1 [49]. Bronchial hyperresponsiveness remained unaffected in a small group of patients [53]. Severity of exacerbations was influenced in one study together with improvements in a number of clinical variables [45].

Long-term studies

Four 3-year studies have been performed in patients with different degrees of COPD severity, with the aim of evaluating the effect of an inhaled corticosteroid on the decline in FEV_1 [54–57]. These studies are summarized in Table 58.2.

The Copenhagen City Heart Study (CCHS) started in the mid-1970s with a random age-stratified sample of 19 327 individuals [54]. Between 1992 and 1994, 10 127 individuals were questioned about their respiratory symptoms and spirometry was performed. Subjects with an FEV_1 : VC ratio of $\leq 70\%$ and no self-reported asthma were referred to the study for further examination. Reversibility tests with a β_2 -agonist and with oral prednisolone were conducted, and individuals with a reversibility more than 15% in one or both of the tests were excluded from the study. A total of 290 patients (40% being symptom-free) were finally randomized to treatment with budesonide or placebo (see Table 58.2). The mean age of the patients was 59 years,

Table 58.2 Summary of placebo-controlled, parallel-group, 3-year studies with inhaled corticosteroids in patients with COPD.

Author [Ref.]	Study population	No. of patients Mean age Inhaled corticosteroid, daily dose	Per cent smokers Smoking history	Mean FEV_1 (mean \pm SD) and FEV_1 % predicted	Decline in postbronchodilator FEV_1 , mL/year	Other effects

BHR, bronchial hyperresponsiveness; b.i.d., twice daily; BUD, budesonide; FEV_1 , forced expiratory volume in 1 s; FP, fluticasone propionate; P, placebo; pMDI, pressurized metered dose inhaler; QoL, quality of life; SD, standard deviation; TA, triamcinolone acetate.

40% were women and 77% were current smokers. Overall, patients had very mild COPD (mean FEV_1 86% of predicted normal). There was no difference between groups for the decline in FEV_1 , exacerbation rates or presence of respiratory symptoms.

The EUROSCOP (European Respiratory Study on Chronic Obstructive Pulmonary Disease) was a double-blind placebo-controlled trial evaluating the effect of budesonide compared with placebo [55]. After a smoking cessation period, subjects who were unable to stop smoking ($n = 1277$) were included and 912 of those (71%) completed the study. The reasons for withdrawal – non-compliance, adverse events and loss of follow-up – were similar in both groups. The patients' mean age was 52 years, 27% were women and mean FEV_1 was 77% of predicted normal. During the first 6 months of the study, FEV_1 improved at a rate of 17 mL/year in the budesonide group compared with a decline of 81 mL/year in the placebo group ($P < 0.001$). Subsequently, the annual decline in postbronchodilator FEV_1 was not statistically significantly different between

the groups (see Table 58.2). However, during this period more patients in the placebo group showed a rapid decline in FEV_1 (more than 60 mL/year): 55% of patients in the placebo group compared with 49% in the budesonide group ($P = 0.06$). Of the 912 subjects completing the study, the median decline in FEV_1 over the 3-year period was 140 mL with budesonide and 180 mL with placebo ($P = 0.05$). Subjects with a smoking history of less than 36 pack-years at enrolment had a reduction of 190 mL with placebo and 120 mL with budesonide ($P < 0.001$) (Fig. 58.2). There was no difference in decline in FEV_1 in subjects with a smoking history of more than 36 pack-years ($P = 0.57$). The incidence of exacerbations was not evaluated. A *post hoc* analysis revealed that treatment with budesonide had significantly reduced the incidence of cardio-vascular events [58]. A frequency of 6% was seen in the placebo group compared with 3% in the budesonide group ($P < 0.05$). This may indicate that treatment with inhaled corticosteroids can also influence systemic components of COPD.

The ISOLDE (Inhaled Steroids in Obstructive Lung

Figure 58.2 Median change in forced expiratory volume in 1 s (FEV_1) as compared with the value at randomization (month 0) in the placebo and budesonide groups in patients with ≤ 36 pack-year smoking history. (From Pauwels *et al.* [55] with permission.)

Disease in Europe) study included symptomatic patients with COPD (i.e. with more severe illness than those in the two studies cited above) [56]. A total of 751 patients with a mean baseline postbronchodilator FEV_1 of 1.4 L (50% of predicted normal) were included. Patients with a bronchodilator reversibility to 400 μ g salbutamol of more than 10% predicted normal were excluded from the study. Patients were treated for 3 years with 1000 μ g/day FP or placebo (see Table 58.2). No difference in the annual decline of FEV_1 was observed between the groups (see Table 58.2). However, the predicted mean FEV_1 in the FP group at 3 and 36 months was 76 and 100 mL higher, respectively, compared with placebo (mixed effects model; $P < 0.001$). There was no significant correlation between the FEV_1 response to oral corticosteroids or FP ($P = 0.056$). The rate of exacerbations (defined as a worsening of respiratory symptoms requiring treatment with oral corticosteroids and/or antibiotics) was lower in the FP group (0.99 per year compared with 1.32 per year in the placebo group) as were the withdrawals because of respiratory symptoms (19% compared with 25% in the placebo group; $P = 0.034$). The rate of decline in respiratory health status was significantly lower in the FP group compared with placebo (total respiratory questionnaire score: 3.2 vs 2.0 units/year, respectively; $P = 0.004$). This difference was interpreted as a delay in average time for clinically important reduction in health status from 15 to 24 months.

The Lung Health Study II was a randomized placebo-controlled trial in the USA [57]. Smokers and ex-smokers who had participated in the previous Lung Health Study I [59] and who had a baseline FEV_1 of 30–90% of predicted normal and a FEV_1 : FVC ratio of less than 70% were

recruited. Of these, 1116 patients were randomized to treatment with triamcinolone or placebo (see Table 58.2). The patients' mean age was 56 years and mean postbronchodilator FEV_1 was 68% of predicted normal. The mean duration of follow-up was 40 months. During the study, the rate of decline of postbronchodilator FEV_1 was not statistically significantly different between the groups (see Table 58.2). However, the steroid-treated patients experienced fewer respiratory symptoms ($P = 0.005$) and had fewer visits to a physician because of respiratory problems ($P = 0.03$) compared with those receiving placebo. Furthermore, patients receiving triamcinolone showed lower airway reactivity in response to methacholine challenge at 9 and 33 months (both $P = 0.02$).

Meta-analyses of the long-term studies

Two recent meta-analyses evaluated the effect of inhaled corticosteroids on the decline in FEV_1 . Highland *et al.* [60] included six studies with 3571 patients in their review [44,47,54–57] and reported that the summary estimate for the difference in FEV_1 decline between placebo and active treatment was -5.0 ± 3.2 mL/year (95% CI, -11.2 – 1.2 mL/year; $P = 0.11$). The authors concluded that inhaled corticosteroids use was not associated with the annual rate of FEV_1 decline. Using data from the same plus two additional studies [42,43], Sutherland *et al.* [61] included 3715 patients in their analysis. In this meta-analysis, treatment with inhaled corticosteroids was shown to reduce the rate of FEV_1 decline by 7.7 mL/year (95% CI, 1.3 – 14.2 mL/year; $P = 0.02$). A meta-analysis of high-dose regimens revealed an even greater effect of 9.9 mL/year (95% CI, 2.3 – 17.5 mL/year; $P = 0.01$) compared with the meta-analysis of all studies. The authors concluded that inhaled corticosteroid treatment for ≥ 2 years slows the rate of decline in lung function in patients with COPD.

How is it possible that two meta-analyses performed at the same time and using similar datasets can reach different conclusions? The similarities and differences between the two analyses were reviewed by Burge and Lewis [62]. The difference appears to partly depend the results of a study in patients with early COPD [54]. The benefits of inhaled corticosteroids in this largely asymptomatic patient group is limited. In their analyses, Highland *et al.* presumed a 3.1 mL/year greater rate of FEV_1 decline in the budesonide group, while Sutherland *et al.* correctly interpreted the data as showing a 3.1 mL/year improvement in FEV_1 in patients receiving an inhaled corticosteroid. Furthermore, differences in the interpretation of standard errors (P values) and choice of patient groups (in studies involving subgroups of patients) are further confounding factors. In other words, these vastly different conclusions stemmed directly from differences in the interpretation of almost identical datasets [62]. However, based on detailed reviews of these recent

meta-analyses and the results of long-term clinical studies, it can be concluded that treatment with inhaled corticosteroids do modify disease progression and slow the decline in FEV_1 in patients with COPD.

Conclusions

The four long-term studies of inhaled corticosteroids in patients with mild to moderate COPD did not show a significant effect on the decline in postbronchodilator FEV_1 compared with placebo. A recent meta-analysis, however, demonstrated a significant effect on the rate of decline of FEV_1 , which was even greater in patients on a high-dose inhaled corticosteroid regimen. In addition, an increase in FEV_1 has been observed during the first 3–6 months of treatment and a lower reactivity in response to methacholine was seen in one study, where it was investigated. Improvements in respiratory symptoms and health-related quality of life have also been reported. A reduction in exacerbation rate was found in the two studies that included patients with more severe COPD.

Responders and non-responders

Several studies have investigated whether the response to a 2-week course of oral corticosteroids can predict the subsequent benefit of treatment with an inhaled corticosteroid. Selroos [63] investigated whether a 10-day course of oral prednisolone (30–40 mg/day) could predict the future response to an inhaled corticosteroid. A group of 52 patients with stable COPD and no significant response to an inhaled β_2 -agonist were included. Their mean $FEV_1 \pm SD$ was 1.7 ± 0.4 L. Of these, 12 steroid responders were identified (increase in $FEV_1 \geq 15\%$). Subsequently all 52 patients received 1600 $\mu\text{g/day}$ budesonide for 6 months. During this phase, nine of the prednisolone responders maintained their improved airway function. Moreover, eight of the initial 40 non-responders to prednisolone demonstrated a significant improvement with budesonide. Thus, responders could not be identified and the benefit of long-term treatment with budesonide could not be predicted based on the short course of oral prednisolone.

Boothman-Burrell *et al.* [64] performed a double-blind placebo-controlled cross-over study in 18 patients with COPD. Treatment consisted of 1000 μg BDP or placebo twice daily for 3 months. At the end of each treatment period patients received 30 mg prednisone for 10 days. The two treatment phases were separated by a 1-month wash-out period. The predictive value of the prednisone response was 0% and 81% for a positive and negative outcome, respectively.

Davies *et al.* [65] performed a study in 127 patients with stable COPD (mean FEV_1 of less than 40% of predicted normal). Initial spirometry was performed after treatment with 5 mg nebulized salbutamol, and after a 2-week course

of oral prednisolone. Thereafter, patients were treated by two physicians with different treatment policies. One prescribed inhaled BDP (800 $\mu\text{g/day}$) to all patients, whereas the other gave BDP only to those with a positive prednisolone test. Results of 104 patients were evaluated after treatment for 1 year. Of these, 31% were unresponsive to salbutamol and prednisolone at baseline, 46% were responsive to salbutamol but not to prednisolone, and 23% responded to both. The results showed that after treatment for 1 year the prednisolone responders had higher FEV_1 values and less symptoms ($P < 0.02$ for both) than the steroid non-responders, indicating a value of the prednisolone test on a group level. However, there were more ex-smokers and more patients with blood eosinophilia among the responders.

Reversibility tests from 1048 patients with airway obstruction and with a FEV_1 of less than 60% of predicted normal and a $FEV_1 : FVC$ ratio less than 60% were analysed in another study before and after a 7-day course of 30 mg prednisone [66]. Spirometry was performed before and 30 min after inhalation of 300 μg salbutamol and 60 μg ipratropium bromide. The frequency distribution of the bronchodilator and steroid responses (in addition to the combinations of responses) were all unimodal, making any distinction between nosological subgroups arbitrary. Similarly, in another Danish study [54], the predictive value of a 2-week course of 37.5 mg prednisolone on the effects of 6 months' treatment with budesonide or placebo was evaluated in 37 patients with stable COPD. No significant differences in spirometry values, symptoms or number of exacerbations were found between the budesonide and placebo groups. The authors concluded that a 2-week course of prednisolone was of no value in choosing subsequent long-term therapy.

Before the double-blind phase of the 3-year ISOLDE study (FP vs placebo), patients received a 2-week course of 0.6 mg/kg/day oral prednisolone during which the response in terms of FEV_1 improvement was registered. A reversibility test with salbutamol was also conducted. Neither the short-term response to bronchodilator treatment nor the response to prednisolone could predict the long-term response [67,68].

Conclusion

A 2-week course with oral prednisolone is unnecessary to perform as it has no predictive value for the subsequent response to an inhaled corticosteroid.

Withdrawal of inhaled corticosteroids

In patients with COPD, it is often easier to detect a change in response when treatment is stopped.

Run-in phase data from a total of 272 patients recruited for the ISOLDE study [56] were analysed in an observational study [69]. Of the patients entering the 8-week

run-in phase, 160 had been treated with an inhaled corticosteroid prior to study entry, whereas 112 had not. All patients were clinically stable for at least 6 weeks; there were no differences in baseline lung function, bronchodilator reversibility or smoking history between patients previously receiving an inhaled corticosteroid, compared with those who had not. Inhaled corticosteroid treatment was discontinued during the first week of the 8-week run-in period before randomization. During the remaining 7 weeks, 38% of patients previously treated with inhaled steroids experienced an acute exacerbation of COPD compared with 6% of those patients not receiving prior inhaled corticosteroid treatment. The daily dose of inhaled steroids in the year preceding the study was slightly higher in patients who experienced an exacerbation, compared with those who did not have an acute worsening; however, this difference was not statistically significant. There was no correlation between the total dose of inhaled or oral corticosteroids used in the year before the study and the time to first exacerbation.

O'Brian *et al.* [70] investigated what happened when inhaled corticosteroid treatment was stopped in a group of 24 men with moderate to severe COPD (mean age 67 years; mean FEV_1 1.6 L = 47% of predicted normal). This was a double-blind randomized placebo-controlled cross-over study. Patients entering the study received 100 µg BDP q.i.d. or placebo for 3 weeks and had a 3-week wash-out period before receiving the alternate treatment. They underwent lung function tests (spirometry, diffusion capacity), had health-related quality of life (HRQL) testing, sputum examination for inflammatory markers, and performed a 6-min walking test before randomization and 3 weeks after each treatment period. Fifteen patients completed the study. Even if the BDP dose was relatively low, the results showed that withdrawal of treatment resulted in a statistically significant deterioration in lung function and increase in exercise-induced dyspnoea.

The COPE study was a 6-month single-centre parallel-group double-blind study evaluating the effect of withdrawal of inhaled FP after 4 months' treatment in a group of patients with COPD [71]. Overall, 509 of the 615 patients recruited to the study were eligible for inclusion. A total of 263 patients started an open-label 4-month treatment phase with 500 µg FP b.i.d. and 40 µg ipratropium q.i.d. to optimize their clinical status. Their mean age was 64 years, 84% were men, and baseline postbronchodilator FEV_1 was 54% of predicted normal. More than 80% of the patients had previously used an inhaled corticosteroid. After the open-label phase, patients were randomized to continuous treatment with FP ($n = 123$) or placebo ($n = 121$) for 6 months and contacted the study centre as soon as there was a change in their well-being. Exacerbations (defined as a worsening of respiratory symptoms requiring treatment

with oral corticosteroids or antibiotics) occurred in 47% of the patients receiving FP compared with 57% in the placebo group. The hazard ratio for the first exacerbation was 1.5 (95% CI, 1.1–2.1) with placebo compared with FP. A total of 26 patients (22%) in the placebo group had a recurrent rapid exacerbation and were changed to open-label FP treatment, compared with six patients (5%) receiving FP. The relative risk for this was 4.4 (95% CI, 1.9–10.3). Statistically significant differences in health status (St. George's Respiratory Questionnaire [SGRQ]) total scores, activity and symptom domain scores were observed between the groups. There were no differences in postbronchodilator FEV_1 , exertion dyspnoea (Borg scale), or in distance walked during 6 min with active treatment or placebo.

Conclusions

Withdrawal of inhaled corticosteroids in patients with moderate to severe COPD has resulted in an increased incidence of exacerbations compared with continuous treatment, and in deterioration of health-related quality of life. The results indicate that inhaled corticosteroids should be withdrawn with caution in patients with COPD. Indeed, patients should be monitored carefully as the effect of inhaled corticosteroids may be more apparent after treatment has been withdrawn.

Effect of inhaled corticosteroids on acute exacerbations

COPD exacerbations are serious events which may be life-threatening [72]. Frequent exacerbations impair health-related quality of life [73] and lung function decline is faster in patients with frequent exacerbations compared with patients having no or only a few exacerbations [74]. To date, there is no universal definition of a COPD exacerbation, which makes comparison of the preventive effects of treatment on exacerbations difficult [75]. However, action-driven definitions of exacerbations (episodes requiring medical intervention with oral corticosteroids and/or antibiotics and/or hospitalization) are considered more objective than symptom-based definitions to compare therapeutic interventions in a clinical trial setting [76].

In the ISOLDE study, exacerbations were defined as events requiring treatment with oral corticosteroids or antibiotics. The study showed a 25% reduction in the yearly rate of exacerbations in patients treated with FP compared with placebo ($P = 0.026$) [56], but did not indicate which patients showed greatest benefit. Jones *et al.* [77] performed a *post hoc* analysis of these data and divided the study population into those with mild ($FEV_1 \geq 50\%$ predicted normal) and moderate to severe (FEV_1 of less than 50% predicted normal) disease. There were 391 patients with mild COPD (195 FP-treated) and 359 with moderate

Figure 58.3 Percentage of patients having ≥ 1 corticosteroid-treated exacerbation per year in placebo and fluticasone propionate treated groups split by disease severity. #, $P = 0.02$; ¶, $P = 0.01$. (From Jones *et al.* [77] with permission.)

to severe disease (180 FP-treated). Over the 3-year study period, 29% of patients with mild disease and 16% of patients with moderate to severe disease had no exacerbations; the median exacerbation rate was significantly lower in the mild disease group ($P < 0.0001$). There were significantly fewer exacerbations in the FP group (0.99 exacerbations per year) compared with placebo (1.32 exacerbations per year; $P = 0.026$). This significant effect was largely confined to the moderate to severe group: median number of exacerbations per year was 1.47 and 1.75 in the FP and placebo groups, respectively ($P < 0.022$). In patients with moderate to severe disease, 52% had a corticosteroid-treated exacerbation compared with 30% of those in the mild group ($P < 0.0001$). The rate of these exacerbations was significantly lower in FP-treated patients compared with placebo ($P < 0.001$). FP reduced the number of patients experiencing one or more exacerbations per year by half in both patient groups (Fig. 58.3). Reversibility to bronchodilator or prednisolone did not identify patients in whom FP had an effect on exacerbations.

In a 6-month study comparing FP with placebo, active treatment reduced the incidence of severe exacerbations (defined as a need for hospitalization) [45]. Thus, an effect on the severity of exacerbations was demonstrated. In this shorter term study, however, no effect on the time to the first exacerbation was found. A meta-analysis based on nine studies with 3976 patients [44–48,54–57], including four with a systemic steroid run-in phase, reported a 30% reduction in COPD exacerbations (risk ratio 0.70; 95% CI, 0.58–0.84) with inhaled corticosteroid treatment [8].

Three placebo-controlled 12-month studies have compared the efficacy of combinations of an inhaled corticosteroid and an inhaled long-acting β_2 -agonist (fluticasone/

salmeterol and budesonide/formoterol) with the individual monocomponents in patients with moderate to severe COPD [9–11]. Exacerbations were an important endpoint in these studies, and further information has been obtained that relates to the efficacy of inhaled corticosteroids alone on the incidence and rate of exacerbations. These studies are discussed later in this chapter.

Conclusions

The effect of inhaled corticosteroids on COPD exacerbations defined as action-driven events (a course of oral corticosteroids and/or antibiotics and/or hospitalization) appears to be confined to patients with moderate to severe disease. Reversibility to treatment with a β_2 -agonist or oral prednisolone does not predict the efficacy. Treatment with inhaled corticosteroids has been shown to reduce both the severity of exacerbations and the number and rate of severe exacerbations.

Inhaled corticosteroids and survival/mortality

Frequent exacerbations are associated with increased mortality in COPD [78,79]. Deterioration in health-related quality of life appears to be the best predictor of rehospitalization and mortality in COPD [80]. Several studies have also shown that exacerbations necessitating hospitalization increase the mortality in COPD [81–83]. To date, no prospective studies to evaluate the effect of treatment with inhaled corticosteroids on mortality have been reported. In the meta-analysis by Alsaeedi *et al.* [8], which included five randomized placebo-controlled trials measuring this endpoint, a 16% reduction in mortality compared with non-inhaled corticosteroid treatment was observed. However, this reduction was not statistically significant.

Sin and Tu [84] conducted a population-based cohort study using databases in Ontario, Canada ($n = 22\,620$) to determine the association between inhaled corticosteroid therapy and the combined risk of repeat hospitalization and all-cause mortality in elderly patients (mean age 75 years) with COPD. Patients who received inhaled corticosteroid therapy within 90 days after discharge from hospital had 24% fewer repeat hospitalizations for COPD (95% CI, 20–29%) and were 29% less likely to die during 1 year of follow-up after adjustment for a number of confounding factors (95% CI, 22–35%). Very similar results were reported by Soriano *et al.* [85] who used an UK General Practice Research Database ($n = 4665$) and demonstrated that regular use of inhaled corticosteroids was associated with increased survival of COPD patients managed in primary care compared with patients receiving bronchodilators other than long-acting inhaled β_2 -agonists and no inhaled corticosteroids. They also compared rehospitalization in a retrospective cohort of 3636 patients with COPD and found the use of inhaled corticosteroid (with or

Figure 58.4 Multivariate analysis of time to rehospitalization or death in patients with COPD using inhaled corticosteroids (ICS) and long-acting β -agonists (LABAs). OCS, oral corticosteroids. (From Soriano *et al.* [86] with permission.)

without a long-acting β_2 -agonist) was associated with a reduction of rehospitalization or death (Fig. 58.4) [86]. The use of inhaled corticosteroids in this database cohort was shown to be associated with markers of increased disease severity, but not with a number of other potential confounding factors that could explain the benefits observed in mortality or risk of hospitalization [87].

In another study, Sin and Man [88] used hospital discharge data from Alberta, Canada ($n = 6740$) for COPD patients ≥ 65 years and reported a 25% relative reduction in risk for all-cause mortality in patients on inhaled corticosteroids. Furthermore, patients receiving medium or high-dose therapy showed lower risks than patients receiving low doses of inhaled corticosteroids.

Reductions in mortality of 40–42% in COPD patients using inhaled corticosteroids have been reported in other studies. Mapel *et al.* conducted a cohort study to examine the relationship between survival and use of inhaled corticosteroids and/or long-acting inhaled β_2 -agonists in COPD ($n = 1288$) and compared the results with those of a control group ($n = 397$) [89]. They found that COPD patients who used an inhaled corticosteroid alone or in combination with a long-acting β_2 -agonist had substantially improved survival even after adjustment for asthma and other confounding factors. However, a time-dependent analysis based on seven Veterans Administration clinics in the USA (inhaled corticosteroids $n = 2654$; no inhaled corticosteroids $n = 5398$) demonstrated no reduction in mortality in the corticosteroid-treated population compared with the control group [90].

It has been argued that the effects of inhaled corticosteroids on survival and mortality in these non-randomized cohort studies may be confounded by a number of factors [91], most notably ‘the immortal time bias’. This type of survival bias occurs when assessing exposure to inhaled corticosteroids after some patients have died, meaning that those who survive have a theoretically greater amount of time to receive therapy with an inhaled corticosteroid.

However, even after adjusting for this effect and reanalysis of the data, Sin *et al.* [92] reported that inhaled corticosteroid treatment was still associated with a 21% reduction in hospitalization and mortality rate. Furthermore, at least one of the cohort studies [89] appears to be free from such bias, suggesting that this effect is real. An additional analysis showed that in patients with COPD, the use of inhaled corticosteroids for 3 years in those with moderate to severe disease improved quality-adjusted life expectancy at a cost that was similar to that of other therapies commonly used in clinical practice [93].

Finally, Sin *et al.* [94] conducted a pooled analysis, based on intention to treat, of individual patient data from seven randomised studies ($n = 5085$) [9–11,54–57]. The effects of inhaled corticosteroids and placebo were compared over at least 12 months in patients with stable COPD. Inhaled corticosteroids reduced all-cause mortality by about 25%. The beneficial effect appeared to be especially noticeable in women and former smokers. Also patients with COPD and respiratory insufficiency requiring domiciliary oxygen treatment with inhaled corticosteroids have improved survival [95].

Conclusions

Some retrospective cohort studies, but not all, have indicated a reduced risk for rehospitalization and mortality in COPD patients using inhaled corticosteroids after treatment in hospital for an acute exacerbation of COPD compared with patients not using inhaled corticosteroids. The improved quality-adjusted life expectancy has been achieved without an increase in costs. Results of prospective studies are warranted.

Inhaled corticosteroids and long-acting inhaled β_2 -agonists

Six placebo-controlled studies have been published evaluating the efficacy of an inhaled corticosteroid and a long-acting inhaled β_2 -agonist (fluticasone/salmeterol and

budesonide/formoterol) in the same inhaler [9–11,96–99] in comparison with the monocomponents (i.e. inhaled corticosteroid alone and a long-acting inhaled β_2 -agonist alone) and placebo. These studies are summarized in Table 58.3. Three 12-month studies were designed specifically to evaluate the effect of combination therapies on exacerbations in patients with COPD [9–11].

In a 12-month parallel-group study with four treatment arms, 500 μg FP, 50 μg salmeterol and 500 μg FP/50 μg salmeterol b.i.d. were compared with placebo in 1465 patients with COPD (GOLD stage II–IV) [10]. Combination treatment with FP/salmeterol significantly improved FEV_1 compared with placebo (treatment difference 133 mL; $P < 0.0001$); a significant difference was also observed with FP alone (95 mL; $P < 0.0001$). The mean exacerbation rate (defined as a worsening of COPD symptoms requiring antibiotics, oral corticosteroids, or both) per patient per year was also reduced by 25% ($P < 0.0001$) with FP/salmeterol, and by 20% ($P = 0.0027$) and 19% ($P = 0.0033$) with salmeterol and FP, respectively, compared with placebo. There were no significant differences between active treatment groups with regard to reduction in exacerbation frequency or time to first exacerbation. A statistically significant improvement in health status (as measured by SGRQ total score) was observed at 12 months in the FP/salmeterol treatment group compared with placebo (treatment difference -2.2 [$P = 0.0003$]) and FP (treatment difference -1.4 [$P = 0.021$]).

Szafranski *et al.* [9] enrolled 812 patients with COPD (GOLD stages III–IV) into a 12-month placebo-controlled study. Patients were randomized to treatment with either 400 μg budesonide b.i.d., 9 μg formoterol b.i.d., 400 μg budesonide/9 μg formoterol b.i.d. (Symbicort 160/4.5 μg labelled as delivered doses), or placebo. During the 12-month study period, all active treatments increased FEV_1 compared with placebo (budesonide/formoterol, 15% [$P < 0.001$], formoterol, 14% [$P < 0.001$] and budesonide, 9% [$P < 0.001$]). Budesonide/formoterol was more effective than budesonide alone at improving lung function ($P < 0.001$). In addition, budesonide/formoterol sustained improvements in FEV_1 throughout the study period, compared with both budesonide and placebo.

Patients treated with budesonide/formoterol and budesonide alone had fewer exacerbations requiring the use of oral corticosteroids and/or antibiotics and/or hospitalization (1.4 and 1.6 per patient per year, respectively) compared with 1.8 for formoterol and 1.9 for placebo ($P < 0.05$ budesonide/formoterol vs placebo and formoterol). The lowest number of oral corticosteroid courses per patient per year was observed with budesonide/formoterol (0.74) and budesonide (0.76) treatment compared with formoterol (1.04) and placebo (1.07). Both budesonide/formoterol and budesonide treatment reduced the number of oral corticosteroid courses required to treat an exacerbation (31%

[$P = 0.027$] and 29% [$P = 0.045$], respectively). Furthermore, budesonide/formoterol, but not budesonide alone, significantly improved SGRQ total score compared with placebo ($P < 0.01$) during the study. The mean change in SGRQ total score with budesonide/formoterol compared with placebo (-3.9) approached clinical relevance (where a change of 4 points represents a clinically important difference relevant to the patient).

Calverley *et al.* [11] recruited 1022 COPD patients of a similar type to those recruited by Szafranski *et al.* [9] in another 12-month placebo-controlled study. In this study, treatment was intensified with 30 mg oral prednisolone once daily and 9 μg formoterol b.i.d. during a 2-week run-in period to optimize patients' level of disease control. This type of design was used to test a clinically relevant situation (i.e. whether short-term improvements achieved after treatment intensification could be maintained with inhaled therapy). Patients were randomized to treatment as outlined in the Szafranski *et al.* study [9]. Budesonide/formoterol maintained improvements in FEV_1 achieved with treatment intensification. In contrast, FEV_1 declined rapidly in the other active treatment groups and placebo. This difference was significant with budesonide//formoterol compared with placebo (14%; $P = 0.001$), budesonide (11%; $P < 0.001$) and formoterol (5%; $P = 0.002$), but not with budesonide versus placebo (2%). The median time to first exacerbation requiring medical intervention (oral antibiotics and/or corticosteroids or hospitalization) with budesonide/formoterol in combination and budesonide alone was 254 days and 178 days, respectively, compared with 154 days with formoterol (a long-acting bronchodilator – the current standard of care) and 96 days in the placebo group. In this study, the statistical power was in the hazard rate or time to first exacerbation analysis: -28.5% for budesonide/formoterol versus placebo ($P < 0.01$), -30% versus formoterol ($P = 0.003$) and -21% versus budesonide ($P = 0.033$). Combination therapy and budesonide alone was also associated with a lower mean exacerbation rate (1.4 and 1.6 exacerbations per patient per year, respectively) compared with placebo (1.8) and formoterol (1.9). Importantly, budesonide/formoterol also prolonged the time to first oral corticosteroid course compared with placebo (-42% versus placebo; $P < 0.001$) as did budesonide (-14% vs placebo; $P = 0.009$). The effect of budesonide/formoterol was greater than the sum of its constituent components. With regard to improvements in exacerbation status, budesonide/formoterol significantly improved SGRQ total score compared with other active treatments and placebo. All active treatment groups improved the total score versus placebo, but the greatest difference and clinically significant difference (-7.5) was observed with budesonide/formoterol. Inhaled corticosteroid and long-acting inhaled β_2 -agonist combination therapy improved symptoms and use of reliever medication in all three 12-month studies.

Table 58.3 Summary of placebo-controlled COPD studies investigating the efficacy of combinations of an inhaled corticosteroid and an inhaled long-acting β_2 -agonist compared with the inhaled steroid and the inhaled β_2 -agonist alone.

Using the UK General Practice Research Database Kiri *et al.* [99] obtained 437 pairs of patients with moderate-to-severe COPD who either used an inhaled corticosteroid together with a long-acting or a short-acting inhaled β_2 -agonist. In a multivariate analysis they found a 38% risk reduction ($P < 0.007$) among patients given the inhaled steroid with the long-acting relative to those using the short-acting bronchodilator.

Numbers needed to treat

The 'number needed to treat' (NNT) was developed to provide a simple, clinically relevant measure of treatment effects [100]. In COPD the NNT values, defined as the number of patients who need to be treated with the combination inhaler for 1 year to avoid one severe exacerbation compared with the long-acting bronchodilator alone, has been calculated. For budesonide/formoterol the NNT values in the studies by Szafranski *et al.* [9] and Calverley *et al.* [11] were 2.1 and 2.4 [101]. The corresponding value in the study by Calverley *et al.* [10] for salmeterol/fluticasone have been 14 [102]. This figure has to be interpreted with caution as no statistically significant difference in exacerbation rates was seen in the study between salmeterol and the combination product, which is necessary for a proper calculation of NNT values.

Conclusions

In patients with moderate to severe COPD (FEV_1 less than 50% of predicted normal) combination treatment with an inhaled corticosteroid and a long-acting β_2 -agonist in the same inhaler has provided clinically important and statistically significant effects. A clear reduction in exacerbations rates, time to first severe exacerbation and in symptoms, together with great improvements in health-related quality of life, have been observed.

Tolerability and safety of corticosteroids in COPD

The safety and tolerability of inhaled corticosteroids in patients with asthma have been well documented in several papers (e.g. Barnes *et al.* [38]). However, patients with COPD differ from those with asthma and results obtained in studies of healthy subjects or patients with asthma may not be applicable to those with COPD, who are often older and have a significant smoking history with other concomitant smoking-related diseases. In addition, patients are often physically inactive because of respiratory problems such as dyspnoea. It may be difficult therefore to distinguish between treatment-induced adverse effects and the symptoms and signs caused by tobacco smoking and comorbidities.

Many studies in patients with asthma have reported changes in markers of hypothalamic–pituitary–adrenal (HPA) function and bone formation; however, clinical risks

in terms of adrenal crisis or bone fractures are rare. The adverse effects and the benefit–risk ratio of inhaled corticosteroids in the treatment of patients with COPD have recently been reviewed [103,104].

This review focuses on the pharmacokinetics of inhaled corticosteroids in patients with COPD and adverse effects reported in the long-term placebo-controlled studies.

Pharmacokinetics

Few controlled studies have evaluated the pulmonary pharmacokinetics of inhaled corticosteroids in patients with COPD. Providing the patient's inhalation effort is acceptable, studies with budesonide have shown no difference in kinetics between patients with COPD and healthy subjects, but a higher systemic availability for FP than for budesonide [105]. For FP, significant differences have been observed between healthy control subjects and patients with asthma [106,107] and COPD [108], with systemic effects in healthy subjects being greater than in patients with airway obstruction. For FP a linear relation has been found between the degree of airway obstruction and the systemic activity of FP [109]. A plausible explanation for the difference in systemic activity between budesonide and FP may be the difference in water–lipid solubility between the substances. FP is significantly less water soluble, has a much higher volume of distribution with a corresponding significantly longer elimination half-life, and is therefore retained for a longer time in the tissues.

The results of FP studies demonstrating a difference between patients and healthy subjects may be caused by a more central drug deposition in patients. A centrally deposited lipophilic substance may be more easily transported away from the airways by the mucociliary clearance than a more peripherally deposited one, thus resulting in less systemic activity.

Topical adverse effects

Adverse effects associated with inhaled corticosteroid treatment include voice problems (hoarseness, dysphonia), sore throat and oropharyngeal candidiasis. They are generally caused by the deposition of corticosteroids in the oropharynx and on the vocal cords, but are more frequent in people misusing their voice (e.g. teachers, switch board operators, sport coaches). They also depend on dosing frequency and the total daily dose, but not on duration of treatment [110]. The choice of delivery device also influences the incidence of local side-effects [110]. Inhalation through devices with an inherent resistance (e.g. Turbuhaler) opens up the vocal cords and thereby minimize deposition on the vocal cords. A significant reduction in the frequency of local side-effects was observed in a 4-year study in 154 patients with obstructive airway diseases (29 with COPD) treated with an inhaled corticosteroid (BDP or budesonide pMDI attached

to a large volume spacer) for 2 years, when they changed treatment to budesonide delivered via Turbuhaler for the next 2 years [111].

In the EUROSCOP study, 5% of budesonide and 2% of placebo-treated patients had oropharyngeal candidiasis ($P < 0.001$) and 7% and 5% of patients, respectively, reported hoarseness or sore throat [55]. In the ISOLDE trial, 21% of the patients in the FP group had dysphonia or sore throat compared with 12% in the placebo group [56]. *Candida* infections were found in 11% and 7%, respectively.

In the corticosteroid/long-acting β_2 -agonist combination studies, more topical adverse events were reported in the groups receiving treatment with the inhaled corticosteroid than in the placebo and long-acting β_2 -agonist groups. In the 6-month study by Mahler *et al.* [96] candidiasis was found in less than 1% in the placebo and salmeterol groups but in 10% in the FP and 7% in the combined FP/salmeterol groups. In the 12-month study with the same treatments [10], the frequency of oropharyngeal candidiasis was 1% during treatment with placebo and salmeterol, and 6% during the treatments including FP.

Systemic adverse effects

Hypothalamic–pituitary–adrenal axis

Treatment with oral corticosteroids in daily doses of more than 7.5 mg usually causes signs of suppression of the HPA axis and patients may develop moon face, acne, arterial hypertension, osteoporosis with bone fractures, disturbed carbohydrate metabolism, mental and behavioural disturbances, and other signs and symptoms. Few systemic side-effects have been reported with inhaled corticosteroid treatment, but it should be remembered that individual susceptibility – in addition to dose–response for systemic effects – does exist.

In the 6-month study in which patients received 1000 $\mu\text{g}/\text{day}$ FP or placebo, the mean serum cortisol level was significantly lower with FP at 6 months (345 nmol/L) compared with placebo (385 nmol/L; $P = 0.02$), but no obvious clinical signs of adverse effects were seen [45]. A total of 19 patients (14% of 134 patients) in the FP group and 13 patients (11% of 116 patients) in the placebo group had cortisol values below the reference range.

In the ISOLDE study, morning serum cortisol was measured at baseline and every 6 months during treatment in 372 FP-treated and 370 placebo-treated patients [56]. A small – but statistically significant – decrease in mean values was observed in the FP group ($P = 0.03$). Overall, 5% of the FP-treated patients had values below the normal range.

Osteoporosis and fractures

Long-term oral corticosteroid treatment is associated with osteoporosis and an increased risk of fractures. In a study in 117 patients with chronic lung diseases, the cumulative

prednisolone dose was strongly related to fracture risk, and this effect was found to be independent of its more modest impact on bone mineral density [112].

Several studies in patients with asthma have failed to identify an increased frequency of bone fractures or lower bone density in patients receiving long-term inhaled corticosteroid therapy [38]. However, a population-based case–control study in the UK suggested that there is a dose–response relationship between inhaled corticosteroid use and hip fractures, even after adjusting for the annual number of courses of oral corticosteroids [113]. In older subjects, the recent use of inhaled corticosteroids was associated with a dose-related increase in hip fractures.

In the placebo-controlled EUROSCOP study, patients with mild COPD received 800 $\mu\text{g}/\text{day}$ budesonide [55]. Bone mineral density (BMD) was measured at the L2–L4 vertebrae and femoral neck, trochanter and Ward triangle by dual-energy X-ray absorptiometry at baseline and after 6, 12, 24 and 36 months in 82 budesonide and 79 placebo-treated patients. No detrimental effect of budesonide treatment was observed [114]. Radiographs of the thoracic and lumbar spine (before and after 3 years' study treatment) were also obtained in 322 budesonide and 331 placebo-treated patients. At randomization, 43 patients (13%) in the budesonide group and 38 (12%) in the placebo group had at least one vertebral fracture. At the end of the study, five new fractures occurred in the budesonide group and three in the placebo group. This difference was not statistically significant.

In the ISOLDE study, 751 patients were followed for 3 years during treatment with 1000 g/day FP [56]. The incidence of bone fractures was low in both treatment groups (FP 2%; placebo 4.5%).

In the Lung Health Study, 559 patients were treated with 1200 $\mu\text{g}/\text{day}$ triamcinolone for 3 years [57]. Bone density values for the lumbar spine were available at baseline and after treatment for 1 and 3 years in 328 patients, and for the femoral neck in 359 patients. For femoral neck, the percentage of change (mean \pm SE) from baseline to 3 years was $-2.00 \pm 0.35\%$ in the inhaled corticosteroid group and $-0.22 \pm 0.32\%$ with placebo ($P < 0.001$). For lumbar spine, the percentage of change was $-0.35 \pm 0.33\%$ in the steroid-treated group and $+0.98 \pm 0.36\%$ in the placebo group ($P = 0.007$). Fractures were not reported.

Postcapsular cataracts

The incidence of cataracts in the EUROSCOP study was less than 5% and was equally distributed between budesonide and placebo-treated patients [55]. In the ISOLDE study, the incidence of cataracts was 1.3% in the FP group and 1.9% in the placebo group [56]. The Lung Health Study group reported a much higher incidence of cataracts, but this was equally distributed between triamcinolone and placebo treatments (22% vs 20%) [57].

Skin bruises

Oral and high-dose inhaled corticosteroid treatments are associated with an increased incidence of purpura and dermal thinning compared with low-dose inhaled corticosteroid and placebo treatments [115]. The tendency to bruise easily is a well-known adverse effect of inhaled corticosteroid treatment. A study of patients with asthma showed that the prevalence of bruising increased with age, dose of inhaled corticosteroids and duration of treatment [116].

In the EUROSCOP study, bruising on a defined area of the forearm was recorded on a regular basis [55]. At clinic visits, bruising was found in 10% of patients taking budesonide compared with 4% in the placebo group ($P < 0.001$). In the ISOLDE study, which included spontaneous reporting of adverse events, 7% of FP-treated and 4% of placebo-treated patients reported bruising [56]. In the Lung Health Study, in which younger patients were enrolled, the annual incidence of bruising was 0.8% in the triamcinolone group compared with 0.4% in the placebo group (based on patient questioning every 3 months) [57].

It should be noted that, as there are methodological differences between the various studies, the incidence of adverse events reported may differ. In general terms, however, an inhaled corticosteroid with a high systemic bioavailability results in a higher systemic activity than a compound with a low systemic availability when administered at equally effective clinical doses. Data of comparative studies in patients with COPD are lacking.

Other adverse effects

The EUROSCOP study reported similar incidences of diabetes, myopathy, and cardiovascular and gastrointestinal disorders in both the budesonide and placebo groups [55]. The ISOLDE study [56] and the Lung Health Study [57] did not mention these adverse effects. None of the four recent long-term studies reported an increased risk of respiratory or systemic infections in the groups of patients using inhaled corticosteroids [54–57].

Conclusions

Corticosteroids have an important place in the treatment of patients with COPD. Systemic corticosteroids are beneficial for the treatment of acute exacerbations, but should not be used for maintenance treatment because of the associated risk of side-effects.

The role of inhaled corticosteroids in COPD management has been debated for some time. Short- and medium-term studies of inhaled corticosteroids have generally documented small effects of treatment, mostly in patients or subgroups with features of asthma, although an overall improvement in FEV_1 and an effect on decline in FEV_1 have

been reported. The four long-term placebo-controlled studies that have more rigorously excluded patients with asthma and have evaluated the effects of inhaled corticosteroids on FEV_1 decline were all negative; there was no significant difference between active treatment and placebo. Thus, no disease-modifying effect could be demonstrated. However, compared with placebo, an initial improvement over the first 3–6 months was demonstrated with inhaled corticosteroid treatment and one study showed an effect on bronchial hyperresponsiveness. Nevertheless, a meta-analysis of the four studies demonstrated a statistically significant effect on the FEV_1 decline in the order of 7–10 mL/year, which may represent a clinically meaningful improvement for the patient.

Inhaled corticosteroid treatment modifies the severity of acute exacerbations, reduces the risk of severe exacerbations, reduces symptoms associated with COPD, and improves health status and exercise tolerance. Patients with more severe disease (FEV_1 of less than 50% of predicted normal, rapid decline in FEV_1), a short smoking history and asthma-like features respond better than the rest of the patient population. Inhaled corticosteroid treatment may also reduce the number of rehospitalizations and deaths from a worsening of COPD. Importantly, discontinuing treatment with inhaled corticosteroids in patients with COPD has been shown to increase the risk of experiencing an exacerbation. Reversibility testing with bronchodilators or oral corticosteroids is not indicative of a treatment effect, as they do not predict the response to subsequent long-term treatment with inhaled corticosteroids. To date, no dose-response studies have been reported; however, the daily doses used are those believed to be safe in the long term.

Dysphonia and oropharyngeal candidiasis are the most frequently reported local adverse effects when using inhaled corticosteroids. Systemic side-effects are dose-dependent but are rare with clinically approved doses. Indeed, less lipophilic inhaled corticosteroids (e.g. budesonide with a high first-pass metabolism in the liver) are associated with an improved adverse event profile, compared with older agents such as BDP and triamcinolone, and more lipophilic compounds such as FP. It may be difficult to distinguish between COPD- and smoking-related adverse events, and those caused by treatment with inhaled corticosteroids. Nevertheless, the benefit–risk ratio for inhaled corticosteroids is clearly positive in the subgroups of patients with COPD mentioned previously. Whether inhaled corticosteroid treatment in patients with COPD is also cost-effective depends on the frequency of exacerbations – which can now be prevented. Further prospective controlled studies evaluating the effect of inhaled corticosteroids on long-term mortality are warranted.

At this stage, it seems appropriate to recommend treatment with inhaled corticosteroids for all patients with

frequent exacerbations and for those with poor airway function and HRQL. To date, patients with mild COPD as a group have not been shown to benefit from treatment with inhaled corticosteroids or inhaled corticosteroid/long-acting inhaled β_2 -agonist combinations in clinical trials. However, the recent meta-analysis by Sutherland *et al.* [61] reported positive treatment benefits in patients with COPD, including those with mild disease. The recent results with combination therapy are clinically important as they demonstrate improved treatment benefits compared with inhaled corticosteroids alone in patients at risk of COPD exacerbations.

CHAPTER 59

Phosphodiesterase 4 inhibitors in the treatment of COPD

Hermann Tenor, Daniela S. Bundschuh, Christian Schudt, Dirk Bredenbröker and Armin Hatzelmann

Characterization and understanding of the molecular mechanisms underlying the control of airway integrity have led to the identification of new targets for drug development. The mechanism of 3',5'-cyclic adenosine monophosphate (cAMP)-mediated modulation of inflammation and bronchiolar tone is illustrated in Figure 59.1 [1,2]. In this context, inhibitors selective for cAMP-hydrolysing phosphodiesterase 4 (PDE4) represent a new class of agents with anti-inflammatory activities that appear to confer significant benefits in animal models of airway disease and

therapeutic efficacy in patients with chronic obstructive pulmonary disease (COPD). Indeed, many of the immune effector cells implicated in the pathogenesis of COPD – neutrophils, macrophages and CD8⁺ T cells – express PDE4. Hence, targeting PDE4 provides an opportunity for the design of new drugs. The anti-inflammatory activity of PDE4 inhibitors may improve clinical symptoms and potentially alter or modify disease progression. Thus, PDE4 inhibitors could represent novel drugs that may overcome limitations of existing therapies.

This chapter provides a state-of-the-art review and update on PDE4 inhibitors in COPD, including a review of the rationale, known mechanisms of action, clinical profile and development status of the leading agents. The chapter concludes with an outlook on future perspectives for PDE4 inhibitors in the treatment of COPD.

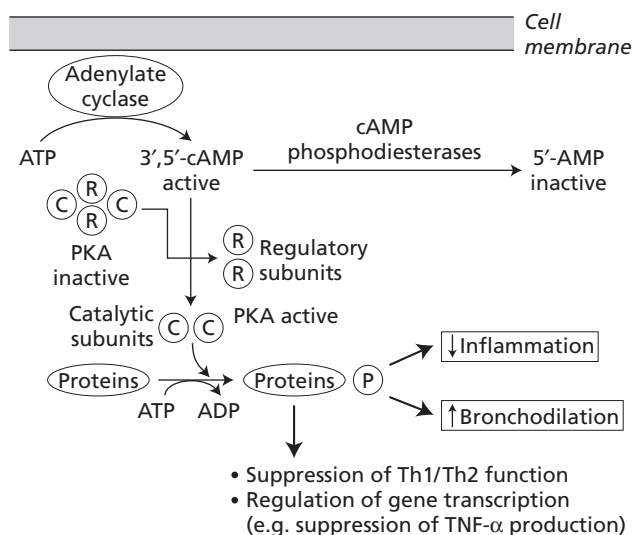

Figure 59.1 Increases in cyclic adenosine monophosphate (cAMP), either through activation of adenylate cyclase (e.g. β -agonist therapy) or inhibition of cAMP metabolism, activate protein kinase A (PKA), which in turn catalyses the phosphorylation of proteins that result in anti-inflammatory effects or bronchorelaxation [1]. ADP, adenosine diphosphate; ATP, adenosine triphosphate; P, phosphate; Th, T-helper cell; TNF- α , tumor necrosis factor α . (Adapted with permission from ALTANA Pharma AG [2].)

Phosphodiesterases

Cellular levels of cyclic nucleotides are regulated through activation of adenylate and guanylate cyclase and rapid inactivation by PDEs. With respect to the latter, at least 11 families have been characterized based on substrate specificity and sensitivity to PDE inhibitors [3]. These isozymes catalyse the hydrolysis of cyclic nucleotides cAMP and cyclic guanosine monophosphate (cGMP) to 5'-AMP and 5'-GMP, respectively, in a highly regulated manner. More than 50 isoforms or splice variants of PDEs have been identified. Of the human PDE isozymes described, PDE4, 7 and 8, are specific for cAMP; PDE1A, 5, 6 and 9 are selective for cGMP; and PDE1B, 1C, 2, 3, 10 and 11 have dual specificity for cAMP and cGMP. In turn, many of these PDE isozymes have been found in human lung tissue (e.g. PDE1, 3, 4 and 7).

The relative success of theophylline – considered a non-selective inhibitor of PDEs among other mechanisms

of action such as adenosine receptor antagonism – in the treatment of airway disease has provided a rationale for pursuing PDE inhibitors. However, the non-selective activity of theophylline has generally been associated with substantial adverse effects (e.g. intractable seizures, persistent vomiting and cardiac arrhythmias), which, in turn, have limited the use of this non-selective agent in COPD. Of particular importance is that many of the PDE isozymes, particularly the PDE4 isozyme, have been localized to inflammatory and immunocompetent cells, including neutrophils, CD8⁺ T cells and macrophages, among others [4,5]. These findings provided the impetus for development and clinical testing of PDE inhibitors with greater selectivity for particular isozymes.

Of the 11 PDE families, the PDE4 family has been of most interest to investigators for the treatment of inflammatory diseases of the airways because of the localization of these enzymes in lung structures and broad distribution in pro-inflammatory and immunocompetent cells.

Phosphodiesterase 4

There are four PDE4 subtypes (PDE4A, B, C and D); each is the product of a separate gene, the expression of which results in a myriad of gene splice variants [6]. All of the PDE4 variants have complete specificity for cAMP [3]; however, inhibitors may display some preferences for a particular subtype. Likewise, different effector cells exhibit differing sensitivities to PDE4 inhibitors [7]. Investigations are ongoing to further elucidate the role of PDE4 splice variant diversity and cellular and subcellular localization of these proteins.

Isoforms from all four PDE4 gene variants are found in the human lung [6,8–10]. PDE4 is a major regulator of cAMP metabolism in a variety of pro-inflammatory and immune cells associated with COPD [11–13], including neutrophils [5], macrophages, CD8⁺ T cells [4] and eosinophils [5]. In animal and human tissue studies, PDE4 has also been localized to epithelial cells, endothelial cells, fibroblasts and smooth muscle cells [14–18].

Tissue-specific expression of various splice variants should be considered in understanding how these gene products contribute to cellular responses to cAMP. This may, in part, account for the differential sensitivities of the various effector cells to inhibition via PDE4 inhibitors.

PDE4 inhibitors – anti-inflammatory activity

Biological activity of PDE4 inhibitors can be broadly categorized into effects on pro-inflammatory effector cells or pathways [4,14,16,19–32]. The majority of studies have been performed in *in vitro* systems, many of which involved human cells or tissues, and in animal models of inflammation.

The bronchodilatory activities of non-selective PDE4 inhibitors such as theophylline are generally well recognized. Briefly, PDE4 inhibitor-induced bronchodilation is mediated through increases in intracellular cAMP and subsequent relaxation of bronchiolar smooth muscle (see Fig. 59.1) [1,2]. On the other hand, controversy remains on the effects of PDE4 inhibitors on their own in human bronchial smooth muscle contractility. In fact, acute bronchodilatory activity in patients with COPD has not been observed with selective PDE4 inhibitors; therefore, these newer agents are not considered bronchodilators [33].

Of greater interest with respect to modulating the natural history of COPD are the potential anti-inflammatory effects of PDE4 inhibitors. The *in vitro* and preclinical anti-inflammatory activities have been of considerable interest, and potential anti-inflammatory effects of PDE4 inhibitors are illustrated in Figure 59.2 [2].

The best-characterized cellular component implicated in the pathophysiology of COPD is the neutrophil. COPD is associated with a marked increase in the number and activation level of neutrophils [19–21]. Additionally, neutrophils from patients with COPD produce more reactive oxygen species (ROS), which may support pulmonary inflammation [22]. Inhibitors of PDE4 also suppress neutrophil ROS and leukotriene B₄ (LTB₄) generation, degranulation, CD11b presentation and chemotaxis. Additionally, the PDE4 inhibitor BAY 19-8004 inhibited lipopolysaccharide (LPS)-induced neutrophil influx in a rat model of neutrophilic lung inflammation [24].

Another inflammatory cell implicated in the pathogenesis of airway disease is the CD8⁺ T lymphocyte. Indeed, smokers with symptoms of chronic bronchitis and chronic airflow limitation demonstrate an increased proportion of CD8⁺ T lymphocytes infiltrating the peripheral airway walls [19]. PDE4 isozymes regulate the levels of cAMP in these cells and, as a result, suppress proliferation. Indeed, in CD8⁺ human peripheral blood T lymphocytes, treatment with rolipram significantly ($P < 0.05$) reduced mitogen-evoked production of interleukin-2 (IL-2) and γ -interferon (IFN- γ) [4]. Translating this into the clinic, in a trial comparing cilomilast with placebo, Gamble *et al.* [26] reported a significant ($P < 0.01$) reduction in CD8⁺ T cells in bronchial biopsies from cilomilast-treated COPD patients. This was the first report of PDE4-mediated reduction in CD8⁺ T cells over the clinical dosing range.

Macrophages represent a major source of TNF- α , and overproduction of TNF- α is believed to have a pathogenic role in COPD. Macrophages are increased in the sputum of smokers with chronic bronchitis [19]. The potential role of cAMP and PDE4 in mediating LPS-activated TNF- α responses was investigated in mice deficient in PDE4B and PDE4D [25]. In that study, LPS induction of TNF- α was decreased by approximately 90% in mice deficient in

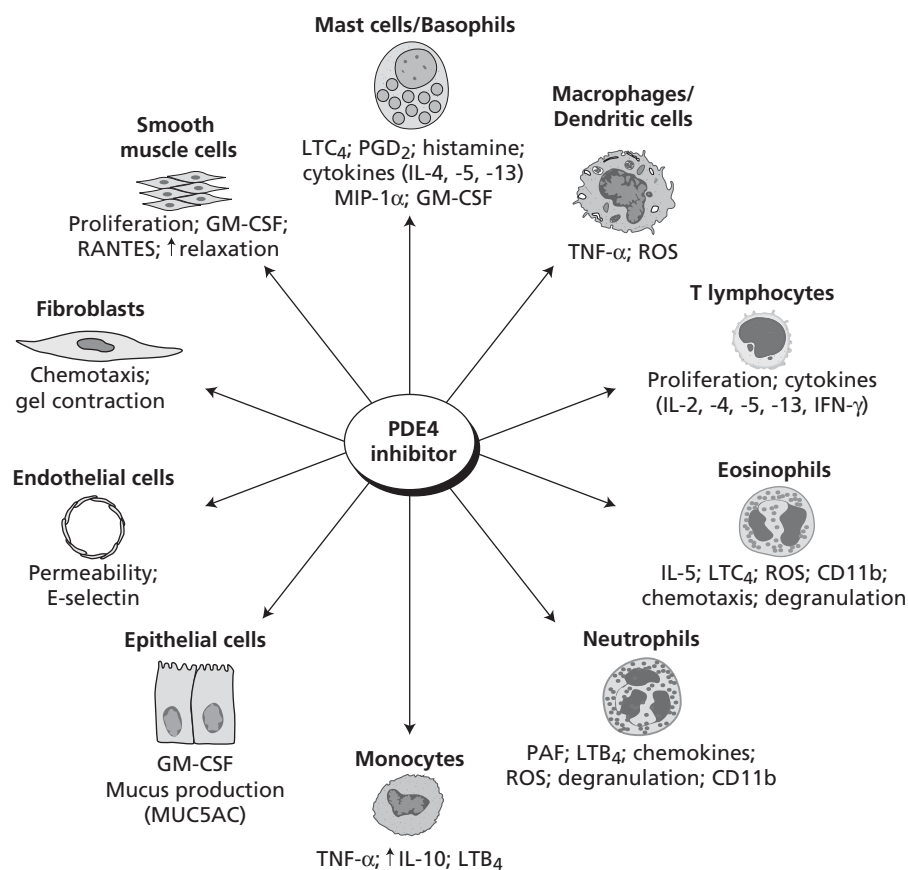

Figure 59.2 Phosphodiesterase 4 (PDE4) inhibitors broadly target cellular components of respiratory diseases, e.g. COPD.

In animal models and *in vitro* experiments, PDE inhibitors may reduce proliferation and infiltration of inflammatory cells and decrease the release of inflammatory and cytotoxic mediators (e.g. pro-inflammatory cytokines). GM-CSF, granulocyte–macrophage colony-stimulating factor; IFN- γ , γ -interferon; IL, interleukin; LTB₄, leukotriene B₄; LTC₄, leukotriene C₄; MIP-1 α , macrophage inflammatory protein 1 α ; PAF, platelet activating factor; PGD₂, prostaglandin D₂; RANTES, regulated on activation, normal T cell expressed and secreted; ROS, reactive oxygen species; TNF- α , tumour necrosis factor α . (Adapted with permission from ALTANA Pharma AG [2].)

PDE4B, suggesting a possible role for PDE4 inhibitors in controlling this response [25].

Additionally, therapies that mitigate the fibrotic process (i.e. fibrotic scar) caused by repeated repair processes may be able to slow progressive loss of function in many lung diseases. For example, fibroblast accumulation in and subsequent contraction of the surrounding matrix of small airways is associated with airway lumen narrowing. This can potentially lead to progressive loss of lung function in patients with COPD [16]. cAMP has been shown to regulate fibroblast chemotaxis and contraction. Kohyama *et al.* [16] showed that the PDE4 inhibitors rolipram and cilomilast suppressed fibroblast chemotaxis and fibroblast-mediated collagen gel contraction, at least suggesting that these agents have the potential to suppress fibroblast activity and block the development of progressive fibrosis.

Because epithelial cells have a critical role in airway inflammation, agents that inhibit pro-inflammatory medi-

ator release may help control COPD. PDE4 is a predominant PDE isozyme expressed in airway epithelial cells [14,29]. One report [30] demonstrated that the selective PDE4 inhibitor rolipram concentration-dependently inhibited IL-1 β -induced release of granulocyte–macrophage colony-stimulating factor (GM-CSF) from BEAS2B human bronchial epithelial cells with IC₅₀ of about 1 μ M and a maximum inhibition of 80% at 10 μ M. Human bronchial epithelial cells orchestrate mucociliary clearance, an important airway defense mechanism. Mucus overproduction may contribute to peripheral airway obstruction in COPD. PDE4 inhibitors were shown to reduce MUC5AC from human lung epithelial cells [34]. Cl-secretion over the CFTR channel that is activated by cAMP contributes to maintain the critical height of periciliary liquid required for ciliary mucus transportation supporting pathogen clearance. Cigarette smoke decreased CFTR expression and function *in vitro* and an acquired CFTR deficiency was

reported in the nasal respiratory epithelium of cigarette smokers [35]. Selective inhibition of PDE4 was shown to support CFTR activity in Calu-3 airway epithelial cells [36]. In a rat model of neutrophilic lung inflammation, the selective PDE4 inhibitor BAY 19-8004 reduced mucus hypersecretion, as indicated by a decrease in MUC5 mRNA expression *in vivo* [24].

Taken together, the results of these studies suggest that PDE4 inhibition has potentially far-reaching effects on inflammatory cells and pathways involved in the pathogenesis of COPD. Potential anti-inflammatory effects of PDE4 inhibition are likely to account, at least in part, for the clinical efficacy and therapeutic benefits increasingly reported in clinical trials of PDE4 inhibitor therapy in patients with COPD and other inflammatory diseases of the airways.

Non-selective PDE inhibitors

Theophylline

The methylxanthine theophylline (3,7-dihydro-1,3-dimethyl-1H-purine-2,6-dione), has been used as a bronchodilator in patients with COPD for decades (Fig. 59.3a) [37–44]. Theophylline acts non-selectively through inhibition of all major PDE isozymes and adenosine receptor antagonism, and has broad activity in animal models and in patients with COPD [45]. Theophylline exhibits a narrow therapeutic index, with a concentration of more than 50 μM

Figure 59.3 Chemical structures of: (a) the non-selective inhibitor theophylline; (b) the first-generation phosphodiesterase 4 (PDE4) inhibitor rolipram, and the selective PDE4 inhibitors; (c) cilomilast; and (d) roflumilast (b–d). (Adapted from PharmaPress Ltd and Martin [37] with permission.)

required to inhibit PDEs in airway smooth muscles (bronchodilatation) [45,46], and therefore has modest activity as a primary bronchodilator. In addition, theophylline inhibits the activation of some key inflammatory cells *in vitro*; however, concentrations required are greater than those that could likely be achieved therapeutically in patients [47]. Thus, the contribution of these latter effects to the clinical efficacy of theophylline is still under debate.

Theophylline at concentrations as low as 1 μM , i.e. well within the therapeutic range have recently been reported to restore the reduced HDAC activity and responsiveness to glucocorticoids that is observed in macrophages from smokers with COPD [48]. Theophylline exhibits variable interpatient pharmacokinetics and, consequently, drug levels are difficult to predict and drug blood level monitoring is required. Oral formulations exhibit a slow onset of action and sustained-release formulations are preferred because they provide more predictable pharmacokinetics [49]. Theophylline also exhibits a variety of drug interactions, limiting its usefulness in a patient population with a variety of comorbidities.

Although variable effects on exercise tolerance and clinical symptoms (e.g. dyspnoea) have been reported [40,43], theophylline is only recommended as third-line therapy in the treatment of COPD. However, a meta-analysis did not recommend theophylline in the treatment of COPD exacerbations [50]. Further, because of its non-selective inhibition of PDEs, adenosine receptor antagonism, stimulation of calcium mobilization, and inhibition of phosphoinositide 3-kinase, theophylline is associated with a high incidence of side-effects within its therapeutic range. For example, serious side-effects such as cardiac arrhythmias and seizures have been associated with non-selective adenosine receptor antagonism [38,51]. Because of the limited value of theophylline formulations in patients with COPD, researchers have focused on PDE4 inhibitors with improved therapeutic ratios and safety profiles.

Selective PDE4 inhibitors

Rolipram

Rolipram (4-[3-cyclopentyloxy-4-methoxyphenyl]-2-pyrrolidinone) is an archetypal PDE4 inhibitor that exhibits a multitude of biological effects, including anti-inflammatory activities (see Fig. 59.3b) [37,52,53]. Because of its ability to cross the blood–brain barrier, this agent was initially investigated in the treatment of depression [53–55]. Rolipram is selective for PDE4 and does not appreciably inhibit PDE 1, 2, 3 or 5 [7]. The PDE4 enzyme exists in at least two conformations, with rolipram selectivity for these two conformations differing by more than 100-fold

[56]. To distinguish these two types of rolipram selectivity, investigators have identified these two conformations as either the high-affinity rolipram binding site (HARBS) or the low-affinity rolipram binding site (LARBS) [57]. The high-affinity interaction with rolipram and PDE4 is thought to be related to the presence of metal cofactors (e.g. Mg^{2+}) located in the active site of PDE4 [58,59]. Preferential binding to the HARBS has been suspected to be responsible for central nervous system (e.g. nausea and emesis) and cardiovascular effects.

Because of its ability to inhibit pulmonary eosinophilia, airway inflammation, oedema and airway hyperreactivity *in vitro* and in animal models [18,60–65], rolipram was investigated as a potential treatment for asthma. However, it exhibited a low therapeutic ratio and unfavourable side-effect profile, including nausea and emesis thought to be linked to its high affinity binding to the HARBS conformation, thereby restricting its therapeutic utility [66,67]. Therefore, safety issues, including dose-limiting gastrointestinal adverse events, stopped clinical development of rolipram. Despite its failure as a clinically useful agent in the treatment of inflammatory airway diseases, rolipram is currently valued as a standard or control agent for *in vitro* and preclinical studies with newer, more selective PDE4 inhibitors. The remainder of the chapter focuses on the only two PDE4 inhibitors in late-stage clinical development in the treatment of COPD: cilomilast and roflumilast.

Cilomilast

Cilomilast (SB 207499; *cis*-4-cyano-4-[3-(cyclopentyloxy)-4-methoxy-phenyl]cyclohexanecarboxylic acid) is a PDE4 inhibitor that was originally under clinical investigation in the treatment of asthma, but development for this indication was discontinued because of poor efficacy (see Fig. 59.3c) [37]. Cilomilast is selective for PDE4 and does not appreciably inhibit PDE1, 2, 3 or 5 at concentrations $\leq 10 \mu M$ [68]. Of the four isoforms in the PDE4 family, cilomilast is approximately 10-fold more selective for PDE4D than the other three isoforms (PDE4A, B and C) [69]. For example, the IC_{50} of cilomilast is 13 nM for PDE4D, compared with the next highest selectivity of 120 nM for PDE4B [69]. In addition, cilomilast has approximately equal affinity for the two conformations of PDE4, LARBS and HARBS, whereas rolipram has a 60-fold greater affinity (i.e. lower IC_{50}) for the HARBS conformation (Table 59.1) [68]. This results in a higher cilomilast selectivity for the preferred PDE4 conformation, LARBS, and has translated into an improved therapeutic ratio compared with rolipram.

Preclinical and human *ex vivo* data

Several studies in animal models and human samples have

Table 59.1 Phosphodiesterase 4 inhibitor affinity for phosphodiesterase 4 conformations. (Data from Christensen *et al.* [68].)

Agent	IC_{50} , nM		
	LARBS	HARBS	LARBS/HARBS ratio
Rolipram	300	5	60
Cilomilast	95	120	0.8

HARBS, high-affinity rolipram binding site; IC_{50} , 50% inhibitory concentration; LARBS, low-affinity rolipram binding site.

investigated the anti-inflammatory potential of cilomilast in the treatment of COPD. Dose-dependent inhibition of LPS-induced pulmonary inflammation has been reported in a rat model of pulmonary neutrophilia, and attenuation of pulmonary neutrophilia and oedema has been observed in a guinea pig model of pulmonary neutrophilia [70,71]. In a human monocyte adoptive transfer model, 50 mg/kg oral cilomilast inhibited LPS-stimulated TNF- α production by 79% compared with vehicle [72]. This was similar to the level of inhibition by rolipram and has been confirmed in other studies [73].

Studies have also indicated that cilomilast was comparably potent with rolipram to inhibit fMLP-induced neutrophil degranulation, however maximum inhibition was modest with approximately 30% [73,74]. Further, bronchial epithelial and sputum cells were obtained from patients with moderate COPD or from normal controls and were cultured for 24 h in the presence or absence of 1 μM cilomilast (final concentration determined by a series of dose–response curves) [75]. Cilomilast reduced TNF- α release in both bronchial epithelial and sputum cells ($P = 0.005$), suppressed GM-CSF release in sputum cells ($P = 0.003$), but did not significantly inhibit IL-8 secretion.

Fibroblast accumulation is thought to have a role in the fibrosis of small airways, and has been associated with airway lumen narrowing. The activity of cilomilast was tested in two *in vitro* models of tissue remodelling: a model of recruitment of fibroblasts to sites of ongoing fibrosis and a model of the wound repair process that in the airway directly leads to airway narrowing [16]. Cilomilast 10 μM inhibited human fetal lung fibroblast chemotaxis toward the chemoattractant fibronectin to $40.5 \pm 7.3\%$ ($P < 0.05$) of control. The PDE4 inhibitor also significantly inhibited fibroblast-mediated type I collagen gel contraction reflected by an approximately 1.7-fold increase in collagen gel size with 10 μM cilomilast compared to control.

In another study, which used the three-dimensional type I collagen gel culture system with human fetal lung

fibroblasts incubated with TNF- α (to induce matrix metalloproteinases [MMPs]) and neutrophil elastase (to activate MMPs), cilomilast inhibited the degradation of the collagen matrix secondary to suppressing MMP-1 and MMP-9 release and MMP-1 activation [76]. In view of recent evidence that neutrophil elastase (NE) triggers oxidant stress (77) and activates EGFR and downstream signalling [78] in lung fibroblasts that by inference are linked through MMP activation as this cascade is well-described in airway epithelial cells one may postulate that the PDE4 inhibitor restricts MMP activation by reducing NE-induced oxygen radical formation.

In addition to animal and *in vitro* models, patients have been tested for the ability of cilomilast to mitigate inflammatory pathways in the lung. In a 12-week study designed to measure the anti-inflammatory effects of cilomilast, patients ($n = 59$) with moderate COPD were randomized to receive 15 mg cilomilast twice daily (b.i.d.) or placebo [26]. Induced sputum differential cell counts were obtained at baseline; weeks 1, 2, 4, 8, 10 and 12; and 7–10 days after study completion; and bronchial biopsies were obtained at baseline and week 10. Cilomilast did not alter neutrophil elastase and IL-8 concentrations or result in significant changes from baseline in percentage of sputum neutrophils during treatment. However, Poisson regression analysis showed a significant ($P < 0.01$) reduction of 48% for CD8⁺ T-lymphocyte subsets and a significant ($P = 0.001$) reduction of 47% for CD68⁺ macrophages compared with placebo. Although not powered to show changes in pulmonary function, there was no cilomilast treatment-related effect on forced expiratory volume in 1 s (FEV_1). Overall, these data suggest that cilomilast has the potential to exert anti-inflammatory effects *in vivo*.

Pharmacokinetics

The pharmacokinetics of intravenous and oral administration of cilomilast has been evaluated in 16 healthy men [79]. Two separate experiments were performed in volunteers receiving 4 mg cilomilast by intravenous administration over 1 h or a single 15-mg oral dose (Table 59.2) [79]. Similar pharmacokinetic profiles were observed with the two modes of administration, with dose-dependent pharmacokinetics and a low cilomilast clearance rate. A half-life of approximately 8 h suggested that cilomilast b.i.d. dosing would be an appropriate regimen for further clinical studies. Cilomilast also had a high oral bioavailability, with a mean absolute bioavailability of 103% (95% confidence interval [CI], 98–109%) for a 15-mg tablet. The dose linearity of oral cilomilast up to 15 mg b.i.d. has also been confirmed in a randomized placebo-controlled dose-ranging study [80]. Because pharmacokinetics and oral bioavailability can be affected by time of administration and coadministration with other medications, several studies were conducted

to determine potential pharmacokinetic alterations for cilomilast and other medications.

The effect of food absorption on cilomilast bioavailability was evaluated in 28 healthy volunteers who were administered two single 15-mg oral doses of cilomilast: 1 dose after a 10-h overnight fast and 1 dose 5 min after a high-fat breakfast (see Table 59.2) [79]. Overall, data suggested that coadministration with food did not affect cilomilast bioavailability. In addition, neither coadministration of an antacid [79] nor timing (morning or evening) of drug administration (see Table 59.2) [79] appreciably affected the pharmacokinetics of cilomilast.

Pharmacodynamic studies in healthy volunteers indicated no significant drug interactions between cilomilast and digoxin, erythromycin, salbutamol, theophylline or warfarin [81–85]. In renally impaired patients, the half-life and unbound cilomilast area under the curve (AUC) increased progressively with increasing renal impairment because of decreases in unbound cilomilast clearance and plasma protein binding [86]. In addition, renal clearance of the active metabolite of cilomilast decreased with increasing renal impairment, with the unbound AUC ratio of the metabolite to cilomilast in severe renal impairment (creatinine clearance less than 30 mL/min) twice that observed in healthy volunteers. The investigators recommended that cilomilast not be administered to patients with severe renal impairment.

Efficacy in COPD

The efficacy of cilomilast has been investigated in a number of clinical studies. A 6-week placebo-controlled dose-ranging trial was conducted to determine the efficacy, safety and dose–response of cilomilast in patients with COPD [87]. Patients ($n = 424$) were randomized to receive 5, 10 or 15 mg cilomilast b.i.d. or matching placebo for 6 weeks. A total of 355 patients completed the study. Only patients treated at the highest dose level experienced consistent improvements in both prebronchodilator and postbronchodilator pulmonary function tests. Patients treated with 15 mg cilomilast b.i.d. had a significantly greater increase in mean trough prebronchodilator FEV_1 compared with placebo at week 6 ($P < 0.0001$) [87]. At week 6, there were also significant improvements in mean postbronchodilator FEV_1 ($P < 0.0096$), prebronchodilator forced vital capacity (FVC ; $P = 0.001$) and peak expiratory flow rate ($P < 0.0001$) compared with placebo. However, there were no significant differences between placebo and the three dose levels of cilomilast in quality of life measures from the St. George's Respiratory Questionnaire (SGRQ).

Four pivotal, randomized double-blind placebo-controlled parallel-group phase III studies ($n = 647$ – 825 per study) were conducted to determine the efficacy of cilomilast in patients with COPD that was poorly reversible ($\leq 15\%$ or

AUC_{0–∞}, area under the concentration–time curve from 0 to infinity; C_{max}, maximum (plasma) concentration; CI, confidence interval; CL, total (plasma) clearance; IV, intravenous; NR, not reported; SD, standard deviation; T_{max}, time to C_{max}; t_{1/2}, half-life; V_{ss}, volume of distribution at steady state.

≤ 200 mL) by albuterol [88,89]. Patients were treated with 15 mg cilomilast b.i.d. or placebo b.i.d. for 24 weeks after a 4-week single-blind run-in period. A primary endpoint in these studies was the change from baseline in trough FEV₁.

Only two of the four studies demonstrated a significant change from baseline in trough FEV₁ at study endpoint versus placebo (Fig. 59.4) [88,89]. Three of the four studies showed only a 30–40 mL improvement (i.e. mean change from baseline) in FEV₁ for patients treated with cilomilast. In addition, there was a decline in placebo trough FEV₁ for three of the four trials, particularly during the first few weeks of the study, which could not be adequately explained by investigators. Based on the data, cilomilast did not substantially improve lung function but appeared to delay a decline in (i.e. maintained) lung function (see Fig. 59.4) [88]. However on 5 September 2003, the Pulmonary-Allergy Drugs Advisory Committee of the US Food and Drug Administration stated that one could not draw this conclusion based on the short duration (6 months) of the study. Therefore, this committee did not recommend

approval of cilomilast for the maintenance of lung function (FEV₁) and recommended that longer term studies (e.g. 1 year) be conducted.

Reports from one of the pivotal phase III studies noted significant improvements in several lung function parameters, such as FVC (P = 0.001) and trough 25–75% forced expiratory flow (P = 0.003) in patients treated with cilomilast compared with placebo [90,91]. In addition to improvement in lung function, the risk of a patient experiencing ≥ 1 COPD exacerbation (i.e. self-treated, physician intervention or hospitalization) was reduced by 44% (P = 0.0001) [92]. For any exacerbation, 74% of patients treated with cilomilast were exacerbation-free compared with 62% of patients treated with placebo (P = 0.0077).

For the four pivotal phase III studies, the change from baseline in total score of the SGRQ was a primary efficacy variable in addition to the change from baseline in trough FEV₁. However, only one (Study 039) of the four studies demonstrated a statistically significant and minimal clinically meaningful (more than 4-point change) improvement

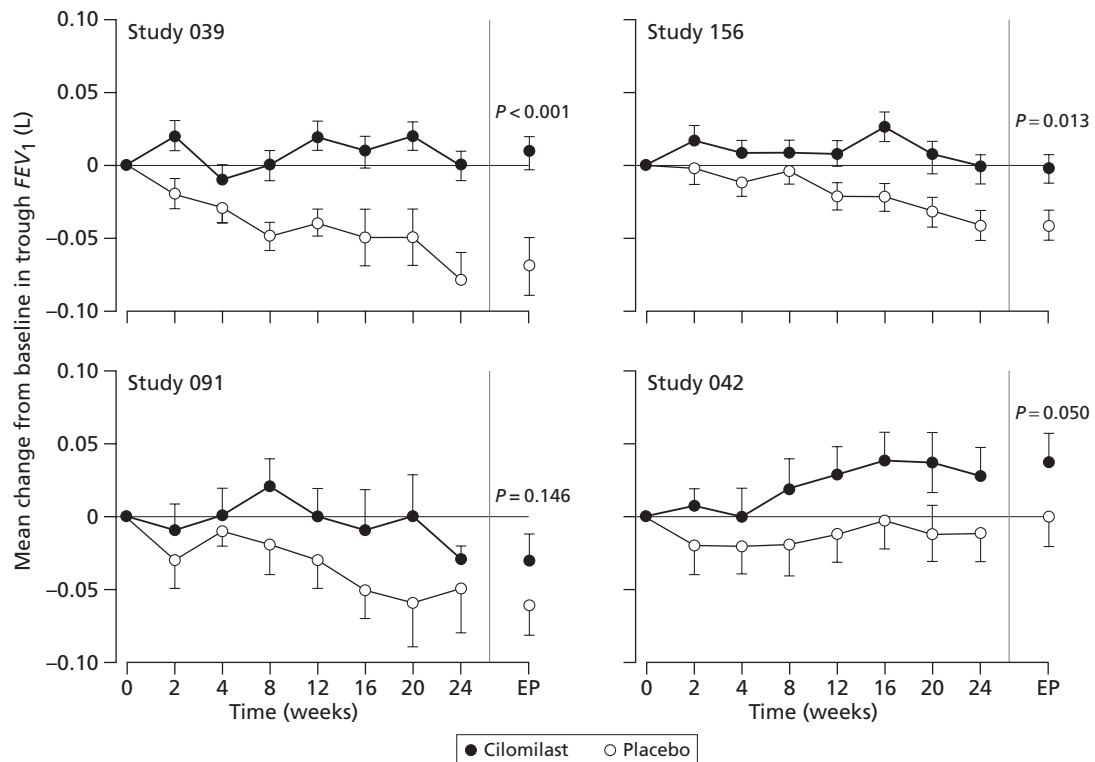

Figure 59.4 Mean change from baseline in trough forced expiratory volume in 1 s (FEV_1) with 15 mg cilomilast twice daily (b.i.d.) versus placebo for four pivotal randomized double-blind phase III trials. EP, endpoint. (Adapted from US Food and Drug Administration [88].)

in SGRQ total score [89]. In addition, this study noted significant improvements at the study endpoint for Short Form-36 scores for physical function ($P = 0.017$) and general health perceptions ($P = 0.02$) compared with placebo treatment [90].

A prospective analysis was also conducted to determine health-care utilization in patients treated with 15 mg cilomilast b.i.d. ($n = 431$) versus placebo ($n = 216$) during one of the pivotal 6-month double-blind trials [93]. Cilomilast was associated with significantly ($P = 0.004$) less cumulative health-care resource utilization (11.0% versus 21.1% for placebo), including physician visits ($P = 0.002$), emergency room visits ($P = 0.004$) and hospitalizations ($P = 0.021$).

Safety in COPD

Cilomilast was generally well tolerated in a series of phase II and III studies. In a dose-ranging study, the most common drug-related adverse event was nausea, reported in 1%, 1%, 12% and 11% of patients in the placebo, 5, 10 and 15 mg dose groups, respectively [87]. The most common serious adverse event was COPD exacerbation. In addition, the most common reason for withdrawal from the study was respiratory disorder, which occurred more often in the placebo ($n = 6$) and 5 mg cilomilast ($n = 6$) dose groups. Overall, there was no cilomilast dose-related trend or signi-

ficant difference in incidence versus placebo for any serious adverse event.

A pooled analysis of 6-month phase III studies indicated that, collectively, gastrointestinal adverse events were the most common complication, reported more often in patients treated with cilomilast compared with placebo (Table 59.3) [94]. For example, nausea was reported in 12% of 1374 patients treated with cilomilast compared with 4% of 684 patients treated with placebo. In addition, diarrhoea, abdominal pain, dyspepsia and vomiting were also reported more frequently in patients treated with cilomilast compared with placebo (see Table 59.3) [94]. Gastrointestinal adverse events were generally self-limited and were mild to moderate in intensity. However, gastrointestinal adverse events were the most frequent reason for discontinuations because of adverse events [89]. Cilomilast preferentially binds PDE4D, and animal studies have suggested that preferential inhibition of PDE4D may account for side-effects such as vomiting [95].

Roflumilast

Roflumilast (3-cyclopropylmethoxy-4-difluoromethoxy-*N*-[3,5-dichloropyridyl-4-yl]-benzamide) [96] is a PDE4 inhibitor currently in phase III clinical development for

Table 59.3 Cilomilast: most frequently reported adverse events. (Adapted from Compton *et al.* [94] with permission.)

Adverse event	Patients, <i>n</i> (%)

COPD, Chronic obstructive pulmonary disease.

the treatment of COPD and asthma (see Fig. 59.3d) [37]. Compared with cilomilast and rolipram, roflumilast has more than 100-fold higher potency in inhibiting PDE4, as reflected by IC₅₀ values of 0.8 nM for roflumilast versus 120 nM for cilomilast and 210 nM for rolipram [7]. *In vivo*, roflumilast is metabolized to roflumilast N-oxide. Both the potent PDE4 inhibition (IC₅₀ = 2 nM) and selectivity of roflumilast are preserved by roflumilast N-oxide. Because of its long half-life, the active metabolite substantially contributes to the overall clinical efficacy of roflumilast.

Preclinical and *in vitro* data

Evidence from *in vitro* and *in vivo* studies supports the broad

anti-inflammatory activity of roflumilast because its target, PDE4, is widely expressed in cells involved in inflammation. The potency of roflumilast and its active metabolite, roflumilast N-oxide, has been demonstrated in many *in vitro* cell models. Half-maximum inhibition values in the lower nanomolar range suppressed human cell functions (Table 59.4) [7] and corresponded well to inhibition of PDE4 activity in a cell-free system. The maximum efficacy attained with a PDE4 inhibitor in functional cell-based assays *in vitro* is dictated by the additional expression of PDE families other than PDE4. In addition, a threshold cAMP concentration is a prerequisite for the activity of a PDE4 inhibitor. Neutrophils, eosinophils and monocytes isolated from human peripheral blood almost exclusively express PDE4. As a consequence, maximum inhibition (efficacy) by roflumilast or roflumilast N-oxide of LPS-induced TNF- α synthesis in monocytes is approximately 80%, and complete inhibition of fMLP-stimulated LTB₄ synthesis from neutrophils is observed.

Macrophages for preclinical studies are obtained by *in vitro* differentiation of monocytes incubated in human AB serum for several days. This transition to monocyte-derived macrophages is associated with up-regulation of genes for PDE3 and PDE1 and reduced expression of PDE4 [32]. Macrophages differentiated from monocytes in human AB serum are considered to be similar to human alveolar macrophages and, importantly, have a comparable PDE expression profile [97]. In contrast to monocytes, a PDE4 inhibitor alone has virtually no effect on LPS-induced TNF- α generation in monocyte-derived macrophages. Even at a concentration of 10 nM prostaglandin E₂ (PGE₂) to stimulate cAMP formation, the maximum inhibition attained with PDE4 inhibitors was only 20%. In addition,

Table 59.4 Inhibition of inflammatory activities by phosphodiesterase 4 inhibitors. (Adapted with permission from Hatzelmann *et al.* [7].)

Cell type	Measured parameter	IC value, nM	Roflumilast			
			Roflumilast	N-oxide	Cilomilast	Rolipram
Neutrophil	ROS	IC ₃₅	4	8	60	20
	LTB ₄	IC ₅₀	2	5	40	11
Monocyte	TNF- α	IC ₄₀	21	17	1300	330
Macrophage	TNF- α	IC ₃₅	13	12	130	10

concomitant inhibition of PDE3 did not augment the efficacy of PDE4 inhibitors. However, in the presence of both 1 μM motapizone to inhibit PDE3 and 10 nM PGE₂ to stimulate cAMP formation, roflumilast concentration-dependently suppressed LPS-induced TNF- α formation to a maximum of approximately 70%. These results reflect additional PDE3 expression and subthreshold baseline cAMP synthesis in macrophages. Under these experimental conditions, the administration of a PDE3 inhibitor in the presence of a cAMP-generating system enables the PDE4 inhibitor to suppress LPS-induced TNF- α synthesis [32,97].

How might these findings translate to the clinical situation in COPD? Activated macrophages in distal airways produce mediators such as TNF- α , MMP-12, ROS and LTB₄ that may orchestrate inflammation and remodelling in COPD. For example, mice deficient in macrophage elastase (MMP-12) were not susceptible to cigarette smoke-induced emphysema [98]. Importantly, transgenic pulmonary expression of constitutive or inducible TNF- α was associated with characteristics of emphysema (e.g. alveolar airspace enlargement) [99,100]. In inducible TNF- α transgenic mice, macrophage metalloelastase (MMP-12) mRNA was enhanced, and increased numbers of CD8⁺ T cells were observed in the lung parenchyma [100]. Conversely, TNF- α receptor deficient mice did not exhibit an acute cigarette smoke-induced increase in neutrophils and macrophages (obtained by bronchoalveolar lavage) or markers of connective tissue breakdown, such as desmosine or hydroxyproline [101]. Data from a recent study [102] indicated that TNF- α levels might determine the extent of neutrophilic airway infiltration via up-regulation of E-selectin in endothelial cells. In addition, alveolar macrophages exposed to cigarette smoke *in vitro* produced substantial amounts of TNF- α [102]. Cigarette smoke also contains bioactive amounts of LPS that may further contribute to macrophage TNF- α formation [103].

Overall, these data strongly support a pre-eminent role for macrophage-produced TNF- α in the different manifestations of COPD. Although ineffective by itself, a PDE4 inhibitor such as roflumilast strongly suppresses LPS-induced TNF- α generation in the presence of PGE₂ if PDE3 activity is blocked. In COPD patients, an increase in exhaled PGE₂ levels was shown [104] and probably reflects elevated prostaglandin generation in airway cells. In fact, there are many cellular sources of up-regulated PGE₂ associated with lung inflammation [105], including fibroblasts [106], smooth muscle cells [107] and alveolar macrophages [108].

Expression of inducible nitric oxide synthase (iNOS) was increased in cells such as neutrophils or macrophages recovered from induced sputum of patients with COPD [109]. Human macrophages express NO-sensitive guanylyl cyclase [110], and up-regulated NO generation in COPD may increase cGMP levels in pulmonary macrophages. cGMP is a strong inhibitor of PDE3 activity and, therefore,

iNOS-derived NO might translate into PDE3 inhibition in endogenous macrophages. Taken together, it may be hypothesized that excessive cellular activation and infiltration within the small airways of patients with COPD create clinically relevant PGE₂ concentrations and PDE3 inhibition, thus allowing potent suppression of human lung macrophage TNF- α generation by roflumilast. The presence of PGE₂ or other mediators in COPD may further up-regulate PDE4 activity in the lung macrophages. In fact, it is well known that PDE4 is subject to extensive regulation on both the transcriptional and post-transcriptional levels [111]. For example, in human monocytes LPS enhances PDE4B2 expression [112]. Such increased levels of PDE4 may then further accentuate the efficacy of a PDE4 inhibitor.

Contrary to the situation in the small airways in patients with COPD, roflumilast may have little effect on macrophages in larger airways, and this may be advantageous given the role of macrophages in host defence. In addition, at least in asthma, the relative resistance of macrophages toward PDE4 inhibitors might be considered favourable because a subpopulation of immunosuppressive alveolar macrophages has been shown to inhibit bronchial T-cell reactivity [113].

The ability of roflumilast to interfere with CD4⁺ T-cell proliferation and cytokine generation has been investigated [7]. CD4⁺ T cells were purified from human peripheral blood using an immunomagnetic procedure. Cells were then preincubated with various PDE4 inhibitors and co-stimulated with anti-CD3 (0.3 $\mu\text{g}/\text{well}$) and anti-CD28 (3 $\mu\text{g}/\text{mL}$) for 72 h. As a surrogate of proliferation, incorporation of [³H]-thymidine was assessed during the final 18 h of incubation. Cytokine levels from culture supernatants were also measured after the incubation period. Roflumilast and roflumilast N-oxide suppressed [³H]-thymidine incorporation and inhibited production of IL-2, IL-4 and IFN- γ , with half-maximum efficacy values between 1 and 8 nmol. Maximum inhibition (efficacy) by roflumilast ranged from 40% for IL-2 synthesis to 70% for IFN- γ formation.

Previous studies have shown that the PDE4 inhibitor rolipram reduced anti-CD3/anti-CD28-induced IL-13 formation by human T cells by up to 40% [114]. Resting CD4⁺ T cells primarily express PDE4 and PDE3, but also express PDE7 [4,97]. Co-stimulation with anti-CD3/anti-CD28 induced novel expression of PDE1B protein [114]. In the presence of a PDE3 inhibitor, which by itself has little effect, the efficacy of a PDE4 inhibitor in suppressing T-cell functions was increased, reflecting the functional role of the additionally expressed PDE3 [4,115]. Thus, the incomplete inhibition of CD4⁺ T-cell functions by PDE4 inhibitors indicates that other PDE isozymes may also contribute to cAMP regulation in relevant subcellular compartments of T lymphocytes. The T cells that were co-stimulated with anti-CD3/anti-CD28 responded with a rapid and transient

increase in PDE4 activity [114] that was insensitive to cycloheximide or actinomycin D. The increased PDE4 activity may originate in a recruitment of PDE4B2 to the CD3–T-cell receptor (TCR) complex after CD3 ligation that is associated with tyrosine phosphorylation of this PDE4 splicing variant [116]. Stimulation of human T cells stably transfected with a tetracycline-sensitive PDE4B2 construct by activated antigen-presenting cells rapidly up-regulated tetracycline-triggered PDE4 activity. This was associated with recruitment to the lipid raft membrane microdomains close to the immunological synapse. These PDE4B2-transfected cells generated greater amounts of IL-2 after specific antigen stimulation compared with wild type lymphocytes [117], supporting findings that PDE4 inhibitors such as roflumilast reduce IL-2 synthesis.

These data provide conclusive evidence that recruitment of PDE4B2 to the TCR complex – and its subsequent activation – alleviates T-cell activation induced by specific antigen presentation. This is probably based on down-regulation of cAMP within the lipid raft subcellular signalling complex. It may be inferred that PDE4 inhibitors, by targeting the enzyme in its strategic position near the TCR, increase cAMP levels in the lipid raft signalling complex and result in efficient reduction of T-cell activation. Long-term transcriptional regulation of PDE4 by cAMP-generating systems has been described in human T cells. Incubation with fenoterol or 8-bromo-cAMP for several hours resulted in enhanced PDE4 activity, particularly PDE4D2 [118].

Up-regulation of cAMP-dependent PDE4 has been discussed as an important mechanism of heterologous desensitization to β_2 -agonists. In fact, use of PDE4 inhibitors has been suggested to delay tolerance to therapeutic β_2 -agonists and endogenous catecholamines or PGE₂ [119].

In COPD, the role of CD8⁺ T cells has been a key focus because these cells appear to be increased both in the airway mucosa and regional lymph nodes [120]. Comparable to CD4⁺ T cells, PDE3, PDE4 and PDE7 activities were detected in unstimulated CD8⁺ T cells [4,97]. Roflumilast and roflumilast-N-oxide potentially reduced antiCD3/antiCD28-induced granzyme B and IL-2 release from [3H] thymidine incorporation in purified human peripheral blood CD8⁺ T-cells with IC₅₀ from 1–10 nM and in presence of 10 μ M motapizone to block PDE3 [121].

Comparison of potencies of the PDE4 inhibitors roflumilast, roflumilast N-oxide, rolipram and cilomilast for their inhibition of monocyte and macrophage TNF- α synthesis and CD4⁺ T-cell functions (e.g. proliferation, cytokine generation), versus inhibition of neutrophil LTB₄ and ROS release revealed that rolipram and cilomilast were substantially less potent inhibitors of monocytes and T lymphocytes than of neutrophils [7]. Conversely, the potencies of roflumilast and roflumilast N-oxide in suppressing monocyte, T cell, macrophage and neutrophil

functions were comparable (see Table 59.4) [7]. The ability of rolipram to reduce neutrophil (IC₅₀ = 11 nM for LTB₄ and 20 nmol for ROS) and macrophage (IC₅₀ = 10 nM for TNF- α formation) functions was greater than for inhibition of PDE4 activity (IC₅₀ = 210 nM) [7]. This was not the case with roflumilast and roflumilast N-oxide, in which potency levels for inhibition of neutrophil and macrophage functions were slightly lower compared with PDE4 inhibition. Monocyte and T-cell functions, however, were attenuated with a potency corresponding to levels of inhibition of PDE4 activity by all of the PDE4 inhibitors tested.

PDE4 proteins assume at least two interconvertible conformational states, which may be distinguished by their binding of rolipram with different affinities. Association of PDE4 inhibitors with the LARBS conformation is reflected by inhibition of catalytic activity. Binding of PDE4 inhibitors to the HARBS conformation is assessed by competition assays with [³H]-rolipram. For rolipram, binding to the HARBS was observed at an IC₅₀ of approximately 5 nM whereas inhibition of catalytic activity corresponding to the LARBS was observed at an IC₅₀ of approximately 120 nM [74]. Studies with various PDE4 inhibitors demonstrated that reduction of neutrophil functions correlated with the HARBS (i.e. inhibition of [³H]-rolipram binding), whereas suppression of monocytes was correlated with the LARBS (i.e. inhibition of PDE4 catalysis) [74]. In addition, evidence published during the past decade indicates that interaction of compounds with the HARBS correlates with emesis and other central nervous system-related effects [122–124]. For rolipram, preferential binding to the HARBS versus the LARBS explains its more potent inhibition of neutrophil LTB₄ and ROS generation versus monocyte TNF- α synthesis and PDE4 catalytic activity and the early occurrence of emesis. Roflumilast attenuates the above-mentioned neutrophil and monocyte functions with comparable potency. Indeed, roflumilast was shown to bind HARBS and LARBS with comparable affinity (K_i = 1.5–3 nM) [125] and this may finally allow that improvement of lung function in COPD associated with low emetic risk as observed in clinical studies with roflumilast.

The binding of cilomilast to HARBS and LARBS has been reported as approximately equal [71]. However, in our laboratory cilomilast was about 25-fold more potent in inhibiting neutrophil LTB₄ or ROS generation than monocyte TNF- α synthesis [7]. The preferential inhibition of PDE4D (IC₅₀ = 4 nM) over PDE4B (IC₅₀ = 99 nM) [126] by cilomilast might explain this finding. In contrast, roflumilast and roflumilast N-oxide inhibited PDE4A, B and D equipotently [127]. Generation of LPS-induced TNF- α appears to be governed by PDE4B, as lipopolysaccharide-induced TNF- α formation was nearly eliminated in PDE4B –/– mice [25].

Whether neutrophil ROS and LTB₄ formation is primarily regulated by PDE4D over PDE4B remains to be explored.

It was shown that neutrophils exhibit PDE4D > PDE4B however, both subtypes are equally involved in neutrophil chemotaxis [128]. In summary, *in vitro* assays with inflammatory cells PDE4 reflected the higher potency of roflumilast over cilomilast to inhibit PDE4 and this was particularly marked in monocytes and T lymphocytes. In parallel, roflumilast was more potent than cilomilast to reduce LPS-induced plasma TNF- α *in vivo* (EC50 of 0.2 vs. 93 $\mu\text{mol/kg}$, respectively) [96].

Recently, the potency and efficacy of roflumilast and its active metabolite were explored in other *in vitro* and *in vivo* systems of relevance in COPD. Neutrophil studies were complemented by findings that roflumilast and roflumilast N-oxide reduced fMLP-induced degranulation (i.e. release of neutrophil elastase, MPO and MMP-9) with IC50 = 1–2 nM [129] and also CD11b presentation [130]. Considering airway epithelial cells roflumilast strongly suppressed MUC5AC mRNA and protein in cultured human bronchial slices and in A549 cells, roflumilast was more potent than cilomilast or rolipram in this respect. [34]. These data indicate that roflumilast may assist to reduce mucus overproduction in peripheral airways in COPD. Roflumilast or roflumilast N-oxide suppressed an array of functions in cell types involved in pulmonary remodelling in COPD. In human lung fibroblasts roflumilast N-oxide inhibited TNF- α induced up-regulation of ICAM-1 cell adhesion molecule and Eotaxin release with IC50 around 1–3 nM. In addition, TGF β 1 induced expression of α -smooth muscle actin, a surrogate of myofibroblast transition was reduced by roflumilast N-oxide [131]. Further, roflumilast (1 μM) reduced TGF β 1 induced chemotaxis and collagen gel contraction [132]. In human pulmonary artery smooth muscle cells roflumilast decreased [3H]thymidine incorporation triggered by PDGF with IC50 = 4.4 nM in presence of 3 nM cicaprost [133]. Human airway smooth muscle cells produce extracellular matrix proteins and roflumilast (1 μM) suppressed TGF β -induced CTGF, collagen I and fibronectin in bronchial rings and deposition of fibronectin from bronchial smooth muscle cells [134]. Roflumilast and its N-oxide potently reduced serum-induced [3H]thymidine incorporation in these cells with IC50 = 1–3 nM [135]. *In vivo*, roflumilast at 0.1–10 $\mu\text{mol/kg}$ p.o. dose-dependently inhibited leucocyte-endothelial interaction triggered by LPS as assessed by intravital microscopy in rats [130]. Importantly, roflumilast (5 mg/kg/d p.o.) prevented cigarette-smoke induced emphysema in mice in a chronic study over 7 months [136]. From these results one may hypothesize that roflumilast alleviates airway and pulmonary vascular remodelling in COPD. In summary, preclinical data suggest a therapeutic benefit of roflumilast in COPD.

Pharmacokinetics

The pharmacokinetics of intravenous and oral administra-

tion of roflumilast has been evaluated in a randomized, two-period cross-over study [137]. Twelve healthy male volunteers received a single oral dose of 500 μg and an intravenous 150 μg dose infused over a 15-min period. After infusion, the plasma concentration of roflumilast showed a rapid distribution and long apparent terminal plasma disposition half time of about 15 h. The active metabolite roflumilast N-oxide achieved a plateau-like concentration about 4 h after infusion (C_{max} at about 8 h). This concentration was maintained for several hours and declined slowly with an apparent terminal fall time of 23 h. Roflumilast N-oxide accounts for about 87% of PDE4 inhibitor exposition. Absolute bioavailability of oral 500 μg roflumilast (relative to the short-term i.v. infusion) was high with 79% [137].

A double-blind parallel-group dose-ranging study was conducted in 18 healthy volunteers to determine the pharmacokinetics of roflumilast and roflumilast N-oxide, the active metabolite of roflumilast [138]. Volunteers received 500 μg roflumilast once daily during days 1–7, 750 μg once daily during days 8–14 and 1000 μg once daily during days 15–21. Pharmacokinetic parameters for days 7, 14 and 21 are shown in Table 59.5. Roflumilast exhibited linear pharmacokinetics in the dose range of 500–1000 μg . Roflumilast and roflumilast N-oxide exhibited a prolonged half-life of approximately 15 and 20 h, respectively, providing a rationale for a once-daily dosing regimen. Roflumilast was well tolerated at all dose levels tested. From the AUC values obtained after repeated dosing over 7 days it is obvious that roflumilast N-oxide accounted for > 90% of PDE4 inhibitor exposition. Considering binding to human plasma proteins for roflumilast and roflumilast-N-oxide being 98.9% and 96.6%, respectively, the pharmacokinetic profile at day 7 following repeated dosing with 500 μg once daily roflumilast as currently used in clinical trials reveals plasma concentrations of 1–2 nM unbound roflumilast-N-oxide within the dosing periods. At these concentrations PDE4 activity and numerous cellular functions are inhibited by approximately 50%.

Concomitant drug administration and time of administration were investigated to determine potential pharmacokinetic alterations for roflumilast and other medications. The effect of food intake on the pharmacokinetics of roflumilast and roflumilast N-oxide was evaluated in a two-period cross-over study [139]. Twelve healthy volunteers received a single 500- μg oral dose of roflumilast in a fasted state and after a high-fat breakfast [139]. Similar to findings with cilomilast [79], point estimates (test/reference ratios for maximum concentration [C_{max}]) indicated that a high-fat meal reduced the absorption. The point estimate for C_{max} for roflumilast was 0.59 (90% CI, 0.49–0.70) and was 0.95 (90% CI, 0.90–1.01) for roflumilast N-oxide. This indicated that C_{max} was reduced for roflumilast but not for the active

Table 59.5 Geometric mean pharmacokinetic parameters for roflumilast. (Data from Bethke *et al.* [138].)

Parameter	Oral multiple dose*					
	Roflumilast			Roflumilast N-oxide		
	500 µg (n = 18)	750 µg (n = 18)	1000 µg (n = 18)	500 µg (n = 18)	750 µg (n = 18)	1000 µg (n = 18)
C_{max} , µg/L (68% range)	4.7 (3.7–6.1)	8.2 (6.0–11.0)	11.1 (8.3–15.0)	20.7 (17.2–24.8)	33.7 (27.3–41.7)	50.6 (43.7–58.5)
$AUC_{0-\infty}$, µg/h/L (68% range)	32.6 (24.0–44.4)	50.8 (36.9–70.0)	65.9 (49.5–87.8)	347.2 (284.7–423.3)	587.3 (462.3–746.2)	799.9 (638.5–1002.1)
$t_{1/2}$, h (68% range)	14.3 (10.05–21.75)	13.7 (12.38–19.90)	14.7 (9.0–22.8)	NR (8.7–21.7)	NR (10.4–20.7)	19.6 (15.1–25.6)

* Dose-escalation study of 7-day dose regimen for each dose with pharmacokinetic parameter measurements on day 7 for each dose.
 $AUC_{0-\infty}$, area under the concentration–time curve from 0 to infinity; C_{max} , maximum plasma concentration; IV, intravenous; NR, not reported;
 $t_{1/2}$, half-life.

metabolite. The point estimate for AUC for roflumilast was 1.12 (90% CI, 1.00–1.25) and was 0.91 (90% CI, 0.79–1.04) for roflumilast N-oxide, indicating that AUC values for roflumilast and the active metabolite were not affected by food intake. Therefore, administration of roflumilast with or without food did not affect the bioavailability of roflumilast or roflumilast N-oxide.

Potential influences of time of administration on pharmacokinetic parameters were evaluated in a two-period cross-over study conducted in 16 healthy volunteers who received a single oral dose of 500 µg roflumilast in the morning or in the evening [140]. During the first 12-h time period after drug administration, the pharmacokinetics of roflumilast varied between morning and evening administration with regard to C_{max} (marginally lower with evening dosing) and time to C_{max} (slightly longer with evening dosing). In contrast, AUC did not differ between the times of administration, suggesting that exposure to roflumilast and roflumilast N-oxide was unaffected. Overall, the time of roflumilast administration (morning or evening) did not significantly influence the pharmacokinetics of roflumilast or roflumilast N-oxide.

Pharmacodynamic studies in healthy volunteers have also indicated no effect of smoking status on the pharmacokinetics of roflumilast and roflumilast N-oxide [141]. Furthermore, no relevant drug interactions between roflumilast and budesonide, salbutamol or warfarin have been observed [141–144]. A study of 12 patients with severe renal impairment (creatinine clearance ≥ 10 and ≤ 30 mL/min) and 12 healthy control-matched volunteers found no statistically significant difference in pharmacokinetic characteristics between the two groups [145]. In contrast to cilomilast, no dose adjustment for roflumilast is expected to be required in patients with severe renal impairment.

Efficacy and safety of COPD

Preliminary clinical phase II data suggested that roflumilast could improve lung function in patients with COPD while being well tolerated [146,147].

The efficacy and safety of roflumilast have been further investigated in a large phase III double-blind dose-ranging parallel-group study [148]. Patients with moderate to severe COPD were randomized to receive placebo ($n = 280$), oral roflumilast 250 µg ($n = 576$) or 500 µg ($n = 555$) once daily for 24 weeks after an initial 4-week run-in period. Treatment with both roflumilast doses resulted in statistically significant improvements in pre- and post-bronchodilator FEV_1 (Fig. 59.5) versus placebo, with differences of 88 mL (pre-bronchodilator FEV_1) and 97 mL (post-bronchodilator FEV_1) with 500 µg roflumilast [148]. Significant improvements with roflumilast versus placebo were also seen for further lung function variables (FVC , FEV_6 and FEF_{25-75} , all post-bronchodilator [148]).

Roflumilast was well tolerated at both dose levels tested (Table 59.6) [148]. The incidence of adverse events was comparable between placebo (62%) and the two treatment groups (66–67%) [148]. In the 500 µg dose group, the most commonly reported gastrointestinal events were nausea and diarrhoea, occurring in 9% and 5% of patients, respectively. These adverse events were generally mild to moderate in intensity. Vomiting was rare ($\leq 1\%$) in both dose groups and was similar to the incidence reported in patients treated with placebo. Importantly, roflumilast displayed an improved gastrointestinal side-effect profile compared with cilomilast (see Table 59.3) [94], which caused a higher incidence of gastrointestinal adverse events (e.g. 12.5% for nausea). Roflumilast and its N-oxide show no preference for the PDE4 D-subtype and no preference for the HARBS [125] which may explain why roflumilast

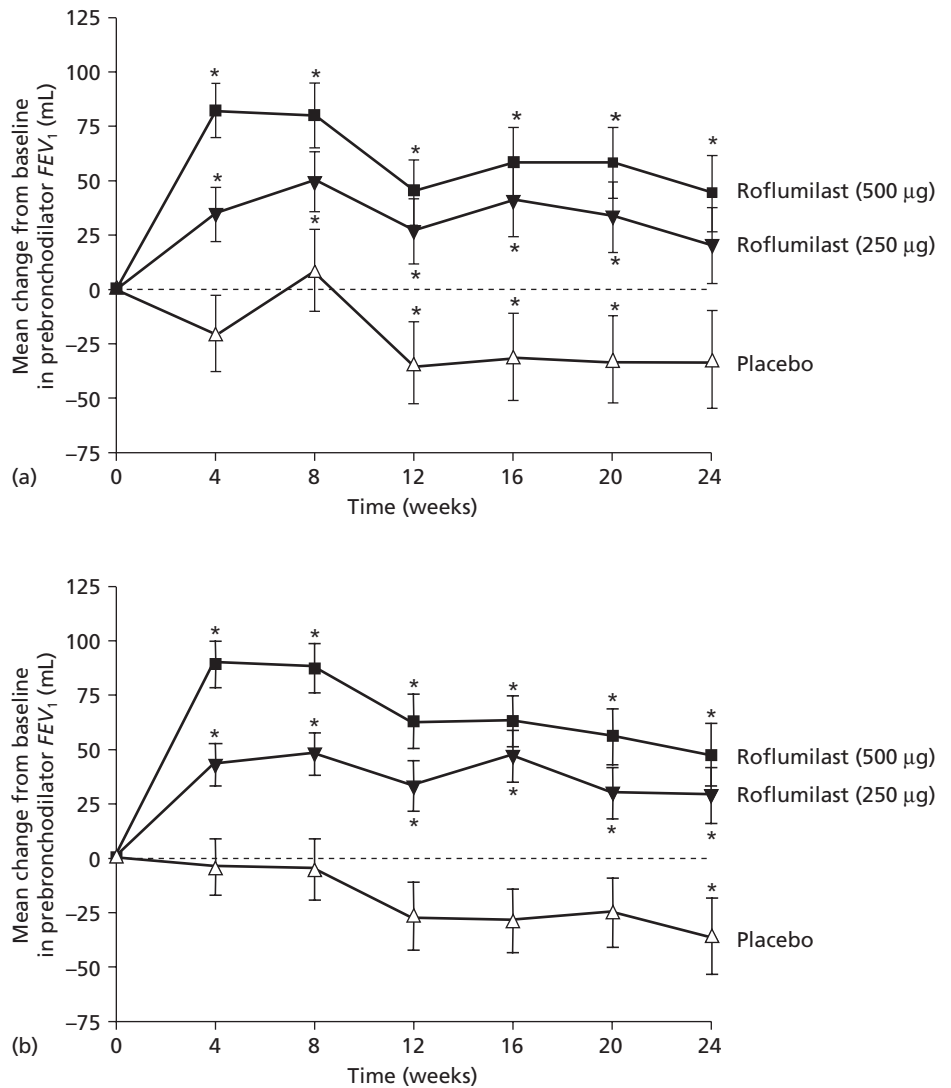

Figure 59.5 Mean change from baseline in pre-bronchodilator (a) and post-bronchodilator (b) forced expiratory volume in 1 s (FEV_1) with roflumilast 250 or 500 µg once daily. Data are least square means \pm standard errors. * $p < 0.05$ versus baseline. (Adapted from Rabe *et al.* [148].)

shows a more favourable gastrointestinal safety profile compared with cilomilast.

Further data that support the promising role of roflumilast in the treatment of COPD come from a recently completed study which involved more than 1500 patients with severe to very severe COPD. In this study 500 µg oral roflumilast once daily administered for 12 months led to a significant improvement in pre- and post-bronchodilator FEV_1 [149] and resulted in fewer exacerbations in patients with very severe COPD [150] who are likely to exacerbate more frequently. Due to these promising treatment outcomes with 500 µg oral roflumilast once daily, further trials are currently underway.

Future role of PDE4 inhibitors

Currently, there is no disease-modifying (i.e. controller)

therapy available that effectively addresses the underlying pathology of COPD. In present-day practice, medications (e.g. anticholinergics and long-acting β -agonists) are administered to treat or control the symptoms of the disease. However, the anti-inflammatory activities (e.g. neutrophil, macrophage or $CD8^+$ cell-targeted) associated with improved PDE4 inhibitors may provide an opportunity to interfere with the pathophysiology of COPD and positively influence the disease rather than solely treat the symptoms. Significant improvements in lung function, reduction in exacerbation rates and improvement in quality of life have already been demonstrated in clinical trials. In this context, selective PDE4 inhibitors will likely have an important value as first-line therapy in the treatment and management of COPD. Further studies are needed to elucidate the long-term effects of PDE4 inhibitors on the cause and progression of COPD. Future studies may also identify additional health-related benefits with the administration of PDE4

Table 59.6 Roflumilast: most frequently reported adverse events. (Adapted from Rabe *et al.* [148])

Adverse event	Patients (%)		
	Placebo <i>n</i> = 280	Roflumilast	
		250 µg <i>n</i> = 576	500 µg <i>n</i> = 555
COPD exacerbation*	65 (23)	135 (23)	113 (20)
Nasopharyngitis	19 (7)	42 (7)	46 (8)
Diarrhoea NOS	6 (2)	28 (5)	50 (9)
Upper respiratory tract infection	14 (5)	27 (5)	23 (4)
Nausea	2 (1)	16 (3)	27 (5)

* Only moderate and severe exacerbations were reported as adverse events.
COPD, chronic obstructive pulmonary disease; NOS, not otherwise specified.

inhibitors, particularly in combination with other once-daily maintenance therapies, such as inhaled anticholinergic drugs (e.g. tiotropium) and long-acting β -agonists.

Because the pathogenesis and clinical manifestations of COPD are not restricted to pulmonary inflammation and structural airway remodelling, the role of PDE4 inhibitors in modifying the systemic manifestations (e.g. skeletal muscle atrophy) of COPD will be of significant interest. For example, systemic oxidative stress, modifications in circulating inflammatory cells (e.g. neutrophils) and increased levels of proinflammatory cytokines (e.g. TNF- α) in the peripheral circulation have all been observed in patients with COPD [151–153]. In addition, skeletal muscle apoptosis (i.e. wasting) is also a frequently observed complication of COPD. Studies have suggested that inflammatory cytokines (e.g. TNF- α) may contribute to muscle wasting and protein loss via a nuclear factor κ B-dependent pathway [153]. Further, this signalling pathway is regulated by endogenous ROS [153]. Additional studies have shown that systemic inflammation can produce iNOS in skeletal muscle, stimulating NO production [154]. These data have been supported by clinical studies [155]. Although data are lacking that explore the effects of PDE4 inhibitors on systemic inflammation and iNOS expression in skeletal muscle, *in vitro* data have shown that PDE4 inhibitors are beneficial in down-regulating cytokine-induced iNOS expression and NO production in human chondrocytes [156]. Therefore, future studies with PDE4 inhibitors may identify systemic benefits for patients with COPD. The anti-inflammatory activities and potential systemic effects of PDE4 inhibitors in patients with COPD represent a challenging area for further research.

Conclusions

PDE4 has a critical role in the disease pathophysiology of COPD, including key activities in inflammatory cells (e.g. neutrophils) and inflammatory cytokine profiles. With the current lack of disease-modifying agents available in the COPD armamentarium, PDE4 inhibitors provide a novel opportunity to shift or change the treatment paradigm for COPD. Comprehensive preclinical data support the potent anti-inflammatory properties of selective PDE4 inhibitors. The more favourable safety profiles (e.g. gastrointestinal adverse events) observed with newer generation PDE4 inhibitors (e.g. roflumilast) are encouraging. Furthermore, data with selective PDE4 inhibitors support sustained lung function improvements, reduction in COPD exacerbations and improved health-related quality of life benefits with long-term therapy.

The PDE4 inhibitors cilomilast and roflumilast share some important characteristics (e.g. high bioavailability, oral dosing capabilities, low risk of drug–drug interactions). However, with regard to efficacy and safety, key differences between cilomilast and roflumilast have shown that roflumilast may provide a higher therapeutic index for patients with COPD. For example, roflumilast has an improved therapeutic ratio and is more potent than cilomilast in inhibiting PDE4 activity. The pharmacokinetics of roflumilast and its active metabolite, roflumilast N-oxide, allow once daily dosing versus twice daily dosing for cilomilast. Roflumilast shows efficacy in both COPD and asthma and is in late-stage clinical development for both indications, whereas clinical development of cilomilast was discontinued in asthma because of poor efficacy.

The next decade promises exciting new opportunities in the management of COPD – targeting the disease pathophysiology (i.e. disease modifying) rather than just the clinical symptoms. Importantly, long-term studies on morbidity and mortality in patients treated with selective PDE4 inhibitors are anticipated and may further validate PDE4 inhibitors for effective treatment of COPD.

CHAPTER 60

Antibiotic therapy in patients with COPD

Michael S. Niederman

Patients with chronic bronchitis commonly have disease exacerbations, and antibiotics are commonly used as part of the therapy for this condition, even though bacterial infection is present in no more than 50% of exacerbations. Although a recent meta-analysis has concluded that antibiotics are of benefit, compared to placebo, for acute exacerbations of chronic bronchitis (AECB), not all patients require such therapy [1]. One way to decide who should be treated is to count the number of 'cardinal symptoms' of exacerbation: increased dyspnoea, increased sputum volume and increased sputum purulence. In one study, Anthonisen *et al.* [2] graded exacerbations as type I if all three symptoms were present; type II if only two symptoms were present; and type III if only one symptom was present, and found a benefit for antibiotic therapy in the 80% of patients with either type I or II exacerbations. Even if antibiotics are used, some experts believe that the choice of a specific agent is not important with regard to patient outcome [3]. In fact, a recent consensus statement of the American College of Physicians and the American College of Chest Physicians, as well as the GOLD guidelines for COPD support this concept [4]. In spite of this view, guidelines for the therapy of AECB have been published, and they take the approach that there are differences in the bacteriology of exacerbations in different patient populations, necessitating that therapy be given in different ways for different subsets of patients [5]. Implicit in these guidelines is the belief that the benefits of antibiotics may be more dramatic for patients with more severe illness, where the impact of no therapy, or failed therapy, may be catastrophic leading to hospitalization and even mechanical ventilation.

This discussion explores the use of antibiotics in COPD patients, focusing primarily on their role in acute exacerbations, but also considering the issue of pneumonia in the COPD patient. The rationale for the use of antibiotics in exacerbations, as well as the target organisms and principles of antibiotic usage are examined. Finally, the concept

that specific antibiotics should be used in specific patients is discussed.

Why should antibiotics be used in AECB?

Patients usually have exacerbations of COPD each year, with only one-third of all patients having less than three episodes, one-third having three episodes and one-third having four or more episodes [6]. One recent study examined the cost of treating AECB in the USA, although the estimates related to total outpatient cost were limited by the available data, and thus the study probably underestimated the number of outpatients treated annually [7]. Using 1994 data, the authors estimated that there were 280 000 admissions for AECB and over 10 million outpatient visits for this illness, a ratio of 30 : 1 for outpatient management versus inpatient care. For the admitted patients, the mean length of stay for those 65 years and older was 6.3 days at a total cost of 1.1 billion dollars, while younger patients had a mean length of stay of 5.8 days at a total cost of 419 million dollars. For the outpatients, 5.8 million episodes are in those aged 65 or older, while 4.2 million episodes were in the younger population. When care was given out of the hospital, for those treated in an office, emergency room or hospital clinic, the cost of an exacerbation was \$74, \$76 and \$159, respectively [7]. In contrast, for an inpatient, the average cost was \$5516 per episode. In both the outpatient and inpatient setting, antibiotics made up a small amount of total cost, accounting for 15% and 11%, respectively, of all costs. The data in this study make it very clear that if an antibiotic is used during exacerbation, and it can prevent hospitalization, it will be a highly cost-effective therapy, given the large difference in the cost of care in these two settings.

The arguments in favour of using antibiotics in many patients with exacerbations come from several areas (Table 60.1):

Table 60.1 Why antibiotics should be used in acute exacerbations of chronic bronchitis.

Bacteriological data show a role for bacteria in exacerbations

- Quantitative cultures
- Strain-specific data

Serological data show a role for bacteria in exacerbations

- Strain-specific antibody responses for *Haemophilus influenzae*

Inflammatory events in the airway are linked to bacteria

- Antibiotics might prevent progressive airways damage by breaking the vicious cycle of infection and airway injury

Antibiotics lead to a reduced duration of symptoms and more patients with a clinical cure and fewer with a clinical deterioration than placebo

- May help avoid hospitalization
- May help return to work sooner
- Certain agents may prolong time between exacerbations

May prevent some severe airway infections from progressing to pneumonia

1 Bacteriological and serological data show a role for bacterial infection in acute exacerbations.

2 Inflammatory events in the airway can be linked to the presence of bacteria, and the elimination of bacteria is associated with reduced signs of inflammation.

3 Prospective randomized placebo-controlled trials show a benefit for antibiotics, especially in more severe exacerbations.

4 Antibiotics may prevent some patients with severe exacerbations from progressing to pneumonia.

Bacteriological and serological data showing a role of bacteria in exacerbations

When sputum is cultured from a patient with chronic bronchitis, bacteria are often present, with non-typable *Haemophilus influenzae*, pneumococcus and *Moraxella catarrhalis* being the most commonly recovered pathogens. The uncertainty about the role of bacteria in AECB results from the observation that the same organisms may be present when the patient is clinically stable or when the patient is having an acute exacerbation, reflecting the fact that these patients have chronic tracheobronchial colonization. While most bacteriological data are qualitative, a number of studies have examined quantitative cultures of lower respiratory tract secretions using a bronchoscopic protected specimen brush in this population, and demonstrated that many patients with exacerbations have large numbers of bacteria, often more than are present in the absence of exacerbation symptoms [8–11]. To date, at least four

studies have used quantitative cultures and found that at least 50% of patients with exacerbations (as opposed to fewer who are stable) have concentrations of bacteria in their lower airways that are comparable to the concentrations that are present in patients with pneumonia (more than 1000 colony-forming units [CFU]/mL) [8–11]. Thus, exacerbations can be accompanied by as many organisms as are present during invasive infection. In one outpatient study of 40 stable patients, only 25% had organisms present at more than 1000 CFU/mL, while 52% of 29 patients with exacerbations had concentrations of bacteria at this level [9]. In fact, if a concentration of more than 10 000 CFU/mL was used, then only 5% of the stable patients had these many bacteria, compared with 24% of the patients with exacerbation.

Still, the question remains, how is it possible for bacteria to cause exacerbations if the same organisms are present when a patient is stable or when the patient is ill. This issue was recently evaluated by Sethi *et al.* [12] who studied the bacteriology of respiratory secretions in a longitudinal study of outpatients with chronic bronchitis. Using molecular typing, they found that even when patients had the same organism in the airway over time, the specific surface-exposed epitopes changed, because patients were acquiring new 'strains' of the same organism. They found that when a new strain was acquired of either pneumococcus, *H. influenzae* or *M. catarrhalis*, the likelihood of exacerbation was increased more than twofold. In fact, the authors found that 33% of clinic visits associated with acquisition of a new bacterial strain were accompanied by an exacerbation, compared with 15.4% of visits without the acquisition of a new bacterial strain [12]. These findings answer the question as to how it is possible for bacteria to cause exacerbations, while having the same organism present persistently. In addition, they provide a mechanism for bacteria to be pathogenic; the organisms lead to exacerbation once they are of a new strain type, and are able to evade host defences.

More recently, the same authors have found that the acquisition of a new strain is associated with a strain-specific antibody response, at least for new strains of *H. influenzae*, but this phenomenon still needs to be studied for other organisms. They found that if patients acquired a new strain at the time of an exacerbation, a specific antibody response to this strain (by ELISA assay) was present 58.3% of the time, while only 15.2% of exacerbations characterized by the presence of a persistent strain were accompanied by an antibody response [13]. Similar findings were seen when bactericidal antibodies were measured. The specificity of the bactericidal antibody response was demonstrated because only 12% of heterologous strains of *H. influenzae* were killed by new bactericidal antibodies that developed after an exacerbation. These findings are consistent with

previous serological studies that did not demonstrate an antibody response to laboratory strains of *H. influenzae* following an exacerbation because these strains can be viewed as heterologous, and not homologous. In the instance of persistence of a pre-existing strain at the time of exacerbation, the absence of an antibody response implies that another bacteria (to which antibodies were not measured), or a virus, could have caused the exacerbation.

Inflammation and the vicious cycle hypothesis

The presence of bacteria in the airway of the COPD patient is met by an inflammatory response that arises from the bacteria themselves (through the production of exoproducts) and the patient's response to bacteria (primarily through neutrophilic by-products). The presence of bacteria in the airway is associated with a variety of inflammatory cytokines, and the levels of these products are increased when bacteria are present, compared with when they are absent, and when the sputum appears purulent [14,15]. The vicious cycle hypothesis states that the presence of bacteria in the airways initiates inflammation, which in turn injures the lung and the injury propagates favourable growth conditions for the bacteria to persist [16,17]. One by-product of inflammation is neutrophilic elastase, an enzyme that could lead to lung tissue destruction. Thus, the presence of bacteria in the airway could lead to inflammation, which in turn leads to more favourable growth conditions for bacteria, more inflammation and more growth and, as this cycle continues, inflammatory enzymes accelerate the loss of lung function.

In spite of this idea, only one of four prospective studies have shown that a more rapid decline in lung function occurs in patients with more frequent exacerbations (16). More recently, a 4-year study of 109 patients categorized individuals into high and low frequency of exacerbations, and found that those with frequent exacerbations had a faster decline in forced expiratory volume in 1 s (FEV_1) than those with infrequent exacerbations [18]. Although the vicious cycle concept is still unproven in COPD, it is a more clearly established mechanism in patients with another closely related obstructive lung disease, bronchiectasis.

Secondary bacterial infection can follow viral bronchitis

Many patients with AECB have preceding viral infections, which could serve either as the cause of exacerbation, or could create conditions in the airway that predispose to secondary bacterial infection [19]. In a study of 83 patients with COPD, 64% of exacerbations were preceded by cold symptoms within the previous 18 days. In the group as a whole, 39% of exacerbations had a virus detected during

the period of symptoms, and the presence of virus was associated with symptoms of sore throat, but not with any of the symptoms of purulent sputum, increased sputum volume or increased dyspnoea [20]. Of the viruses found, rhinovirus was present in 58% of exacerbations, and the next most common agents were respiratory syncytial virus and coronavirus. Another study used case-control methodology to evaluate 85 patients with AECB and 42 patients with stable COPD [21]. Respiratory viruses were present in the sputum and nasal lavage in 56% of exacerbations and in 19% without exacerbation. The most common viruses were picornavirus, influenza A and respiratory syncytial virus. More recently, Tan *et al.* [22] examined respiratory secretions from 14 patients hospitalized with COPD and used the polymerase chain reaction to detect six common respiratory viruses. Overall, 64% had a virus present, with influenza, picornavirus and adenovirus predominating [22].

If antibiotics are used empirically for AECB, and many patients have documented viral infection, does this mean antibiotics are not of value? This remains uncertain, because antibiotics could prevent secondary bacterial infections that result from the airway changes induced by viral infection. Smith *et al.* [23] observed an increased rate of culturing *H. influenzae* from the respiratory secretions of patients with documented influenza infection. Colonization rates first increased 7 days after influenza infection, and persisted at increased levels for at least 30 days. The authors also observed a similar trend after herpesvirus and rhinovirus infection, but this trend was not as significant as after influenza. In addition, herpesvirus infection was associated with an increased likelihood of bronchial secretions being colonized by *Streptococcus pneumoniae*. More data are needed to determine whether antibiotics can prevent secondary colonization and if so, whether this therapy is associated with less frequent bacterial exacerbations and with clinical benefit.

Outcomes of antibiotic therapy trials in AECB

There are data from a variety of sources that show a benefit for antibiotics in patients with AECB. A number of prospective, randomized, placebo-controlled trials of antibiotics in chronic bronchitis have shown some benefit during acute exacerbations, but no benefit if used to prevent exacerbations [1,2,17]. One recent meta-analysis evaluated nine randomized and placebo-controlled trials of antibiotic therapy in AECB, conducted between 1957 and 1992 [1], and showed a small beneficial effect of antibiotic therapy when the endpoints were overall benefit and change in peak flow rate. Another analysis of placebo-controlled trials for AECB, conducted by Ball [24], reached similar conclusions. A consensus statement of the American College of Physicians and American College of Chest Physicians

evaluated 11 randomized placebo-controlled studies of antibiotics and concluded that this therapy had benefit, but primarily in patients with more severe and symptomatic exacerbations [4,25]. This analysis did recognize that most of the trials were performed in an era before antibiotic resistance was common, and the benefit of new, more broad-spectrum antibiotics could not be directly defined [4,25]. Two other studies of relevance to this issue were not included in any of the large analyses. One was an Italian study comparing amoxicillin/clavulanate to placebo, which showed a benefit for antibiotics, especially for patients with severe lung dysfunction, defined as an FEV_1 of less than 33% of predicted [26]. The other study was a retrospective evaluation of patients discharged from a US emergency department with and without antibiotics, following an acute exacerbation of COPD [27]. In that study, 362 emergency visits were evaluated, and 92 patients did not receive antibiotics, while 270 did. The relapse rate was significantly lower for antibiotic-treated patients compared with those without therapy (19% vs 32%). In addition, there was a trend to fewer hospitalizations for the antibiotic-treated patients. Interestingly, although the failure to use antibiotics led to a higher relapse rate than antibiotic therapy, the use of amoxicillin led to the highest relapse rate of all, implying that an ineffective therapy (which amoxicillin could be, for a variety of reasons) was worse than no therapy. A multivariate analysis supported the finding of reduced relapse risk with antibiotics, implying that even after correcting for confounding factors, antibiotic therapy had benefit.

Probably the best single study of AECB was that of Anthonisen *et al.* [2], reported in 1987 from Canada. A total of 362 exacerbations in 173 patients were evaluated in a placebo-controlled, randomized, double-blinded study design. When patients were treated with an antibiotic, therapy was continued for 10 days, and the antibiotics used were either co-trimoxazole, amoxicillin or doxycycline. The authors used these antibiotics interchangeably, believing that any antibiotic was equally effective, an assumption that may not be correct, because of our current understanding of differences among patients and because of an increased frequency of antibiotic resistance, compared with the early 1980s. In the study, each exacerbation was graded as type I, II or III, according to the number of cardinal symptoms present. Approximately 40% of all exacerbations were the most severe, type I, with all three cardinal symptoms present; 40% were type II with two symptoms present; and 20% were type III, having only one symptom present. Antibiotic-treated patients did significantly better than placebo-treated patients, showing a more rapid return of peak flow, a greater percentage of patients showing clinical success and a smaller percentage showing clinical failure. The benefits of antibiotic therapy

were most clearly evident in patients with at least two cardinal symptoms present: the 80% of individuals with type I or II exacerbations. Patients with type III exacerbations had a high spontaneous resolution rate, and antibiotics were no better than placebo.

The data from Anthonisen *et al.*'s [2] study suggest that antibiotics should be given to patients who have at least two of the three cardinal symptoms present. This is a clinical approach, which is more likely to be useful than simply reserving antibiotics for episodes that are suspected to be bacterial and not viral in origin. Even though as many as half of all episodes are non-bacterial, there are data suggesting that clinical features cannot reliably distinguish these episodes from bacterial exacerbations, although sputum purulence may help [15]. In one study of 54 patients with severe (requiring mechanical ventilation) episodes of bronchial infection complicating COPD, 27 patients had bacteria recovered from the airway, using a bronchoscopic protected specimen brush sampling technique [8]. When patients with secretions containing bacteria were compared with those with sterile secretions, there were no differences with regard to duration of symptoms, fever, white blood cell count or degree of hypoxaemia.

Antibiotics could reduce the burden of bacteria in the airway and prevent pneumonia

Often, a stable bronchitic patient has chronic tracheo-bronchial colonization, but with fewer bacteria than are present during an exacerbation. If a sputum Gram's stain is performed, patients have fewer than two organisms per oil immersion field when stable, but more than 8–18 per field at the time of an exacerbation [28]. Several bronchoscopy studies have examined the concentration of bacteria in the airway of chronic bronchitis patients studied when stable, and during an exacerbation. Monso *et al.* [9] performed protected specimen brush (PSB) sampling in 40 stable outpatients with COPD and 29 outpatients with acute exacerbations. In that study, 25% of the stable patients and 52% of the exacerbation patients had positive respiratory secretion cultures. Quantitatively, patients with an exacerbation had more bacteria, with 24% having more than 10^4 organisms/mL, compared with only 5% of the stable patients having this finding. Similar findings have been made in patients with more severe illness, but the specific bacteria that are present may differ. In one study of 50 mechanically ventilated patients with COPD, 72% had potentially pathogenic organisms present, including *Pseudomonas aeruginosa* or other enteric Gram-negative bacteria in 28% of patients [10]. In another similar study of 54 patients with severe exacerbations, requiring mechanical ventilation, Fagon *et al.* [8] found that nearly half of the patients had more than 10^3 organisms/mL on a PSB sample.

Because PSB has been used to define the presence or absence of pneumonia in hospitalized patients with lung infiltrates, and because a concentration of more than 10^3 organisms/mL is thought to indicate the presence of pneumonia, it is clear that many patients with AECB have as many bacteria in their airway as if they had pneumonia. These observations suggest that for a more severe exacerbation, associated with a high concentration of bacteria, antibiotics could theoretically reduce this bacterial burden, and possibly prevent some patients from progressing to parenchymal lung infection (such as pneumonia). In support of this possibility is one study of 93 patients with severe exacerbations who were randomized to an antibiotic (ofloxacin) or placebo while managed in the hospital with mechanical ventilation. The antibiotic-treated patients had a significantly lower in-hospital and intensive care unit (ICU) mortality, primarily related to the avoidance of pneumonia [29]. In fact, significantly fewer antibiotic-treated patients developed pneumonia, compared with placebo-treated patients, and the need for additional antibiotics was lower for the antibiotic-treated patients. Thus, for severe exacerbations, antibiotics are clearly beneficial, primarily by reducing bacterial burden and preventing pneumonia.

The relationship of pneumonia to AECB

While some patients with AECB may progress to pneumonia, and antibiotics are potentially useful to avoid this complication, the distinction between airway and parenchymal infection in COPD patients is sometimes unclear. In 1996, Torres *et al.* [30] documented that pneumonia is common in certain COPD patients. Among 124 COPD patients with community-acquired pneumonia, the mean age was 56 years, 19% had chronic respiratory failure (hypoxaemia or hypercarbia), 25% had a previous episode of pneumonia, and the mean FEV_1 was 40% of predicted normal. Almost all patients had symptoms of fever (83%), increased dyspnoea (93%) and cough (85%). The predominant pathogen was pneumococcus (in 43% of those with an aetiological diagnosis), followed by *Chlamydia pneumoniae* (12%), *Haemophilus influenzae* (9%) and *Legionella pneumophila* (9%).

Lieberman *et al.* [31] have recently reported their experience with 219 patients with symptomatic exacerbations of COPD and compared the clinical risks and presenting features of those with pneumonia during an exacerbation and those with no lung infiltrate. The population had at least one of the three cardinal symptoms of exacerbation, but there was no significant difference in the number of symptoms present when the patients had pneumonia, compared with when they did not. Overall, 26% of the pneumonia patients and 22% of the non-pneumonic patients had a type III exacerbation, with only one of the three cardinal

symptoms present. Thus, if antibiotics were withheld in all COPD patients with only one such symptom, some with pneumonia would not have been treated. Thus, to identify this population, a chest radiograph is needed. The patients who did have pneumonia had an abrupt onset of symptoms, fever, focal crepitations on examination and severe hypoxaemia more often than those without pneumonia. Those with pneumonia had a higher mortality rate, a greater need for mechanical ventilation and a longer duration of hospitalization. Based on these findings, it may be important to realize that the distinction between pneumonia and acute airway infection is often difficult to make clinically but, because the outcomes are so different, a chest radiograph may be valuable to identify rapidly those with parenchymal lung infection. Given the difficulty of clinically separating pneumonia from bronchitis in the COPD patient and the ability of antibiotics to prevent some patients from developing pneumonia, the value of antibiotics for those with severe exacerbations seems clear.

Likely bacteria in AECB and the frequency of antibiotic resistance

Spectrum of pathogens and the frequency of antibiotic resistance

The exact frequency of bacterial infection in AECB is debated, and the role of viruses, allergens and airway irritants in exacerbations is difficult to estimate. However, as many as half of all exacerbations may be associated with bacteria and the three most common organisms present during AECB are *H. influenzae*, pneumococcus and *M. catarrhalis*, with the frequency of these organisms, and the likelihood that they are antibiotic resistant, varying with the country, specific patient features and the severity of exacerbation. In outpatients with exacerbations of mild severity, *H. influenzae* predominates, followed by the other organisms (pneumococcus and *M. catarrhalis*), but Gram-negative infection is relatively uncommon [9]. In patients with severe exacerbation, *H. influenzae* is less common, with *H. parainfluenzae* being the most common organism isolated from bronchoscopy samples, and Gram-negative bacteria are also frequently isolated [8].

Haemophilus influenzae is generally the most common isolate in patients with AECB, but is usually non-encapsulated and thus non-typable. In recent years, these organisms have developed a high frequency of beta-lactamase production, with as many as 40% having these enzymes present, a finding which makes traditional beta-lactam antibiotics (such as ampicillin or amoxicillin) potentially ineffective. While as many as 40% of *H. influenzae* produce this enzyme, some organisms produce so much of this product that they

can even be resistant to amoxicillin/clavulanate [32]. In addition, in one study, 2.5% of these organisms were ampicillin resistant through another mechanism, alteration of penicillin-binding proteins [32]. Beta-lactamase production is even more common with *M. catarrhalis*, and one study found these enzymes in 95% of 723 isolates [33]. If infection with this Gram-negative coccus is likely, then beta-lactam resistance should be assumed to be present.

Pneumococcal resistance to common antibiotics is increasingly frequent, being present in as many as 40% of all isolates, although much of this resistance is intermediate and not high-level resistance, and thus the implications of resistance to antibiotic therapy are uncertain [34,35]. Resistance is more likely if patients have identified risk factors, including: age over 65 years, alcoholism, beta-lactam therapy within the past 3 months, multiple medical comorbidities and immunosuppressive illness [35,36]. In addition, resistance can occur to multiple other antibiotic classes, including macrolides and quinolones. Throughout the 1990s, the frequency of macrolide-resistant pneumococcus rose to over 30%, but in the USA, much of this was caused by an efflux-mediated mechanism (*mef* gene) allowing the bacteria to remove the antibiotic from the cytoplasm, rather than altered binding of the macrolide to the bacterial ribosome (*erm* gene) [37]. The magnitude of resistance associated with the *mef* mechanism is much lower than the magnitude of resistance due to the *erm* mechanism, and this may explain why macrolides have generally continued to be successful for the therapy of AECB and community-acquired pneumonia (CAP) [38]. Efflux resistance may not be clinically relevant because it is a relatively low level of resistance, but also because it may be overcome by adequate dosing of macrolides, combined with good penetration at the site of infection.

In recent years, the use of quinolones has exploded, often in situations where they are not indicated [39], and consequently pneumococcal resistance to these agents has begun to emerge. Among the commonly used quinolones for AECB, the relative activity against pneumococci, from most to least active is: gemifloxacin, moxifloxacin, gatifloxacin, levofloxacin and ciprofloxacin [40,41]. Pneumococcal resistance has occurred most commonly to the least active pneumococcal agents, but appears to be a particular problem for the COPD patient. In adults, the airway of the COPD patient has been the breeding ground for pneumococcal resistance to a variety of agents, including the new quinolones [42]. This can be explained because these patients are chronically colonized, frequently immunosuppressed (with corticosteroids), elderly and exposed to repeated courses of antibiotics, and all of these factors are known to promote the emergence of antibiotic resistance [36]. One concern has been that repeated exposures to less active agents can promote resistance to the entire class of

quinolones [43], and thus there may be some advantage to selecting the most active anti-pneumococcal agent in the class in an effort to assure efficacy and minimize the subsequent emergence of resistance.

In a large number of studies, investigators have found that recent exposure to any antibiotic predicts subsequent pneumococcal resistance to that same class of antibiotics. This finding has been shown for beta-lactams, if used within the last 3 months [36]; macrolides (although only for the *mef* mechanism of resistance) [37]; and quinolones, if used in the last 12 months [42]. One recent study has found that use of macrolides or beta-lactams within the past 6 months predisposes patients with bacteraemic pneumococcal pneumonia to a high rate of infection with penicillin non-susceptible organisms [44]. Interestingly, this finding did not apply to recent quinolone use, but even if quinolones do not promote penicillin-resistant pneumococci, repeated use can predispose to quinolone-resistant pneumococci [45]. In view of these data, one strategy for minimizing future resistance in pneumococci for the AECB patient is 'patient-specific antibiotic rotation', a strategy that requires the patient to be treated for subsequent exacerbations with a different class of antibiotic than was used in previous exacerbations. The value of this approach still needs confirmation but, in the past, many patients with AECB received the same antibiotic repeatedly, for multiple exacerbations, and this approach may have been driving antibiotic resistance to a high frequency in this population.

The role of atypical pathogens in AECB is uncertain, but some studies have found a high frequency of infection with *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* in exacerbation patients, and these pathogens may coexist with bacterial pathogens [46]. In one study, patients with positive serology for *C. pneumoniae* at the time of exacerbation had the same frequency of cough, dyspnoea, fever, sputum production, tachypnoea and tachycardia as patients with negative serology [46]. These findings do not definitively establish an aetiological role for these organisms, and many therapy trials have not shown superiority when an antibiotic regimen is used that covers atypical organisms, compared with one that does not.

Enteric Gram-negative bacteria, including *Pseudomonas aeruginosa*, have also been isolated from some patients with AECB [47,48]. Although the frequency of these pathogens is not high in all patients, they are much more common in those who are admitted to hospital, especially in patients with severe airflow obstruction and in those with respiratory failure requiring mechanical ventilation [47,48]. In fact, when patients had an $FEV_1 \leq 35\%$ of predicted, more than half of the pathogens isolated from patients admitted with an exacerbation in one study had Gram-negative organisms present, including *P. aeruginosa* [47]. Although not all investigators have confirmed this finding, these

organisms have also been reported to be more common in patients with an FEV_1 of less than 50% than in patients with better lung function [48], and these organisms were present in nearly 30% of patients with severe exacerbations requiring mechanical ventilation [10].

Relationship of bacteriology to specific patient features

The identity of the likely bacterium present during an acute exacerbation is variable and related to a number of patient features including: severity of exacerbation, age (≥ 65 years), frequency of exacerbations, presence of comorbid cardiopulmonary disease, frequency of antibiotic therapy, use of corticosteroids and the severity of obstructive airways disease (FEV_1 as a percentage of predicted) [5,6,47,48].

Bronchoscopic studies have shown that as the severity of exacerbation increases, the bacteriology of the exacerbation becomes more complex, involving more Gram-negatives, and more antibiotic-resistant pathogens. For stable outpatients with AECB, the three common 'core organisms' (*H. influenzae*, pneumococcus and *M. catarrhalis*) predominate. However, in patients requiring mechanical ventilation for AECB, Gram-negative organisms are seen with increasing frequency [8,10]. In addition, these organisms are also more common in patients with severe airflow obstruction, defined in different studies as an FEV_1 (as % predicted) below 50% or 35% [47,48].

Other studies have identified the frequency of exacerbations and the presence of comorbid cardiopulmonary disease as factors to be considered in defining patients who are infected with pathogens that are difficult to treat with standard antibiotic therapy. In one study of 471 outpatients with AECB, the likelihood of a patient having a recurrence after therapy for exacerbation was related to the presence of underlying cardiopulmonary disease, and the history of how many exacerbations were present in the preceding year [6]. If patients had less than three exacerbations per year, then the recurrence rate was 9.1%, compared with a 13.1% rate in those with 3–4 exacerbations per year and 18.4% in those with more than four exacerbations per year. A factor such as age is also important in predicting bacteriology, because age over 65 years has been identified as a risk factor for airway colonization by Gram-negative organisms, and for antibiotic resistance if pneumococcus is present [35,36,49].

In one recently published guideline for antibiotic therapy of AECB, many of these patient features were used to predict the likely pathogens causing exacerbation [5]. Such stratification serves two purposes: first, to predict the likely pathogens and the likelihood of antibiotic resistance and, secondly, to identify patients who may do poorly with an exacerbation if not given a rapidly effective therapy. For

stratification purposes, complicated AECB patients, at risk for beta-lactam resistance and Gram-negative infection, are those with FEV_1 of less than 50% predicted, more than four exacerbations per year, cardiac disease, use of home oxygen, chronic oral steroid therapy and use of antibiotics in the past 3 months. Patient features that make *Pseudomonas* and multidrug-resistant Gram-negative organisms more likely are the presence of an FEV_1 of less than 35% predicted or the presence of more than one of the risk factors listed above.

Principles of antibiotic use

Mechanisms of bacterial killing

Antibiotics disrupt bacterial growth by preventing the formation of an intact cell wall, by interfering with protein synthesis or by inhibiting common metabolic pathways [50,51]. Agents that interfere with cell wall synthesis or with other key metabolic functions of the organism can kill bacteria and are termed 'bactericidal'. These agents include penicillins, cephalosporins, aminoglycosides, fluoroquinolones, vancomycin, rifampin and metronidazole. Agents that inhibit the growth of bacteria and rely on host defences to eliminate the organisms are termed 'bacteriostatic' and these agents include the macrolides, tetracyclines, sulfa drugs, chloramphenicol and clindamycin. The distinction between bacteriostatic and bacteriocidal agents may be most relevant in patients with impaired neutrophil function (neutropenia) or in those with deep-seated infections such as endocarditis or meningitis. However, in the therapy of AECB, these distinctions may not be clinically relevant, and the value of an agent is probably best predicted by its activity against the aetiological pathogen. In fact, in one analysis, there was a strong correlation ($r = 0.9$) between the ability of an antibiotic to eradicate an organism from the sputum with the clinical response rate, regardless of the mechanism of bacterial killing [52]. These findings suggest that the activity of an antibiotic, relative to the susceptibility of the aetiological pathogen, is the most important determinant of clinical outcome.

The activity of an antimicrobial agent can be defined by the minimum inhibitory concentration (MIC) required to inhibit *in vitro* the growth of 90% of a standard sized inoculum in broth culture. The lower the MIC number is, the more active an agent is against its target pathogen. However, the use of MIC values to predict antimicrobial effect only takes into account whether an agent can achieve adequate levels in serum. When an infection is in the airways, as in patients with AECB, then the MIC value may not adequately predict killing in the lung. Thus, if an agent penetrates well into respiratory secretions (such as a

quinolone) and its concentrations in the airway exceed serum levels, the MIC values may underestimate the antibacterial effect [53]. Conversely a poorly penetrating agent (such as an aminoglycoside) may be less effective clinically at certain sites of respiratory infection than expected on the basis of *in vitro* MIC values.

Even if an antibiotic reaches the site of airway infection, not all bactericidal agents kill bacteria in the same fashion, and this information should be used to optimize dosing regimens [54]. Certain agents, especially the quinolones and aminoglycosides, kill bacteria in what has been described as a 'concentration dependent fashion', meaning that the higher the serum level relative to the MIC and the higher the area under the concentration–time curve (AUC) relative to the MIC, the more effective the agent. Optimization of the peak/MIC ratio or the AUC/MIC (defined as the area under the inhibition curve, or AUC), can lead to more rapid killing of bacteria and less chance of selecting for resistance [53–55]. In theory, the optimal way to administer these agents would be to take a 24-h dose and administer it once a day to achieve high peak concentrations. In addition, increasing the dosage to the highest level tolerated can also optimize these pharmacokinetic parameters. In the case of quinolone therapy of pneumonia, increasing the dosage of ciprofloxacin or levofloxacin to 400 mg every 8 h or 750 mg/day, respectively, has led to more rapid resolution of symptoms and the ability to eradicate organisms that would be unable to be eradicated at lower doses [56,57]. However, there are agents that do not achieve a greater effect with higher concentrations, but rather kill in relation to how long they exceed the MIC of the target organism, and the activity of these agents can be enhanced by maximizing time above the MIC of the target organism. For these drugs, optimal effect could be achieved by prolonged serum concentrations that are above the MIC, but it is not necessary to have these concentrations exceed the MIC value by more than a factor of 4, or to exceed the MIC of the target organism for more than 40% of the dosing interval [54]. Optimal dosing of these agents could be achieved with prolonged release preparations (such as the new formulation of amoxicillin/clavulanate), or by continuous intravenous infusion.

Craig [54] has recently reviewed and clarified some of these concepts related to bactericidal killing mechanisms. Agents that kill in a concentration-dependent fashion include the aminoglycosides, the fluoroquinolones and metronidazole (Table 60.2). Studies with quinolones have shown that in the therapy of pneumococcus with levofloxacin, both clinical and microbiological success were more likely if the peak/MIC ratio exceeded 12 [55]. In addition, it is necessary to maintain a peak/MIC ratio of at least 8–10 to prevent the emergence of resistance during therapy [53–55]. In studies of critically ill patients with

ciprofloxacin, the best predictor of clinical and microbiological efficacy against *P. aeruginosa* was an AUC/MIC ratio of at least 125 [58]. The efficacy of aminoglycosides has also been related to both the AUC/MIC and peak/MIC ratios [54]. Agents that kill in a time-dependent fashion have a saturation of killing effect once the concentrations exceed 4–5 times the MIC, and time of exposure above MIC is the key to their effect. In this group of antimicrobials are beta-lactam antibiotics, vancomycin, clindamycin and the macrolides. In designing dosing regimens, it is important to realize that it may not be necessary to keep the concentration of antibiotics above the MIC for the entire dosing interval. Craig [54] has shown in animal models that with penicillins and cephalosporins, bacteriological cure will occur 85–100% of the time if the concentration of these agents exceed the MIC for at least 40% of the dosing interval. Maximal killing occurs once concentrations exceed the MIC for 60–70% of the dosing interval.

Another killing mechanism that may have relevance for some antibiotics is the postantibiotic effect (PAE), which refers to the continued suppression of bacterial growth after the concentration of the antibiotic falls below the MIC of the target organism [54]. While most antibiotics have a PAE against Gram-positive organisms, prolonged PAEs against Gram-negative organisms occur with the aminoglycosides, quinolones, tetracyclines and macrolides. Little or no PAE against Gram-negative organisms occurs with beta-lactam agents with the exception of the carbapenems (imipenem and meropenem). Fortunately, the agents with a prolonged PAE tend to be the same agents that kill in a concentration-

dependent fashion, and this is why once daily dosing of agents such as the aminoglycosides has been successful [59]. With once daily dosing, high peaks are achieved, thus maximizing concentration-dependent killing; low troughs result, thus minimizing nephrotoxicity; and the prolonged PAE is relied upon to keep killing bacteria at the times when low trough concentrations occur. A recent meta-analysis has shown the efficacy and safety of once daily aminoglycoside dosing, although this type of regimen is not substantially safer or more effective than traditional regimens [59]. In the therapy of complicated AECB, aminoglycosides are sometimes required, but aerosol therapy is now an option, and this approach may overcome some of the concerns with the dosing and toxicity of systemic aminoglycosides.

Penetration to site of infection and route of administration

In the therapy of AECB, the antibiotic must reach the bronchial mucosa, the primary site of infection, in order to be effective. Antibiotics can concentrate in a variety of sites in the lung, including the sputum, the bronchial epithelium, the lung parenchyma, the epithelial lining fluid and phagocytic cells [60]. Although it is unclear which site is most relevant in the therapy of AECB, concentrations in the mucosa and sputum are probably the most important. Some drugs reach lung tissue only when inflammation is present, while others, primarily lipid-soluble agents, are inflammation independent and can penetrate in the absence of increased capillary permeability. These lipid-soluble agents include the macrolides, tetracyclines, quinolones and co-trimoxazole, and all of these agents can achieve good penetration into the sputum or the bronchial mucosa. Penetration of the antibiotic is reflected by how high the sputum level is, relative to the MIC of the target organism. For a quinolone such as ciprofloxacin, the sputum/MIC ratio for *H. influenzae* and *M. catarrhalis* exceeds a value of 60. The macrolide azithromycin has a sputum/MIC ratio for *H. influenzae* and pneumococcus that also exceeds 60. Although the ratio for clarithromycin against *H. influenzae* is considerably lower, the ratio for the agent against pneumococcus exceeds a value of 250 [61]. In addition, agents such as the macrolides, quinolones and clindamycin are actively transported into phagocytic cells and achieve very high levels at this site. The clinical relevance of these findings remains uncertain, but may explain why some agents remain clinically effective when good bronchial penetration occurs even when serum levels are not high, relative to the MIC of the target organism. The agents that are relatively lipid insoluble, and thus penetrate poorly and are inflammation dependent include the aminoglycosides, the penicillins and the cephalosporins (Table 60.3).

The route of administration may also impact on phar-

Table 60.3 Penetration of common antibiotics into respiratory secretions.

macokinetics and respiratory concentrations. If an agent is given intravenously, the serum levels peak rapidly, while oral administration generally leads to a lower peak level, but antibiotics can be formulated for slow release after oral administration, and allow for prolonged concentration in the serum (as with extended-release preparations of amoxicillin/clavulanate and clarithromycin). One way to avoid concerns about antibiotic penetration is to deliver the antibiotic via the aerosol route. There are no good studies of this approach in AECB, but aerosolized aminoglycosides have been used as adjunctive therapy for pneumonia and nosocomial tracheobronchitis, as well as for exacerbations of airway diseases such as bronchiectasis and cystic fibrosis [62]. In one placebo-controlled trial, inhaled tobramycin was used twice daily for 4 weeks in bronchiectasis patients who were colonized with *P. aeruginosa*, and the treatment led to a reduction in bacterial count but no change in the frequency of exacerbation or antibiotic use; however, the number of patients studied was small [62].

Ease of use of common antibiotics and frequency of administration

As with any therapy, the patient must complete a full course of therapy with an antibiotic to assure maximal efficacy. Previous studies have shown that compliance with short-term antibiotic regimens ranges from 56% to 89% [63]. Patients are less likely to comply with a prescribed regimen if they are already taking multiple medications, if side-effects occur, if dosing is more than twice a day, if use conflicts with their lifestyle and if the consequences of non-compliance seem minimal. In a Gallup survey, 54% of all Americans reported that they did not finish a course of antibiotics as prescribed. In fact, 54% stopped antibiotics once they felt better, even if they had not finished a full course of therapy [64]. In addition, many reported missing a scheduled dose. When questioned, 82% of the respondents preferred an antibiotic that can be given once

or twice a day, and only 5% were willing to be treated for a 14-day course [64].

These findings should be considered when prescribing an antibiotic for AECB. Fortunately, a number of appropriate antibiotics can be given once or twice daily. Once daily dosing is available with azithromycin and extended-release clarithromycin, telithromycin and the new quinolones (gatifloxacin, levofloxacin and moxifloxacin). Other oral antibiotics are also available for once daily dosing, but do not represent ideal drugs from an antimicrobial spectrum and these include cefixime, ceftibutin and dirithromycin. Twice daily dosing is available with amoxicillin/clavulanate, cefpodoxime, cefprozil, ceftibutin, cefuroxime, ciprofloxacin, clarithromycin, doxycycline, ofloxacin and co-trimoxazole. In general, patients with AECB should receive one of these agents because it is unlikely that an agent given more often will be taken as prescribed.

Duration of therapy

Most clinical trials in AECB have used durations of therapy of 7–10 days. However, a number of recent trials have successfully used shorter durations of therapy, especially with agents that are active against drug-resistant pathogens. Thus, 5 days of therapy has been adequate for the new quinolones, the ketolide telithromycin, and 3-day therapy has been effective for azithromycin and quinolones, in selected populations [65–72].

Desired features of an ideal antibiotic for AECB

Although a current evidence-based consensus statement concluded that all antibiotics are equivalent in AECB, there may be some advantages to specific agents, particularly in certain patient populations [5]. However, this is difficult to prove, because most studies of AECB therapy have been conducted for the purposes of licensing a new antimicrobial and have been designed to include just enough patients to show equivalence between the tested agents. In addition, these antibiotic trials have rarely defined different therapies for different types of patients, lumping patients of all disease severity together in one clinical trial. Several newer trials, described below, have suggested that certain agents may have value over other agents for specific patient populations [67,73,74]. Ideally, an antibiotic that is used for AECB should have several features (Table 60.4):

- 1 Activity against the most common and most likely (for each patient type) aetiological pathogens, but certainly with activity against *H. influenzae*, pneumococcus and *M. catarrhalis*;
- 2 resistance to destruction by bacterial beta-lactamases;
- 3 good penetration into the sputum and bronchial mucosa;
- 4 easy to take (no more than twice daily), with few side-effects; and

Table 60.4 Characteristics of the ideal antibiotic for acute exacerbations of chronic bronchitis.

Active against the likely pathogens for each patient type:

- Always active against pneumococcus, *Haemophilus influenzae*, and possibly atypical pathogens
- In selected patients, active against resistant organisms and enteric Gram-negative bacteria

Resistant to destruction by bacterial beta-lactamases (*H. influenzae* and *Moraxella catarrhalis*)

Good penetration into sputum and bronchial tissue

- High sputum/MIC ratio against target organisms

Likelihood of compliance with the prescribed regimen is high: once or twice daily dosing, few side-effects

Cost effective

- Prevention of hospitalization, prolonged time between exacerbations

MIC, minimum inhibitory concentration.

- 5 cost effective, considering factors such as prevention of hospitalization and prolongation of time between exacerbations.

Properties of specific antimicrobial agents

A number of agents are commonly used to treat patients with AECB. They generally fall into the following drug classes: macrolides and azalides (erythromycin, clarithromycin and azithromycin), tetracyclines, ketolides, co-trimoxazole, beta-lactams (penicillins and cephalosporins) and fluoroquinolones.

Macrolides

Macrolides are bacteriostatic agents that bind to the 50S ribosomal subunit of the target bacteria and inhibit RNA-dependent protein synthesis. The macrolides have good activity against pneumococci, as well as atypical pathogens (*C. pneumoniae*, *M. pneumoniae*, *Legionella*), but the older erythromycin-type drugs are not active against *H. influenzae*, can interact with theophylline to increase levels and have poor intestinal tolerance, making it difficult to use these agents in patients with AECB. The newer macrolide agents include azithromycin (also referred to as an azalide) and clarithromycin. These agents have enhanced activity against *H. influenzae* (including beta-lactamase producing strains) although, on an MIC basis, azithromycin is more active [50,51]. The macrolides are also active against *M. catarrhalis*, although the newer agents have enhanced

activity against this pathogen compared with the older agents. Among the newer macrolides, azithromycin is more active than erythromycin against not only *H. influenzae* and *M. catarrhalis*, but also *M. pneumoniae*. However, clarithromycin is more active against *S. pneumoniae*, *Legionella* and *C. pneumoniae* [50,51]. Azithromycin has no theophylline interaction, while clarithromycin has the same potential for interaction as erythromycin.

Both of the newer agents have better intestinal tolerance than erythromycin and penetrate well into sputum, lung tissue and phagocytes. Clarithromycin, which has an active 14-hydroxy metabolite that is antibacterial, is administered twice a day orally at a dose of 500-mg for 7–10 days in the treatment of AECB. A new preparation of extended-release clarithromycin is administered as a 1000-mg dose once daily and has been effective with a 7-day course of therapy [75]. Azithromycin has a longer half-life than clarithromycin, and concentrates in tissues, achieving very low serum levels when administered orally. The dose for oral therapy of AECB is 500 mg on day 1, followed by 250 mg/day on days 2–5. Alternatively, this drug can be administered for AECB in a dosage of 500 mg/day for 3 days, and this regimen has efficacy comparable to other agents administered for a longer duration [69,70]. For the hospitalized patient, an intravenous preparation of azithromycin is available and is administered at 500 mg/day, with the duration defined by the clinical course of the patient

Although macrolides remain an important therapeutic option for AECB, pneumococcal resistance is becoming increasingly common, being present in as many as 35–40% of all pneumococci [37]. In addition, macrolide resistance can also coexist with penicillin resistance, and as many as 30–40% of penicillin-resistant pneumococci are also erythromycin resistant [36,37]. The clinical relevance of these *in vitro* findings remains to be defined. However, there are two forms of macrolide resistance: one involving efflux of the antibiotic from the bacterial cell, and the other involving altered ribosomal binding of the antibiotic. The former mechanism is associated with much lower levels of resistance than the latter, and is present in two-thirds of the macrolide-resistant pneumococci in the USA. The latter form of resistance is fortunately less common because, if present, it is unlikely that macrolide therapy for pneumococcal infection would be effective.

Clinical trials of macrolides in AECB have documented efficacy for clarithromycin (including the extended-release preparation) and azithromycin [69,70,75,76]. In general, these agents have been equivalent to other classes of antibiotics, including quinolones (azithromycin versus levofloxacin and moxifloxacin, clarithromycin versus gatifloxacin), and beta-lactams (clarithromycin and azithromycin equivalent to amoxicillin/clavulanate) [65,70,76–79]. In spite of general equivalence to other, newer agents, in one

retrospective analysis, azithromycin was among a group of antibiotics that led to less relapses and a prolonged duration of time from one exacerbation to the next compared with older agents, in patients with recurrent exacerbations [73]. However, in a comparative study with a quinolone (gemifloxacin), clarithromycin was less effective in preventing relapses, particularly if the pathogen was *H. influenzae* [67].

Macrolides have other effects beyond their antibacterial action, and may be anti-inflammatory, reducing the amount of sputum production in chronic bronchitis patients [80]. The role of macrolides in preventing exacerbations of COPD through their anti-inflammatory actions is unknown, but chronic macrolide therapy has been shown to reduce the frequency of exacerbations in patients with cystic fibrosis [81].

Tetracyclines

The tetracyclines, like the macrolides, are also bacteriostatic agents, which act by binding the 30S ribosomal subunit and interfering with protein synthesis. These agents can be used in AECB because they are active against *H. influenzae* and atypical pathogens, but there are reports of increasing resistance among pneumococci [50,51]. In the USA, pneumococcal resistance to tetracyclines may be approaching 20%, and may exceed 50% among organisms with high-level penicillin resistance [5]. Photosensitivity is the major side-effect, limiting the use of these agents in sun-exposed patients.

Ketolides

This new class of antibiotics is a semi-synthetic derivative of the macrolides, with a 14-member ring structure, and substitution of a keto group at the C3 site. These agents act to inhibit ribosomal protein synthesis in bacteria, by binding to two different sites on the 50S ribosomal subunit and, because of enhanced binding affinity and the binding to multiples sites, are able to avoid some of the resistance problems associated with the macrolides [82]. In addition, this class of antibiotics has a poor affinity for the pneumococcal efflux pump. Because of these characteristics, ketolides are active against pneumococci that are macrolide resistant by either the *erm* or *mef* mechanism. Ketolides are also active against *H. influenzae*, but *in vitro* activity is not quite as high as with azithromycin. In clinical trials, the eradication rate of *H. influenzae* by telithromycin has been 84% [82]. In addition, these agents have activity against the atypical pathogens. Ketolides concentrate well in the respiratory tract and in white blood cells, and kill bacteria in a concentration-dependent fashion, unlike the macrolides which kill in a time-dependent manner. In clinical trials, a ketolide, telithromycin, has been evaluated and has been administered at 800 mg/day for 5 days. This regimen has been compared with a 10-day course of amoxicillin/

clavulanic acid (500 mg t.i.d.) or cefuroxime (500 mg b.i.d.) and found to be equivalent [66,82]. Telithromycin was as active as comparators in patients above the age of 65 years, in those with worse lung function and in those with multiple comorbid illnesses. Bacteriological success was equivalent to comparators when the infecting pathogen was either pneumococcus or *H. influenzae* [82]. Side-effects are primarily intestinal with nausea and diarrhoea occurring in some patients, but liver function abnormalities and cardiac QT prolongation have been reported, but are uncommon. There does not appear to be an interaction with theophylline.

Co-trimoxazole

This combination antibiotic has been used as a mainstay for the therapy of AECB because of its antimicrobial spectrum, ease of use and low cost [83]. It has bactericidal activity against pneumococcus, *H. influenzae* and *M. catarrhalis*, but not against atypical pathogens. Recently, it has become less popular because of the emergence of pneumococcal resistance at rates of at least 30%, because 80–90% of organisms that are penicillin-resistant are also resistant to co-trimoxazole [36]. The sulfa component of the drug inhibits the bacterial enzyme responsible for forming the immediate precursor of folic acid, dihydropterotic acid. Trimethoprim is synergistic with the sulfa component because it inhibits the activity of bacterial dihydrofolate reductase. Co-trimoxazole is available in a fixed combination of 1 : 5 (trimethoprim : sulfamethoxazole), and is given as either 80/400 or 160/800 mg orally twice a day for 10 days, but the dosage should be adjusted in renal failure. An intravenous preparation is also available. Side-effects generally result from the sulfa component and include rash, gastrointestinal upset and occasional renal failure (especially in elderly patients).

Beta-lactam antibiotics

These bactericidal antibiotics, which include the penicillins, cephalosporins and other agents, have in common the presence of a beta-lactam ring, which is bound to a five-membered thiazolidine ring in the case of the penicillins and to a six-membered dihydrothiazine ring in the case of the cephalosporins [50,51]. Modifications in the thiazolidine ring can lead to agents such as the penems (imipenem and meropenem), while absence of the second ring structure characterizes the monobactams (aztreonam). These agents can also be combined with beta-lactamase inhibitors such as sulbactam, tazobactam or clavulanic acid to create the beta-lactam/beta-lactamase inhibitor drugs. These combination agents extend the antimicrobial spectrum of the beta-lactams by providing a substrate (sulbactam, clavulanic acid, tazobactam) for the bacterial beta-lactamases, thereby preserving the antibacterial activity of the parent compound. Beta-lactam antibiotics work by interfering with

the synthesis of bacterial cell wall peptidoglycans by binding to bacterial penicillin-binding proteins.

The penicillins used for AECB include the aminopenicillins (ampicillin, amoxicillin) and the beta-lactam/beta-lactamase inhibitor combinations. The anti-pseudomonal penicillins (piperacillin, ticarcillin) are available only intravenously, and as a beta-lactamase inhibitor combination (piperacillin/tazobactam, ticarcillin/clavulanate) and are not commonly used for AECB. The beta-lactamase inhibitor combination most commonly used for oral therapy of AECB is amoxicillin/clavulanate. The addition of clavulanic acid makes this agent resistant to bacterial beta-lactamases, an important concern in patients with AECB, but some *H. influenzae* organisms can hyperproduce these enzymes and even be resistant to amoxicillin/clavulanate [33].

Amoxicillin/clavulanate had been given as 500/125 mg t.i.d or 875/125 mg b.i.d. for 10 days, and has been effective therapy for AECB. Clinical trials have shown equivalence to azithromycin and to moxifloxacin, when given for 7–10 days [26,83–85]. It may offer an advantage over amoxicillin alone, because this agent is susceptible to destruction by bacterial beta-lactamases, a feature that may explain the observation of high failures rates with amoxicillin (54%) but not with amoxicillin/clavulanate (9%) in patients presenting to an emergency department with AECB [27]. Recently, with concerns about pneumococcal resistance, a new preparation of amoxicillin/clavulanate has been developed with a slow release formulation and with more amoxicillin relative to clavulanate, and the dosage is 2000/125 mg b.i.d. This new preparation would be active against resistant pneumococci with MIC values of at least 2 mg/L. Although this high-dose preparation is not approved in the USA for AECB therapy, clinical trials have shown efficacy similar to levofloxacin and clarithromycin [78].

The cephalosporins span from first to fourth generation, but the fourth-generation agents are not available for oral therapy of AECB [83,86]. The earlier agents were generally active against Gram-positive organisms, but did not have extended activity for the more complex Gram-negative organisms, or anaerobes, and were susceptible to destruction by bacterial beta-lactamases. The newer generation agents are generally more specialized, with broad-spectrum activity and with more mechanisms to resist breakdown by bacterial enzymes. The second-generation and newer agents are resistant to bacterial beta-lactamases, and the oral agents that are active against resistant pneumococci include cefuroxime, cefprozil and cefpodoxime [86]. The intravenous third- and fourth-generation agents active against penicillin-resistant pneumococci include ceftriaxone, cefotaxime and cefepime, while ceftazidime is less reliable against this organism. Intravenous agents are occasionally used in hospitalized patients, and cefepime and ceftazidime have activity against *P. aeruginosa*. Although cephalosporins

have been used successfully to treat AECB, they have not always been as successful as quinolones, amoxicillin/clavulanate and the macrolides in patients with recurrent infections [73], but have been effective at preventing relapses in AECB among patients seen in an emergency room setting [27].

Fluoroquinolones

These bactericidal agents act by inhibiting bacterial DNA gyrase and thus interfere with DNA replication, repair, transcription and other cellular processes [40,53]. DNA gyrase is only one form of a bacterial topoisomerase enzyme that is inhibited by quinolones, and activity against other such enzymes is part of the effect of a variety of quinolones [40,83]. The earlier quinolones (such as ciprofloxacin and ofloxacin) are active primarily against DNA gyrase, which accounts for their good activity against Gram-negative organisms. The newer agents (gatifloxacin, gemifloxacin, levofloxacin and moxifloxacin) bind both DNA gyrase and topoisomerase IV, and have extended their activity to Gram-positive organisms, including drug-resistant *Streptococcus pneumoniae* (DRSP). Resistance to quinolones can occur through mutations in the topoisomerase enzymes, by altered permeability of the bacterial cell wall or by efflux. The quinolones kill in a concentration-dependent fashion, and thus optimal antibacterial activity can be achieved with infrequent dosing, and with high peak concentrations and high AUCs. In addition, because quinolones have a PAE against both Gram-positive and Gram-negative organisms, they can continue to kill even after local concentrations fall below the MIC of the target organism [53]. These properties make the quinolones well-suited to infrequent dosing, with the ideal being once daily dosing, particularly given the relatively long half-life of the newer compounds. The only factor limiting a switch to once daily dosing for all quinolones is the toxicity associated with high doses of some agents (such as ciprofloxacin), particularly concerns related to neurotoxicity and possible seizures.

There are two features of quinolones that make them well-suited to respiratory infections. First, they penetrate well into respiratory secretions and inflammatory cells, achieving concentrations that usually exceed serum levels, and thus these agents may be clinically more effective than predicted by MIC values. This may explain the observation that quinolones are often better than other agents in prolonging the 'disease-free' interval between exacerbations [87]. Secondly, these agents are highly bioavailable with oral administration and thus similar levels can be reached if administered orally or intravenously. This has allowed some patients to remain on oral therapy out of the hospital and still receive a highly active antimicrobial regimen.

The fluoroquinolones have excellent antimicrobial activity against beta-lactamase producing *H. influenzae*

and *M. catarrhalis*, making them very useful for patients with AECB. However, the newer agents (gatifloxacin, gemifloxacin, levofloxacin and moxifloxacin) extend the activity of the quinolones by Gram-positive activity, as well as by being more active against *C. pneumoniae* and *M. pneumoniae* than the older agents [53]. The new agents are also highly effective against *L. pneumophila*. However, if *P. aeruginosa* is the target organism, then only ciprofloxacin (750 mg b.i.d. orally or 400 mg 8-hourly intravenously) or levofloxacin (750 mg/day) are active enough for clinical use. Because the older agents, ciprofloxacin and ofloxacin, have borderline activity against pneumococcus, if they are used for AECB, the dose must be increased, and in one study, ciprofloxacin was administered at 750 mg b.i.d., and led to efficacy in the therapy of complex patients with AECB [88].

Among the newer agents, their *in vitro* activity against pneumococcus is variable, with the agents listed in the order of most to least active (on an MIC basis) as: gemifloxacin, moxifloxacin, gatifloxacin and levofloxacin (Table 60.5) [40,41,53]. All of these agents also have long half-lives, generally allowing for once daily dosing, although the half-lives of these drugs vary from 6 h for levofloxacin to more than 15 h for moxifloxacin and gemifloxacin. The agents also differ in the degree of protein binding, with agents that have a low degree of binding having higher free concentrations in the serum. The relevance of this feature to clinical outcome is uncertain, but agents such as levofloxacin and moxifloxacin are not highly protein bound. Although the new agents are highly active against pneumococci, both penicillin sensitive and resistant organisms, there is some concern that with widespread use, pneumococcal resistance to these agents will increase [40,41,43]. In addition, one recent study has shown that as organisms become penicillin resistant, they are also more likely to be quinolone resistant [41]. With this in mind, pneumococci are more likely to be resistant to the agents with the lowest pneumococcal activity (as listed above). Although

Table 60.5 Activity of fluoroquinolones against pneumococcus.

Agent	MIC 90 (mg/L)	C _{max} (mg/L)
Ciprofloxacin (500 mg)	2.0	3.0
Gatifloxacin (400 mg)	0.5	4.2
Gemifloxacin (320 mg)	0.125	1.5
Levofloxacin (500 mg)	1.0	5.7
Moxifloxacin (400 mg)	0.25	4.5

C_{max}, maximum plasma concentration; MIC, minimum inhibitory concentration.

resistance of pneumococci to quinolones is still not common, it has developed in Asia, particularly to levofloxacin, in COPD patients who have been given repeated courses of therapy [89]. Other risk factors for quinolone resistance among pneumococci are recent hospitalization and residence in a nursing home. One concern for the future efficacy of the quinolones in AECB patients has been their widespread use in outpatients with a variety of illnesses, who may be better treated with another antibiotic or who may not even need antibiotic therapy [39].

One major distinction among these new quinolones is their profile of toxic side-effects. A number of agents have been removed from clinical use because of toxicities such as QT prolongation (grepafloxacin), phototoxicity (sparfloxacin) and liver necrosis (trovafloxacin). Recently, gatifloxacin use has been curtailed because of drug-induced glucose abnormalities (hypo- and hyperglycaemia), especially in diabetics. The side-effects of the other new agents have generally been minimal but, as with any therapy, the risks of use should be weighed against the benefits.

In clinical trials, all of the newer agents have been effective with 5 days of therapy. The dosing of gatifloxacin is 400 mg/day, gemifloxacin 320 mg/day, levofloxacin 500 mg/day and moxifloxacin 400 mg/day. In many situations, the newer agents are considered to be therapeutically equivalent, but some investigators have considered that the risk of promoting pneumococcal quinolone resistance may be higher with agents that have higher MIC values, and thus have recommended using the most active agents preferentially [40]. When compared with other classes of antibiotics, the quinolones have the ability to prolong the disease-free interval, a feature that was first described with ciprofloxacin [67,74,87].

While most studies have not shown quinolones to be more effective than other antibiotics used to treat AECB, two recent studies have reported improved outcomes with the newer agents [67,74]. In one study, 320 mg/day gemifloxacin for 5 days was compared with 500 mg clarithromycin b.i.d. for 7 days and, although both agents showed similar clinical success rates initially, gemifloxacin led to a higher bacteriological success rates, especially for *H. influenzae* [67]. In addition, gemifloxacin-treated patients had fewer recurrences after 26 weeks, and fewer hospitalizations. In another study, 5 days of moxifloxacin was compared with therapy with one of three standard agents given for 7 days (amoxicillin, cefuroxime or clarithromycin) [74]. Patients in this study had established chronic bronchitis with at least two exacerbations in the preceding year, and those given moxifloxacin had less need for additional antibiotics and a longer disease-free interval than those given the comparator. These two studies are interesting because they focused on long-term endpoints, and documented a potential advantage of the new quinolones

compared with other accepted therapies of AECB. The fact that differences only became evident when outcomes other than short-term results were evaluated may explain why many prior studies concluded that all antibiotics used for AECB are equivalent.

Cost effectiveness of antibiotic therapy in AECB

Although it is difficult to determine how to best define the cost effectiveness of antibiotic therapy, it is quite clear that multiple factors, in addition to acquisition cost, should be considered. For example, an agent that costs little to buy, but has limited efficacy, might cause a patient to miss several days of work, and thus be less cost effective than a more expensive agent that was able to cure the patient rapidly. Other economic endpoints that should be considered in defining a cost-effective antibiotic for AECB include the prevention of hospitalization, the duration of disease-free interval, the need for other medications and the development of antimicrobial resistance [90,91].

One study looking at this issue was a prospective randomized trial of quinolone therapy (with ciprofloxacin) versus usual care, involving 240 patients with AECB managed by their family physicians [90]. For the group as a whole, quinolone therapy was not substantially better than usual care, but for certain patient subsets it appeared to have some advantage. Ciprofloxacin was associated with a better clinical outcome and lower cost for patients who had moderate or severe bronchitis (severity of the acute episode), at least four episodes of AECB in the preceding year, more than 10 years illness, age of at least 56 years and at least three comorbidities, once again confirming the concept that empirical therapy should be modified for different patient groups. All of these findings suggest that if patient profiling is used to prescribe antibiotics, then the benefits of therapy with specific agents for specific patients will be enhanced. Similarly, the study of gemifloxacin versus clarithromycin documented cost efficacy for the quinolone, primarily by the avoidance of hospitalization, physician visits and lost work productivity [92].

Therapy for AECB using patient subsets: should different patients be treated with different therapies?

The bacteriology of exacerbations may vary with specific patient features, and in certain populations, specific therapies may have more value than others. In addition, as patients become increasingly ill, both acutely and chronically, the consequences of ineffective antibiotic therapy of AECB may become more important. Therefore, a number of guidelines have been developed that suggest patient

stratification approaches and suggested therapies for each subset. Most of the guidelines about exacerbations of COPD either do not recommend specific antibiotics or recommend that any antibiotic can be used in any patient population. For example, the statement of the American College of Physicians and the American Society of Internal Medicine, published jointly with the American College of Chest Physicians states 'to date, no randomized, placebo-controlled trials have proved the superiority of the newer broad-spectrum antibiotics' in patients who are likely to have resistant organisms present [4]. Recently, a Canadian guideline was published that made recommendations for specific antibiotic choices for different populations, defined on the basis of the presence of risk factors for treatment failure [5].

In the Canadian guideline, the risk factors for treatment failure in AECB included: frequent exacerbations (odds ratio of 2.11 for those with more than four exacerbations per year), more severe lung dysfunction, ischaemic heart disease or congestive heart failure, increasing age, use of maintenance steroids, use of home oxygen and chronic mucus hypersecretion [5]. Many of these factors also increase risk for hospitalization including cardiopulmonary disease (odds ratio of 8.9), patients with disease of long duration and in those with severe lung dysfunction. Based on these features, the authors identified three groups of patients with AECB: the simple bronchitic, the complicated bronchitic and the patient with chronic suppurative bronchitis (Table 60.6) [5].

Therapy for all patients should target the group of 'core organisms' that are possible for any patient with exacerbation, and these include *H. influenzae* (usually non-typable), *M. catarrhalis*, *S. pneumoniae* and *H. parainfluenzae*. The patient who is at risk for only these organisms is the 'simple bronchitic', defined as a patient with at least two of the three cardinal symptoms of exacerbation, but with no risk factors for treatment failure or hospitalization. This population has an FEV_1 of more than 50% predicted, less than four exacerbations per year and no underlying cardiac disease. These patients are less likely to have resistant pathogens, and could even tolerate treatment failure (although not highly likely) without requiring hospitalization. Therapy for this population was recommended to be a newer macrolide (azithromycin or clarithromycin), a cephalosporin, amoxicillin, co-trimoxazole, or tetracycline (doxycycline); but, in the case of a treatment failure, a fluoroquinolone or beta-lactam/beta-lactamase inhibitor combination could be used as alternative therapies. It is still uncertain, if the patient resides in an area with high rates of antibiotic resistance, whether agents such as amoxicillin and co-trimoxazole will remain as reliable choices.

The complicated patient is more likely to have a resistant pathogen, and is also defined as having at least one adverse outcome risk factor such as: FEV_1 of less than 50% pre-

Table 60.6 Patient stratification and suggested therapy for acute exacerbations of chronic bronchitis. (Only treat those with at least two of the cardinal symptoms of exacerbation.)

Simple bronchitic

$FEV_1 > 50\%$ predicted, < 4 exacerbations/year, and no underlying cardiac disease

- Newer macrolide, cephalosporin, doxycycline
- Amoxicillin, co-trimoxazole (may be a concern in areas with high rates of antibiotic resistance)
- For non-responders: fluoroquinolone, beta-lactam/beta-lactamase inhibitor combination

Complicated bronchitic

At least one of: $FEV_1 < 50\%$ predicted, > 4 exacerbations/year, cardiac disease, need for home oxygen, use of chronic oral corticosteroids, antibiotic use in the past 3 months

- Fluoroquinolone, beta-lactam/beta-lactamase inhibitor
- Consider azithromycin if only one risk factor

Chronic suppurative bronchitis

Constant purulent sputum, and at least one of: bronchiectasis, $FEV_1 < 35\%$ predicted, multiple exacerbations

- Sputum culture may be useful in this group
- Ciprofloxacin orally
- Maybe a role for inhaled aminoglycosides
- Parenteral therapy if admitted

FEV_1 , forced expiratory volume in 1 s.

dicted, more than four exacerbations per year, cardiac disease, use of home oxygen, chronic oral steroid use or antibiotic use in the last 3 months. For this population, the recommended therapies were a fluoroquinolone, or a beta-lactam/beta-lactamase inhibitor combination, but other groups have considered azithromycin to be an acceptable alternative for patients with only one adverse outcome risk factor [77].

The chronic suppurative bronchitic patient is defined as having constant purulent sputum, usually with bronchiectasis or an FEV_1 of less than 35% predicted, or with multiple risk factors such as frequent exacerbations. These patients can be infected with resistant Gram-negative organisms, and thus therapy should be tailored to culture data from sputum samples, but empirical therapy should be directed against *P. aeruginosa*, with ciprofloxacin in outpatients and generally parenteral therapy in hospitalized patients [5].

This stratification scheme must be viewed as a hypothesis that requires prospective verification. Future studies are needed to document that, if patients are managed with this approach to therapy, outcomes are improved. However, retrospective data do support this general approach. In one study, the value of using newer, and more expensive

antibiotics was documented as being both beneficial and cost effective in a population of patients that could be described as mildly complicated. In this study, a group of 60 patients had, on average, more than three exacerbations (a total of 224 exacerbations) and therapy was categorized by the authors as being with first-line (amoxicillin, tetracycline, erythromycin, co-trimoxazole), second-line (cephalosporins) or third-line (amoxicillin/clavulanate, azithromycin, ciprofloxacin) agents [73]. Patients who received third-line agents failed less often than those who received first-line agents (7% vs 19%; $P < 0.05$) [73]. In addition, those given third-line agents were hospitalized less often, and their time between exacerbations was significantly longer than for those given first-line agents. Another study, using a pharmacoeconomic model to evaluate 1102 patients with AECB in previously reported randomized trials, concluded that macrolide therapy and therapy with amoxicillin/clavulanate was more cost effective than therapy with ampicillin and older cephalosporins [91].

In the future, the value of new agents will need to be studied using both traditional and novel endpoints. Thus, in addition to clinical and microbiological success, future studies will need to examine time to clinical resolution, time to return to work or other productive activity, disease-free interval, and the ability of a selected therapy to minimize the future potential for antibiotic resistance.

CHAPTER 61

Antioxidants

Claudio F. Donner

In the normal lung, the balance between antioxidants and oxidants is sufficient to keep the airway lining fluids and extracellular spaces in a highly reduced state and enable normal physiological functions. Any increase in oxidants or decrease in antioxidants can disrupt this balance. The state of imbalance is collectively referred to as oxidative stress and is associated with diverse airway pathologies including asthma, COPD and interstitial lung disease [1,2].

In the last few years, the possible association between free radical-induced oxidative damage in the lung and the development of cigarette smoke-related pathologies (e.g. COPD, lung cancer) has received considerable attention. There is growing evidence of the role of oxidative stress in

COPD [3–5]. Oxygen radicals from endogenous (priming of inflammatory cells) and exogenous sources (cigarette smoke) induce parenchyma and airways wall damage in the lung, as well as interfering in the inflammation process by activation of transcription factors (Fig. 61.1).

Extracellular superoxide dismutase (ECSOD) is the primary extracellular antioxidant enzyme in the lung and is most highly expressed in airway and vascular walls (Fig. 61.2) [2]. The antioxidant defence of the lung seems incapable of controlling the process, as results from measurement of markers of oxidative stress in COPD patients [5,6]. Enhancing the antioxidant defence could be an attractive strategy for the treatment of COPD. An ideal antioxidant would be very specific and not interfere with the normal oxidative function essential for the inflammatory response for several metabolic reactions. A number of metal complexes have been described as superoxide dismutase (SOD) mimetics. AEOL 10113 and AEOL 10150 are positively charged, and the positive charges on the four pyridyl or

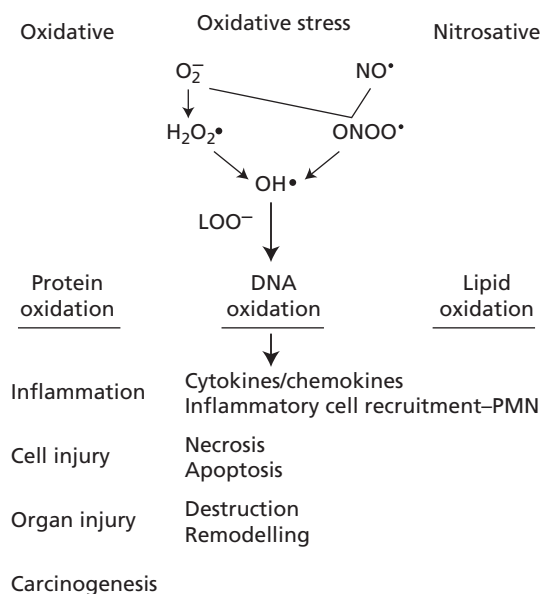

Figure 61.1 Comparative levels of extracellular superoxide dismutase (ECSOD) in various tissues, showing the unique expression in the lung. (From First ERS Lung Science Conference, Taormina, 2003. Copyright J. Crapo.)

Figure 61.2 Schematic representation of oxidative stress. (From First ERS Lung Science Conference, Taormina, 2003. Copyright J. Crapo.)

imidazol groups in these compounds give them distribution and function profiles that mimic ECSOD. Thus, AEOL 10113 and AEOL 10150 possess a broad range of antioxidant activities including mimicking SOD and catalase, and scavenging both lipid peroxides and peroxynitrite [7–9]. Natural antioxidants, such as vitamins, and synthetic ones, such as *N*-acetylcysteine, have been investigated in the clinical setting. However, few compounds have been studied in randomized controlled trials.

In this chapter, antioxidants used in the clinical setting are discussed.

Oxidants and antioxidants

Reactive oxygen species (ROS, or oxidants) and antioxidants have an essential role in aerobic life. Most of the oxygen taken into the body is expelled as CO₂; however, some molecular oxygen (O₂) is converted to water. For this reaction four electrons must be added to the oxygen molecule. Conversion of oxygen to water can result in the formation of several oxygen free radicals (O₂, H₂O₂, OH).

ROS and free radicals are molecules with an impaired number of electrons in the external orbit. Because of the instability in the molecular structure, these compounds are very reactive and interact with fat and proteins, altering cellular structure. Activated phagocytic cells (e.g. neutrophils, macrophages) generate ROS [10]. ROS are present in all cellular compartments: lysosomes, peroxisome, endoplasmic reticulum, mitochondria, cell membranes and cytoplasm. The oxidants formed by the activated cells are not only present intracellularly but also reach the extracellular environment, reacting with proteins and fat molecules causing cellular or tissue damage, which can result in chronic inflammation [11].

Cigarette smoke is a potent source of inhaled oxidants and free radicals present in both gas and tar phase [12]. Cigarette smoke contains approximately 10–15 oxidant molecules per puff and in aqueous solution it can generate hydrogen peroxide and superoxide radicals [13,14].

The organism is protected from oxidative damage by a wide screen of antioxidants. Natural antioxidants can be divided into enzymatic (superoxide dismutase, glutathione, catalase), non-enzymatic synthesized (uric acid, glutathione) and dietary vitamins (vitamins E and C, beta-carotene).

When the amount of oxidants exceeds the available antioxidant defence, oxidative stress ensues. Oxidative stress has been implicated in the pathology of numerous diseases such as atherosclerosis, diabetes, ischaemia–reperfusion injury and cancer. The lung, widely exposed to oxidative injury, is highly dependent on its antioxidant screen. Several chronic (COPD, idiopathic pulmonary fibrosis [IPF], asthma) and non-chronic (adult respiratory distress

syndrome [ARDS], cancer) lung diseases have been related to oxidative stress [11].

Oxidative stress and COPD

Oxidants

An increased number of ROS from exogenous and endogenous sources are present in the lung of COPD patients (Fig. 61.3). Cigarette smoke is irreversibly linked to COPD. Inhaled ROS are derived from tobacco smoke and air pollution. In addition, cigarette smoke induces iron release from ferritin, essential for oxidative processes (Fig. 61.4).

Endogenously ROS are generated by phagocytic cells (neutrophils and macrophages) [10,15]. Activated macrophages and polymorphonuclear neutrophils (PMNs) from smokers release more ROS than cells derived from non-smokers [3,10]. There is evidence that cigarette smoke exposure provokes an accumulation of macrophages and neutrophils [16] in respiratory bronchiole and alveolar septum. Di Stefano *et al.* [17] described an increase of macrophages in bronchial mucosa of patients with chronic bronchitis. This situation escalates during exacerbations when neutrophils and eosinophils increase even further, compared with stable patients [18]. In conclusion, the

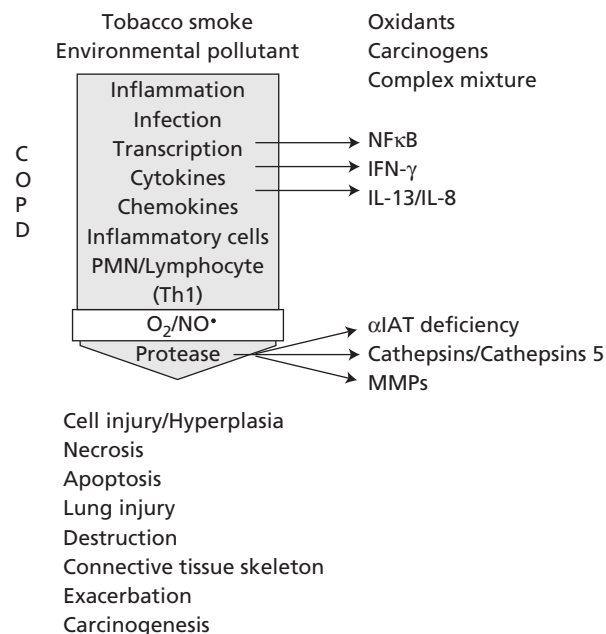

Figure 61.3 Schematic representation of oxidative stress in COPD. IFN- γ , γ -interferon; IL, interleukin; MMP, matrix metalloproteinase; NF κ B, nuclear factor κ B. (From First ERS Lung Science Conference, Taormina, 2003. Copyright J. Crapo.)

Figure 61.4 Oxidative stress resulting from tobacco smoke in normal subjects and in COPD. ccNOS, constitutive calcium/calmodulin regulated nitric oxide synthase; ECSOD, extracellular superoxide dismutase; GPx, glutathione peroxidase; GSH, glutathione; GSNO, NO-donor S-nitrosoglutathione; iNOS, inducible nitric oxide synthase; nNOS, neuronal nitric oxide synthase; NO, nitric oxide; ONOO⁻, peroxynitrite; PMN, polymorphonuclear neutrophil. (From First ERS Lung Science Conference, Taormina, 2003. Copyright J. Crapo.)

number of inflammatory cells is higher in COPD and therefore their potential production of ROS is greater.

Jorres and Magnusen [13] suggested that the cellular activation and tissue damage in COPD patients should be associated with uncontrolled and not site-specific production of ROS, which can generate a chain reaction perpetuating these alterations.

Antioxidants

Pulmonary antioxidants are widely distributed and include both enzymatic and non-enzymatic systems. The intracellular antioxidant system comprises vitamins E and C, beta-carotene and glutathione (GSH). Extracellular fluid contains high levels of antioxidants but is relatively poor in enzymes. GSH in particular is critical in antioxidant pulmonary defence [11].

GSH, a low molecular tripeptide (L-gamma-glutamyl-L-cysteinylglycine) is an important intracellular water-soluble antioxidant. It is present in airways epithelial cells and in pulmonary endothelial cells. In the lung, GSH is also present extracellularly and it reaches high concentrations in the lung epithelial lining fluid (ELF). The concentration of GSH in ELF is approximately 100-fold higher than in plasma. The GSH redox cycle is considered the most

important mechanism for reduction of intracellular hydroperoxides [15]. The antioxidant action of GSH will lead to formation of a non-radical end product: GSSG, oxidized glutathione. Conversely, GSSG can be reduced again to GSH by the enzyme glutathione reductase, enabling the cell to keep a ratio of GSH/GSSG.

Besides its function in maintaining a reducing environment, GSH is also a cofactor for various protective enzymes against oxidative stress. Furthermore, GSH has been implicated in immunomodulation and the inflammatory response [19].

Several animal and human studies [19] show that cigarette smoke alters GSH levels in the lung. An acute fall, as a direct consequence of smoking, is followed by a persistent increase. Smokers have an elevated GSH and GSH peroxidase activity in ELF [20]. Animal and human studies demonstrated that increased GSH levels increase lung permeability [21,22], suggesting a critical role for GSH in maintaining epithelial barrier function. Linden *et al.* [23] found an increased concentration of total GSH in bronchoalveolar lavage (BAL) fluid of chronic bronchitis patients. The GSH concentration was inversely correlated with the forced expiratory volume in 1 s (FEV_1) of these patients.

Rahman and MacNee [11] suggest that the intracellular redox state of the cell has a key role in the regulation and potentiation of the inflammatory response in the cell. Oxidants are implicated in the inflammatory response of the cell via activation of redox-sensitive transcription factors such as nuclear factor κ B (NF- κ B) and activator protein-1 (AP-1). Depletion of GSH or alteration in the balance of GSH/GSSG in favour of the oxidized form causes degradation of the inhibitor form of NF- κ B and consequently its activation. NF- κ B is involved in gene regulation of pro-inflammatory cytokines (e.g. tumour necrosis factor α [TNF- α], interleukin 6 [IL-6], IL-8, vascular cell adhesion molecule 1 [VCAM-1] and intercellular adhesion molecule 1 [ICAM-1]). The activation of the cytokines, caused by oxidative stress, will amplify the inflammatory response, creating a chain reaction.

The same authors show that GSH regulation is one of the factors involved in genetic susceptibility to oxidant-mediated lung damage. Furthermore, GSH redox state and oxidative stress are involved in the expression of pro-inflammatory and antioxidant genes.

Alteration in GSH concentration in BAL and ELF has also been described in several inflammatory pathologies: ARDS [24], IPF [25], cystic fibrosis and asthma [26].

Evidence of oxidative stress in COPD

The short half-life of oxidants makes their direct measurement *in vivo* difficult. In the last few years, several

techniques have been developed that permit the measurement of markers of oxidative stress in COPD patients, using less invasive methods. Increased evidence of oxidative stress in the lung was presented by Maier *et al.* [27], who showed elevated levels of oxidized methionine residues of α_1 -proteinase inhibitor in BAL of smokers with chronic bronchitis. Dekhuijzen *et al.* [6] found increased levels of hydrogen peroxide (H_2O_2) in exhaled breath of COPD patients. Higher levels were found during exacerbations. More recently, Montuschi *et al.* [28] demonstrated increased levels of 8-isoprostane in exhaled air, a marker of lipid peroxidation, confirming the previous data of Pratico *et al.* [29] for the same marker in urine. Elevated plasma levels of thiobarbituric acid-reactive substances (TBARS), another marker of lipid peroxidation, were found in stable and exacerbated COPD patients [30]. Finally, decreased antioxidant capacity in plasma (TEAC) was described by Rahman *et al.* [12] in smokers and in patients with acute exacerbations of COPD. These data confirm the presence of an imbalance between oxidants and antioxidants in COPD and support the use of antioxidants in this pathology.

Pharmacological intervention

The use of antioxidants may be an interesting strategy in the prevention of radical-induced damage. The lung protects itself through several antioxidant systems, including thiol compounds, vitamins and enzymes. Enzymes such as SOD and catalase are large mass polymers, which prevents their intracellular transport and their use by the oral route; therefore their use has been limited to experimental studies. Only thiols and vitamins have been studied in the clinical setting.

Thiols

GSH and cysteine are the most important antioxidant thiols in the lung. Intracellular synthesis of GSH depends on the availability of its natural precursor, L-cysteine [31]. Cysteine has a poor resorption, it is rapidly oxidized and is toxic. These disadvantages are prevented by acetylation of the molecule.

Exogenous GSH must be broken down to the constituent aminoacids. A GSH preparation is available for intravenous use but has never been tested in chronic pulmonary diseases.

N-acetylcysteine

N-acetylcysteine (NAC) is a sulphhydryl group (SH) containing aminoacid residue with an acetyl group on the nitrogen. The thiol group is crucial for its therapeutic effect. NAC has been used in Europe as a mucolytic agent. The mucolytic

action, a result of cleavage of disulphide bonds between mucines and consequent decrease of the viscosity of the mucus, was described by Sheffner *et al.* [32] in the 1970s. More recently, the therapeutic effect of NAC has been primarily ascribed to its antioxidant properties.

NAC is biotransformed very effectively, which explains its low bioavailability. After oral administration, NAC is deacetylated to L-cysteine. Cysteine has a central role in the endogenous thiol metabolism and may be transformed into a large number of molecules, including GSH.

In analogy with the well-established mechanism of action of NAC against liver toxicity resulting from paracetamol (acetaminophen) intoxication [33], GSH has been seen as a link between NAC and therapeutic effects in chronic bronchitis.

Pharmacokinetics

After oral intake of 600 mg/day, the intestinal absorption of NAC is rapid; it can be measured in the plasma after 60 min [34]. NAC is partially deacetylated at intestinal mucosa level and undergoes an intense metabolism after the first hepatic passage. As a consequence, the bioavailability of the unchanged molecule is apparently low (10%). At this dose, NAC could not be detected in BAL fluid [35]. It is important to bear in mind, however, that it is at the hepatic level that its principal conversion into GSH takes place. An increase in bioavailability has been reported after higher doses.

After administration of NAC, plasma level increases in cysteine, GSH and thiolic groups have been measured [35,36]. Also, increased levels of GSH in the lung were measured [36]. However, in COPD patients, after an oral dose of 600 mg NAC, the plasma concentrations of GSH were unchanged, whereas 600 mg NAC three times daily increased GSH plasma concentrations [37]. These data were confirmed by Behr *et al.* [38] in patients with IPF, who also demonstrated a significant increase in total concentration of GSH both in ELF and in the cells after oral administration of 1800 mg/day NAC.

Pendyala and Creaven [39] found a significant increase in GSH in the circulating lymphocytes in healthy volunteers after a single administration of 800 mg/m². Repeated administrations caused an increase in GSH concentration of approximately 20% over baseline.

To understand the effect of NAC on cysteine and GSH levels it is important to note that plasma levels are often non-representative of the situation in the lung because of compartmentalization of GSH need and availability. Furthermore, studies performed after coadministration of NAC (2 g) and paracetamol (2 g) to healthy volunteers showed an increase in cysteine and GSH levels in plasma, when a single administration of NAC was without effect [27,40]. This result suggests that the incorporation of NAC into GSH is dependent on the increased demand, as during oxidative stress.

Rationale for the use of NAC in COPD

NAC can interfere in the pathophysiology of COPD in different ways. Thiol groups are rich in electrons and can act as scavengers, reductants and antioxidants. NAC exerts a direct antioxidant effect through its free thiol group interacting with electrophilic groups of ROS [41]. Aruoma *et al.* [42] investigated the antioxidant action of NAC against hydrogen peroxide, hydroxyl radical, superoxide and hypochlorous acid. NAC is a powerful scavenger of hypochlorous acid and hydroxyl radical, while the reaction with hydrogen peroxide was noted to be slow. NAC's effect in reducing elastase activity was ascribed to the property of scavenging hypochlorous acid.

Besides this direct scavenger effect, NAC's working mechanism has to be related to its function as a GSH precursor. Maintaining adequate intracellular levels of GSH is essential for overcoming the effects of toxic agents such as cigarette smoke. Moldeus *et al.* [41] showed that NAC prevents the decrease of pulmonary GSH in a rat cigarette smoke exposure model and protects the lung against the effects of cigarette smoke. The studies of NAC as a precursor of GSH in humans have been discussed above (see p. 749).

Jeffery *et al.* [43] proved that NAC inhibits mucous cell hyperplasia in rats exposed to cigarette smoke, with the greatest effect in peripheral small airways. Furthermore, NAC tended to reduce the magnitude of permeability changes of the airways mucosa.

Several studies have studied the effect of NAC on inflammatory cells. Kharazmi *et al.* [44] studied the effect of NAC on neutrophils and monocytes *in vitro* and *in vivo*. *In vitro*, NAC was shown to inhibit the chemotaxis and oxidative-burst response of neutrophils and monocytes at approximately millimolar concentration. In a study of healthy volunteers, a single dose (400 mg) of NAC provoked a significant reduction of neutrophil chemoluminescence response following zymosan activation. The author concluded that the inhibition of migration and generation of ROS by phagocytic cells could be of major importance in preventing tissue damage in patients with chronic inflammatory disorders [45]. Three studies were performed to study the effect of NAC on inflammatory cells and mediators in BAL fluid in smokers [46–48]. The results can be summarized as a tendency towards normalization of cell composition with an increase in the proportion of lymphocytes. Activation was reduced as well as lactoferrin. The activity of alveolar macrophages was also measured; an increase in leukotriene B₄ production, a reduction of the production of ROS and an increase in the phagocytic activity of the cells was found.

Marui *et al.* [49] showed the ability of NAC to inhibit the expression of VCAM-1 in human endothelial cells. De Backer *et al.* [50] found a decrease of sputum eosinophil

cationic protein (ECP) levels and reduction of PMN adhesion with a dose of 600 mg/day NAC to COPD patients.

Effect on bacterial colonization

Riise *et al.* [51] described for the first time an effect of NAC on bacterial colonization in a population of smokers with or without chronic obstruction. Patients with chronic obstruction presented the highest number of bacterial colonies. The intrabronchial bacterial colonization was significantly lower ($P < 0.05$) in patients treated with NAC (600 mg/day for several months).

It has already been demonstrated that NAC inhibits bacterial adhesion to epithelial cells [52,53] and that it stimulates the phagocytic activity of macrophages in smokers. More recently, Oddera *et al.* [54] demonstrated *in vitro* that NAC stimulates the intracellular killing of *Staphylococcus aureus* by alveolar macrophages and polymorphonuclear leucocytes of peripheral blood. Riise *et al.* [55] demonstrated that NAC reduces the ability of bacteria (*Streptococcus pneumoniae* and *Haemophilus influenzae*) to adhere to human oropharyngeal epithelial cells. Very recently, an Italian group (Schito University of Genoa) investigated the effect of NAC (in concentration from 0.07–8.0 mg/mL) to inhibit the formation of biofilms in *S. aureus* cultures. NAC was found to inhibit the formation of biofilms in all cultures [56].

A significant number of COPD exacerbations are associated with respiratory viral infection. The role of oxidative stress in relation to viral infections (influenza, rhinovirus) has been recently evaluated. Viral induction of oxidative stress in respiratory cells has been described by Biagioli *et al.* [57]. Rhinovirus induces the production of ROS and consequently stimulates the activation of NF- κ B, a key step in the signal transduction pathway leading to IL-8 production. The same authors demonstrated that NAC blocked IL-8 production in a dose-dependent way by down-regulation of the NF- κ B activation, as also observed by Knobil *et al.* [58]. Pretreatment with NAC attenuated the virus-induced NF- κ B activation and IL-8 release caused by influenza virus in epithelial cells. Further evidence was offered by the work of Ungheri *et al.* [59]. Mice infected intranasally by influenza virus APR/8 showed high BAL levels of xantineoxidase, TNF and IL-6. Oral administration of NAC (1 g/kg/day) significantly reduced the mortality rate of the infected mice.

Systemic effect

In recent years there has been a growing tendency to consider COPD as a systemic disease. Thiols are implicated in several enzymatic reactions in the organism and therefore have an important metabolic role not only in the lung, but also in other systems such as the muscles.

An interesting study was performed by Santini *et al.* [60],

who demonstrated that in COPD patients, red blood cells (RBC) have a low thiol concentration and are morphologically damaged, with possible consequences for oxygen exchange. NAC (1.2 or 1.8 g/day for 2 months) was able to improve the shape of the RBC and elevate the thiol concentration [61]. Quing Lu *et al.* [62] found that treatment with NAC (600 mg/day for 2 weeks) has a positive impact on the smoking-induced negative effects on microcirculatory flow. This effect was enhanced in habitual smokers, suggesting that NAC could improve tissue oxygenation.

Clinical efficacy

In several controlled trials conducted in a large number of chronic bronchitis patients, NAC proved evidence for reduction in symptoms, incidence and duration of exacerbations [63,64] and number of sick days [65]. These results were not reproducible in all the studies [66] and the group of patients studied was not very homogeneous.

To check the efficacy of NAC, Grandjean *et al.* [67] and Stey *et al.* [68] performed a meta-analysis on the results of double-blind placebo controlled clinical trials with common endpoint exacerbations rate, duration of 12–24 weeks, dosage 400–600 mg and similar definition of exacerbations. The Grandjean meta-analysis resulted in a 23% reduction of exacerbations in favour of NAC. The systematic review by Stey *et al.* [68] considered 11 trials with 2001 analysed patients selected following preset criteria. Nine of the eleven trials reported prevention of any exacerbation as the outcome in 1456 patients. With NAC, 48.5% of patients were free of any exacerbation compared with 31.2% in the placebo group. This result was statistical significant; relative benefit = 1.56 (95% confidence interval [CI], 1.37–1.77), with a number needed to treat of 5.8 (95% CI, 4.5–8.1). Only one trial reported the number of patients having exacerbations requiring hospitalization [69]. With NAC, 1.6% of patients were hospitalized within the 24-week study period against 3.4% in the placebo group. The difference was not statistically significant. Stey *et al.* [68] also reported a significant improvement in symptoms: 61.4% in the NAC patients against 34.6% in the placebo group. The tolerability of NAC was very good and comparable to placebo. Comparable results were obtained in a meta-analysis performed by the Cochrane group [70] on mucolytic agents including NAC.

These data seem to suggest that NAC has an effect in reducing the exacerbation rate in the same order of magnitude as other compounds (e.g. inhaled corticosteroids [ICS]), but in a mild disease population. A large number of national and international (Global Initiative for Chronic Obstructive Lung Disease [GOLD], Swiss, Dutch, Spanish, German) guidelines classify NAC as an antioxidant and claim that NAC could have a role in the treatment of patients with recurrent exacerbations [71].

There are few reports on the effect of NAC on other parameters of COPD: FEV_1 decline and quality of life (QoL). Hansen *et al.* [72] studied the effect of 600 mg NAC twice daily on the well-being status of 165 patients with mild to moderate obstruction (FEV_1 of less than 50%), using the General Health Questionnaire (GHQ). NAC was significantly superior to placebo in terms of favourable effect on GHQ score.

Data on the monitoring of lung function were collected in an open, randomized and stratified trial [73] in 113 COPD patients identified in a large population participating in an epidemiological survey (Olin study) in northern Sweden. After 2 years, a significant reduction in FEV_1 decline ($P < 0.03$) in the NAC group was reported. A beneficial effect of NAC was still present after 5 years.

Some interesting data appear on the effect of NAC on markers of oxidative stress. Kasielski and Nowak [74] described a reduction of H_2O_2 in exhaled breath concentrate (EBC) in stable COPD patients treated for 12 months with 600 mg NAC versus placebo. This effect has been confirmed by De Benedetto *et al.* [75] using 1.2 g NAC.

To assess the effect of NAC on the most significant parameters in COPD (exacerbations, FEV_1 decline and QoL) and to justify its long-term use, two phase 3, randomized, placebo-controlled multicentre studies were started. The BRONCUS (Bronchitis Randomised On NAC and Cost-Utility Study) [76] began in June 1997. Patients are treated for 3 years with 600 mg/day NAC on top of standard treatment (including ICS). The main goals of the study are: reduction of exacerbation rate, decline of FEV_1 , QoL assessment and pharmacoeconomic analysis. A total of 523 patients with mild to moderate disease have been recruited. In a group of COPD patients with milder disease, recruited from general practice, the effect of NAC (600 mg/day for 3 years) on exacerbation rate and cost effectiveness has been compared with fluticasone and placebo. The BRONCUS study has demonstrated that 600 mg/day NAC in COPD patients had effects on pulmonary function and exacerbation rate. It improved FEV_1 and vital capacity (VC) initially in patients with FEV_1 of less than 50% of predicted but did not affect the annual decline in these variables. It reduced hyperinflations. It reduce yearly exacerbation rates, with 22% of the patients not taking inhaled corticosteroids [77].

Vitamins

There is clear epidemiological evidence that dietary intake of antioxidant vitamins (vitamins E and C and α -tocopherol) is positively associated with lung function and respiratory symptoms. Large epidemiological studies such as NHANES 1–3 [78–80] demonstrated that higher levels of antioxidant nutrients are associated with better lung

function. Vitamin E in particular could be important in protecting surfactant lipids against oxidation and subsequent lung injury. A temporary vitamin E deficiency induces a reversible change of the expression of pro- and anti-inflammatory markers and of markers defining apoptosis, and reduces surfactant lipid synthesis in alveolar type II cells [81]. The question is whether supplementation of vitamins, outside the dietary intake, can provide benefit to patients. Fairfield and Fleicher [81], in a recent review, found little convincing evidence in favour of supplementation for chronic disease prevention; fruit and vegetables contain a variety of other compounds that may be protective [82]. Bender, in an editorial in the *British Medical Journal* [83], concluded that supplementation will be of little benefit unless intake is inadequate as a result of poor diet.

Conclusions

Smoking, acute exacerbation of COPD and asthma are all associated with a marked oxidant–antioxidant imbalance and with signs of oxidative stress. COPD and asthma are growing worldwide, and represent an ever-increasing burden on national health costs. However, it is not easy to obtain definitive proof that oxidants have a decisive role in the pathogenesis and evolution of these diseases. Because asthma and COPD are chronic progressive diseases, long-term studies in large case series are required. One of the most significant aspects is that the lung oxidant–antioxidant balance is abnormal in cigarette smokers; however, it remains unclear why only certain cigarette smokers develop COPD while others do not. The answer to this question is related to an improved understanding of the nature of the oxidant–antioxidant balance, as well as of the genetic factors and other intrinsic factors, including dietary, that control this balance. In view of these uncertainties, it is not possible to date to specifically document the benefit of antioxidant therapy. Nevertheless, there are some antioxidants that have been sufficiently well investigated and appear very close to giving a definitive positive response concerning their efficacy in the treatment of COPD. In this context, *in vitro* and *in vivo* data show that NAC protects the lungs against toxic agents by increasing pulmonary defence mechanisms through its direct antioxidant role in the rate and severity of exacerbations, and its indirect role as a precursor of GSH synthesis. The long-term use of the drug in COPD patients results in an improvement in respiratory symptoms and in a decrease in the exacerbation rate.

It should be emphasized that there are numerous and important studies in progress, unfortunately often limited to the experimental setting, on new substances that will have an important role in antioxidant therapy in the future.

CHAPTER 62

Mucolytics for COPD

Duncan F. Rogers and Bruce K. Rubin

The role of airway mucus hypersecretion in the pathophysiology of chronic obstructive pulmonary disease (COPD) is debated. Similarly, the use of mucolytic medications in the clinical management of COPD is controversial. Mucus hypersecretion, implicit in the clinical term chronic bronchitis, is one of three pathophysiological entities comprising COPD. The other two components are chronic bronchiolitis (small airways disease) and emphysema (alveolar destruction) [1]. The relative contribution of each component to pathophysiology varies between patients, with the impact of mucus hypersecretion on morbidity and mortality varying accordingly. Thus, although previously included in definitions of COPD [2], the term 'mucus hypersecretion' is omitted from current definitions [3]. Nevertheless, there are many patients in whom airway hypersecretion has clinical significance; for example, patients prone to chest infections [4]. Consequently, development of pharmacotherapeutic compounds to inhibit mucus hypersecretion in these patients is warranted. This chapter:

1 assesses the contribution of airway mucus hypersecretion to the pathophysiology of the 'bronchitic' component of COPD;

2 considers the clinical impact of mucus hypersecretion in COPD; and

3 discusses use of mucolytic and related drugs in the treatment of COPD.

The chapter begins with an overview of airway mucus, mucins and sputum.

Airway mucus and mucins

In health, a thin film of slimy liquid protects the airway surface [5]. The liquid is often referred to as 'mucus' and is a non-homogeneous 1–2% aqueous solution of electrolytes, enzymes and antienzymes, oxidants and antioxidants, bacterial products, antibacterial agents, cell-derived mediators and proteins, plasma-derived mediators and proteins, and

cell debris such as DNA. The mucus forms a bilayer, comprising an upper mucous gel layer and a lower sol layer, with a thin layer of surfactant separating the two [6,7]. Cilia beat in the sol layer, often termed periciliary fluid. Inhaled particles are trapped in the gel layer and, by transportation on the tips of beating cilia, are removed from the airways, a process termed mucociliary clearance. The mucus gel requires an optimal combination of relatively low viscosity and preserved elasticity for efficient ciliary interaction [8]. Viscoelasticity is conferred primarily by high molecular weight mucous glycoproteins, termed mucins, which comprise up to 2% by weight of the mucus [9]. Respiratory tract mucins are produced by epithelial goblet cells [10] and submucosal glands [11], and are long, thread-like molecules composed of monomers joined end-to-end by disulphide bridges. The monomers comprise a highly glycosylated (70–80%) linear peptide sequence, termed apomucin, that is encoded by specific mucin (*MUC*) genes. Eighteen human mucin genes, to date, have been cloned and over 20 identified [12; see also 9, 13–15]. At least 12 are expressed as mRNA in the lower respiratory tract [12]. In the normal, healthy lung, *MUC1*, *MUC4* are expressed at the apical surface of the respiratory epithelium; *MUC2*, *MUC5AC* are generally expressed in goblet cells of the superficial airway epithelium; *MUC5B*, *MUC8*, *MUC19* are expressed in mucosal cells of submucosal glands; *MUC7* is not well-expressed normally and when expressed is localized to the serosal cells of submucosal glands; *MUC11*, *MUC13*, *MUC15*, *MUC20* are also known to be expressed as mRNA in lung tissue [12].

Mucus properties

Before consideration of medications that may affect mucus properties and, hence, mucus clearance, it is essential to understand and define these properties. Often, mucoactive medications are defined by their presumed action on the mucus gel.

Periciliary fluid viscosity and depth affect mucociliary clearance. If this fluid is too viscous the cilia will not be able to beat effectively, and the decreased ciliary velocity will decrease mucociliary clearance. This principle is well established for water-propelling cilia, but for the periciliary fluid in the two-layer airway mucociliary system, periciliary fluid viscosity is unknown. Active ion transport and associated transepithelial water flux are probably important in modulating periciliary fluid viscosity [16]. Transepithelial protein fluxes may also contribute to periciliary fluid viscosity [17]. The efficient transfer of momentum between the cilia and the mucus layer requires the cilia to be firmly in contact with the mucus during their forward stroke, while minimally interacting with it during the return stroke. Thus, mucociliary clearance will also decrease if the periciliary fluid is either too deep or too shallow. The characteristics of mucus that affect mucociliary clearance are depth and viscoelasticity [18]. Although mucus that is too deep hinders clearance by cilia, it may be better suited to clearance by cough [19].

Rheology is the study of the deformation (strain) of matter with applied stress. Viscosity (energy loss or G') is a property of liquids and an ideal or Newtonian liquid can be described strictly in terms of viscosity. An ideal or Hookian solid is described entirely by elasticity or energy storage (G'') with an applied stress. A non-Newtonian gel such as mucus has both viscous and elastic properties. Both viscosity and elasticity are needed for airway secretion clearance. The elastic component is essential for beating cilia to transmit kinetic energy to the mucus. Viscosity is also essential for effective clearance. Patients who have liquid-like mucus, often termed 'bronchorrhoea', are unable to clear secretions effectively. Mucociliary clearance is much more sensitive to high levels of viscosity, although high levels of elasticity may also impede ciliary transport [20]. A balance between these factors must be maintained for optimal efficiency of mucociliary clearance [21].

Sputum

Expectoration of sputum is a sign of respiratory disease and indicates excessive production (hypersecretion) and retention (impaired clearance) of mucus, as occurs in patients with COPD, respiratory infection, asthma, bronchiectasis and cystic fibrosis (CF). When excessive secretions are expectorated, this substance is called sputum.

The characteristics of mucus change with infection and inflammation. Inflammation leads to mucus hypersecretion, ciliary dysfunction and changes in the composition and property of airway secretions. Inflammatory cells, particularly neutrophils, which are recruited to the airway to combat infection, disappear from the airway either through programmed cell death (apoptosis) or by necrosis. Necrotic

neutrophils release pro-inflammatory mediators that damage the epithelium and recruit more inflammatory cells. They also release DNA and filamentous actin (F-actin) from the cytoskeleton. DNA and F-actin copolymerize to form a second rigid network within airway secretions [22]. Neutrophil-derived myeloperoxidase imparts a characteristic green colour to inflamed airway secretions, and thickened and green secretions are usually described as purulent.

Pathophysiology of mucus hypersecretion in COPD

Mucus hypersecretion in COPD has characteristic features. It was thought that COPD mucus hypersecretion was similar to hypersecretion in asthma and CF. However, it is clear now that there is almost no mucin in the CF airway and with chronic CF or bronchiectasis, the airways fill with similar to pus rather than mucin [23]. Differences in mucus pathophysiology between COPD and asthma have been considered previously [24], and are summarized in Figure 62.1. Mucociliary clearance is also impaired in COPD and is discussed in detail elsewhere in the present volume. In addition, the pulmonary inflammation of COPD (essentially a macrophage-driven neutrophilia) that induces the hypersecretory phenotype of COPD is different from asthma [1].

Sputum production can be up to 100 mL/day in some patients and is associated with excessive airway mucus [25–27]. The increased mucus is associated with goblet cell hyperplasia [25,28] and submucosal gland hypertrophy [25,26,29,30]. Of note is that gland mucous cells are markedly increased relative to serous cells [29]. This is in contrast to asthma where the glands are hypertrophied but otherwise morphologically normal. Gland size correlates with amount of luminal mucus and daily sputum volume [29].

Not all COPD patients exhibit all of the above features of hypersecretion. Not all patients expectorate, not all patients have goblet cell hyperplasia [26,31], and there is overlap in gland size with healthy non-smokers, and between sputum producers and non-producers [28,30,32–34]. Thus, although considered a general feature of COPD, mucus hypersecretion is not always diagnostic.

The mucin composition of airway mucus in patients with COPD may be abnormal. For example, most chronic smokers produce a relatively rigid mucus with more sialic acid and fewer fucose residues [35]. Mucins in sputum from patients with COPD are less acidic than in sputum from control subjects [36], which may relate to altered glycosylation. *MUC5AC* and a low charge glycoform of *MUC5B* are the major mucin species in patients with COPD [37–40], with the low charge glycoform increased above normal levels [41]. Although COPD patients often have airway

Figure 62.1 Schematic diagram of differences in airway mucus pathophysiology between COPD and asthma. Compared with normal (a), in COPD (b) there is increased luminal mucus, goblet cell hyperplasia, submucosal gland hypertrophy (with an increased proportion of mucous to serous cells), an increased ratio of mucin (*MUC*) 5*B* (low charge glycoform) to *MUC5AC* and respiratory infection. In asthma (c) there is increased luminal mucus, marked goblet cell hyperplasia, submucosal gland hypertrophy (although without a marked increase in mucous/serous cell ratio), ‘tethering’ of mucus to goblet cells, and plasma exudation. Many of these differences require confirmation from greater numbers of subjects.

infection it is not clear how this may be related to the change in *MUC5B* glycoforms [3].

In contrast to normal airways, airway goblet cells in COPD patients contain not only *MUC5AC* but also *MUC5B* [39,42] and *MUC2* [9]. This distribution is different to that in patients with asthma or CF, where *MUC5AC* and *MUC5B* show a similar distribution to normal controls [43,44]. Although found inconsistently [27,38], *MUC2* may be increased in inflamed airways, including in CF or COPD [9,41,45].

Epidemiology of mucus hypersecretion in COPD

The contribution of mucus to pathophysiology and clinical symptoms in COPD is controversial [24]. Epidemiological studies sampling hundreds to thousands of subjects in the late 1970s and 1980s found scant evidence for the involvement of mucus in either the mortality or accelerated age-related decline in lung function associated with COPD [46–50]. In all studies, expectorated sputum volume

(sometimes called sputum production) was used as an index of mucus hypersecretion. The relationship between sputum volume and mucus hypersecretion is unclear, particularly in the small airways, the main site of airflow obstruction. The consensus of the studies was that airflow obstruction and mucus hypersecretion were largely independent disease processes.

In contrast, a number of studies in the late 1980s and 1990s found positive associations between sputum production and decline in lung function, hospitalization and death [51–55]. Some of these reports were re-examinations of the same patients, now older, reported previously. The increased risk of death in patients with excessive sputum appears to be brought about by the severity and chronicity of disease and the frequency of infectious exacerbations [4]. Thus, although not associated with disease progression in all cases, mucus hypersecretion contributes to morbidity and mortality in certain groups of patients with COPD, particularly those prone to infection, and possibly as patients age. This highlights the potential importance of developing drugs that inhibit mucus hypersecretion in these patients.

Preliminary considerations for mucolytic therapy of COPD

From the above it may be seen that there is some debate concerning both the pathophysiological and clinical significance of mucus hypersecretion in COPD and, therefore, the therapeutic value of drugs affecting mucus properties. This is evident in the observation that mucolytic agents are not recommended in current guidelines for management of stable COPD [3]. Nevertheless, the clinical symptoms of cough and sputum production, coupled with a perception of the importance of mucus hypersecretion in the pathophysiology of COPD, has prompted renewed interest in research into airway hypersecretion and, in concert, in development of drugs targeting mucus. Because COPD has specific trigger factors and mucus hypersecretory phenotype (see Fig. 62.1), COPD-specific drugs may be required to fulfil the theoretical requirements for treatment of hypersecretion (Table 62.1). There are many medications available that purport to alleviate airway mucus hypersecretion. The mechanism of action of these compounds is mostly unknown or incompletely characterized. For example, *N*-acetylcysteine (NAC) is considered a mucolytic drug, although this activity is not well documented [56], and it is not found in airway secretions after oral dosing [57]. NAC has antioxidant properties [58], and may also have antibacterial activity [59,60]. Ambroxol is another drug with possible multiple mechanisms of action, including antioxidant activity [61] and enhancement of surfactant secretion [62]. Thus, any beneficial clinical effects of mucolytic treatment are not necessarily a result of decreasing mucus viscosity – the definition of a mucolytic.

In the following discussion, compounds will be classified as mucolytics, mucoregulators, expectorants or adhesives according to the following characteristics. Respiratory mucins, in common with other mucins, contain disulphide bonds that contribute to mucus viscosity and gel formation [63,64]. Herein, the term mucolytic refers to compounds

with free sulphhydryl groups that hydrolyse disulphide bonds and reduce mucus viscosity. Other compounds such as proteolytic enzymes and DNase also break up mucus, but do so via mechanisms other than dissociating disulphide bonds in mucin molecules and, as such, are not classic mucolytics and are often termed peptide mucolytics. Other drugs do not have free sulphhydryl groups, or otherwise break up mucus. Nevertheless, in experimental studies they have beneficial actions on various aspects of mucus properties. These compounds are termed non-thiol mucolytics herein. Expectorants probably increase secretion to a point where sufficient mucus is produced to enable it to be coughed up. Expectorants may also hydrate mucus and, thereby, enhance mucociliary clearance. These drugs may also be irritants and facilitate cough to dislodge mucus. Oral expectorants are considered to increase secretion by triggering a vagal reflex via nerve endings in the gastric mucosa. Adhesives reduce mucus adhesiveness, thereby enhancing mucociliary clearance by increasing the efficiency of energy transfer from the cilia. The effectiveness of cough in dislodging secretions will also be enhanced because sputum tenacity, the product of adhesivity and cohesivity (Fig. 62.2), has a marked influence on cough clearance [65].

Mucolytics

N-acetylcysteine

N-acetylcysteine (NAC) is a commonly prescribed mucolytic compound [66] that decreases mucus viscosity *in vitro* [67,68]. In a rat model of chronic bronchitis, oral NAC inhibited cigarette smoke-induced goblet cell hyperplasia [69] and associated mucus hypersecretion [70], when given concurrently with the smoke. More importantly from a clinical and therapeutic standpoint, NAC reduced the time taken for goblet cell numbers to return to normal after cessation of smoke exposure [71]. This may have relevance to treatment of patients with COPD who quit smoking.

Table 62.1 Theoretical requirements for treatment of mucus pathophysiology in COPD.

Overall effect	Component effects
Facilitate mucus clearance (short-term relief of symptoms)	Reduce mucus viscosity (?increase elasticity) Increase ciliary function Induce cough
Reverse hypersecretory phenotype (long-term benefit)	Reduce submucosal gland size Correct increased gland mucous/serous cell ratio Reduce goblet cell number Reverse increased LCGF- <i>MUC5B</i> / <i>MUC5AC</i> ratio
LCGF, low charge glycoform; MUC, mucin gene product.	

Figure 62.2 Tenacity (dynes) is the product of cohesivity and work of adhesion. Sputum tenacity and air flow are the two strongest predictors of cough clearability.

The pharmacokinetics of NAC depend upon the route of administration. Aerosolized inhaled NAC directly reduces mucus viscosity whereas oral NAC has low bioavailability [72], although it is deacetylated to cysteine whose thiol group possesses reducing and antioxidant properties [73]. NAC cannot be detected in plasma or bronchoalveolar lavage fluid following oral dosing for up to 2 weeks [57,74], although increases in plasma cysteine concentrations were reported [57], with associated increased levels of glutathione (GSH) in both plasma [57,74] and lung [57]. However, in patients with COPD, high doses of NAC (600 mg three times daily) are required to elevate plasma GSH levels [75].

Clinical trial data on NAC are variable, and may be related to route of administration. For example, inhaled NAC in patients with chronic bronchitis did not improve dyspnoea, cough, sputum production, lung function or feelings of well-being after treatment for 16 weeks [76]. In contrast, oral NAC increased sputum volume, decreased sputum thickness and improved scores for dyspnoea and ease of expectoration in chronic bronchitis patients [77]. The study also reported improvements in lung function compared with the placebo group, although this should be treated with caution because of differences in lung function between the two groups at baseline. A large placebo-controlled trial in patients with chronic bronchitis found that oral NAC treatment (200 mg twice daily) decreased symptom scores for sputum volume, degree of purulence, 'thickness' of sputum and difficulty in expectoration and severity of cough [78].

A common theme of clinical trials with NAC is reductions in exacerbations [78–80], although this is not always the case [81]. The latter study differed from the former two studies in that patients not only had chronic bronchitis but

also severe airways obstruction. Oral NAC (300 mg twice daily as slow-release tablets) also reduces days off work because of illness in patients with chronic bronchitis [82], while 600 mg twice daily sustained-release NAC improves 'general well-being' [83]. This result should be interpreted with caution because there was an imbalance between groups in 'well-being' scores at the start of the trial.

In the largest and most complete randomized, placebo-controlled, and well-powered study of NAC in COPD to date, 523 patients from 50 European centres were assigned to 600 mg daily NAC or placebo. After 3 years, neither the annual number of exacerbations nor the yearly rate of decline in FEV_1 differed between treatment and control groups. From these data it appears that NAC is ineffective at preventing deterioration in lung function or preventing exacerbations in patients with COPD [84]

Nacystelyn

Nacystelyn is a lysine salt of NAC that has mucolytic and antioxidant properties, and a neutral pH which, when compared with the more acidic NAC (pH 2.2), reduces unwanted side-effects when aerosolized into the lung [85,86]. *In vivo*, nacystelyn has greater mucolytic activity than NAC [87], and *in vitro* has greater antioxidant activity in inhibiting the oxidative burst of human peripheral blood neutrophils [88]. Inhaled nacystelyn has been given to CF patients but, to date, there are no data available regarding its use in COPD.

Methylcysteine hydrochloride

Methylcysteine hydrochloride (mecysteine) is a mucolytic indicated for reduction of sputum viscosity [89]. In a double-blind placebo-controlled trial in chronic bronchitis patients with uncontrolled productive cough, oral methylcysteine markedly decreased sputum viscosity at all time points assessed, increased sputum volume, albeit at one time point only, and improved the subjective assessment of both ease of expectoration and severity and frequency of cough [90]. No side-effects of clinical significance were reported. Further clinical trials of the use of this drug in COPD are warranted.

2-Mercaptoethane sulphonate sodium

2-Mercaptoethane sulphonate sodium (MESNA) is a mucolytic agent that reduces the viscosity of aspirated mucus from patients following surgery [91]. In rabbits, MESNA was the least irritating to the tracheal epithelium of three mucolytic agents examined [92]. In surgical cases requiring mucolytic therapy for mucus retention in the lung, MESNA instillation liquefied the secretions and

facilitated aspiration [91]. There were no side-effects. Specific studies in COPD are required.

Non-thiol mucolytics

Carbocysteine

Carbocysteine (*S*-carboxymethylcysteine) is a cysteine derivative with a blocked sulphhydryl group, and so does not directly break disulphide bonds [93]. Consequently, carbocysteine does not reduce the viscosity of canine tracheal mucus *in vitro* [94] or human nasal mucus [95], but did reduce sputum viscosity in patients with chronic bronchitis who produced viscous secretions [96]. The therapeutic effect of carbocysteine may be via stimulation of intracellular sialyl transferase activity [97]. As a result, newly synthesized mucus would have an increased content of sialomucins and a decreased content of fucomucins. In a rat model of chronic bronchitis, carbocysteine inhibited tracheal mucus hypersecretion [70].

Carbocysteine has been reported to have variable effects in clinical trials. For example, in one study, carbocysteine had no effect on lung clearance, cough, weight of sputum expectorated, lung function or subjective improvement in patients with chronic bronchitis [98]. In contrast, in a 3-month double-blind controlled study of 82 patients with chronic bronchitis, carbocysteine reduced sputum viscosity, increased sputum volume and ease of expectoration, reduced cough frequency, improved lung function and reduced dyspnoea [99]. Similarly, in another double-blind placebo-controlled study in 20 male patients, 2 weeks of oral carbocysteine enhanced the viscoelastic properties of the bronchial secretions, improved clinical parameters, although with no change in lung function [100]. Carbo-cysteine also increased penetration of amoxicillin into bronchial secretions in patients with chronic bronchitis [101], an effect that may be beneficial during infective exacerbations.

Carbocysteine-lys

Carbocysteine-lys is a lysine salt of carbocysteine that diffuses into bronchial mucus [102] and has modest mucolytic activity [103]. Four days' treatment of patients with chronic bronchitis with carbocysteine-lys decreased sputum viscosity and increased mucociliary transport for up to 8 days after cessation of treatment [104]. In a 6-month multicentre double-blind placebo-controlled trial in 622 COPD patients, carbocysteine-lys reduced exacerbations and antibiotic use compared with placebo controls [105]. However, intermittent carbocysteine-lys therapy (1-week courses alternating with 1 week of placebo) was not effective. No serious adverse effects were reported.

Erdosteine

Erdosteine (*N*-(carboxymethylthioacetyl)-homocysteine thiolactone) is a synthetic derivative of the naturally occurring amino acid methionine that was developed as a mucolytic for use in COPD patients [106]. Erdosteine contains two blocked sulphhydryl groups that are 'exposed' after hepatic metabolism of the drug. The freed sulphhydryl groups break down disulphide bonds in mucins [106], and also confer free radical scavenging and antioxidant properties. Erdosteine 300 mg three times daily significantly reduced the viscosity of sputum in 20 male patients with COPD without altering elasticity [107]. These changes were accompanied by reductions in mucin concentration and dry weight. The same dose of drug improved mucociliary transport in 16 former smokers with chronic bronchitis [108].

Erdosteine also appears to have antioxidant activity, leading to significant increases in levels of functional α_1 -antitrypsin (an endogenous antielastase) in healthy smokers [109]. In addition, erdosteine enhances antibiotic penetration into sputum. Twenty four patients with an infective exacerbation of chronic bronchitis were treated with amoxicillin (500 mg three times daily) plus either erdosteine or placebo in a double-blind trial [110]. There was a significantly higher concentration of amoxicillin in the sputum of the erdosteine group, with more rapid sterilization of the sputum. Erdosteine was evaluated in 237 patients with exacerbations of COPD, comparing treatment with amoxicillin (500 mg three times daily) plus erdosteine (300 mg twice daily) with amoxicillin plus placebo [111]. Sputum viscosity and clinical assessment improved with combined therapy, but without changes in sputum volume, body temperature or lung function.

Stepronin

Stepronin (2-(α -theoylthio)propionylglycine lysine salt), like erdosteine, is not itself mucolytic but is metabolised in the intestine to remove a thenoyl moiety and release thio-propionylglycine, which has a free sulphhydryl group that breaks disulphide bonds [112]. It also reduces secretion in cat isolated tracheal submucosal glands [113]. Launched in Italy in 1981 [114], stepronin was developed to treat chronic bronchitis associated with mucus hypersecretion. Side-effects are rare, although cell-mediated hypersensitivity to stepronin has been reported [115].

Expectorants

Bromhexine

Bromhexine (*N*-methyl-*N*-cyclohexane-3,5-dibromo-2-aminobenzylamine hydrochloride) is derived from the

alkaloid vasicine (*Adhatoda vasica nees*). Bromhexine reduces the elasticity and viscosity of mini-pigis tracheal mucus after oral dosing [116] and stimulates mucus secretion by canine tracheal submucosal glands, but not goblet cells [117]. In a multicentre placebo-controlled trial of 237 patients with COPD, oral bromhexine (30 mg twice daily) significantly decreased sputum volume and improved sputum 'quality' and ease of expectoration, cough, dyspnoea, lung function and the physician's overall assessment [118]. Similar to erdosteine and ambroxol (see above), bromhexine increases penetration of antibiotics, amoxicillin and erythromycin, into sputum [119,120].

Ambroxol

Ambroxol is a metabolite of bromhexine (see above) and is probably an expectorant because it stimulates mucus secretion [121]. It does not exhibit anti-inflammatory activity in patients with chronic bronchitis [122]. The effect of ambroxol on mucociliary clearance is variable. For example, ambroxol significantly increased mucociliary transport in one double-blind cross-over study in 12 heavy smokers with chronic bronchitis [123]. In contrast, in another double-blind placebo-controlled trial in 30 patients with COPD and asthma, ambroxol increased mucociliary clearance in only one out of five regions of the lung, compared with an increase in four out of five regions following a β_2 -adrenoceptor agonist [124]. Similar results were found in 14 patients with simple chronic bronchitis [125].

The clinical efficacy of ambroxol is also equivocal. For example, in a controlled study in 60 patients with 'bronchial stasis', 120 mg/day ambroxol increased ease of expectoration and sputum volume, and reduced cough severity and sputum viscosity [126]. In another controlled study, ambroxol improved subjective symptoms and phlegm loosening in 92 patients with chronic bronchitis, but did not improve lung function or diary card entries [127]. In contrast, in a similarly designed study in 90 patients with stable chronic bronchitis who had difficulty clearing secretions, there was no clinical advantage in taking ambroxol [128]. In a 6-month multicentre double-blind controlled trial, ambroxol significantly reduced the frequency of exacerbations in 104 patients with chronic bronchitis compared with 104 patients taking placebo [129]. A similar reduction in frequency of exacerbations was seen in a larger trial of 5635 patients, although the results should be interpreted with caution as the trial was open, prospective and had no control group [130]. In a study in 24 patients with infectious exacerbations of COPD, ambroxol increased the concentration of the antibiotic ofloxacin in lung lavage alveolar cells, although there were no increases in concentration in plasma or bronchial biopsy specimens [131]. Ambroxol was well tolerated in all studies.

Iodides

Although iodides, in particular saturated solutions of potassium iodide (SSKI), have long been used as expectorants, clinical efficacy has not been demonstrated and their use is not recommended because they may induce thyroid disease [132]. A potentially less toxic product is 'iodinated' glycerol (iodopropylidene glycerol), which has been shown to be an effective expectorant in patients with excessive sputum production [133]. However, clinical data are equivocal. For example, in a randomized double-blind placebo-controlled study in 361 patients with chronic bronchitis, 2 months' treatment with iodinated glycerol tablets reduced chest discomfort and frequency and severity of cough, increased ease of expectoration and improved patients' subjective assessment of well-being [134]. However, the physician's evaluation of patients showed no significant difference between treatment and placebo groups, and the study lacked objective measurements of pulmonary function or sputum clearance. Similarly, another placebo-controlled trial found no significant changes in pulmonary function, clinical scores or sputum properties following 16 weeks' treatment with iodinated glycerol [135]. Although considered safe in clinical trials [134,135], iodinated glycerol is associated with adverse side-effects, including hypothyroidism, hyperthyroidism and goitre [136–140]. Chronic iodine poisoning has been reported with long-term use [141].

Domiodol (iodoethylene glycerol) is another iodinated organic compound [142]. In a placebo-controlled cross-over study, domiodol significantly increased volume of secretions and aided ease of expectoration in chronic bronchitis patients [143]. However, the lack of convincing clinical evidence coupled with concerns regarding safety suggests that iodine and iodinated compounds should not be used as mucoregulatory drugs in COPD.

Adhesives

Surfactant can reduce sputum adhesiveness and enhance mucus clearance, thereby improving lung function (Fig. 62.3). Patients with chronic bronchitis have a reduced amount of bronchial surfactant [144], and also have abnormal sputum phospholipid composition [145,146], factors that would tend to decrease clearance. Consequently, decreasing tenacity with surfactant enhances the effectiveness of cough [147]. Fourteen days of aerosolized surfactant (607.5 mg dipalmitoyl phosphotidal choline/day) increased *in vitro* sputum transportability, improved forced expiratory volume in 1 s (FEV_1) and forced vital capacity (FVC) by more than 10%, and decreased trapped thoracic gas (residual volume/total lung capacity [RV/TLC] ratio) by more than 6% in patients with stable chronic bronchitis [148]. This effect persisted for

Figure 62.3 Surfactant therapy in cystic fibrosis. Fourteen days of aerosolized surfactant (Exosurf at 607.5 mg dipalmitoyl phosphotidal choline/day) increased *in vitro* sputum cough transportability and improved forced expiratory volume in 1 s (FEV_1) by more than 10% in patients with stable cystic fibrosis. Pulmonary function returned to baseline within 2 weeks of stopping therapy. (From B.K. Rubin, unpublished data.)

at least a week after treatment was completed. Interestingly, ambroxol is thought to stimulate surfactant secretion.

Some of the expectorant activity of mucolytic and related compounds may be attributed to adhesive action. Decreasing the viscosity of a mucous plug might, theoretically, reduce cough clearance by decreasing the height of the mucus layer. However, if a mucolytic decreased mucus mechanical impedance at the epithelial surface (i.e. frictional adhesive forces), it might 'unstick' secretions from the underlying ciliated epithelium, thereby making airflow-dependent clearance more efficient.

Peptide mucolytics

Recombinant human DNase (dornase alfa)

DNA, released in large amounts from necrosed neutrophils, increases mucus viscosity in purulent lung secretions. Recombinant human DNase I (dornase alfa) has been developed for treatment of mucus hypersecretion in CF [149,150]. Dornase alfa reduces the viscosity of purulent sputum from CF patients (see Plate 62.1; colour plate section falls between pp. 354 and 355) and, in a clinical trial, dornase alfa inhalation decreased the surface adhesivity (and thus the tenacity) of CF sputum, with an associated improvement in lung function [151]. In contrast, in patients with bronchiectasis not caused by CF, dornase alfa did not alter sputum transportability, lung function, dyspnoea or quality of life [152].

Dornase alfa also reduces the viscosity and favourably

alters the surface properties of purulent sputum *in vitro* from patients with chronic bronchitis [153]. Phase II and III clinical trials of the effects of dornase alfa in COPD are, to date, reported only in abstract form, with limited data on patient characteristics, disease severity and concomitant treatment [154–156]. The results of these studies are equivocal. Consequently, at present, dornase alfa is recommended only for use in patients with CF [157].

Gelsolin

Actin is the most prevalent cellular protein in the body, having a vital role in maintaining the structural integrity of cells. In addition to DNA (see above), necrosing cells also release significant quantities of actin. The actin in turn interacts with mucus to increase its viscosity. Gelsolin is the recombinant form of the natural actin-severing agent and reduces sputum viscosity in patients with CF [158]. Clinical trials of gelsolin in patients with respiratory diseases, including chronic bronchitis, have not been reported.

Conclusions

Current guidelines do not recommend mucolytics in the management of COPD [3]. Despite this, numerous mucolytic and related drugs are available worldwide, with *N*-acetylcysteine, bromhexine and carbocysteine listed extensively in international pharmacopoeiae [66]. The discrepancy between drug listing and recommended treatment is related to the inconsistency in data from clinical trials of mucolytic drugs [159]. Many mucoactive compounds have an impressive preclinical profile but subsequently are entered into imprecise clinical trials of a design leading to ambiguity in interpretation. Two meta-analyses of clinical trials in COPD, one on mucolytics [160], the other on *N*-acetylcysteine [161], excluded 70–80% of the reported trials because they did not conform to standard criteria including being double blind and placebo controlled, of sufficient duration and of sufficient power, and with well-defined primary endpoints or outcome measures. Better clinical studies are required and should conform to current guidelines for clinical trials of mucolytics [162,163]. Data on rate of hospital admissions in response to mucolytic treatment would be useful because this outcome measure contributes greatly to the costs of treating severe COPD. Two systematic reviews analysed clinical trials in COPD, one for mucolytics and exacerbations [80], the other for *N*-acetylcysteine [161], and concluded that treatment for 2–6 months with oral mucolytic drugs was associated with a 23–29% reduction in exacerbation rate.

The conclusion from the present chapter and the meta-analyses [80,160] is that maintenance treatment with

mucolytic or related drugs is not associated with significant improvements in lung function in patients with COPD. However, treatment with certain mucolytic drugs is associated with a reduction in exacerbations and days of illness [80,161]. The cost effectiveness of treatment of this patient group for up to 6 months a year is debatable [164]. However, the analysis of Poole and Black [80] indicates that patients with more severe COPD benefit more from treatment with mucolytics. Consequently, maintenance mucolytic treatment of patients with severe COPD should be cost effective, and future clinical trials should examine the value of mucolytic drugs in this difficult patient group.

CHAPTER 63

End-of-life and palliative care for patients with COPD

John E. Heffner and Ann L. Heffner

Patients with moderate to severe chronic obstructive pulmonary disease (COPD) experience a progressive disorder characterized by breathlessness, decreased exercise tolerance and episodes of acute exacerbations of airway obstruction. Each exacerbation presents a risk of respiratory failure that may require intubation and ventilatory support. Although most hospitalized patients with COPD managed by mechanical ventilation survive to hospital discharge, a subset of patients with far advanced disease and poor baseline quality of life have a low probability of weaning from mechanical ventilation and regaining their prehospitalization functional capacity. Such patients face either a prolonged period of ventilatory support at the end of life or considerations of withdrawal of life support after a trial of aggressive restorative care. Other patients with end-stage COPD may elect to avoid hospitalization during the final stages of their disease if the burden of life-supportive care exceeds its anticipated benefit.

Meeting the needs of patients with moderate to severe COPD at the end of life requires advance care planning and appropriate palliative services directed by skilled caregivers [1,2]. Unfortunately, most observers note extensive deficiencies in the USA with the provision of care to patients with terminal medical conditions [3]. Recently, even greater deficiencies in end-of-life and palliative care have been noted to exist for patients with COPD as compared with other terminal conditions, such as lung cancer [4,5], even though patients with chronic lung disease have similar physical and psychosocial needs [6].

Although the reasons for these deficiencies are uncertain, lack of patient desire for comprehensive end-of-life care does not appear to contribute. Patients with advanced symptomatic COPD desire information about life-supportive care and advance care planning [7] but voice disappointment with the amount of educational information typically provided by their physicians [8].

This chapter focuses on the nature of the ethical decisions

faced by patients with advanced COPD and describes general approaches to advance care planning and palliative care. Expert clinicians who have pioneered the modern management of COPD have deep roots in offering a message of hope, aspirations for a high quality of life, and comprehensive supportive care to promote an active and functional lifestyle for patients [9,10]. We believe end-of-life care and advance care planning fits well into this rich medical tradition.

Outcome predictions and advance care planning

Patients hospitalized for an acute exacerbation of their airway disease represent a subgroup of patients with COPD who have a guarded prognosis. Although 89% of patients survive the initial hospitalization [3], hospital survival decreases to 76% if intubation and mechanical ventilation are required [4]. Survival measured at 1 year after hospitalization decreases to 59%, which is a marker for the underlying severity of COPD among patients who require hospitalization for exacerbations [11]. Those patients who survive hospitalization frequently experience a poor quality of life after discharge because of unremitting respiratory symptoms [11].

Clinicians faced with assisting patients with advance care planning would benefit from accurate prognostic information that could guide an individual patient toward understanding his or her likely clinical course. Such information would enable the patient and their family to weigh the relative benefits and burdens of life-supportive care as they consider their wishes regarding the desired level of medical care. Unfortunately, the ability to predict clinical outcome of hospitalized patients with COPD is marginal at best. No clinical characteristics available at the time of hospital admission identify with sufficient accuracy which patients

will follow an unfavourable clinical course [12–14]. Available systems utilize a complex combination of clinical factors to estimate the probability of a specific outcome for populations of patients and lose validity when applied to individual patients with COPD. Moreover, most prediction models presented in the literature have not been validated in independent cohorts. Also, the Study to Understand Prognoses and Preferences for Outcome and Risks of Treatment (SUPPORT) demonstrated that physicians have limited ability to incorporate prognosticating information into their clinical practices [3].

The ability to predict the mortality of ambulatory patients is even more challenging. Single variables, such as forced expiratory volume in 1 s (FEV_1), have limited predictive accuracy for individual patients [15]. Multidimensional disease staging systems that consider variables such as dyspnoea, health status and exercise capacity are only now being developed [16]. Fan *et al.* [17] recently demonstrated that quality of life, as assessed by a condition-specific measure (Seattle Obstructive Lung Disease Questionnaire), was a strong predictor of hospitalization and all-cause mortality. The application of these measures to specific patients to assist advance care planning awaits further investigation.

Without accurate predictors of clinical outcomes for individual patients, caregivers must recognize the ethical dilemmas that arise in caring for patients with advanced COPD, assist patients with the uncertainties of advance care planning and understand the perspectives of patients with advanced lung disease who may face end-of-life decisions. Autonomy is the predominant ethical principle that drives end-of-life decision-making in the USA [18]. Most patients with advanced COPD wish to make their own decisions regarding life-supportive care even after they lose decision-making capacity. More than 80% of patients with advanced COPD enrolled in pulmonary rehabilitation programmes would choose to direct decisions regarding intubation and mechanical ventilation by either communicating with their physicians directly or through an appointed surrogate or instrument of advance care planning [7].

To make informed decisions, patients need knowledge of the nature of alternative therapeutic decisions (e.g. intubation, mechanical ventilation, tracheotomy) and their probable outcomes. The complexity of advanced life-supportive care requires physicians to discuss these interventions with patients in advance of their need. Unfortunately, only 19% of patients with advanced lung disease enrolled in pulmonary rehabilitation programmes have discussed with their physicians the appropriateness of life-supportive care relative to their lung condition and 15% have discussed the nature of intubation and mechanical ventilation [7]. Consequently, less than 15% of patients with advanced lung disease have confidence that their physicians understand their end-of-life wishes, even though most of these

patients have strong opinions regarding end-of-life care [7]. A clear understanding of the potential value of life-supportive care is important because patients with terminal conditions, such as lung cancer, usually retain a more optimistic and less accurate estimate of their survival compared to their physicians [19]. Patients with severe lung disease alter their willingness to accept life-supportive care once informed of a low likelihood of survival or recovery to an acceptable functional status [7,20].

Multiple studies confirm that patients with a broad category of conditions and their physicians agree that physicians should initiate discussions about end-of-life care [7,21,22]. Many barriers exist, however, to the completion of these discussions. Most studies that examine these barriers demonstrate that physicians identify more barriers than patients [23]. The majority of these barriers pertain to concern that patients will not be receptive to these discussions or that the patient's condition has not yet advanced enough to warrant these discussions [23–25].

Multiple interventions to promote more patient–physician discussions related to advance care planning have been examined. Unfortunately, policy interventions, case manager facilitators in inpatient settings, computer prompts to electronic medical records and physician education have provided only marginal effects [3,26–28]. Greater research is needed to understand the barriers that limit the occurrence of these discussions [24]. The variability of the barriers to these communications suggests that multiple interventions, both educational and health system related, are required [23,29].

In face of these barriers, physicians should develop their own strategies for inviting their patients with COPD to discuss advance care planning. An increasing body of knowledge has developed to assist physicians in initiating end-of-life discussions with their patients [30–34]. These strategies recommend that physicians introduce these discussions in a manner that does not trigger understandable patient reactions that their physicians have new concerns about their imminent death, a sense of hopelessness or futility, a negative view of their disease status, or an interest in abandoning restorative care. Introducing these discussions during intervals of stable or good health defuse some of these concerns. Also, specific measures have been recommended to assist patients' acceptance of these discussions. These measures include neutral topic introductions, certain prompting cues and phrasing, focused listening, efforts to gain patient goals and values, clarifying strategies, avoiding too much discussion about specific treatment details, and a series of open-ended questions (Table 63.1) [30–39].

Although most patients with advanced lung disease desire advance care planning discussions with their physicians, a small minority (less than 5%) do not because of concerns that these discussions may provoke anxiety [7].

Table 63.1 Open-ended questions to promote end-of-life discussions with patients. (Adapted from Lo *et al.* [35].)*General*

What are your greatest concerns about your illness?
 What are your and your family's thoughts about your care?
 What are your greatest hopes and fears related to your illness?
 Tell me about the most difficult part of this illness?
 What would you hope for the future?
 When you think about your future, what is most important to you?

Questions to determine patient interest in spiritual and existential matters

In thinking about this illness, is faith (religion, spirituality) important to you?
 In earlier times before your illness, has faith (religion, spirituality) been important to you?
 Are you able to talk with someone about religious matters?
 Would you wish to talk about religious matters with someone?

Questions for patients who wish to pursue spiritual and existential matters

What would you like to accomplish during the rest of your life?
 Do you have thoughts as to why you became ill?
 If you were to die today, what would be left undone?
 What do you think happens after you die?
 What legacy do you want to leave your family were you to die today?
 After your death, what do you want your family to remember about you?

Most patients with chronic health conditions, however, do not find these discussions anxiety provoking, and some studies note more end-of-life information from physicians decrease depression scores [7,30,40–43]. Patients who initially refuse these discussions may become more receptive after they receive general information regarding the nature of their disease and the progressive course of COPD [44]. Patients may benefit from reading materials on advance care planning in preparation for physician discussions.

Even when patient–physician discussions about end-of-life care occur, they frequently do not achieve the patient's goals. Patients with COPD and other terminal conditions prefer to receive straightforward, honest and relevant information about their specific prognosis and circumstances [8,45,46]. Unfortunately, physicians often deliberately soften their discussion of prognosis when they sense patients harbour more optimistic prognostic outlooks in an effort to avoid extinguishing hope [47]. Also, physicians spend 75% of such conversations talking and allow little time for patients to state their wishes for therapy and personal values

[48–50]. Few data exist regarding interventions to enhance these discussions. Randomized trials demonstrate that an intensive communication skills workshop over several days can improve physician communication skills [37].

Timing and setting for advance care planning

Most patients with advanced lung disease prefer discussions about advance care planning to occur in outpatient settings during periods of stable health [7]. Physicians usually defer these discussions until patients have far advanced disease. McNeely *et al.* [25] observed that pulmonary physicians delayed discussions with their patients about end-of-life care until their patients experienced recent hospitalizations and marked decreases in FEV_1 . Sullivan *et al.* [24] noted that physicians used clinical metrics, such as poor nutritional status or low FEV_1 , to trigger end-of-life discussions. In contrast, patients with COPD demonstrate an interest in receiving this information regardless of the severity of their disease. Heffner *et al.* [7] demonstrated that no measure of lung disease severity was associated with desire among pulmonary rehabilitation patients to discuss end-of-life issues with their physicians. Pfeifer *et al.* [51] reported that the desire for an end-of-life discussion with their physicians expressed by 100 patients with COPD presenting for pulmonary function testing was not associated with FEV_1 , oral corticosteroid use, functional status score, hospitalizations in the past year or previous mechanical ventilation.

Ideally, these discussions should occur with the first diagnosis of COPD as soon as a primary care provider establishes a therapeutic relationship. Generally, the caregiver most closely involved with the patient's care should initiate these discussions, which has been termed 'captaincy' [52]. In the absence of physician initiative, however, other caregivers can promote the completion of these discussions by educating patients to expect that these discussions should occur.

One study heightened these patient expectations through an educational programme on advance care planning in a pulmonary rehabilitation programme [7]. Patients enrolled in pulmonary rehabilitation consider their non-physician rehabilitation programme educators as acceptable sources of information on life-supportive care [7]. A before–after study demonstrated that end-of-life education in pulmonary rehabilitation increases the adoption rate for instruments of advance care planning and completion of patient–physician discussions about end-of-life care [20]. Although 70% of pulmonary rehabilitation programme directors consider end-of-life education as an appropriate component of their curriculum, fewer than 10% of programmes in the USA provide their enrolled patients these educational opportunities [53].

Nature of advance care planning

Advance care planning has traditionally focused on methods to address plans for the use of life-sustaining treatments. Methods have included written advance directives, surrogate decisions by families, friends or physicians, and discussions between patients and their physicians.

Advance care planning with the completion of formal written instruments, such as living wills and durable powers of attorney for health care, were met with optimism when introduced into health care that would allow the patient to direct their own end-of-life care or identify a proxy who could convey the patient's wishes after the patient lost decision-making capacity. These documents, however, face major barriers in implementation and have not achieved their goals of promoting patient autonomy [54,55]. Only 10–20% of patients complete advance directives and these instruments, when present, have limited impact on future care [56–60]. Also, the decisions of surrogates correspond poorly with the wishes and desires of the patient for whom decisions are being made [56]. Uncertainty in the minds of surrogates regarding the appropriateness of their decisions often lead them to favour more intense life-supportive interventions that warranted by the patient's previously expressed wishes or the likelihood of a favourable clinical outcome [56,59,61–63].

The utility of advance directives may be improved if they are tailored to a specific patient's underlying condition and clinical events that they will most likely experience [64,65]. However, because most patients request that physicians and surrogates overrule their wishes contained within advance directives if unique clinical circumstances occur [66,67], written advance directives should be considered for most patients as general statements regarding treatment preferences rather than specific directives that cannot be altered. This indicates that both medical and ethical decision making at the end of life is a shared process and the principle of beneficence on the part of both the physician and the family may at times equal or override patient autonomy [68,69].

Limitations of written advance directives and surrogate decision making prompt medical professionals to adopt a broader approach to advance care planning that incorporates the patient's perspective [70]. Most physicians consider advance directives to be operational tools to determine which life-sustaining interventions should be applied in various clinical circumstances. In contrast, patients have more comprehensive goals that centre on preparing for death, achieving a sense of control over their lives, and fortifying personal relationships with friends and families. Patient goals, therefore, are less operational and more orientated toward their psychological, emotional and spiritual needs.

Consequently, the emphasis of discussions on end-of-life care may shift from patient–physician discussions on the use of life-supportive interventions to patient–family–friend communication. This communication has a purpose of strengthening relationships and sharing decisions regarding life-supportive care through mutual support. Physicians, with their patient's permission, can promote this dialogue by involving families in advance care planning and encouraging discussions within families regarding the end-of-life decisions that patients may eventually face [18]. Caregivers can enrich these discussions by providing the patient with educational materials and resources that enhance informed decisions. In this model, emphasis shifts from the completion of written advance directives to an ongoing dialogue between patients, caregivers and families regarding the prognosis of the patient's condition, likely outcomes of various treatment interventions, and the values and goals that the patient would wish to have fulfilled [70].

Physicians frequently overlook the spiritual context of these discussions. Most patients with pulmonary or other medical conditions wish to discuss spiritual and religious topics with their physicians [19,46,71]. Physicians, however, either omit or perform poorly in conversations about the spiritual needs of their patients, despite guidance in the literature for approaching these discussions [35,72]. Physicians in this setting are challenged to balance the need to maintain their professional boundaries yet recognize their patient's spiritual concerns in the clinical environment [73].

Withdrawal of life-supportive care

Comprehensive advance care planning for patients with COPD assists in the identification of patients with far advanced symptomatic disease who wish to withhold ventilatory support at the end of life. Other patients with end-stage disease who fail a trial of aggressive restorative care benefit from a humane withdrawal of life support after it is initiated. Extensive legal, ethical and moral justification exists for the withdrawal of life-supportive care at the end of life when it is no longer desired or no longer provides comfort to the patient [74]. Less consensus exists regarding the specific practical steps for withdrawing life-supportive care. Observational studies demonstrate extensive practice variation both within and between institutions in the timing and methods of life-support withdrawal [75–78].

For patients with COPD receiving ventilatory support, practical steps begin with a validation of the decision to withdraw life support with the patient (when possible), family and all team members who participate in patient care. This process 'shares the burden of decision making'

[79]. Informed consent is then obtained. Although the sequencing and manner for withdrawal of life support is complex and varies on the basis of patient, family and institutional needs, an explicit and organized approach improves patient care [80]. Preprinted order sheets and established policies and procedures enhance amelioration of patient and family discomfort and promote the acceptance of the process by bedside caregivers [81].

Essential elements of an organized approach include adequate treatment of the patient's pain, anxiety and suffering that is present or anticipated to occur after withdrawal of ventilatory support. Patient surrogates and family members of patients dying in the intensive care unit (ICU) rank pain control, availability of family at the bedside, and efforts to address dyspnoea as the most important factors that promote a peaceful and satisfying death experience [82]. Aggressive symptom control with opioids and sedatives, even if such treatment accelerates death, has received endorsement under the 'principle of double effect', which allows such treatment if the *intent* is not to hasten death [83]. In actual practice, the amount of morphine used during withdrawal of life support does not correlate with the duration of survival, which is a function of ventilatory status at the time support is withdrawn [81]. Careful planning is required to manage the patient who has received neuromuscular paralytic agents before the decision to withdraw support [84]. Several reviews provide extensive discussions of the practical aspects of the withdrawal of life-supportive care [79,80,84].

Palliative care

Hospitalized patients with acute exacerbations of COPD who choose to have life-supportive care withheld or withdrawn require expert care to relieve their pain and suffering and manage their end-of-life care [85]. Special considerations are required for terminal patients with COPD who choose to avoid hospitalization and die at home. Both groups of patients may experience distressing physiological symptoms of pain, cough, dyspnoea, anxiety, agitation, confusion, fatigue and depression [86,87]. Patients may also experience discomfort related to their sense of completion with their life affairs, meaning to their life, and relationships with their family and friends. Unresolved issues in these areas can cause 'existential suffering' at the end of life, which often surpasses physiological symptoms as a source of distress for dying patients [88,89]. Caregivers versed in palliative care can address these symptoms and experiences to improve the quality of life in the last days of patients' lives.

The goals of palliative care encompass the comprehensive management of physical, psychological, social and spiritual

needs of patients [90]. It attempts to improve the life of not only ill patients, but also for family members through the interaction of an interdisciplinary team of physicians, nurses, social workers, home health agencies, pharmacists, chaplains, and physical and occupational therapists. Although death is nearly always hard, palliative care services work to ensure that death is not horrible. Palliative principles of managing symptoms at the end of life derive from hospice care and focus on both pharmacological and non-pharmacological interventions (Tables 63.2 and 63.3) [83,87,91–94].

Patients hospitalized with endstage COPD in an acute care setting benefit from the coordinated services provided by a hospital-based multidisciplinary palliative care team [95]. These teams provide the necessary skills to control physical and psychological symptoms and assist patients to die with as much comfort as possible. In the absence of a coordinated team approach to palliative care in the inpatient setting, families of dying patients report that as many as 50% of patients experience moderate to severe pain during the last days of their lives [96].

Palliative care for the hospitalized patient with COPD begins with goal setting. Efforts to set goals for individual patients should be proactive and deliberate, with attention to the needs of the individual patient. Initial questions that assist goal setting include: 'What is best for this patient and the patient's family?', 'What can we achieve?' and 'How can we go about achieving it?' [97]. The role of the critical care or ward nurse in identifying when treatment goals require revision to emphasize palliative over restorative care is critical because of the extensive opportunities nurses have to interact with patients and families. The palliative care team considers the family in setting goals to support family members in their roles as surrogate decision-makers and to address their needs for care themselves. Addressing family needs requires a shift toward 'family-focused care', which requires hospital administrative and services changes akin to the dramatic shift in inpatient obstetric services that included the family in labour and delivery [98]. Shannon [98] reviews the elements of 'family-focused care' and practical measures to address family needs during the death of a hospitalized patient.

After goal setting, symptom assessment assists the selection of palliative care interventions and the monitoring of their effect [95]. Objective assessment tools for pain allow implementation of treatment algorithms that provide rapid dosage escalations or drug changes to control symptoms quickly [99–102]. Assessment techniques for the hospitalized patient with pain utilize verbal and non-verbal methods that incorporate physiological measures of pain [96,103,104]. Puntillo [97] has reviewed available assessment tools for the inpatient setting.

In managing dyspnoea at the end of life, objective

Table 63.2 Pharmacological interventions to improve symptoms for patients with COPD at the end of life.

Indication	Drug	Commonly used doses
Dyspnoea	Morphine	
	Oral	5–10 mg every 4 h
	Rectal	5–10 mg every 4 h
	IV, SC	Titrate to relieve dyspnoea
	Nebulized	5 mg in 2 mL normal saline every 4 h with hand-held nebulizer. Benefit from this route of administration remains controversial
	Benzodiazepines	
	Lorazepam oral, sublingual, IV	1–2 mg every 1–4 h
	Diazepam oral, IV (IV risks phlebitis)	2.5–25 mg/day
	Midazolam SC, IV, sublingual	5–10 mg SC then 10–30 mg continuous subcutaneous infusion/24 h
Cough	Opioids	
	Codeine linctus oral	30–60 mg every 4 h
	Morphine linctus oral	2.5–5 mg every 4 h
	Methadone linctus oral	2 mg every 4 h
	Inhaled anaesthetics	
	Bupivacaine 0.25%	5 mg every 4–6 h
Retained secretions	Anticholinergic agents	
	Scopolamine hydrobromide SC	0.4–0.6 mg every 4–6 h then 1.2–1.6 mg/24 h continuous SC infusion
	Transdermal patch	Every 72 h
	Hyoscyamine SC	0.25–0.5 mg every 4–6 h
	Mucokinetic agents	
	Carbocysteine oral	750 mg t.i.d.

IV, intravenous; SC, subcutaneous; t.i.d., three times daily.

Table 63.3 Non-pharmacological interventions to relieve intractable dyspnoea at the end of life.

Non-invasive positive pressure ventilation – Face mask ventilation has been used for patients who refuse intubation and mechanical ventilation to relieve intractable suffering and maintain cognition at the end of life [117]

Patient positioning

Relaxation techniques

Guided imagery

Fans with directed cool air

Pursed-lip breathing

Diaphragmatic training

Energy conservation techniques

measures of dyspnoea can guide therapy but are rarely used [94], in contrast to the frequent use of pain scales for guiding analgesia therapy. Absence of objective measures promote under-recognition of the need to treat severe

dyspnoea, which is experienced by 56% of COPD patients during their terminal hospitalization [4]. Uncontrolled dyspnoea produces anxiety, fear and dread, and warrants aggressive management. Unfortunately, specific interventions to relieve dyspnoea do not exist, which requires physicians to use opioids and sedatives that partially relieve dyspnoea and also manage the associated distress of anxiety, discomfort and fear (see Tables 63.2 and 63.3). Recent systematic reviews of sedative therapy for symptom relief in the terminally ill recognize that sedatives ‘relieve intolerable and refractory distress by the reduction in patient consciousness’ [105]. Although depression of consciousness is not the primary goal of palliative sedation therapy for dyspnoeic patients, it becomes a necessary by-product of palliative care.

Use of sedatives for the non-intubated patient with disabling dyspnoea at the end of life commonly engenders physicians’ concern that they will be participating in a form of euthanasia or will become subject to legal action [106]. Forty percent of surveyed neurologists in one study, for

instance, believed that administering intravenous morphine to severely dyspnoeic patients with amyotrophic lateral sclerosis would be considered euthanasia [107]. Caregivers can gain confidence in aggressively using sedatives to relieve severe dyspnoea if they direct therapy with pre-established treatment algorithms and guidelines to direct therapy. These guidelines explicitly express the purpose of sedative and opioid therapy, which is to relieve symptoms and distress rather than to accelerate death. Clear indications for advancing therapy document the purpose of dosing schedules and prevent misinterpretations of intent. Family requests to advance therapy to bring death and end patient suffering more quickly signal the need for family support rather than an acceleration of therapy.

Recent data further support the conclusion that symptom relief for dying patients represents aggressive palliative care rather than euthanasia. Sykes *et al.* [108] reported that adequate sedative therapy to relieve symptoms rarely accelerates death or invokes the principle of double effect. Similarly, Wilson *et al.* [101] demonstrated that patients who receive morphine after withdrawal of ventilatory support have a longer survival time than patients who do not, which suggests a protective effect from physiological stress-related consequences of severe dyspnoea. Daly *et al.* [81] did not observe a correlation between sedative and opioid use after withdrawal of mechanical ventilation and survival time. Ongoing dialogues regarding end-of-life care within hospitals and other clinical units draw on available resources that separate myths from realities of sedative palliative care to promote quality patient care [109,110].

Hospice services provide opportunities for respite care, assisted living and end-of-life care [11,112], which unfortunately is frequently neglected for terminal patients with COPD [113,114]. Spouses of patients with advanced COPD often endure negative impacts on the quality of their own lives [115]. Neglect in offering patients and their families appropriate resources for supportive end-of-life care results in unnecessary admissions to acute care hospitals for worsening respiratory symptoms. Many episodes of worsening dyspnoea in patients coming to the end of life can be avoided in a reliable care system with effective treatment of dyspnoea (with assurance of terminal sedation if warranted) and with comprehensive advance care planning. Most patients eventually choose not to use ventilator support, or to use it only for a time-limited span, if they can be sure of competent relief of terrifying dyspnoea [116].

Conclusions

Patients with moderate to severe COPD as defined by FEV_1 face a high likelihood that their disease adversely affects the quality of their lives. The progressive course of COPD

punctuated by episodes of acute respiratory failure necessitates decisions about the relative benefit and burdens of life-supportive care. In facing these decisions, patients and families benefit from advance care planning initiated by physicians during intervals of stable health. Physicians should not reserve these discussions for patients with endstage disease considering that severity of COPD is not associated with patient interest in and receptiveness for these discussions. Once the burden outstrips the benefits of aggressive life restorative care, pulmonary and critical care physicians must skillfully engage the patient in discussions that promote 'shared decision making' about end-of-life care. These decisions allow the introduction of palliative services to control symptoms and the initiation of an appropriate treatment plan that meets the patient's life values and goals during the terminal stages of COPD. Caregivers' skilled understanding of ethical issues related to end-of-life and palliative care prevent the dying patient with COPD and his or her family from experiencing death as a horrible event.

CHAPTER 64

Economic burden of COPD

David H. Au and Sean D. Sullivan

Chronic obstructive pulmonary disease (COPD) refers to a set of conditions made up primarily of chronic bronchitis and emphysema accompanied by permanent and not fully reversible airflow limitation. COPD is a prevalent and costly condition. As will be discussed in subsequent sections and based on current projections of disease prevalence, the full economic burden of COPD worldwide has yet to be appreciated. From the patients' perspectives, the economic burden of COPD will likely increase because of loss of productivity from themselves and/or family members. Independent of the health payer system, expenditure for patients is also likely to increase because of the costs of pharmaceutical therapies as well as inpatient and outpatient care. Because COPD is a chronic incurable illness, patients will also bear the burden of COPD on diminished health status and health-related quality of life. The prevalence of COPD is increasing worldwide and from a societal perspective, the economic burden from lost productivity, increased health-care expenditures and premature mortality will also increase. Within the constraints of budgetary limitations, the costs associated with technological and pharmaceutical therapies need to be balanced with their effectiveness. Many health payers base the decision to fund new therapies on their cost and cost effectiveness. If preventive measures were implemented today and were 100% effective, COPD would continue to contribute significant morbidity and mortality for decades to come. This article reviews our current understanding of the economic burden of COPD.

Epidemiology of COPD: prevalence and trends

Various survey designs that rely on patient self-report, presence of airflow limitation and physician diagnosis are likely to produce biased estimates of true disease prevalence [1]. A recent review of the literature found that among 32

studies representing 17 countries, COPD prevalence varied from 0.2% to 18.3% [2]. In the USA, the National Health Interview Survey estimated the prevalence of COPD in 2000 to be approximately 10.5 million persons based on patient self-reported affirmation that in the past 12 months a doctor or other health-care professional had told them that they had either emphysema or chronic bronchitis [3]. In contrast, as part of the National Health and Nutrition Examination Survey III (NHANES III) conducted between 1988 and 1994, a randomly selected subsample of patients performed spirometric evaluations without bronchodilation [4]. For reporting purposes, airflow limitation was defined as a forced expiratory volume in 1 s to forced vital capacity (FEV_1/FVC) ratio of less than 70% and severity was determined by patients having mild obstruction if the FEV_1 was greater than 80% predicted, and moderate obstruction if the FEV_1 was less than 80% predicted. Using these definitions, Mannino *et al.* [5] reported that there were more than 24 million Americans who have some lung dysfunction, half having moderate obstruction. Recently, Confronting COPD, a study sponsored by GlaxoSmithKline, performed probability sampling in North America and the European Union which included more than 200 000 households [6]. Patients were considered to have COPD if they reported a physician diagnosis of emphysema or chronic bronchitis, were aged over 45 years and had smoked for more than 10 years. Results from this study suggest that the prevalence of COPD in Western industrialized countries in North America and Europe varied from 3.2% (France) to 5.4% (Netherlands). In Asia, reliable estimates of COPD prevalence are difficult to ascertain. In 1997, a survey suggested that the prevalence of COPD in Japan was only 0.2% [7]. A more recent estimate has suggested that the prevalence rate is closer to 8.5% among people over the age of 40 years [8]. Similarly, a study of the Korean population, which used a design similar to NHANES III and had a 50% response rate, estimated the prevalence of COPD to be 8.1% [9].

From an epidemiological standpoint, the definition used to identify patients with COPD directly affects the estimates of prevalence and burden of disease [1]. Even among well-respected societal recommendations, there is sufficient variation in definitions to lead to large disparities in estimates of COPD prevalence. For example, the American Thoracic Society (ATS) states that COPD is comprised of chronic bronchitis and emphysema that leads to irreversible loss of airflow [10]. The definition of chronic bronchitis and emphysema are defined on clinical and anatomical bases, respectively. The precise definition of irreversible airflow limitation was not defined, but was reviewed in another related ATS document on interpretation of pulmonary function testing [11]. The European Respiratory guidelines, although similar in requirement of irreversible airflow limitation, do not require that COPD be caused solely by chronic bronchitis and emphysema [12]. Recently, the GOLD guidelines published recommendations that a clinical history in conjunction with an FEV_1/FVC ratio of less than 70% was consistent with a diagnosis of COPD [13].

Risk factors for development of COPD

Tobacco smoke remains the leading risk factor for the development of COPD worldwide. International prevalence trends are consistent with those countries that have the greatest proportion of smokers also having the highest prevalence of COPD. Data from NHANES III demonstrated that among Caucasian men and women, current smokers had a prevalence of COPD of 14.2% and 13.6%, respectively; ex-smokers had a prevalence of 6.9% and 6.8%, respectively; and never smokers had a prevalence of 3.3% and 3.1%, respectively [14]. With changing behaviour patterns and an increase in consumption of tobacco by women, the prevalence of COPD among women and men are nearly equal in some industrialized countries [3,5,15]. Although not entirely clear, there is some evidence to suggest that women may be more susceptible to the effects of tobacco smoke than men [16,17]. Exposure to occupational dusts and chemicals or home biomass fuel used in cooking or home heating, in addition to or independent of tobacco smoke, has been associated with increased risk of COPD development [18–25].

Genetic factors, including gene–environment interactions, almost certainly play a significant part in the development of COPD [26–30] but which genetic factors lead to the development of COPD has not been elucidated. However, there is evidence to suggest that COPD risk may be higher in those with a previous family history of COPD. Some of these studies are difficult to interpret because of similar behaviour and exposures among family members. The most classic genetic factor is α_1 -antitrypsin deficiency [30], which leads to panacinar emphysema.

Recently, the World Health Organization warned of the growing effects of non-communicable diseases. In 1990, COPD contributed to nearly 5% of deaths worldwide and was the fifth leading cause of death [31]. Likewise, there are a number of concerning statistics that have continued to emerge. Unlike every other major cause of morbidity and mortality in the USA, between 1965 and 1998, COPD mortality increased 163%. This is in contrast to coronary artery disease and cerebrovascular disease which demonstrated a 59% and 64% reduction in age-adjusted mortality, respectively [13,15]. Incidence of COPD in women has continued to rise and is comparable or higher than in men. Although reports have suggested that the prevalence of COPD in men may have plateaued, prevalence in women has steadily increased over the past two decades [5,32]. Moreover, in 2000, in the USA, women achieved the dubious distinction of surpassing men in the absolute number of COPD deaths (men vs women), although men still lead women in age-adjusted mortality [5]. Recent projections from the Netherlands suggest that by the year 2015, the prevalence of COPD will increase by 43% in men and 142% in women, after adjusting for projected decline in smoking status within the population [33]. Most of the projected prevalence of COPD will be from the direct effect of past smoking history. Even if there were no new smokers and all current smokers were to stop consuming tobacco products, 90% of the projected prevalence will be attributed to current and past use of tobacco [33,34].

Global burden of COPD

Costs associated with illnesses are often divided into those that result from direct management of disease, including medications, and clinical visits and indirect consequences, including work days lost, loss of productivity resulting from illness or premature death. The National Heart, Lung and Blood Institute (NHLBI) estimated that in 2002, the US total costs for patients with COPD was 32.1 billion dollars (Fig. 64.1) [35].

As demonstrated in Figure 64.1, direct costs represented approximately half of the total expenditures and, of these, 40.6% (\$7.3 billion) of direct costs were related to hospital visits. Of the indirect costs, nearly 51.8% (\$7.3 billion) were attributed to loss of income and productivity from early loss of life. In unadjusted dollars, this represents a relative increase of 34.3% in costs relative to 1993 when the total cost to treat COPD was \$23.9 billion. The greatest increase cost was associated with premature mortality increasing from \$4.5 billion to \$7.3 billion. The results of this study are in agreement with other studies examining the cost of COPD. In the Netherlands, health-care costs for patients with COPD are projected to increase by 90% and possibly as much as 140% between 1994 and 2015 [33].

Figure 64.1 Costs in the USA associated with COPD in 2002.

Figure 64.2 Proportion of cumulative expenditures as a percentage of the population. (From Strassels *et al.* [37] with permission.)

Women account for a larger proportion of the increase cost than men, mainly because of the relative increased prevalence of COPD in women. Hospital admission for patients with COPD is also a major contributor to costs in the USA, accounting for 45–68% of total expenditure [36–38]. Compared with patients of similar age and gender, patients with COPD consistently have more hospital admissions, longer lengths of hospital stay and 2–3 times the costs [39]. In other countries, the largest proportions of costs are associated with COPD treatment medications. For example, in the UK, 57% of costs are associated with medication use and only 17% are related to hospital admissions [40]. These are similar to a recent study which demonstrated that medications costs were similar to hospital admission costs in Germany [41]. Current predictions suggest that the importance of COPD to patient burden and economic significance is likely to continue to increase.

Costs of treatment and COPD severity

The greatest costs of COPD are associated with a relative minority of patients. At least three separate studies demonstrated that costs for COPD are not proportionally distributed among all patients with COPD, rather 10–20% of patients with COPD account for the majority (45–74%) of total direct expenditure (Fig. 64.2) [36–38].

One reason is that the relative distribution of costs changes with severity of illness. Several studies have demonstrated that there is a direct relationship between the severity of COPD, as measured by health status and/or airflow limitation, and the risk of COPD-related hospitalizations and mortality [39,42,43]. There is evidence that there is both a proportional increase in utilization of all medical care services, including proportional increases in pharmacy cost, outpatient and hospital care across COPD severity [42], as well as a non-proportional increase in severity-

related services including need for long-term oxygen therapy (LTOT) and hospitalizations [37,38,44,45].

There have been very few studies that have examined the indirect costs associated with COPD severity. In a Swedish study, the proportion of indirect costs relative to total costs increased generally with severity of disease [45]. For patients with the most severe to least severe disease (FEV_1 less than 40%, 40–59%, 60–79% and greater than 80%), indirect costs represented 58%, 68%, 52% and 28% of total costs in each stratum, respectively. Furthermore, total indirect costs for the most severe category were 89 times greater than those in the least severe stratum (at COPD risk), and 15 times greater than those with mild disease. The direct costs associated with COPD treatment also increase with severity and are reviewed in Figure 64.3 [44]. Several studies have demonstrated that direct costs increase mainly because of hospitalization (45–70% of total direct costs), medication acquisition (7–40%) and oxygen therapy (5–20%) [39,44].

Figure 64.3 Direct costs associated with severity of illness.

Burden of disease from the patient's perspective

COPD represents a significant burden to the patient and their caregivers. From an economic standpoint, most studies have focused primarily on the perspective of the payer or society. Most cost-of-illnesses have not addressed the burden imposed by COPD from the patient's perspective. The direct costs of COPD to patients are likely to vary based on socioeconomic status and place of residence. In nations with national health coverage, direct medical costs will be generally limited. In countries such as the USA where there are multiple types of health-care payers, direct costs to the

patient will vary based on coverage. For many patients with COPD over the age of 65, the Medicare programme provides coverage for outpatient and inpatient medical services; however, Medicare will not cover the majority of prescription-associated costs. Medicaid is available to those patients who are among the most socioeconomically challenged. Patients of higher economic status are more likely to be able to afford supplemental medication coverage or be covered by health plans that include medication coverage. A number of studies suggest that medication costs increase with severity of disease and the GOLD recommendations suggest that medications should be added with progressive symptoms [13]. A list of commonly used inhaled medications and charges are described in Table 64.1. Because

Act, actuation; MDI, metered dose inhaler.

15–40% of direct costs are derived from medications, patients who are economically disadvantaged and not covered by private health insurance or Medicaid, will be most directly affected by the costs associated with medication acquisition [39,44].

The effects of COPD on patients' health status and health-related quality of life (HRQoL) have been extensively reviewed [46]. In short, however, COPD has large detrimental effects on HRQoL using a variety of condition-specific and generic instruments. COPD has larger effects on HRQoL than other common chronic illness such as arthritis, prostate cancer, diabetes and hypertension. Confronting COPD demonstrated that 61% of patients with COPD reported that their health was fair to very poor [6]. Thirty per cent of patients reported that COPD affected their sex lives to a varying degree and 59% reported that COPD affected their normal physical exertion. Of patients under the age of 65, 45% reported that they had missed work because of COPD. Although COPD is a disease that affects many retired patients, 25% of patients over the age of 65 reported work loss secondary to COPD.

The disability adjusted life years was developed as part of the Global Burden of Disease Study as a composite measure of health status and health outcome that incorporates dimensions of premature life years lost and loss of productivity resulting from illness and injury [31]. In 1990, of the 30 most common disorders, COPD was the 12th leading cause of disability adjusted life years and sixth among non-infectious aetiologies. The effects of tobacco smoke will have the highest relative effects on non-third world countries, where the risk of mortality associated with infectious diseases are less apparent. Current projections suggest that COPD will rise from the 12th to the sixth leading cause of disability adjusted life years by the year 2020.

COPD exacerbations

Strategies to reduce costs associated with treatment of exacerbations

Because of the large proportion of costs associated with exacerbations, even strategies that have relatively small effects on COPD exacerbation rates may have large effects on reducing total costs [40]. Also, evidence would suggest that a large proportion of costs are associated with treatment failure. There have been a number of interventions that appear reasonable and effective and may lead to improvement in clinical outcomes and reduced costs. These interventions include non-invasive positive pressure ventilation (NIPPV), decreasing severity or managing patients outside of the hospital setting, and decisions about antibiotic use.

Controversy about antibiotics for treatment of acute exacerbations of COPD

Bacteria have clearly been implicated in the risk of COPD exacerbation; however, the use of antibiotics for all COPD exacerbations is probably not indicated [47,48]. An infectious aetiology in an acute exacerbation of COPD can be detected in 30–50% of cases and, of those with infectious aetiologies, viruses account for a significant proportion of these cases [49]. The best available evidence would suggest that antibiotics will most likely benefit those with severe exacerbations defined as a triad of worsening dyspnoea, increased sputum production and sputum volume [50]. A meta-analysis of antibiotics for COPD suggests a small but statistically significant benefit of using antibiotics for COPD exacerbations [10]. From a cost perspective, there are a number of important issues including prevention of relapse, need for hospitalization and the costs of antibiotic-resistant organisms in the community [51–53]. These issues have been reviewed in detail [51]. A recent economic analysis of resistance to medications, including antibiotics, suggested that the best policy may be to have a mixed treatment approach that may lessen the possibility of resistance to a single class of agents [52].

The issue of resistance and compliance with antibiotics also raises the question of the best choice of antibiotics for patients with COPD exacerbations. Currently, there is little evidence to support the choice of any specific antibiotic when considering clinical efficacy [54–60]. In a retrospective study of 60 patients with 224 exacerbations, Destache *et al.* [61] demonstrated that the initial costs of first-line antibiotic agents were significantly less than broader spectrum second- and third-line antibiotics, but may have less resource utilization. This study has significant methodological issues including no adjustments for prior COPD exacerbations and violations of independence in statistical analysis. Other studies have suggested that ciprofloxacin when compared to usual care may be cost-effective from the societal perspective (\$18 588 per quality-adjusted life year [QALY]), however, there was no difference in time to resolution of symptoms [62]. Another study suggested that when comparing the macrolides azithromycin with clarithromycin among patients with lower respiratory track infections, patients taking azithromycin were able to return to work sooner, although there were no additional benefits in respect to clinical outcomes [63].

Mechanical ventilation and non-invasive positive pressure ventilation

Mechanical ventilation is costly for patients with severe COPD. In a secondary data analysis of the Study to Understand Prognoses and Preferences for Outcome and Risks of Treatment (SUPPORT), Ely *et al.* [64] compared patients requiring mechanical ventilation. In comparison to patients

with other causes of respiratory failure, patients with COPD had similar length of stay (COPD 9 days), days of mechanical ventilation (COPD 5.5 vs other 5.0) and total hospital costs (COPD \$24 217 vs other \$27 672); however, they had appreciably more respiratory care costs (COPD \$4064 vs other \$2342). Of the median cost difference, 74% could be attributed to costs associated with bronchodilators and pulse oximetry. Despite the high costs associated with mechanical ventilation, Anon *et al.* [65] examined the cost–utility of mechanical ventilation for acute respiratory failure among 20 oxygen-dependant COPD patients. Despite having a high 1-year mortality of 75%, Anon *et al.* estimated that in the best and worst case scenarios the cost was \$26 283/QALY (US) and \$44 602/QALY (US), respectively.

Interventions that reduce the need for invasive mechanical ventilation have been demonstrated to reduce hospital costs and mortality. Shortly after the introduction of NIPPV, there were concerns about its costs because of a lack of reimbursement from insurers [66] and clinical availability [67,68]. There is currently little doubt of the effectiveness of NIPPV, used in a select group of COPD patients with acute respiratory failure, as a therapeutic cost-saving strategy. There have now been several meta-analyses that consistently demonstrate that NIPPV reduces the odds of in-hospital mortality and mechanical ventilation when compared with standard therapy [69–71]. In addition, in one study the cost savings from a payer's perspective was \$3244 (Canadian dollars, 1996) per patient hospitalization. Another study suggested that resource use, as measured by physician, respiratory therapist and nursing time, was similar to standard therapy for the first 48 h, but fell dramatically in favour of the NIPPV group after 48 h [69]. The use of NIPPV has risen dramatically, especially among patients with COPD [72]. Bilevel pressure-cycled ventilation has become the most common mode of ventilation.

Early discharge or avoiding hospitalizations by home management as a strategy to reduce costs

Hernandez *et al.* [73] recently described a randomized controlled trial of patients referred to an emergency room for COPD exacerbations. After excluding those who required imperative hospitalization, 222 patients were randomized to home hospitalization versus usual care. The programme consisted of a specialized team who encouraged immediate or early discharge, a comprehensive and tailored therapeutic approach to care, including education and a respiratory skilled nurse and/or a free-phone consultation. Treatment was considered to fail if a patient subsequently required hospitalization or had more than five home consultations with the nurse. The study was designed from the perspective of the payer. The costs associated with the intervention were nearly 60% of the usual care group (home hospitalization vs usual care: 1255.12 [95% CI 978.51–1568.04] vs 2033.51 [95% CI 1547.05–2556.81], in Euros, year 2000).

The number of days of hospitalization was significantly less in the intervention group. In addition, although there was no reduction in treatment failures that required hospitalization, there was a significant reduction in readmission to the emergency department for relapse and significant improvements in patient disease knowledge, home rehabilitation, inhalation technique and HRQoL. These results are supported by the results of Skwarska *et al.* [74], who demonstrated that supported discharge of selected patients resulted in fewer readmissions for treatment failure and a cost differential of 867 pounds/patient (home support 877 vs usual care 1753). In addition, observational data suggest that early outpatient follow-up visits after an emergency room visit was associated with a lower risk for repeat visits in the subsequent 90 days (hazard ratio 0.79; 95% CI 0.73–0.86) [75]. Also, interventions such as a home respiratory care visit after hospitalization may save as much as \$2625/patient-hospitalization through reduced need for rehospitalization [76].

The home setting has also been employed to reduce COPD exacerbation relapse. In a recent study by Bourbeau *et al.* [77], patients who had COPD hospitalizations were randomized to an 8-week programme of weekly home visits followed by monthly telephone calls for 10 additional months to promote patient self-management. In this study, hospital admissions for COPD were reduced by 40%, with number of days/person in hospital decreasing by 42%. Unscheduled visits to primary care physicians and emergency room visits were reduced by 59% and 41%, respectively, while the number of scheduled visits to the primary care physician increased by 15%.

Long-term oxygen therapy

The beneficial effect on mortality of LTOT for patients with hypoxaemic respiratory failure has been clearly demonstrated [78,79]. However, LTOT is a major source of expenditure associated with outpatient therapy for COPD and is naturally associated with severity of illness. Based on COPD stage, Hilleman *et al.* [44] demonstrated that as a percentage of COPD costs, LTOT costs were associated with stage (0.0% cost for stage 1 disease, 13.8% for stage 2 disease and 18.6% of stage 3 disease). This is consistent with the results of others who have found that LTOT represented as much as 73% of outpatient expenditure for COPD [80]. The cost of LTOT in the USA in 1998, after mandated reductions in reimbursement, was 1.3 billion dollars or 28% of the durable medical equipment expenditure [81]. The Fifth Oxygen Consensus Conference made a number of recommendations that either reduced direct expenditure or improved the cost effectiveness of oxygen therapy. The most important of these focused on improving adherence to oxygen therapy [82]. Because many of the costs of LTOT are fixed, improving patient adherence would likely lead to improvements in cost effectiveness. Inappropriate use of oxygen may also be a source of potential cost savings.

Several studies have demonstrated that adherence to guidelines for LTOT is low [80,83,84]. These studies suggest that many patients who receive oxygen are not hypoxic. In addition, re-evaluation during a period of stability is recommended after the initial prescription for LTOT. In one study, only 19 of 226 patients had re-evaluation, 11 of whom were found not to need further LTOT [84]. Finally, several studies have examined the delivery of LTOT by cylinder or concentrator [80,85–87]. These studies together suggest that for patients who will likely need LTOT for a prolonged period of time (more than 3 months), oxygen concentrators are more cost effective.

Smoking cessation

Smoking cessation remains the most important therapy in COPD. It is the only therapy that has been definitively demonstrated to slow the progression of airflow limitation [16]. In addition to the effects on lung function, smoking cessation has immediate effects on cardiovascular disease and future risk of cancer. Independent of COPD in 1998, smoking-attributable medical expenditure was estimated by the Centers for Disease Control (CDC) at \$75.5 billion. For the 46 million adult smokers in 1999, these costs were derived from \$1760 for loss productivity and \$1623 in excess medical expenditure [88]. In addition, smokers had greater absenteeism and less productivity at work but after smoking cessation had improvements in absenteeism and productivity [89]. Multiple studies have demonstrated the effectiveness of smoking cessation and smoking cessation programmes. A recent review summarized the findings from 157 studies, including 112 individual studies of adverse events, four systematic reviews, 17 economic studies and 13 individual studies of effectiveness [90]. Based on the literature contained in this review, the authors found that 1–3 life-years were saved per quitter. A decision model was built to compare the cost effectiveness of four smoking cessation interventions: counselling or advice about smoking cessation, advice plus nicotine replacement (NRT), advice plus bupropion SR and advice plus NRT and bupropion SR in combination. The incremental costs per quality of life-year saved was approximately £1000–2400 for NRT, £640–1500 for bupropion SR and £900–2000 for combination of NRT and bupropion SR. In a separate report by the same authors, when compared with counselling alone, they found similar results with incremental costs per life year saved was \$1411–3455 for NRT, \$920–2150 for bupropion and \$1282–2836 for combination of NRT and bupropion SR [91]. Cornuz *et al.* [92] performed cost-effectiveness ratios for pharmacotherapies for nicotine dependence and found that all first-line therapies for smoking cessation were cost effective, but the cost effectiveness varied widely by age and gender.

Coverage by health payers for tobacco cessation programmes has been a concern in part because of increased

costs to the system. Fishman *et al.* [93] examined health-care expenditures in a non-for-profit mixed model Health Maintenance Organization (HMO) in western Washington State. This retrospective cohort study found that costs in the first year after cessation were higher for former smokers but that costs fell by the second year and were statistically not different for the subsequent 6 years. Cumulative health-care expenditure was lower for former smokers by the seventh year. This study supports the widely held notion adopted by the UK National Health Service programme that smoking cessation is cost effective not only from the perspective of the individual, but also for the payer.

Pulmonary rehabilitation

Pulmonary rehabilitation is a multifaceted intervention that has been demonstrated to improve HRQoL, patient self-efficacy and exercise endurance [94,95]. The costs of these programmes are somewhat dependent on the provision in the rehabilitation programme. Goldstein *et al.* [96] reported the costs associated with a 6-month rehabilitation programme that included 2 months of inpatient hospitalization followed by 4 months of outpatient therapy. The incremental cost of this programme relative to usual care was \$11 597 (Canadian). The proportion of patients who had a 0.5 point or more increase on each of the domains of the Chronic Respiratory Disease Questionnaire (CRQ) ranged between 0.23 and 0.39. On average, pulmonary rehabilitation lead to an improvement in 6-minute walk test of 38 m. Troosters *et al.* [95] performed a 6-month outpatient programme of exercise three times weekly for 3 months followed by twice weekly for the remainder of the programme. The mean cost of the intervention was \$2615 ± 625 and resulted on average in an improvement of 52 m on 6-minute walk tests. Home rehabilitation produces similar effects on exercise endurance, but the effect may be more sustained than those in shorter inpatient or outpatient programmes [97,98]. From a cost-saving perspective, pulmonary rehabilitation has been demonstrated to decrease hospitalizations for COPD exacerbations, although this effect has not been consistently demonstrated in the literature.

Bronchodilators

Despite the fact that bronchodilators are the mainstay of therapy for patients with obstructive lung disease, there is a surprisingly sparse literature about the cost effectiveness of these medications. As demonstrated in Figure 64.3, medication acquisition costs as a function of COPD severity do not increase as rapidly as other costs. Thus, medication costs as a proportion of total of costs are least among patients with the most severe disease and greatest at the least severe stages.

Ipratropium bromide either alone or in combination with albuterol has been demonstrated to result in fewer health-care costs than either albuterol (cost over 85-day study period per patient: ipratropium \$156; ipratropium plus albuterol \$197; albuterol alone \$269) [99], or theophylline alone (theophylline \$121.40 per patient per therapy-month, ipratropium \$84.56 per patient per therapy-month) [100]. In both studies, the reductions in cost were principally brought about by reductions in health-care utilization, including hospitalization, emergency room visits and unscheduled visits for COPD exacerbations.

There have been two studies to compare long-acting β -agonists with either usual care or ipratropium bromide. Jones *et al.* [101] recently reported that the addition of salmeterol to usual care had higher overall costs, but found that the addition of salmeterol had the incremental cost of £5.67 per symptom-free night. Hogan *et al.* [102] compared two doses of formoterol (12 and 24 μ g) with ipratropium bromide with respect to the cost effectiveness on producing bronchodilatation (FEV_1) and quality of life. Ipratropium bromide had incremental cost effectiveness ratios that were more favourable than either doses of formoterol (increment of 0.137 L: ipratropium bromide \$273.03/ FEV_1 ; formoterol, 12 μ g 1611.32/ FEV_1 or 24 μ g dominated) when compared with placebo. In contrast, when examining the effects on HRQoL, the 12 μ g dose of formoterol appeared to be more effective (\$25.20/change QoL score) than either the 24 μ g dose of formoterol or ipratropium bromide (both dominated) when compared with placebo. More recently, Oostenbrink *et al.* [103] performed a prospective cost-effectiveness analysis along two 1-year randomized control trials of tiotropium compared with ipratropium bromide. Mean annual medical costs were 1721 euros for tiotropium and 1541 euros for ipratropium bromide. Of the higher costs of medication acquisition costs of tiotropium (cost difference 453 euros), 60% was offset by reductions in medical expenditures associated with fewer hospitalizations and unscheduled visits for COPD. The incremental cost-effectiveness ratio was 667 euros per exacerbation and 1084 euros per patient for clinically meaningful improvements in HRQoL. The cost and cost effectiveness presented in this study were likely conservative estimates given that indirect costs such as days of work missed were not included in the cost estimates.

Corticosteroids

Inhaled corticosteroids and risk of COPD exacerbation and mortality

The utility of inhaled corticosteroids among patients with COPD remains controversial. There have been four

large well-performed randomized controlled trials that demonstrate no improvement in the rate of FEV_1 decline for patients with various degrees of COPD severity [104–107]. The medications included in these trials utilize inhaled corticosteroids of varying potency and include triamcinalone, fluticasone and budesonide. A recent meta-analysis identified nine randomized controlled trials of inhaled corticosteroids among patients with COPD [108]. Six of the nine trials reported risk of COPD exacerbations associated with inhaled corticosteroids in comparison with placebo. Two of the six reported no benefit in COPD exacerbation risk and when combined with the remaining four trials, inhaled corticosteroids were associated with a 30% reduction (RR, 0.70; 95% CI, 0.58–0.84) in exacerbation. Ayres *et al.* [109] have recently demonstrated that fluticasone in comparison with placebo had no effects on total costs (direct and indirect); however, they suggested that the incremental cost effectiveness may favour inhaled fluticasone with the cost of remaining exacerbation free estimated at £0.25/day from the payer's perspective. There have now been three trials that combine inhaled corticosteroids with long-acting β -agonists in comparison with individual components [110–112]. All trials examined the effects of combination therapy on exacerbation risk. The results of these trials consistently demonstrate that all treatment arms were better than placebo; however, these studies could not demonstrate consistent improvement in exacerbation risk between individual components and combinations.

In observational trials, the association of inhaled corticosteroids on risk of mortality has been mixed. In two observational trials, inhaled corticosteroids that were assessed at baseline and required limited exposure, defined as either single or three prescriptions for inhaled corticosteroids, were associated with a decreased risk of all-cause mortality as long as 3 years after exposure assessment [113,114]. These two trials have been questioned, largely because of the minimal exposure requirements and concern over immortal person time bias [115,116]. Two follow-up trials that utilized time-dependent exposures of inhaled corticosteroids assessments could not confirm a survival benefit associated with inhaled corticosteroids [115,116]. One of these trials used three methods to assess inhaled corticosteroid use and required at least 80% compliance with filling prescriptions for inhaled corticosteroids [115].

The GOLD COPD treatment guidelines endorse the use of inhaled corticosteroids for the treatment of moderate to severe COPD but also states that 'Prolonged treatment with inhaled glucocorticoids does not modify the long-term decline in FEV_1 in patients with COPD' [13]. Whether inhaled corticosteroids will be cost effective has yet to be determined; however, a clinical trial is currently underway to determine the effects of COPD exacerbation as a primary

outcome. In one study, Sin *et al.* [117] examined the cost effectiveness of inhaled corticosteroids in treating COPD. Among patients with stage 2 or 3 disease, the cost effectiveness of the inhaled corticosteroids was \$17 000/QALY. In contrast to prospective studies of cost effectiveness performed along clinical trials [103,118], assumptions about condition severity, treatment and outcomes were derived from a literature review that included heterogeneous patient populations, varying entry criteria and exclusions. In addition, the results appeared to be highly dependent upon the assumptions that inhaled corticosteroids would lead to a 16% reduction in mortality and that the effectiveness of inhaled corticosteroids (in contrast to the effectiveness of inhaled corticosteroids) was 30% in reducing COPD exacerbations. The reliability of the estimates was also difficult to assess because of the lack of acceptability curves.

Lung volume reduction surgery

Although lung volume reduction surgery was not a new concept in 1994, Cooper *et al.* [119] reported beneficial effects of this operation on patients with severe emphysema. This and subsequent reports fuelled a prolific increase in the use of this procedure for emphysema. Early reports suggested improvement in pulmonary function tests, LTOT and HRQoL [120–128]. However, these reports were clouded by differential follow-up and reports of 1-year postoperative mortality of up to 17% [129]. In response to these lingering questions, the Health Care Financing Administration (HCFA) announced that it would no longer reimburse for lung volume reduction surgery. At the same time, HCFA, along with the NHLBI and the Agency for Healthcare Research and Quality (AHRQ) announced plans for the National Emphysema Treatment Trial (NETT) [130]. This randomized clinical trial was designed to compare the best current medical therapy and best current medical therapy plus lung volume reduction surgery with all-cause mortality as the primary outcome measure. The trial enrolled 1358 patients from 17 medical centres. Interim analysis demonstrated that patients who had an FEV_1 of less than 20% predicted and either a DLCO less than 20% or homogeneous emphysema on chest computed tomography had excessive risk of mortality and were subsequently excluded from the trial [131]. Of the remaining 1218 patients, no benefit in mortality was detected at 24 months [132]. In *post hoc* subgroup analysis, it appeared that there was a potential benefit in survival, exercise capacity and HRQoL among those patients who had upper lobe emphysema and low exercise capabilities after pulmonary rehabilitation. A prospective cost-effectiveness analysis was also performed as part of this trial [118]. This

trial used the societal perspective to determine the quality-adjusted life year gained. The Quality of Well Being scale was used to derive health state preferences, and cost estimates were calculated to be in 2002 dollars. Not surprisingly, in the first 12 months, hospital days, days of ambulatory care and nursing home admissions were greater in the surgical treatment group, but by 12–24 months there were more hospital admissions in the medical treatment group and no difference in any resource use between 24 and 36 months. Direct and total costs also followed similar trends, with the surgical arm having higher costs at 12 months (direct \$61 415 vs 15 738 and total \$71 515 vs 23 371), but having less direct and total cost at 13–24 months (direct \$9474 vs 13 222, total \$13 222 vs 21 319) and similar costs between 25 and 36 months (direct \$10 199 vs 12 303, total \$14 215 vs 17 870). The estimated quality-adjusted life year gained at 3 years after initiation was \$190 000. Comparing direct cost only, the estimate quality-adjusted life year gained at 3 years was \$193 000. Stratifying by those with upper lobe disease and exercise capacity, the cost-effectiveness ratio for those who had upper lobe disease and low exercise capacity was \$98 000 at 3 years. The next most effective group, those who had upper lobe disease and high exercise capacity had a cost-effectiveness ratio of \$240 000 at 3 years. Estimates of 10-year cost-effectiveness ratios was \$53 000/QALY; however, the cost-effectiveness acceptability curves suggested significant instability in this estimate. In comparison to other common surgical procedures, medical therapy plus lung volume reduction surgery appears costly: coronary artery bypass graft \$8300–64 000/QALY, lung transplantation \$130 000–220 000/QALY, heart transplantation \$65 000/QALY.

Conclusions

COPD is a prevalent problem and the economic effects are not isolated to Western countries. Worldwide, the prevalence of COPD will likely increase and outside the USA and western Europe, the cost of COPD has not been estimated. It is clear, however, that even if preventive measures were implemented today and were 100% effective, COPD will continue to contribute significant morbidity and mortality for decades to come.

Despite the substantial costs associated with the condition, there are surprisingly few data to support decision making for health payers on cost-effective therapy. Relative to effects of other conditions, research on COPD is underfunded [133]. Greater emphasis and a stronger commitment from non-commercial-based research are necessary to encourage significant advancements.

CHAPTER 65

Pharmacoepidemiology of COPD

Joan B. Soriano

Pharmacoepidemiology is the study of the effects of drugs on disease and its determinants in large numbers of population by means of observational data. The pharmacoepidemiology of chronic obstructive pulmonary disease (COPD) has flourished recently, as a hypothesis-generating method. Ahead of ongoing randomized controlled trials, associations such as the increased mortality in COPD users of short-acting anticholinergics or the increased survival in COPD users of inhaled corticosteroids were formulated from pharmacoepidemiological studies. Standardization of methods and replication of single studies by independent investigators in other populations are needed. However, because of the absence of randomization intrinsic in any observational research, the advantages and limitations of these studies, and the interpretation of the direction and magnitude of their results are of great importance. Whenever possible, confirmation of results in carefully conducted randomized controlled trials in COPD patients is needed.

Introduction

Radical is the vision of Sackett *et al.* 'to keep up with the clinical literature, doctors should discard at once all articles on treatment that are not randomized trials' [1]. However, clinicians have long recognized the value of non-experimental research. Quoting Sir Austin Bradford Hill, one of the developers of the randomized trial methodology: 'Any belief that the randomized controlled trial (RCT) is the only way in medical research would mean not only that the pendulum had swung too far but that it had swung off its hook' [2]. The concordance of results of large clinical trials with well-conducted observational studies and meta-analyses of smaller RCTs, and its predictive power, has been the subject of recent reviews [3,4]. Some of the strengths of observational evidence versus RCTs include large numbers of real-life patients and not pure non-representative case

patients, and particularly the inclusion of elderly patients with additional comorbidities, often excluded in clinical research. Duration of follow-up can be also longer, and power to detect rare adverse events is greater.

Clinicians have often considered COPD as a 'Cinderella' disease, unattractive and self-inflicted, with little to offer and even less to expect. However, the contrary is true for respiratory epidemiologists, for whom COPD is indeed a 'dream' disease. COPD is a disease with a huge and increasing burden in society, affecting women as well as men, in developed and developing countries, and the age at COPD diagnosis is becoming younger. To date, respiratory epidemiology has not been as comprehensively developed as cancer or cardiovascular epidemiology. In clinical research, COPD has also been hindered by a shortage of large decisive trials involving tens of thousands of individuals. The clinical epidemiology of COPD is comprehensively presented elsewhere in this book (see Chapter 10); however, the study of beneficial effects (efficacy and effectiveness) and adverse effects (safety) of respiratory drugs in general, and of COPD drugs in particular, has not been well covered in respiratory clinical trials to date. Ultimate reasons for this are beyond the scope of this chapter, but most likely include: nihilism of the condition by patients and their doctors, an adaptation phenomenon in COPD patients similar to other long-lasting chronic conditions, the natural history of COPD *per se*, confusion regarding tobacco as the overwhelming cause but with other causative risk factors involved, and a difficulty to set thresholds for diagnosis and severity grading. Adding insult to injury, the historical lack of interest in COPD research is notorious compared with less severe, less common diseases of worldwide distribution. Gross *et al.* [5] identified COPD as an important example of the disproportionate lack of research funding provided by the US National Institutes of Health with relation to the burden of disease for society. Compared with AIDS, breast cancer, diabetes mellitus and dementia, all of which received

relatively generous funding, research on perinatal conditions, peptic ulcer and COPD (the worst of them all) was underfunded.

Pharmacoepidemiology, the discipline that deals with the study of the effects of drugs in large numbers of individuals by means of observational data [6,7], seems to lead the way in COPD research ahead of largely absent or ongoing clinical trial data. In a recent comprehensive review of respiratory epidemiology in Europe [8], the term pharmacoepidemiology was not mentioned, and a search in Medline (October 2005) for the terms 'COPD' and 'pharmacoepidemiology' produced only four hits.

It has been difficult to study COPD medications until recently, as most drugs licensed for COPD are extensions of drugs developed to treat asthma or other conditions. Often, general practitioners apply sensible practical criteria when managing COPD patients. During the early 1990s, as no therapeutic options were available to manage their COPD patients other than advice to quit smoking, oxygen therapy and short-acting bronchodilators, general practitioners and primary care doctors started to try interventions that were successful in asthma. The pharmacoepidemiological study of this sensible approach by several research groups in different countries has created a recent effervescence of observational data in COPD and drugs. As highlighted in two recent editorials, observational studies are hypothesis-generating, and these hypotheses can be later confirmed (or rejected) in other observational independent studies or newly conducted trials [9,10]. Finally, RCTs are not unbiased, contrary to common assumptions. The recent large 1-year RCTs of combination therapy in COPD [11,12] have clearly shown differential drop-out rates, with large withdrawal numbers in placebo groups complicating interpretation and likely producing an underestimation of treatment effects. Therefore, pharmacoepidemiological studies, which allow for larger and more inclusive cohorts with longer durations of follow-up, could complement and help to interpret findings from RCTs. Consistency in the direction and magnitude of outcomes by independent researchers in different populations of patients is the real power of pharmacoepidemiology.

Asthma pharmacoepidemiology

To expand on COPD pharmacoepidemiology later, it is necessary to briefly mention that there is already extensive literature on the pharmacoepidemiology of asthma [13]. In spite of more than 30 years of asthma RCTs, some outcomes are difficult to assess with the RCT methodology [14]. In particular, asthma mortality and exacerbations have escaped trialists for years. It was not until recently that the beneficial effects of low-dose inhaled corticosteroids

(ICS) in preventing asthma deaths was demonstrated [15]. In addition to these Canadian findings, results have been replicated in the UK [16]. Similar beneficial results were also reported for use of low-dose ICS in preventing asthma hospitalizations [17–19]. The pharmacoepidemiology of asthma has recently been reviewed elsewhere [20].

Methodological issues when conducting/assessing COPD pharmacoepidemiology

To date, a number of databases have been explored to conduct COPD pharmacoepidemiology, including the Saskatchewan, Alberta and Ontario databases in Canada, the General Practice Research Database (GPRD) and UK Mediplus in the UK, Lovelace BCBS and Veteran Affairs in the USA, and Pharmo in the Netherlands. Collaborations pooling and comparing several of these databases are being established [21]. There are a number of challenges when conducting pharmacoepidemiological studies. Ideally, protocols with observational data should reflect the situation of a randomized clinical trial. A list of items (Table 65.1), not to be considered in comprehensive detail, should help the reader to develop greater awareness when conducting or assessing COPD pharmacoepidemiology.

Strategies of differential diagnosis of COPD/exclusion of asthma

The ability to differentiate COPD from asthma or other conditions is obviously critical. The effectiveness of ICS has been very well established in asthma, but it is the subject of debate in COPD. Thus, because the inclusion of asthma patients may exaggerate the effectiveness of respiratory medications in COPD studies, the study population must have clear criteria to identify COPD and exclude asthma

Table 65.1 Challenges when conducting/assessing COPD pharmacoepidemiology.

Strategies of differential diagnosis of COPD/exclusion of asthma
Confounding by indication
Reference groups: matching or restriction?

Drug exposure: onset, chronic, regular treatment
Dose-response relationships
Biases
Comorbidities
Main outcome and endpoints
Statistical analysis

patients. In particular, definitions and criteria based on physician's reported diagnosis, drug treatment and age must be carefully combined to optimize the diagnosis of COPD. GOLD and other COPD international guidelines use descriptions rather than definitions of COPD, and the challenge that a clinician faces with an individual patient is magnified when using observational data. However, some clinicians consider that the relevance of this misdiagnosis is exaggerated, as it seems much more likely that COPD patients may be classified as 'asthmatic' than asthmatics falsely being labelled as having COPD, although evidence to support this statement is scarce. Several strategies used to differentiate COPD from asthma in observational data research include: age restriction above 50 years or older thresholds; and primary care physician-diagnosed patients or patients discharged from hospital with a primary diagnosis compatible with COPD. However, it is important not to select a population with little resemblance to the target population, as the introduction of inappropriate exclusion criteria will create bias. Moreover, it is advisable to conduct validation studies of individual COPD definitions [22–25].

Confounding by indication

Confounding by indication is a major source of bias, perhaps the most important in pharmacoepidemiology. It is also referred to as confounding by severity, confounding by indication for a prescription, indication bias or channelling [26].

Confounding by indication is caused by the absence of randomization in the allocation of treatment, inherent in observational research. It exists when patients who receive different treatments also differ in their risk of adverse outcomes, independent of the treatment received [27]. In general, confounding by indication occurs when an observed association between a drug and an outcome is caused by the underlying illness or its severity, and not to any effect of the drug. In simple terms, patients with a disease who are treated with drug A would be expected to be sicker than those not so treated. In this case the risk factor under study is the drug and the outcome variable under study is the clinical variable that the drug is supposed to change.

In COPD, confounding by indication can be controlled by proper adjustment for underlying severity when available, such as previous use of health resources (i.e. history of COPD hospitalizations or emergency room visits), and the profile of use of other drugs for COPD.

Another type of bias, protopathic bias [28], can be found in COPD studies. Although related to confounding by indication, it is slightly different. It may occur when a particular manoeuvre is started, stopped or changed because of the baseline manifestation caused by a disease or other particular event. Then the event happens to be in the causal pathway

between an exposure and the event. In COPD, protopathic bias occurs when a drug is used both as chronic and acute therapy. To avoid exposure misclassification in pharmacoepidemiological studies, some advocate using time-dependent analysis. However, respiratory drugs such as bronchodilators and steroids are also used during acute exacerbations. Thus, by using a time-dependent analysis, these drugs could be incorrectly shown to increase morbidity and mortality, which in reality is related to exacerbation itself.

Reference groups: matching or restriction?

It has been standard in respiratory epidemiology to compare users of one drug versus non-users of that drug, for instance COPD patients with or without prescriptions for ICS. However, it is possible that patients with a disease treated with drug A may be sicker than those not so treated with drug A. A partial solution is to compare patients with a disease who are treated with drug A versus those treated with drug B (i.e. the recommended treatment by COPD national or international clinical guidelines). Other solutions for the choice of reference groups are matching by demographic variables at baseline or restricting the analyses to only male, only older COPD patients or only those without a clinical suspicion of asthma, etc.

Time: date of clinical incidence of COPD, right- and left-truncation, censoring, rates, immortal time period

A recent report has underlined the major problems that can potentially occur when time to different events and outcomes, and different designs, are applied in COPD pharmacoepidemiology [29]. The issue on time control relates to the choice of design: cohort or case-control (Fig. 65.1). In addition, whether the events of interest are acute, or whether regular treatment is required to attain the effectiveness under study, needs to be considered with respect to drug exposure. Drug exposure also affects the choice of the reference group and whether this group can include patients who do not currently use a given drug but who used them previously, or patients who are restricted to other drugs or classes of drugs. With these classifications and the question of timing of use, one must then be concerned about issues of exposure misclassification. For instance, patients who are not using a drug might be wrongly classified as users and vice versa. The exposure and its timing will also relate to the analysis of the data and, particularly, whether exposure is fixed, such as for the intention-to-treat approach, or time-dependent, such as that used in nested case-control analysis.

The COPD patients under study may be incident (newly diagnosed patients) or prevalent (patients well into their

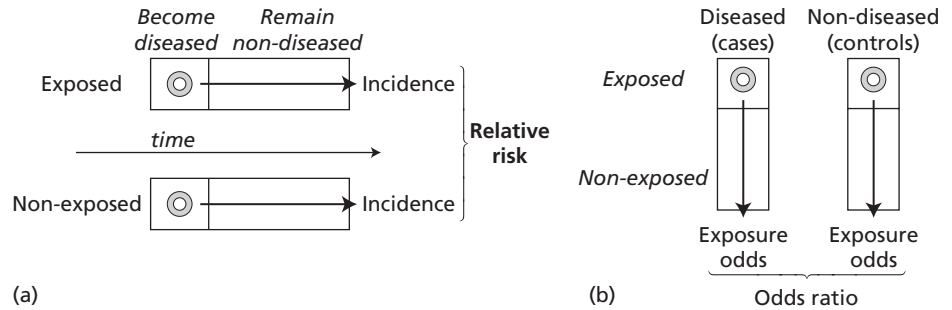

Figure 65.1 Basic analytical approach in: (a) cohort study; and (b) case-control study.

disease). It has to be determined whether patients at time zero already have had COPD for some time or have already been exposed to the drug under study. It may be preferable to use incident cohorts where new treatment or new disease defines time zero for the cohorts. If this is not possible, the duration of prior COPD or prior drug use should be examined and accounted for in the analysis. The choice of time zero is important and may be taken as the date of first COPD diagnosis, the date of the first hospitalization for COPD, the date of any hospitalization for COPD or the first time a drug was used. Finally, in all cohort studies that involve time-dependent exposure, immortal time should be explored. Immortal time periods, defined by follow-up times during which patients cannot, by definition, incur the outcome, have to be identified and accounted for with a proper analysis. In addition, studies that improperly exclude immortal time or do not account for it in the proper exposure group should be identified and assessed with respect to bias. As a rule of thumb, the duration of the immortal time period should equal the duration of the window of drug exposure.

Drug exposure: onset or chronic regular treatment

It is particularly relevant whether exposure is selected at cohort entry or at the time of the outcome under study. When studying harmful drug effects and acute events, the closer the assessment of drug exposure to the outcome under study seems fundamental, and a nested case-control is the design of choice. However, when searching for unanticipated beneficial effects of chronic regular drug treatment, the cohort design mirroring a RCT is to be considered first.

Dose-response relationship

Dose-response is one of the 10 Hill criteria for causality [30]. Ideally, once an association between a drug and a COPD outcome is considered causal, searching for a dose-response or a threshold indicates consistency and adds further evidence of causality.

Bias

There are three major types of bias in epidemiological research: selection bias, information bias and confounding. Selection bias includes referral bias, self-selection bias, prevalence study bias and protopathic bias. Information bias can be of differential misclassification (recall bias, detection bias) or non-differential misclassification; and there are many types of confounding. Confounding by indication will need to be tackled appropriately in any COPD pharmacoepidemiological study.

Comorbidity

Because COPD is not only a respiratory disorder but also a systemic disease, and because smoking has non-COPD effects, it is common that COPD patients have comorbid conditions associated. A modified Charlson comorbidity index helps quantitatively and qualitatively to assess imbalances in the distribution of comorbidities between drug exposure groups [31].

Main outcome and endpoints

To date, most RCTs in COPD have been powered to pulmonary function [32]. Observational studies permit observation of more relevant endpoints for the clinician and in particular to the patient, such as survival or time to next exacerbation.

Statistical analysis

The choice of statistical analysis, depending on the study design, cohort or case-control, is an important methodological aspect that requires extensive discussion [33].

Beneficial or adverse effects of COPD medications in epidemiological studies

A number of interventions in COPD have been assessed using pharmacoepidemiological methods. Outcomes of

observational studies on antibiotics, oral theophyllines, anticholinergics, *N*-acetylcysteine, long-acting β_2 -agonists (LABA), ICS and combination treatment are summarized below. It is important to note the scarcity of available data on COPD pharmacoepidemiology, most of which has only been available from the late 1990s.

Antibiotics

It is relatively surprising that after the original RCTs on the efficacy of antibiotics to treat or prevent exacerbations of COPD [34], little has been published regarding their effectiveness in the real world [35]. A recent report [36], from a population-based retrospective cohort study in Ontario, Canada, determined the association between outpatient use of oral antibiotics and 30-day all-cause mortality following hospitalization in a group of elderly COPD patients. Outpatient use of antibiotics was associated with a significant reduction in the 30-day mortality following hospitalization (odds ratio [OR] 0.83; 95% confidence interval [CI], 0.75–0.92). Use of macrolides had the lowest relative odds for mortality (OR 0.58; 95% CI, 0.47–0.73), while use of fluoroquinolones had the worst relative odds (OR 0.98; 95% CI, 0.84–1.15). However, another report from the same group identified an increased risk of COPD hospital readmission with antibiotic use (relative risk [RR] 1.17; 95% CI, 1.10–1.23) [37].

Oral theophyllines

Available evidence investigating the effect of oral theophyllines on COPD mortality, from well-conducted RCTs or from observational studies, is too scarce to draw any meaningful conclusions [38].

Anticholinergics

A paper by Benayoun *et al.* [39] on the concomitant use of ipratropium bromide and inhaled β_2 -agonists in a single inhaler reported that it did not significantly alter the treatment of COPD and resulted in appreciable cost savings relative to using both drugs separately. Although an initial epidemiological study indicated an absence of increased mortality in COPD patients [40], there is open controversy regarding the safety of short-acting anticholinergics. Studies comparing short-acting combinations (ipratropium plus albuterol or metaproterenol) with short-acting β_2 -agonists or anticholinergic monotherapies may have been too small or too short to conclude anything about COPD mortality and survival [41–43].

In UK patients with asthma and COPD [44], treatment with ipratropium bromide at discharge from hospital was associated with an increased risk of death from asthma (OR 4.04; 95% CI, 1.47–11.13) and from COPD (OR 7.75; 95% CI, 2.21–27.14), even after adjusting for peak flow, cardiovascular comorbidity, smoking history and age at onset of asthma. In Denmark [45], ipratropium bromide was associated with a relative risk of increased mortality of 2.0 (95% CI, 1.5–2.6) for COPD and 3.6 (95% CI, 1.8–7.1) for asthma patients. After adjustment for confounding factors, including forced expiratory volume in 1 s (FEV_1), smoking habits, asthma medication and presence of cor pulmonale, the relative risk for COPD remained increased at 1.6 for COPD (95% CI, 1.2–2.1) and 2.4 for asthma (95% CI, 1.2–5.0). A recent report from the 5-year Lung Health Study RCT [46], has shown that deaths and hospitalizations for cardiovascular disease and coronary artery disease were more common in the smoking intervention plus ipratropium bromide, than in the smoking intervention plus placebo inhaler group, and the differences approached statistical significance. Later correspondence has not yet clarified this finding [47,48]. Garcia-Aymerich *et al.* [49], in a prospective cohort of 340 COPD patients recruited during an admission for an exacerbation in four tertiary hospitals in Barcelona (Spain) followed for 1 year, reported that taking anticholinergic drugs was associated with an increased risk of COPD readmission of 1.81 (95% CI, 1.11–2.94). The authors concluded that the excess risk associated with anticholinergic drugs might be partially caused by confounding by indication. A recent reanalysis of this study with additional control for confounding by indication [50], reduced but did not negate this association. Residual confounding may still account for part of the remaining excess risk, but true adverse effects of this treatment cannot be excluded.

Regarding long-acting anticholinergics, five RCTs of the once-daily, inhaled long-acting anticholinergic bronchodilator tiotropium compared with either placebo or ipratropium bromide are available, including 3574 patients with moderate to severe COPD [51–55]. However, these trials are too short and underpowered to allow evaluation of the effect of tiotropium on all-cause mortality, and no observational studies are yet available.

N-acetylcysteine

Several epidemiological studies have assessed the effect of oral antioxidant *N*-acetylcysteine (NAC) in the prevention of rehospitalization for COPD exacerbations. In the Dutch Pharmo database [56], it was observed that NAC reduced the risk of COPD rehospitalization up to 1 year by approximately 30% and that this risk reduction was dose dependent. This positive result was consistent with three previous

6-month RCTs [57–59], and two recent meta-analyses of RCTs [60,61]. Methodological concerns about the account of immortal time and bias in the Pharmo study were recently raised [62]. The Bronchitis Randomized On NAC Cost-Utility Study (BRONCUS) [63] is an ongoing 3-year, randomized, double-blind, placebo-controlled, parallel group study in 10 European countries designed to assess the effectiveness of NAC in altering the decline in FEV_1 , exacerbation rate and quality of life in patients with moderate to severe COPD.

Long-acting β_2 -agonists

The use of LABAs has caused some concern about serious adverse events and mortality in COPD and in adult asthmatics [64]. Many COPD patients have a number of cardiovascular comorbidities, and the specificity of LABA effects in the β_2 -adrenoceptor is not so specific or selective in practice, and therefore could cause cardiac events.

Only one observational study, the Serevent Nationwide Surveillance Study [65], indicated a small non-significant trend towards increased mortality with salmeterol and this was in patients with asthma. However, in a posterior, large prescription-event monitoring study of 15 407 patients given salmeterol and observed for a minimum of 1 year [66], no evidence was found that salmeterol contributed to death in any of the patients. On careful examination of the clinical records, all deaths appeared to have been due to natural causes, suggesting that advanced age and severity of disease were the most likely factors contributing to mortality in the population studied.

In an UK GPRD study [67], salmeterol use was not associated with an increase in short-term mortality compared with ipratropium bromide and theophylline.

In a case-control study of admissions to the intensive care unit for asthma in 14 major hospitals within the Wessex region in 1992, the use of salmeterol by patients with chronic severe asthma or COPD was not associated with an increased risk of a near-fatal attack of asthma or COPD [68].

In a meta-analysis of all RCTs of salmeterol versus placebo in COPD [69], treatment with salmeterol ranging from 12 to 52 weeks showed no increased risk of cardiovascular adverse events compared with placebo (RR 1.03; 95% CI, 0.8–1.3), and both groups had a similar incidence of cardiovascular events (8%), including cardiovascular deaths. The conclusions that salmeterol does not increase mortality in patients with COPD was also shared in a recent review [70]. Finally, in another meta-analysis, the impact of LABAs as a drug class on COPD mortality was also assessed [71]. Nine randomized placebo-controlled trials of LABAs with 3-month or longer follow-up were identified,

including 4198 patients with moderate to severe COPD. No significant difference in all-cause mortality was observed (RR 0.76; 95% CI, 0.39–1.48).

Inhaled corticosteroids

Perhaps the most active area in pharmacoepidemiological research today is the study of the observational effects of ICS in COPD, involving several groups worldwide. Although all RCTs to date and most respiratory physicians are interested in lung function, COPD patients are not. As reviewed by van der Molen *et al.* [72], COPD patients are mainly interested in breathlessness in daily life, not being able to control breathlessness during an exacerbation, their symptoms getting worse, catching a cold and, above all, staying alive. It is appropriate to review randomized experimental evidence on exacerbations and survival at this point. A meta-analysis of published results of RCTs reported that there was a risk reduction in COPD exacerbation rate of 30% (RR 0.70; 95% CI, 0.58–0.74) and a 16% non-significant reduction in mortality in the five trials that measured this outcome (RR 0.84; 95% CI, 0.60–1.18) [73]. Although these trials were not designed or powered to detect differences in survival or COPD rehospitalization, this meta-analysis indicates a strong signal for unexpected beneficial effects of ICS on these outcomes.

Sin and Tu [37] used the Ontario health databases in Canada and found that elderly patients (65 years or older) who received at least one dispensation of ICS within 90 days of hospital discharge had a 26% lower adjusted risk for respiratory hospitalization and all-cause mortality than did those who did not receive these medications (RR 0.74; 95% CI, 0.71–0.78).

The results of Sin and Tu on reduced rehospitalization or death after a first COPD hospitalization associated with ICS were replicated in the UK GPRD population [74]. Additionally, an association with survival in COPD patients prescribed with combination treatment of fluticasone propionate (an ICS) and salmeterol xinafoate (a LABA), was observed in UK COPD patients diagnosed at primary care [75]. Survival at year 3 was significantly greater in fluticasone propionate and/or salmeterol users (78.6%) than in the reference group (63.6%). After adjusting for confounders, the survival advantage observed was highest in combined users of fluticasone propionate and salmeterol (RR 0.48; 95% CI, 0.31–0.73), followed by users of fluticasone propionate alone (RR 0.62; 95% CI, 0.45–0.85) and non-significantly by regular users of salmeterol alone (RR 0.79; 95% CI, 0.58–1.07) versus the reference group made up of users of short-acting bronchodilators.

In a second study from Sin and Man [76], administrative databases in Alberta, Canada were used to evaluate the

Table 65.2 Summary of methods in inhaled corticosteroids observational studies focused on survival.

Figure 65.2 Survival in the Inhaled Steroids in Obstructive Lung Disease in Europe (ISOLDE) randomized controlled trial (RCT). Time to death during 3 years of follow-up of patients while receiving study treatment. (From Waterhouse *et al.* [82] [abstract], kindly forwarded from Professor S. Burge.)

Figure 65.3 Survival in the Inhaled Steroids in Obstructive Lung Disease in Europe (ISOLDE) randomized controlled trial (RCT). Time to death during 3 years of follow-up including all deaths obtained from UK central registers. (From Waterhouse *et al.* [82] [abstract], kindly forwarded from Professor S. Burge.)

long-term effects of ICS among elderly COPD patients and to determine whether the survival benefits were dose dependent. Patients who received at least one dispensation of ICS during follow-up (average follow-up 32 months) had a 25% relative reduction in the risk for all-cause mortality (RR 0.75; 95% CI, 0.68–0.82) compared with those who did not receive any ICS during follow-up. Patients on medium (501–1000 µg/day beclometasone equivalent) or high-dose therapy (more than 1 mg/day beclometasone) had lower risks for mortality than those on low doses (RR 0.77; 95% CI, 0.69–0.86 for low dose; RR 0.48; 95% CI, 0.37–0.63 for medium dose; and RR 0.55; 95% CI, 0.44–0.69 for high dose). The McGill group in Montreal has challenged these results [29,77,78] and found no association with survival, or mortality, of ICS in the Saskatchewan COPD population. Additionally, Fan *et al.* [79] reported in a time-dependent study of outpatients with COPD, adherence to ICS use was not associated with a decreased risk of mortality.

To date, groups determining outcomes of rehospitalization and mortality in COPD populations are using somewhat heterogeneous methods (Table 65.2). This heterogeneity might explain some or most of the differences in direction and magnitude of results. Nevertheless, any possible beneficial effects of ICS should be balanced against any adverse effects in the acute or long-term management in COPD [80].

Interestingly, no past RCTs mentioned in the meta-analysis of RCTs [73] had been powered to detect survival. However, reanalysis of old RCTs might provide further insights into the possible beneficial effects of ICS in COPD. In the Inhaled Steroids in Obstructive Lung Disease in Europe (ISOLDE) trial, the results of the 3-year study of 751 patients with moderate to severe COPD randomized

to the ICS fluticasone propionate or placebo reported no differences in survival as per the protocol (Fig. 65.2) [81]. However, when an extensive search of life status for missing and withdrawn individuals from the protocol was undertaken, including searching national UK death registries, a survival advantage in the fluticasone propionate arm was suggested, although not statistically significant ($P=0.069$) (Fig. 65.3) [82].

To help settle the controversy on the effect of ICS and combination treatment in COPD survival, and in the absence of a higher level of evidence coming from new RCTs, yet more sophisticated analyses of old RCTs are worth exploring. Of interest, a new tool called patient-level pooled analysis is currently available. A pooled analysis follows the principle of traditional meta-analysis, but instead of grouping published results, it collects the raw data at the individual level, creates a new database, and analyses data as if they were a new RCT. Although patient-level pooled analyses are more difficult to conduct than those based on published data, they are more desirable, because patient-level pooled analyses are more powerful and less susceptible to methodological biases than those that rely exclusively on published reports [83]. Results of the pooled analysis known as Inhaled Steroid Effect Evaluation in COPD (ISEEC) have recently become available [84]. ISEEC aimed to reanalyse original data at the individual level from the seven available large long-term COPD RCTs with ICS or placebo that had life status recorded, including the Lung Health Study 2 (LHS-2), Copenhagen City Lung Study (CCLS), Inhaled Steroids in Obstructive Lung Disease in Europe (ISOLDE), European Respiratory Society Study on Chronic Obstructive Pulmonary Disease (EUROSCOP), TRIal of Inhaled STeroids AND long-acting β_2 -agonists (TRISTAN), Szafranski's trial, and Calverley's trial. The most important

and novel finding of ISEEC was that therapy with ICS was associated with a 27% reduction in all-cause mortality among individuals with stable COPD (adjusted hazard ratio [HR] 0.73; 95% CI, 0.55–0.96). The beneficial effects of these medications appeared to be especially pronounced in female COPD patients (adjusted HR 0.46), former smokers (adjusted HR 0.60) and in those with a baseline postbronchodilator FEV_1 of less than 60% predicted (adjusted HR 0.67). The findings of ISEEC might be considered surprising in terms of direction and magnitude, as each of the seven RCTs included did not identify this survival signal per se. ISEEC adds weight and consistency to the direction and magnitude of the hypothesis of beneficial associations of ICS in COPD formulated earlier via observational pharmacoepidemiological studies.

One important lesson for ongoing and future RCTs is that withdrawn individuals tend to be very informative. Past COPD RCTs did not study individuals withdrawn from study protocols as they were not contributing to respiratory function measurements. The Towards a Revolution in COPD Health (TORCH) study is an RCT designed to investigate the long-term effects of the salmeterol/fluticasone propionate combination (Advair/Seretide) at a strength of 50/500 µg twice daily compared with salmeterol alone, fluticasone propionate alone, or placebo, on survival of COPD subjects over 3 years of treatment [85]. The primary analysis is a difference in all-cause mortality rates in patients randomized to salmeterol/fluticasone propionate combination versus placebo. The secondary efficacy endpoints include rate of COPD exacerbations and health status. Other secondary endpoints include other mortality and exacerbation endpoints, requirement for long-term oxygen therapy, and clinic lung function. Safety endpoints include adverse events, with additional information on bone fractures. TORCH is a multicentre randomized double-blind parallel-group placebo-controlled study conducted in 45 countries worldwide of approximately 6200 male and female outpatients aged 40–80 years with a baseline FEV_1 of less than 60% of predicted normal, an established clinical history of COPD (as per the European Respiratory Society [ERS] consensus statement), current or ex-smokers with a smoking history of at least 10 pack-years, poor reversibility of airflow obstruction (defined as less than 10% increase in FEV_1 as a percentage of normal predicted 30 min after inhalation of 400 µg salbutamol via metered dose inhaler [MDI] and spacer), and baseline FEV_1 /forced vital capacity (FVC) ratio less than or equal to 70%. The first TORCH patient was recruited in September 2000, and results should be available early in 2006.

In 2002, it was announced a new large-scale 4-year study to look at the impact of long-term treatment with the long-acting anticholinergic bronchodilator tiotropium bromide (Spiriva) on lung function in COPD. The Understanding

Potential Long-term Impacts on Function with Tiotropium (UPLIFT) trial will enrol up to 6000 patients in 37 countries and examine whether tiotropium bromide reduces the rate of lung function decline over time. It will also assess quality of life, exacerbations, hospitalizations and mortality [86]. The inclusion criteria of UPLIFT include a clinical diagnosis of COPD, age 40 years or older, smoking history of 10 pack-years or more, a maximal postbronchodilator FEV_1 of less than 70% of predicted and an FEV_1 /FVC of less than 70%, and the ability to perform satisfactory spirometry. Patients are excluded if they had a respiratory infection or an exacerbation of COPD in the 4 weeks prior to screening, a history of asthma or pulmonary resection, used supplemental oxygen more than 12 h/day, or had a significant disease other than COPD that, in the opinion of the investigator, may influence the results of the study or the patient's ability to participate in the study. The presence or absence of reversibility to the bronchodilator was not an entry criterion in UPLIFT. Patients are permitted to continue using all previously prescribed respiratory medications other than inhaled anticholinergics, provided the prescriptions had not changed in the 6 weeks prior to randomization. Of interest, there are no restrictions for medications prescribed for treatment of exacerbations.

The ongoing TORCH and UPLIFT RCTs have a focus on mortality, the former being powered on it. Complete assessment of life status of all randomized patients during the entire period of follow-up is a necessity. Issues to interpret this intention-to-treat approach have been elegantly presented elsewhere and results are expected between 2006 and 2007 [87].

Future directions

Pharmacoepidemiology leads the way in COPD research, ahead of forthcoming COPD clinical trials data [33]. Data from clinical trials are classified as evidence A or B in the GOLD guidelines [88]. In the meantime, interpretation of pharmacoepidemiological studies, particularly on the direction and magnitude of survival results in COPD, has to be balanced with other sources of available data. The traditional skepticism towards observational evidence has to be put into perspective and its quality must be objectively assessed. Guidelines are now being presented on how to evaluate the quality of evidence from observational research [89]. To confirm or reject the effects of observational studies, standardization of methods, and of course independent replication by other researchers can help to clarify evidence C for GOLD and for the community. More good pharmacoepidemiology is needed, as well as more good RCTs. Eventually, randomized trials are the most robust tool to support and implement any medical intervention with

solid experimental evidence. However, in COPD and other conditions, even with more and larger RCTs, outcomes in some disease endpoints and some rare adverse events will only be detected post-marketing by means of epidemiological and surveillance methods. The main problem interpreting pharmacoepidemiology – confounding by indication – will remain. It is a high price to pay but unavoidable because of the absence of randomization in observational research. Apart from the classic ways to deal with the problems described earlier, several alternative designs and analytical strategies have been proposed to deal with time-dependent variables, and specifically to avoid confounding by indication. Thus, case cross-over [90], G-estimation [91] and marginal structural [92] models might be considered for future studies in COPD patients. Other methods to be explored include multilevel analysis [93] and propensity score techniques [94]. On the latter, very recently a propensity score design within a UK pharmacoepidemiology cohort was reported [95] and its results add further evidence to the discussion on the effectiveness of ICS in COPD [96].

Future applications of meta-analysis [97] and pharmacogenetics [98] will still have a role in COPD. Short-term drug-associated serious events are more likely to be detected in selected COPD populations. Long-term genomics techniques can be incorporated into population data to map genetic risk factors for COPD and drug responses. Tissue specimens might be linked to clinical data in certain data resources like clinical trials, *ad hoc* cohorts, case registries, and cross-sectional and longitudinal population samples, giving a 'real world' perspective to COPD pharmacogenetics.

Finally, we must be aware that COPD pharmacoepidemiology is merely in its infancy, compared with a successful history in cardiovascular and cancer research for longer than 30 years, and even for at least 15 years in asthma pharmacoepidemiology. Most likely, old methods have to be adapted and perhaps new methods developed to study drugs in COPD by means of observational data. COPD has been a Cinderella disease for clinicians but should be considered a dream disease for respiratory epidemiologists. Perhaps, with time, COPD will be like Snow White. It has been kept in a long sleep by all sides, and now it is time to kiss it awake.

CHAPTER 66

Social and behavioural impact of COPD – research opportunities

Suzanne S. Hurd and Claude Lenfant

Health-care professionals, patients, families, community leaders and policy makers struggle to understand interactions between health and behaviour and to use that knowledge to improve the health status of individuals and populations.

For patients with COPD, as with other chronic illnesses, health and behaviour are related in numerous ways, yet those interactions are neither simple nor straightforward. Psychosocial variables (e.g. depression, anxiety, self-esteem, optimism and social support), demographics (including age and socioeconomic status) and disease variables (such as dyspnoea, disease severity and functional status) all impact on quality of life for COPD patients.

Except for smoking cessation, factors in the development and manifestation of COPD have not received the attention of behavioural scientists or experts in health education that is warranted by the public health importance of this chronic lung disease. COPD management programmes are being implemented in several countries based on the Global Initiative for Chronic Obstructive Lung Disease (GOLD) [1] initiative, and much will be learned about how COPD patients can learn to cope with their disease in a variety of health-care settings.

This chapter describes some of the social and behavioural aspects of care that impact on COPD patients and areas where behavioural research is beginning to make a contribution, or where further research is warranted. For many years, health-care workers have had a rather nihilistic approach to care of COPD patients and to make a positive impact will require a modification of this negative approach. Effective management of COPD is no longer the responsibility of the pulmonary disease specialist alone, but requires a team approach that includes a variety of disciplines [2].

Behavioural impact of COPD

It is well documented that COPD patients experience gross difficulties in their emotional functioning, sleep and rest,

physical mobility, social interaction, activities of daily living, recreation, work and finance. They frequently experience depression and anxiety and have a reduced quality of life [3]. In the early 1960s, it was reported that impairment of the psychosocial functioning and quality of life of the patient with COPD could exacerbate existing symptoms and decrease compliance with treatment [4]. In the 1980s, the Nocturnal Oxygen Therapy Trial (NOTT) [5] compared COPD patients with a group of healthy controls on four dimensions of life quality: emotional function, social role function, daily living activities and ability to engage in enjoyable hobbies and recreational pastimes. COPD patients were impaired in almost all respects: they were dissatisfied with life, tense, depressed, confused and socially withdrawn; quality of life was significantly related to severity of the disease. Study patients performed significantly worse on virtually all neuropsychological tests [5].

In 1983, another multicentre clinical trial, the Intermittent Positive Pressure Breathing Study (IPPB) [6], included patients with less severe COPD. Patients were between ages 30 and 74 years with prebronchodilator forced expiratory volume in 1 second (FEV_1) less than 60% predicted, and the patient group had a Pao_2 of 66 mmHg. Even though this group of patients was less physically limited than the patients in the NOTT study, they showed approximately equal impairment in psychosocial functioning, indicating that the degree of psychosocial limitation is not determined directly by the degree of pulmonary disease once COPD is present [6].

Since the publication of the NOTT and IPPB clinical trials, considerable research has been undertaken in the area of health and behaviour and the interplay between biological, behavioural and societal influences, although very little of this research is conducted specifically on COPD patients. Much of the current literature on chronic disease relates to cardiovascular diseases, cancer and musculoskeletal diseases (osteoarthritis), and it is expected that future research

on COPD will benefit from the methodology developed from these investigations [7].

Studies on COPD patients have demonstrated that a comprehensive assessment of the effects of COPD requires a battery of instruments that not only tap the disease-specific effects, but also the overall burden of the disease on everyday functioning and emotional well-being [8]. However, many of these instruments have been developed to assess the severely impaired COPD patient.

In the GOLD guidelines [1], a classification of severity includes individuals “at risk” (Stage 0) for COPD as well as categories of mild (Stage 1), moderate (Stage 2), severe (Stage 3) and very severe disease (Stage 4). Including an “at risk” stage in this classification scheme was proposed to provide guidance for detection of early disease. However, to evaluate the impact of interventions, particularly at the early stages, it may be necessary to develop new outcome measures for use by health-care professionals, patients and health-care payers [9].

For example, it has been shown that quality of life is not significantly affected in patients with mild to moderate loss of pulmonary function, possibly because of coping and/or pulmonary reserve capacity [10]. This suggests that generic self-assessment questionnaires are of limited value, and that new measures need to be developed and evaluated to detect the early consequences of COPD. In later stages of the disease, however, current measures appear to be sensitive enough to discriminate between patients with different levels of pulmonary dysfunction [11], and it has been suggested that quality of life should be measured in these patients to evaluate the impact of therapeutic procedures on well-being from the patient’s perspective [12].

Patients with endstage COPD have significantly impaired quality of life and emotional well-being [13]. COPD patients with recurrent exacerbations requiring emergency treatment show a significant association between treatment failure and anxiety and/or depression [14]. Poor emotional functioning of female patients with severe COPD at the time of prescription of long-term oxygen therapy (LTOT) was shown to be associated with increased mortality [15]. In one study, it was noted that emotional well-being of COPD patients may not be as well met in terms of medical and social care compared with those of patients with lung cancer [13]. In this study, both COPD and lung cancer patients reported a lack of information from professionals regarding diagnosis, prognosis and social support, although patients’ information needs were disparate and often conflicting.

Coping and COPD

Coping efforts are important in the process of adaptation to illness. Studies on the role of coping strategies, levels of self-efficacy (extent of the belief that one is, or is not capable of

performing a particular behaviour, or set of behaviours) and social support (involving both benefits and costs) in predicting adjustment for COPD patients warrants further investigation [3]. This concept may be particularly important to study in COPD given the nihilistic approach to management of this illness that has permeated the health-care system.

Results from prospective longitudinal studies of breast cancer patients from diagnosis through treatment and recovery [16,17] have shown that successful coping is facilitated by optimism – the tendency to anticipate positive outcomes [7]. Through the use of strategies including acceptance, positive thinking and problem solving, optimism is associated with lower psychological distress (reduced symptoms of anxiety and depression). Conversely, pessimistic thinking is associated with avoidance and social withdrawal which are related to higher symptoms of anxiety and depression [16,17]. Patients who are more prone to poor coping have histories of social isolation, recent losses or multiple obligations [18].

Breast cancer patients who learn to use more direct and confrontational coping strategies are less distressed than those who use avoidance and denial [19]. Furthermore, a “fighting spirit” about the illness leads to a probability of longer survival [20,21]. Research suggests that belief one has control over the *cause* of the disease leads to poor outcome, whereas belief in control over the *course* of the disease leads to better outcome [21].

An interesting study comparing illness perceptions and coping strategies in patients with three different chronic diseases (rheumatoid arthritis, COPD and psoriasis) indicated a strong illness identity, passive coping, belief in a long illness duration, belief in more severe consequences and an unfavourable score on medical variables were associated with worse outcome on disease-specific measures of functioning and on general role and social functioning. Coping by seeking social support and a belief in being able to control or cure the disease were significantly related to better functioning [22]. The authors concluded that coping with illness by being active, expressive and thinking positively results in significantly higher levels of functioning, as well as more positive scores on clinical measures of disease.

Evaluation of COPD programmes in several countries will provide a spectrum of how various populations cope with COPD [12,23]. However, based on a growing literature from a number of chronic illnesses, it appears certain that a more optimistic approach to COPD outcomes by health professionals will lead to a better psychosocial adjustment.

Dyspnoea

Dyspnoea, a major symptom of COPD, is an important cause of suffering and disability in patients with advanced disease, and there are several methods to measure the

impact of dyspnea on daily living [24]. Although emotional factors are believed to influence the experience of dyspnea, their role is unclear, as is the relationship between respiratory sensation and behavioural control of breathing. Very little is known about the effects of psychosocial stress on the immune system in COPD patients, exacerbations of the disease and the patient's perception of dyspnea. Psychophysiological studies of the relationship between respiratory sensation and the behavioural control of breathing may be useful in developing approaches to the management of dyspnea.

An objective of current COPD management strategy is to identify individuals early in the course of disease. Individuals who experience dyspnea may find themselves with a symptom of disease, but without a significant reduction in pulmonary function. Unfortunately, physicians may be inclined to inform the individual that there is simply no reason for the dyspnea, and thus appropriate educational efforts for general practitioners are required. All patients with dyspnea should remain physically active in the absence of a medical problem that prohibits it [25].

Prevention and risk factor reduction

The causal link between the chronic inhalation of tobacco smoke and COPD is beyond doubt, and smoking cessation remains the most important goal for patients. It has been well documented that the rate of decline in pulmonary function with increasing age is greater for smokers than for non-smokers. After cessation of smoking, the rate of decline gradually reverts to a more normal rate, although the function that has already been lost is not generally regained [26].

In 1994, the US Agency for Health Care Policy and Research provided clinical guidelines for effective smoking-cessation strategies that summarized the findings of 300 studies [27]. Some of the recommendations included the following:

- Effective smoking cessation treatments are available, and every patient who smokes should be offered one or more of these treatments. A combination of psychosocial counselling and nicotine replacement therapy appears to be the most effective strategy.
- Longer counselling sessions (more than 10 minutes) are more effective than shorter ones (less than 3 minutes). More sessions (more than eight) produce better results than do fewer (under four), but even fewer or shorter sessions still have a more substantial influence on smoking behaviour than do no sessions at all.
- Effective reduction of tobacco use requires that health-care systems make institutional changes that result in systematic identification of, and intervention with, all tobacco users at every visit.

It has been clearly demonstrated that smoking-cessation programmes are a cost-effective way to improve health [28], leading to the recommendation that physicians intervene by discussing smoking and potential treatment with every patient who smokes [29]. However, the trend in smoking-related research has been away from brief interventions studied sequentially to programmes that target smoking at the social, physiological and psychological levels [30]. Smoking cessation interventions targeted to specific needs, barriers and smoking patterns appear to be more effective in promoting higher cessation rates than standard (e.g. NCI Cancer Information Service quit smoking guide) interventions [31].

There are many barriers to effective prevention of COPD:

- Cost of implementation of smoking cessation programmes
- Difficulty in achieving smoking cessation
- Limited awareness of awareness of early signs and symptoms
- Lack of awareness of benefits of early treatment and risk factor modification
- Limited use of immunization for influenza
- Lack of patient knowledge, skills or motivation to follow management regimen
- Lack of knowledge by health-care providers

Although prevention of chronic diseases may be preferable from a public health point of view, current prospects for total elimination of chronic diseases are mostly unrealistic. For this reason, it is important to look at opportunities for preventing loss of physical functioning that often accompanies chronic diseases by identifying determinants of physical disabilities among chronically ill persons and by acting on those determinants [32,33]. For patients with COPD, this will depend not only on medical interventions, but will also require social and psychological interventions.

Rehabilitation programmes and health education

Rehabilitation forms an important component of the management of COPD. A Cochrane review concluded that rehabilitation relieves dyspnea and fatigue and enhances patients' sense of control over their condition. Improvements in most studies were shown to be moderately large and clinically significant, although average improvements in exercise capacity are modest [34].

The optimal duration of pulmonary rehabilitation programmes remains the topic of many investigations. A 7-week course of pulmonary rehabilitation was shown to provide greater benefits to patients than a 4-week course in terms of improvements in health status [35]. A 6-week outpatient-based pulmonary rehabilitation programme appears to benefit quality of life in patients with moderate to severe COPD and benefit was still evident after 24 weeks [36]. Among patients who completed a 6-month programme,

outpatient training resulted in significant and clinically relevant changes in 6-minute walking distance, maximal exercise performance, peripheral and respiratory muscle strength, and quality of life. Most of these effects persisted 18 months after initiation of the programme [37]. In another study, a simple home-based programme of exercise training achieved improvement in exercise tolerance, post-effort dyspnoea, basal dyspnoea and quality of life in COPD patients [38]. It will probably be necessary to examine the most effective – and cost effective – length and duration of outpatient rehabilitation programmes in relation to the appropriate health-care system.

An inpatient pulmonary rehabilitation programme led to improved endurance and functional ambulation, decreased supplemental oxygen use and fewer hospitalizations 1 year after discharge for patients with COPD [39]. However, long-term cost effectiveness and effects on mortality have yet to be elucidated [40].

Self-management education programmes for asthma have been proven to improve a wide range of measures of outcome [41] and are recommended for incorporation into routine asthma care [42]. However, a Cochrane analysis [43] concluded that data available are insufficient for forming recommendations regarding utilization of self-management for COPD and suggested that further research on the effectiveness of self-management programmes should be focused on behavioural change evaluated in well-designed randomized controlled trials with standardized outcomes designed for use in COPD patients, and with long follow-up time so that definite conclusions can be made [43].

Chronic diseases of adulthood have received the least systematic attention with respect to family-focused interventions. There have been many clinical reports and descriptive studies of interventions to assist families struggling with chronic disease. Most studies have been unsystematic and uncontrolled, but they indicate a growing recognition by the clinical community of the need to address family issues and of the utility of basing intervention in a family context [7].

Research opportunities

Because current treatments for COPD provide only modest benefit to the patient, substantial progress in COPD treatment may require the development of entirely new therapeutic approaches. Given the many important deficits of knowledge regarding the understanding of the disease process, and innovative approaches to modification of this process, an increase in basic and clinical research activities on COPD is sorely needed [44].

Research on molecular biology has received considerable attention in the scientific and lay communities as discover-

ies are made on genetic contributions to disease. Some are concerned that attention to molecular biology and genetics will lead to a growing chasm between social, behavioural and biomedical research [45]. However, health problems related to COPD – as in all complex chronic diseases – are brought about by an interaction of sociobehavioural and biological processes. Thus, research is required to understand the interactions in COPD patients between genetics and physiological processes with individual personalities, psychological characteristics, social status and relationships that affect health status.

Clinical trials are required to evaluate the value of behavioural and psychosocial interventions for COPD and the impact of these interventions on health, quality of life and longevity. Research has shown that behaviour can be changed, and that behavioural interventions can successfully teach new behaviours, and attenuate risky behaviours. However, maintaining behaviour change over time – essential for a disease like COPD – is a greater challenge.

Awareness of the signs and symptoms of COPD among the public and the health care community is a major goal of the GOLD programme. While spirometry is recommended to assess and monitor COPD, other measures need to be developed and evaluated in clinical practice.

Individual behaviour, family interactions, community and workplace relationships and resources, and public policy all contribute to health and influence behaviour change. Forming coalition groups at the local level to work with asthma patients has demonstrated that intervention at multiple levels (individual, family, community, society) are most likely to sustain behavioural change. Similar studies are required for patients with COPD. Such efforts should address the psychosocial factors associated with health status (including access to safe places to exercise, access to healthy foods) as well as individual behaviour (maintaining smoking cessation). Interventions aimed at increasing beliefs in personal control and changing beliefs about the course of illness could be associated with improvements in physical well-being and social functioning of patients with COPD [46].

CHAPTER 67

Guidelines

Peter M.A. Calverley

Chronic obstructive pulmonary disease is a complex disorder with many different aspects, as illustrated by the other chapters in this volume. As the management options for COPD have increased so has the perceived need for standardized care and this has led to the development of a series of COPD Guidelines. These documents have the difficult task of addressing the very different needs of those who wish to use them. For the research scientist, they should give a clear conceptual structure to the field of COPD. For the practising clinician, they should offer advice about diagnosis and the best way to manage patients, while for the health-care administrator they should give some indication of the likely costs of COPD care, either explicitly or, more commonly, implicitly by detailing what types of therapy are going to be available for what kinds of patients. COPD Guidelines should be regularly updated, otherwise they fossilize therapy instead of advancing it. As a result, this chapter is likely to be outdated in some specific areas by the time this book is published, let alone by the point at which you purchase your copy. None the less, there is some virtue in considering some of the general features that have affected the structure of these documents and which are likely to impact on future versions. Understanding some of these constraints may help the clinician reading this book to interpret the information with which they are provided.

COPD Guidelines – a brief history

Traditionally, most clinicians developed views about how to manage patients with COPD from discussion with senior colleagues and by reading textbooks and the medical literature. This undoubtedly led to a very fragmented approach to management of this disease, made worse by the historical distinctions of chronic bronchitis and emphysema which were thought of as separate illnesses requiring different treatment approaches. The recognition that these

differing pathologies could produce very similar clinical states occurred during the 1980s when interest moved from the management of very advanced disease with treatment such as domiciliary oxygen [1] to establishing a more rational basis for commonly used therapies such as bronchodilator drugs [2]. The perceived success of the introduction of systematized guidance for the management of asthma [3] led many people to consider undertaking this for patients with COPD. This was initially carried out on a national level, with Canada and Australia leading the way [4,5]. These documents were developed by expert consensus and focused on stating agreed care patterns for patients with COPD. As a result, they looked little different from information obtained in standard medical textbooks or review articles but they had the advantage of being approved by the national pulmonary societies and became a benchmark against which individual institutions could audit their care. This early function of guidelines remains one of the most important reasons for developing these documents.

Subsequently, larger international societies, particularly the American Thoracic Society (ATS), which had already considered in general standards of care for COPD [6,7], and then the European Respiratory Society (ERS) developed specific documents [8]. These differed in scope, content and constituency. The ERS Guidelines tried to encompass all physicians from those working in non-pulmonary specialist practice through to physicians working in large tertiary care institutions. A working definition of COPD was developed and more background to the impact and physiology of the degree of the disease was included. A novel feature of this document was the attempt to produce a series of flow charts, which might help in making specific management decisions. This, unfortunately, did not prove to be the case, largely because of the complexity of the algorithm but also because the charts themselves were never tested in practice before being included in the Guidelines. Thus, decision making at specific arbitrary cut points might appear to have

been sensible in theory, but most clinicians found it hard to apply in those specific areas of practice.

The ATS Standards of Care document took a different approach, focusing much more on hospital-based practice and offering a detailed narrative review which provided ample information about certain areas of specialist care and was more comprehensive than its European counterpart. However, the resulting document was relatively long and difficult to access to discover the answers to specific questions without reading it in its entirety. Moreover, its limited scope restricted its usefulness to the non-pulmonary specialist. Throughout the late 1990s other national society documents were produced which drew similar conclusions to each of these preceding consensus statements but had the advantage of raising awareness of COPD in the individual country. One of the most important of these was the British Thoracic Society (BTS) Guidelines published in 1997 [9]. These were the first guidelines to draw in a wider constituency of interested people, including physicians in internal medicine, emergency medicine, family practice and those with nursing experience. The document was more didactic than others but had the advantage of being easier to read and clearer in its management recommendations. This was the first document to be developed with a specific programme for implementation, an area that remains difficult (see below).

The global scope of COPD and the progressively rising mortality and morbidity with which it is associated [10] led the National Institutes of Health (NIH) and World Health Organization (WHO) to convene a specific workshop group to develop global guidelines for COPD management. This resulted in the Global initiative for chronic Obstructive Lung Disease (GOLD), which produced its background documents and an executive summary in 2001 [11]. The principal aims of GOLD are summarized in Table 67.1 and progress to date suggests that at least some of these are now being met. Like its predecessors, GOLD was based around an expert group of pulmonary physicians and given the diversity of health-care systems it was attempting to address it was probably reasonable not to include individuals representing specific paramedical or patient groups. The intention was initially to establish a knowledge base, which could then be adapted locally for implementation, at which stage aspects specific to these other interested groups would be included. GOLD was the first guidelines to try and offer

some grading of the strength of the evidence behind its recommendations and the grading system used is included in Tables 67.2 and 67.3. Although statements on evidence were based on only partial literature searching initially, subsequent review by other bodies suggest that no main clinical studies available at that time were omitted from the first GOLD review. None the less, the evidence gathering process was not as rigorous as has been undertaken subsequently by other organizations and by GOLD itself.

Two further features of the GOLD process are worth specific comment as neither has been fully addressed previously. From the outset, GOLD considered its role to be not just the formulation of an up-to-date evidence-based management plan, but also the dissemination of this information to as many countries as possible. By working with national opinion leaders and seeking approval for the programme from other interested parties, GOLD has developed rather specific coalitions that suit the general aim of standardizing COPD care but in very different health-care environments. The process of dissemination and implementation of the GOLD guidelines continues and is now moving towards building links with family medicine organizations and patient interest groups. If this can be achieved then an important and broadly based coalition for improving COPD care will have been developed. What is also clear is that specific countries, some of which have already developed perfectly serviceable and locally applicable guidelines, need to have a different approach in their relationships of GOLD from those where there has been no previous history of systematic COPD care. An equally important point is that there should be general agreement between the different guidelines about what COPD comprises. Needless revision of the content of guidelines, or rather futile arguments about the precise definition, are as likely to be counter-productive, especially for those doctors whose primary interest is not COPD. The second important contribution of GOLD has been to develop a mechanism for keeping itself up-to-date and this is discussed in detail below.

The beginning of the new century shows no sign of any reduction in the number of guidelines being produced and the ATS and ERS have now produced a joint guideline which is consensus-based but addresses some of the issues that require more detailed coverage than is possible in a document like that produced by the GOLD group [12]. The other novel aspect of this initiative is its availability as a downloadable Web-based document, which can be used on a personal organizer or similar personal computer. This should help increase accessibility of the information provided and overcome the problem of excessive detail which dogged the original ATS Statement. In the UK the previous BTS guidance has been replaced by national guidelines developed in conjunction with the Government organisation the National Institute of Clinical Excellence (NICE) [13].

Increase awareness of COPD among health professionals, health authorities and the general public
Improve diagnosis, management and prevention
Stimulate research

Table 67.2 National Institutes of Health (NIH)/Global initiative for chronic Obstructive Lung Disease (GOLD) evidence-based assessments.

Description of levels of evidence		
Evidence category	Sources of evidence	Definition
A	RCTs Rich body of data	Evidence is from endpoints of well-designed RCTs that provide a consistent pattern of findings in the population for which the recommendation is made. Category A requires substantial numbers of studies involving substantial numbers of participants
B	RCTs Limited body of data	Evidence is from endpoints of intervention studies that include only a limited number of patients, <i>post hoc</i> or subgroup analysis of RCTs, or meta-analysis of RCTs. In general, Category B pertains when few randomized trials exist, they are small in size, they were undertaken in a population that differs from the target population of the recommendation, or the results are somewhat inconsistent
C	Non-randomized trials Observational studies	Evidence is from outcomes of uncontrolled or non-randomized trials or from observational studies
D	Panel Consensus Judgement	This category is used only in cases where the provision of some guidance was deemed valuable but the clinical literature addressing the subject was deemed insufficient to justify placement in one of the other categories. The Panel Consensus is based on clinical experience or knowledge that does not meet the above-listed criteria

RCT, randomized controlled trial.

Table 67.3 UK evidence-based assessment.

Hierarchy of evidence		Grading of recommendations
Ia	Evidence from meta analysis of randomized controlled trials	A Based on category I evidence
Ib	Evidence from at least one randomized controlled trial	
IIa	Evidence from at least one controlled study without randomization	B Based on category II evidence or extrapolated from category I
IIb	Evidence from at least one other type of quasi experimental study	
III	Evidence from non-experimental descriptive studies, such as comparative studies, correlation studies and case-control studies	C Based on category III evidence or extrapolated from category I or II
IV	Evidence from expert committee reports or opinions and/or clinical experience of respected authorities	D Directly based on category IV evidence or extrapolated from category I, II or III

RCT, randomized controlled trial.

These were the first guidelines based on systematic reviews of the evidence base with an external classification of the strength of the evidence, at least as judged by the quality of the studies (see Tables 67.2 and 67.3). They are a valuable resource for those surveying the COPD literature, saving much unnecessary labour as well as allowing easier updates in the future. Unfortunately what they have gained in com-

prehensive coverage and evidence review has been lost in readability. In the end these guidelines have proven more important as a stimulus to political change in COPD care than as a practical management tool. Finally the GOLD guidance has come full circle and 2006 sees the launch of the second edition of the key resource document from which other guidance was abstracted in the original

executive summary. This provides a chance to review all aspects of our current knowledge about COPD and not just the impact of new therapies.

Defining COPD

Several definitions of COPD have been proposed by the various guidelines and several of these are shown in Table 67.4. No specific ATS definition is given here as until recently this was based on the non-proportional Venn diagram developed by Snider to cope with the differential contributions of the underlying pathology to the individual COPD patient. The most important addition suggested in the recent ATS/ERS guidance is the inclusion of the statement that COPD is a preventable and treatable disorder before the definitions listed in Table 67.4. This is strictly speaking not a defining characteristic but is intended to redress the negative perception of COPD among clinicians and has now been adopted by the GOLD initiative as part of its revised definition. The problems of defining COPD are well known but one further aspect should be stressed here. The definition selected by all guidelines leans towards terms that can be applied practically. Hence, the emphasis is placed on airflow obstruction (reduced forced expiratory

volume in 1 s to forced vital capacity ratio [FEV_1/FVC] or, in the ERS version, slow forced emptying of the lungs) and lack of spontaneous variability (largely fixed in the BTS definition, not fully reversible in GOLD). Most definitions stress the progressive nature of the symptoms and physiological change, and GOLD emphasizes the key role of inhaled insults as a pathogenic mechanism. Based on these approaches, clinicians should be able to identify a patient with COPD and apply an appropriate management strategy. However, these definitions focus on the clinicophysiological outcomes of the processes that are occurring within the lower respiratory tract of the COPD patient. They are not the ideal way of identifying patients when a specific mechanism is to be studied (e.g. regulation of VEGF in the pulmonary endothelium as a mechanism promoting apoptosis in emphysema) [14]. They also do not account for the heterogeneity of the disease. Clearly, not all patients who meet the clinical definitions have a significant degree of emphysema. Thus, studies of this mechanism or indeed of agents to promote alveolar regeneration would not necessarily be appropriate in a clinically defined COPD population. We are still ignorant of the role of individual pathological phenotypes in the natural history of COPD, but the development of these mechanistic studies, together with the availability of quantitative computed tomography (CT) scanning may provide the necessary stimulus to initiate these longer-term investigations. Until such data are available, the definition of COPD will remain a compromise equivalent to that of 'cardiac failure' but without the specificity that allows us to subclassify cardiac dysfunction into systolic and diastolic or determine even more basic causes of the problem such as valvular abnormalities. Clearly, there is much work to be done in this area of COPD research.

Table 67.4 Definitions of chronic obstructive pulmonary disease (COPD).

European Respiratory Society 1995

COPD is a disorder characterized by reduced maximum expiratory flow and slow forced emptying of the lungs; features that do not change markedly over several months. Most of the airflow limitation is caused by varying combinations of airway disease and emphysema; the relative contribution of the two processes is difficult to define *in vivo*

British Thoracic Society 1997

COPD is a chronic, slowly progressive disorder characterized by airflow obstruction (reduced FEV_1 and FEV_1/FVC ratio) that does not change markedly over several months. Most of the lung function impairment is fixed, although some reversibility can be produced by bronchodilator (or other) therapy

GOLD 2001

COPD is a disease state characterized by airflow limitation that is not fully reversible. The airflow limitation is usually both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases

FEV_1 , forced expiratory volume in 1 s; FVC , forced vital capacity.

Classifying disease severity

Clinicians look to guidelines to offer a practical approach to grade the severity of disease and relate this to management decisions. In asthma, this has been indirectly related to the patient's symptoms and is usually based on the amount of rescue medication they use and the type of treatment employed to control symptoms. Although, there is an approximate relationship of this empirical scheme to the diurnal variation to peak flow and/or histamine responsiveness, these measures have never been incorporated as primary outcomes in the staging of asthma severity [3].

A completely different approach has been used in COPD, which may not have always served patients well. Until recently, most guidelines based their staging on the FEV_1 , making the generally reasonable assumption that the lower the FEV_1 as a percentage of predicted, then the greater the

Table 67.5 Spirometric classification of COPD severity.

	<i>FEV₁</i> (% predicted)		
	Mild/stage I	Moderate/stage II	Severe/stage III
European Thoracic Society	> 70	50–69	< 50
American Thoracic Society	> 50	35–49	< 35
British Thoracic Society	60–79	40–59	< 40
GOLD	> 80	50–79 (A) 30–49 (B)	< 30

FEV₁, forced expiratory volume in 1 s; GOLD, Global initiative for chronic Obstructive Lung Disease.

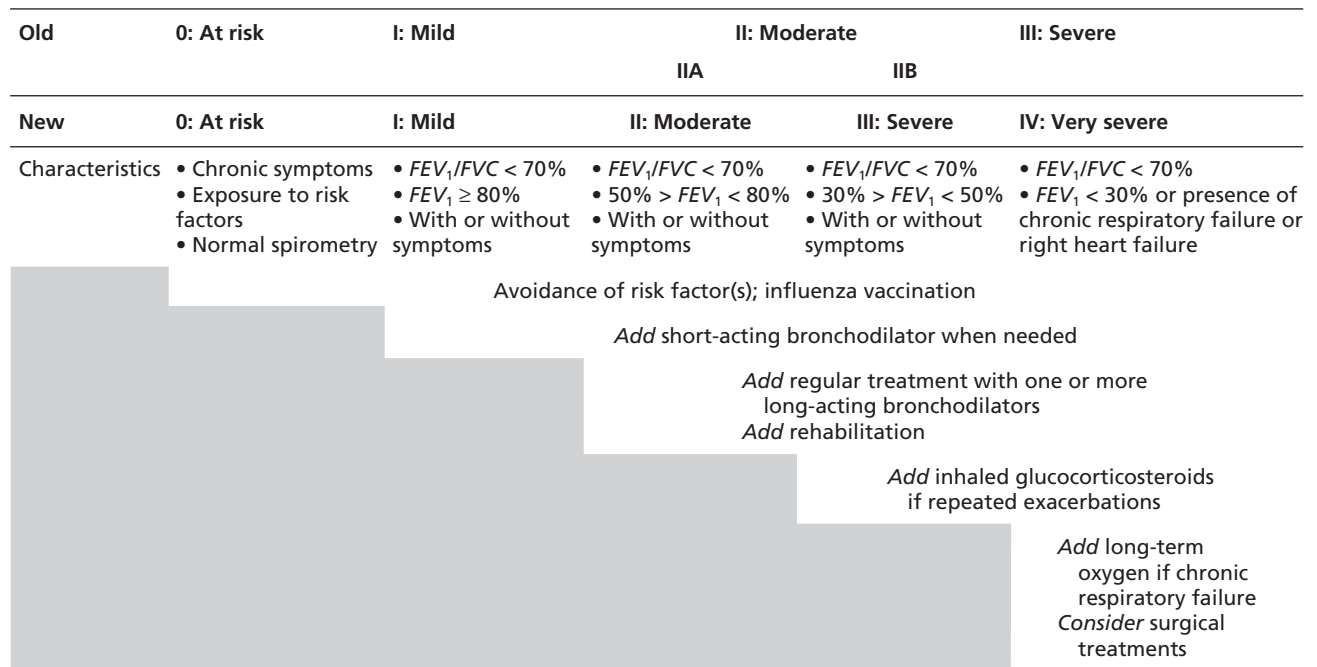

Figure 67.1 The updated Global initiative for chronic Obstructive Lung Disease (GOLD) schema for COPD management. Note the inclusion of the former categorization and its revision. Therapy is cumulative although not all will be needed in any given patient even if they have a specified level of lung function impairment.

pathological and symptomatic severity. Some of the previous proposals about staging are shown in Table 67.5 and the most up-to-date version proposed by GOLD is included in Figure 67.1.

At least three problems limit this approach. The first is practical, as until recently spirometry has not been widely available, and this remains a problem especially in less developed countries and in primary care medicine. Improvements in spirometer design and software are making this measurement much easier to perform. More important is the arbitrary nature of the boundaries selected for the severity classification (see Table 67.5). Disease severity described spirometrically is a continuously distributed vari-

able in any COPD population and *FEV₁* itself will show modest day-to-day variability. Patients who lie close to the selected boundary may therefore be reclassified as more or less severe if seen on a different day.

Most important of all is the relatively poor relationship between health status and spirometry, which means that an individual patient with an *FEV₁* of 60% of predicted can be more symptomatic than one whose *FEV₁* is 45% of predicted, despite the fact that both are given the same treatment. Because the benefits of bronchodilator therapy and rehabilitation are based on symptomatic improvement rather than altered lung mechanics, it is irrational to base management too precisely on a specified level of the *FEV₁*.

The authors of the GOLD Guidelines were aware of this dilemma when they produced their severity scheme. They allowed a wide range of spirometric abnormality to encompass symptomatic disease, now graded as moderate severity in the FEV_1 80–50% of predicted range. In addition they tried, less successfully than they originally anticipated, to stress that symptoms are the management driver in assessing which treatment should be selected. The practical value of identifying patients because they have symptoms is clear but the extension of this to include this ‘stage’ as an inevitable precursor of disease progression has not proven well founded [15]. As a result GOLD stage 0 is set to be downgraded to an at risk with symptoms category in the next version of the GOLD document. It will be interesting to see if the same happens to stage 1 where airflow obstruction is present down to 80% predicted. The NICE guidance opted not to use this stage as there is uncertainty about how closely symptoms relate to obstruction in this group and in how many cases disease progresses. More importantly there is a real problem in the elderly about applying a fixed FEV_1/FVC ratio to define obstruction [16]. Whether this matters clinically is less clear but the risk of over-diagnosis in the elderly can be minimised if only patients in stages II and above are accepted as having clinically important disease [17]. The most severe subgroup of COPD (less than 30% of predicted in GOLD and the forthcoming ATS/ERS scheme) are chosen to highlight a population where persistent daytime hypoxaemia is more likely to be found and hence where continuous domiciliary oxygen treatment is indicated. This clinical problem indicates the weakness of a purely symptom-based method of classifying COPD, as hypoxaemic patients are not necessarily more or less symptomatic than those without this important clinical complication.

Thus, classifying COPD for clinical rather than epidemiological purposes requires a hybrid approach. Several investigators are trying to develop scoring systems based on spirometry, assessment of dyspnoea (such as the Medical Research Council [MRC] dyspnoea scale), arterial oxygen tension, body mass index (an important prognostic sign in more severe disease), with or without some measurement of exercise capacity [18,19]. This approach provides better separation into groups with different prognoses but it is not clear yet whether changes in these indices give us a reliable surrogate endpoint for change in mortality, as blood pressure does in deaths from cerebrovascular disease.

Guidelines and management

Most guidelines clearly distinguish different phases of COPD care and the pattern used by GOLD now seems to be being adopted by other organizations. Thus, there is clear emphasis on issues related to diagnosis, prevention

(which normally means reduction of risk factor exposure), management of stable disease and care of patients with exacerbations. Detailed consideration is given to each of these areas elsewhere in this book, but some general features about the rationale of guidelines is worth considering.

Despite the development of clear definitions (see above), there is still a legacy of confusion about what COPD really is and how it is best diagnosed. The simple message emphasized in GOLD that a diagnosis will normally involve a patient who presents with symptoms (cough, sputum production and/or breathlessness) who also has an appropriate risk factor (e.g. tobacco exposure). Such a patient should undergo spirometry to confirm the diagnosis. Difficulties about access to spirometry make this last step harder than it should be but it is really not acceptable to omit this step in developed countries where this relatively simple test can be easily undertaken. Difficulties, as usual, are made by specialists whose own clinical practice includes the most complex cases and where unrealistic concerns about ‘missing asthma’ have led to a very distorted picture of how patients should be diagnosed. Initial enthusiasm, exemplified in the original BTS Guidelines, for the diagnostic specificity and sensitivity of bronchodilator and corticosteroid treatment trials has now been tempered by experience [20,21] and modified in the subsequent NICE and GOLD recommendations. What these studies have shown is that a clinical diagnosis of COPD is a very good way of defining a population of people whose lung function declines more rapidly than expected over time and whose natural history is punctuated by exacerbations of disease and impaired health status. Reassuring doctors that they can make diagnosis of COPD easily is a major task for future generations of guideline writers.

The importance of smoking cessation is axiomatic in the management of COPD as is the prevention of smoking in the first place. In the Western world in particular, this is the dominant factor driving the incidence of new cases. However, even in these communities, it is not the only contributory factor and other well-established risk factors, including exposure to organic and inorganic dust and specific genetic predispositions, should also be considered. Sadly, removal of these factors will not cure COPD but serves to reduce the deterioration in lung function over time. Recognition that patients whose lungs have been damaged by these environmental and personal exposures will still need care is also an important feature for anyone writing guidelines, particularly thinking of their impact on the health-care provider audience. To date, this aspect has not been stressed sufficiently.

The management of stable disease can be usefully summarized in Figure 67.1, which is taken from the first update of the GOLD recommendations in July 2003. This scheme stresses that treatment is cumulative and can be broadly

related to both the severity of spirometric impairment and the nature and impact of the disease's symptoms. Unsurprisingly, risk avoidance is a feature at all stages of disease severity as is the need to reduce the risk of having attacks of influenza. Although many organizations now advocate that pneumococcal vaccines should be routinely prescribed for COPD patients, this remains a contentious area because most of the data have been derived in younger adults and the efficacy of all the existing vaccines, both 7 and 23 valent forms, is much less documented in this specific group. There is reasonable evidence that the incidence of bacteraemia is reduced, although whether pneumococcal pneumonia, let alone COPD exacerbations, is less common is disputed [22], recent evidence suggesting benefit in those with most severe disease [23]. Given the ambivalent evidence, organizations such as GOLD have not chosen to recommend pneumococcal vaccination routinely but clearly local practice may vary depending upon the immunogeneity of the local strains of organism and there is evidence that community acquired pneumonia is prevented in those with more severe disease.

Within the GOLD classification there is now good evidence that a move to a long-acting inhaled bronchodilator is desirable for any patient with persistent symptoms. Those who have minor symptoms that are readily controlled by short-acting treatment do not need to take this step but this is not the case for most people with clinically important COPD. The more favourable risk-benefit profiles seen with these drugs compared with older therapy such as theophyllines have conditioned these recommendations. Likewise, the understanding that sustained bronchodilatation can itself reduce the number of exacerbations and improve health status over time has given much more confidence to this approach rather than short-acting therapy [24,25]. One further incidental conclusion is that studies in COPD of any medical treatment really need to extend to 1 year, if not longer, before the true impact of therapy can be evaluated. The role of inhaled corticosteroids is now much clearer and the current judgement is that it is only when patients are having frequent exacerbations that the addition of an inhaled corticosteroid to a long-acting bronchodilator can be justified [25,26]. This is quite a different view from the role of inhaled corticosteroids in bronchial asthma and emphasizes the need to actually make a diagnosis and not duck the issue. Although this particular recommendation is clearly linked to a specific level of lung functioning impairment, in practice patients with frequent exacerbations that require medical therapy will be those in whom this treatment is likely to be most effective [27].

Physical therapy is emphasized throughout COPD care and it is to be hoped that facilities for pulmonary rehabilitation will become more widespread and accessible as this undoubtedly produces a significant improvement that lasts

between 12 and 18 months in most people. Maintaining this improvement for longer periods is still an unresolved problem. Likewise, other physical treatments such as oxygen are really confined to the most severely affected patients where they can be very valuable and prolong life. The grounds for surgical therapy with lung volume reduction surgery are now much clearer following the National Emphysema Treatment Trial (NETT) study [28] and this too has been incorporated within the most recent guidelines.

Managing exacerbations has undergone less change than other areas of treatment. An extensive systematic review has been conducted which identified a number of points in exacerbation care [29], all of which were highlighted in previous consensus-based guidelines. The place where care is delivered is clearly system specific and should be addressed in local modifications of these international documents. The initial care normally involves intensification of existing treatment and the addition of oral corticosteroids for which there is good evidence [30,31]. In hospitalized patients, the inability of the patient to cope in the community and their requirement for oxygen treatment often determines whether they are admitted to hospital, although newer approaches to care in the community for those who have been assessed in an emergency room are now available and appear to be acceptable to patients and doctor alike [32,33]. The availability of non-invasive ventilation, which can be conducted even on a general ward with appropriately trained staff [34], has helped to widen treatment opportunities in many communities for COPD patients. Issues about the patient's own wishes for continued intensive care, especially if that were to involve intubation, should be taken into account. This remains a cultural issue that can be best addressed in local variants of international guidelines. However, it is important that this is not omitted as it has major implications for the care of the individual who develops a COPD exacerbation. In all of these guidelines, details of ventilator care with a non-invasive or invasive are usually omitted as it is assumed that this will be undertaken in conjunction with individuals familiar with ICU management, an assumption that seems to be very reasonable.

One challenging area that has recently come to the fore is that of COPD comorbidity. Clinicians have become more aware of the impact of therapy on other systems (e.g. bruising with corticosteroids; tachycardia with β -agonists) but most now accept that loss of muscle bulk, especially in the legs, is a common disease-related feature in COPD. Impaired nutrition and reduced fat-free mass are also frequent once you start to look for them. It is now clear that the risk of cardiac disease including myocardial infarction, osteoporosis and lung cancer are increased in patients with COPD to levels above those seen in patients with comparable smoking histories. Finally the patient who has an unrelated illness which amplifies the effect of COPD on

daily life (e.g. osteoarthritis, impaired vision or diabetes) has much more problems in coping with the difficulties COPD imposes. Thus far our evidence-based guidelines have addressed each condition in the same way so that a patient with four problems is managed by four different and occasionally conflicting sets of rules. The move to some form of more holistic guidance remains a challenge for all who believe in evidence-based care in the future.

Guidelines – practical issues

Several practical points are worth considering which apply to all management guidelines written to date. Each of these recommends management for the average patient who presents with the average symptoms and an average lung function abnormality. In practice, patients are individuals and doctors should still feel free to adapt the guidelines recommendations to individual care. A real danger in all of these documents is that they are seen as invariable patterns of practice, even if they are not always relevant to the specific patient. Clearly, most patients will benefit from following the steps laid out in roughly the order provided. One problem of the stepwise approach illustrated in Figure 67.1 is that it does rather imply that every patient requires every step. Fortunately, newer algorithms identifying specific aspects of patient care and promoting a specific evidence-based response have been developed and their use in the UK NICE Guidelines has been a promising start in this area.

The rise of evidence-based medicine has led to a number of misconceptions about guidelines in general. There seems to be a belief, largely amongst those unfamiliar with the data, that the answer to all questions can be obtained by objectively surveying the literature. This was never the intention of the pioneers of this field nor was the assumption that grade A evidence is necessarily more important than that based on a consensus [35]. It may be that it is not possible to do a randomized controlled trial and certainly none exists for the role of oxygen therapy in the management of severely hypoxaemic patients who exacerbate. None the less, few clinicians would decide not to give oxygen in these circumstances! Moreover, the interpretation of evidence, particularly in COPD, is as important as its collection and analysis. It is easy to look at the outcomes of treatment and say that one treatment is equivalent to another because it changes a commonly measured outcome (e.g. FEV_1). However, it may be that information from longer and larger studies, looking at other outcomes, clearly demonstrates superiority (e.g. the use of long-acting inhaled bronchodilators compared with short-acting ones). Merely aggregating the data without thinking carefully about what it means is unhelpful. This can have more subtle and potentially more important manifestations.

Patients who enter into randomized controlled trials, certainly those with COPD, are often a rather select group of people. Many COPD patients have significant comorbidities, which would lead to their exclusion from studies. Those entering a study that is planned to last for a year are often inadvertently selected by the investigators because the patient's prognosis is believed to be at least 12 months. As a result, the outcomes for patients who are recruited to studies of this kind are much better than those identified using pharmacoepidemiological techniques [36]. This issue is not often identified by those who conduct systematic reviews of literature, which should be sufficiently structured to pick up concerns of this sort. The controversy about simply pooling data in a meta-analysis continues, with the NIH and GOLD sceptical about the role of this form of analysis while Europeans and Canadians are much more enthusiastic. This too has implications in COPD as most of the data favouring the use of drugs, which are described as mucolytics, are based on meta-analysis of data in patients with chronic bronchitis. Those studies looking at COPD patients suggest some benefit but again their methodology is insufficiently strong to lead to a firm recommendation about use. The value of a large prospective trial where all patients belong to the same population at randomisation is clearly shown by the results of the BRONCUS study, which found an effect of the antioxidant/mucolytic drug *N*-acetyl cysteine on exacerbation frequency only in patients not receiving inhaled corticosteroids [37]. It will be interesting to see if other prospective trials, such as the soon to be published TORCH study, can do the same for the confusing data about the impact of inhaled corticosteroids on mortality in COPD.

A major concern in all COPD guidelines is how to keep the content up-to-date. Enormous efforts are required to survey the literature and particularly to meet the exacting standards of evidence-based review. This may explain why there are so few COPD-related studies available even on major government web sites (see www.ahrq.gov). The work of drafting these documents falls on a relatively few individuals and the composition of all of these committees is important as it can influence the shape of the resulting guideline. Having finally got the document to publication stage, it is understandable that most people are not enthusiastic about beginning to revise it again and yet the pace of medical advance is sufficiently fast to make this necessary. The best approach to doing this to date has been that adopted by the GOLD Science Committee which has been clearly detailed in an editorial [38]. Searching for specific terms that are COPD-related may mean that some studies are missed but it is hoped that the knowledge of an expert committee will be wide enough for important observations to be identified, even if conventional indexing misses them. Review by two independent individuals and discussion by

a group of experts about the likely significance of any new data for the previous recommendations provides an important check on the relevance of the guidelines document. Use of the Internet to post the results of this in a planned fashion should allow wide access for all interested parties. The GOLD group are reviewing the whole document on a 5-yearly cycle but annual updates should permit the most up-to-date knowledge to be transmitted to interested parties.

Conclusions

COPD Guidelines continue to be developed, although it is hoped that some maturity in this field has now been reached. The level of evidence available to judge the claims of competing therapies is improving and there is now more openness about how that evidence has been collected and reviewed. The availability of new electronic means of communication has greatly improved accessibility of all guidelines and the concept that these could be downloaded to a pocket computer looks to be practical. Despite their limitations, guidelines provide a standard of care that can be assessed and reviewed. They present a view about COPD that can be tested and modified. As such, they are likely to continue to be an important part of our clinical management of these patients for the foreseeable future. More than this they provide the necessary tools to drive the implementation of COPD care. How best to do this is still debated and no single approach will work in all health care systems. However the group developing COPD guidance, specifically the ATS, ERS and GOLD, are now partners in the new Global Alliance against Respiratory Disease supported by the WHO and tasked with improving global respiratory care. Equally the existence of the NICE guidelines was a crucial step in persuading the UK government to develop a quality standards framework for COPD care, the first time a major developed country has identified the need to address the problems of COPD. Given these specific and political impacts we must be committed to make our guidance up to date, accurate and available to all; no small task for the years ahead.

Pharmacotherapy:
developing therapies

CHAPTER 68

Protease inhibitors

Philip Davies, Malcolm MacCoss and Richard Mumford

Chronic obstructive pulmonary disease (COPD) results from the detrimental effects of inhaled toxic environmental stimuli on processes that maintain the normal function of the lung. The capacity of the host defence system, most obviously its innate component, to protect against toxic insults is remarkable. The development of COPD is insidiously slow and is manifested in only a minority of the population that exposes itself to stimuli such as cigarette smoke [1,2]. Effective host defence in the lung entails the recognition and removal of toxic stimuli by mechanisms that do not impact negatively on the physiological functions of the organ. Another essential aspect of host defence is the removal of damaged cells and extracellular matrices with initiation of repair mechanisms. Failure to fulfil these functions leads to persistent acute and chronic inflammation that can eventually lead to overt disease.

Appropriate expression and regulation of extracellular protease activity is essential for processes that maintain lung health. These functions include the extracellular breakdown and remodelling of damaged matrices as well as formation and inactivation of biologically active peptide and protein mediators. The activity of proteases is regulated by their maintenance as latent precursors, sequestration in intracellular compartments and inhibition by a wide variety of intra- and extracellular inhibitors. Genetically based defects in these regulatory mechanisms or inappropriate expression of protease activity can lead to pathological changes and overt disease. The observations by Laurell and Eriksson that a defect in α_1 -antitrypsin, later shown to be a potent inhibitor of neutrophil elastase, is associated with the increased incidence of COPD led to the formulation of the protease-antiprotease hypothesis [3,4]. In a historical perspective published in 1991, Eriksson [3] concluded that 'Elastase may well be the causal agent in all cases of emphysema'. This conclusion was made with specific reference to neutrophil elastase. This hypothesis has been modified to include a number of other proteases with elastolytic activ-

ity. Moreover, it is likely that the inflammatory processes that lead to elastolysis associated with loss of lung function depend on cleavage of many substrates by both elastolytic and non-elastolytic enzymes. The activities of proteases in inflammation leading to COPD occur in the context of the interactions of recruited cells of the immune system with the local cells and the interstitial tissues of the lung. A total of 553 genes encoding proteases and their catalytically inactive homologues have been annotated in the human genome and many of these are expressed in the lung [5]. This number is significantly increased in COPD as cells of the immune system are recruited and local cells are activated in coordinated responses to inflammatory stimuli. These proteases fall into four distinct classes: the serine/threonine, metallo-, cysteine and aspartyl proteases. The classes that are of most obvious relevance to the pathology of COPD are also the most heavily populated; there are 186 metalloproteases, 176 serine proteases and 143 cysteine proteases.

Detailed knowledge of the three-dimensional structure and catalytic mechanism of these classes of proteases has allowed the development of prototypic inhibitors of great potency and often specificity to match. The challenge for medicinal chemists has been to identify compound classes with mechanistic, pharmacokinetic, pharmacodynamic and toxicological properties that are commensurate with safe long-term use in humans. These efforts have been extensively documented and reviewed [6-15]. Some of these inhibitors have advanced into clinical evaluation [13,16,17] yet there is no clear indication of disease-modifying efficacy for any of them. This is not surprising given the difficulty of establishing such parameters; the experience with evaluating the efficacy of replacement therapy with α_1 -antitrypsin is salutary in this respect as disease progression is measured over a period of years and modification is correspondingly difficult to establish.

Strategies for the development of effective and safe protease inhibitors should benefit from an understanding of

the physiological functions and role in host defence of their target enzyme(s) together with a definition of the shortfall of endogenous regulatory mechanisms that underlie their inappropriate activity in COPD. This knowledge will help define their pharmacological profile and their therapeutic index in the context of any mechanism-based toxicity that could occur during their extended use. Present concepts of inflammatory processes in COPD are discussed as they relate to proteases with a view to identifying how the spatial and temporal regulation of enzyme activity may be disrupted in the microenvironment of the lung during inflammatory responses to inhaled toxins (i.e. which activities of proteases are essential to lung health and which are in inappropriate locations at the wrong time thus leading to disease).

Because pharmacological inhibition of proteases will occur in the presence of endogenous inhibitors, measurements and correlation of the pharmacokinetic and pharmacodynamic properties of protease inhibitors are critical to ensure appropriate inhibition of the target enzyme(s). With this information in hand it will be more realistic to commit the resources required to determine whether pharmacological efficacy has clinical benefit based on the modification of chronic pathological changes. The elucidation of the precise role of individual proteases in COPD is exceedingly difficult, arguably best achieved by specific pharmacological approaches. The surprising robustness and relatively normal phenotype of mice in which a number of individual proteases have been genetically deleted [18,19] suggests that complete pharmacological inhibition of a protease-mediated pathology will not be accompanied by unacceptable mechanism-based toxicity.

Proteases with potential for involvement in inflammation and tissue damage leading to functional pathology in COPD

The irreversible consequences of the degradation of elastic tissue have provided a focus for research on proteases with elastolytic activity. A number of these exist beyond the serine proteases, elastase, cathepsin G and protease 3 (PR3), which are present in large quantities in neutrophils. These include the cysteine cathepsins K, L and S [20,21], the matrix metalloproteases (MMP) MMP-2, MMP-7 [22–25], MMP-9 and MMP-12 [26–30]. These proteases are present in a variety of cells, most notably neutrophils and macrophages. Studies in gene-deleted and transgenic mice have provided a clear indication for the involvement of enzymes such as neutrophil elastase [31], MMP-12 [32,33] and MMP-9 [34] as well as cathepsins L and S [20] in certain aspects of the pathology of COPD.

Based on the complexity of the pathology of COPD, many elastolytic proteases are potential contributors to the disease. These activities are therefore key targets, especially for preservation of elastic recoil function. This is critical because elastic tissue constitutes only a small percentage of tissue mass and has very limited capacity for replacement based on calculations of the half-life of lung elastin [35]. Other non-elastolytic proteases acting on a variety of substrates have diverse and essential roles in mediating events leading to terminal elastolysis [28,29]. Many examples are emerging of how they can indirectly facilitate elastolytic activity, some of which are listed in Table 68.1.

Table 68.1 Elastolytic proteases and non-elastolysins that possess other activities which promote inflammation and tissue damage.

Enzyme	Elastolysin	Indirect effect	Ref.
Neutrophil elastase	Yes	Degradation of MMP inhibitors	[36]
		Stimulation of mucus secretion	[37]
		Cleavage of C3bi and CR1	[38]
		Transcriptional activation	[39]
MMP-2	Yes	Facilitation of aneurysm formation	[40,41]
MMP-7	Yes	Inactivation of α_1 PI	[42]
		Release of active TNF from macrophages	[43]
MMP-9	No	Inactivation of α_1 PI	[44]
MMP-12	Yes	Inactivation of α_1 PI	[29]
		Chemotactic fragments from elastin	[32]
		Activation of neutrophil elastase, cathepsin G and PR3	[45]
DPP1	No	Activation of pro-MMP-7	[24,46]
Plasmin	No	Antigen processing	[47]
Cathepsin S	Yes		
Cathepsin L	Yes		

DPP1, dipeptidyl peptidase 1; MMP, matrix metalloprotease; PR3, protease 3; TNF, tumour necrosis factor.

This is not necessarily unidirectional because proteases sometimes have a negative modulatory effect on processes permissive to elastolysis. This can occur by degradation of peptide-based pro-inflammatory mediators or generation of anti-inflammatory peptides from endogenous substrates. The activity of these proteases is governed by a complex series of spatial and temporal considerations involving the release, activation of proenzymes, catalytic association with substrates and subsequent inactivation by natural inhibitors in the lung microenvironment. Some of the same principles apply to proteases derived from precursors involved in the activation of humoral pathways including the alternative-classical complement cascade, blood coagulation and processing of precursors of vasoactive peptides such as kinins, angiotensins and neurokinins. These will not be discussed further here although they are significant contributors to inflammation in the lung.

Innate immune responses, inflammation and tissue damage in COPD

COPD results from sustained self-perpetuating inflammation leading to tissue damage and structural changes in the lung. The disease is caused by a number of environmental stimuli of which cigarette smoke is the most common [1]. Many components of the humoral, innate and adaptive immune systems are activated in COPD and have been implicated in various aspects of its pathogenesis. This is to be expected given the complexity of cigarette smoke with its content of toxic substances and particles [48]. Tobacco contains more than 4500 compounds in its particulate and vapour phases. Many of these are biologically active, epitomized by nicotine [48]. Other components of cigarette smoke are pro-inflammatory and carcinogenic [48], which result in inflammation that persists for a long time after cessation of smoking [49,50].

Innate immunity is responsible for host responses against infectious and other exogenous agents together with the clearance of endogenous apoptotic cells and damaged tissue [51–54]. Its activation is dependent on genes coded by germline DNA in contrast to the gene rearrangements essential for adaptive immune responses. The convergence and synergies between innate and adaptive immunity has been recognized for over a century by the discoveries of the cellular basis of innate immunity and the role of antibodies as humoral effectors of adaptive immunity [53]. The function of the innate immune response is divided into afferent and efferent or sensing and effector arms, which in turn comprise cellular and humoral components. The cellular sensing functions are mediated through a series of specific receptors, notably the Toll-like receptors (TLR), of which at least 10 have now been identified [53]. They are derived

from ancient precursors associated with host defence responses common to plants and animals and function either individually or in combination to recognize and respond to diverse stimuli. For example, TLR4 acts independently to recognize lipopolysaccharide (LPS), which is probably its only ligand. Other TLRs such as TLR1 and TLR6 can form complexes with TLR2 to broaden the function of TLR2 significantly [53–55]. Beyond the TLRs there exist structurally diverse receptors, loosely described as ‘scavenger receptors’, which recognize a wide variety of exogenous and endogenous ligands [56,57]. Examples with well-characterized endogenous ligands include Class A SR (modified low density lipoprotein), CD36 (modified lipids present on damaged cells), CD14 (LPS binding protein) and mannose receptor (lysosomal hydrolases, myeloperoxidase and other mannose/fucose glycoconjugates). The humoral arm of the innate immune system includes the well-characterized complement, vasoactive precursor and coagulation systems as well as the soluble products of acute phase responses.

Detailed information is not available on how these cellular receptors and humoral precursors recognize and respond to the components of cigarette smoke. However, the lack of major involvement of adaptive immunity in COPD is consistent with its pathogenesis being driven by aberrant function of the innate immune system. The activation of the humoral systems often requires regulated protease activity while activation of cellular receptors leads to signal transduction through a number of pathways including the MAP kinases, nuclear factor κ B (NF- κ B) and others that have been delineated in recent years [58] and shown to be important in host defence as well as homeostasis. These signal transduction responses can facilitate the direct mobilization of intracellular stores of proteases by exocytosis, initiate the activation of latent precursors or the activation of gene programmes for the synthesis and release of new enzymes. It is not surprising that the pathology of COPD is complex because the multiple components of cigarette smoke probably activate several of these cellular receptors, triggering complex downstream responses and the generation of many mediators of inflammation and tissue injury.

While cells of the adaptive immune response have been implicated in various aspects of COPD [59–61], this discussion will pay particular attention to proteases of cells of the innate immune system, notably macrophages [28] and neutrophils [62]. The complex interactions between these two cell types that have evolved to protect the host against infectious agents are evident in COPD. It is ironic that our species has unknowingly or knowingly been unfortunate enough to expose itself to a wide range of non-infectious environmental stimuli that induce the spectrum of diseases that are recognized as the pneumoconioses and

occupational lung diseases [63]. The lumen and interstitial tissues of the lung contain resident populations of macrophages. A primary function of these alveolar macrophages is to sequester and remove these stimuli without triggering tissue injurious inflammation. Lung washouts of smokers contain increased numbers of alveolar macrophages suggesting altered kinetics and transit into the lung of blood monocytes in response to cigarette smoke [19]. This new population of macrophages could include a subset of monocytes that home only to inflamed tissues. This possibility is illustrated by the preferential recruitment of a short-lived CX₃CR1^{lo}CCR2⁺Gr1⁺ subset of adoptively transferred monocytes into the inflamed peritoneal cavity of congenic mice [64]. It is unknown whether these recruited cells include those described as being enriched in serine proteases normally associated with neutrophils [25,65–67]. Alveolar macrophages from smokers appear morphologically activated and are laden with residues from cigarette smoke which they have endocytosed during their residence in the lung.

The understanding of the roles of macrophages in innate immune responses has led to a far better understanding of how neutrophils are recruited to the lungs of cigarette smokers. Neutrophils are rarely present in healthy extravascular tissues; the host probably has multiple mechanisms for ensuring that they are recruited from the circulation only when required. Innate immune responses have evolved in large part to protect against infectious agents and it is not surprising that macrophages normally resident in extravascular tissues have a considerable capacity to recruit and activate neutrophils when their receptors of innate immunity are triggered [68]. While the original protease–antiprotease hypothesis emphasized the role of neutrophil serine proteases in lung destruction, current thinking is much more focused on the role of the macrophage in recruiting neutrophils to the inflamed lung. This is most obviously facilitated by chemokines such as interleukin 8 (IL-8), leukotriene B₄ (LTB₄) and cytokines produced by macrophages in response to inflammatory stimuli. Tumour necrosis factor α (TNF- α) triggers the neutrophil to generate and release its mediators [69]. The severity of elastase-induced emphysema is reduced in double TNF- α receptor knockout mice [70], suggesting that this cytokine may have a key role. Furthermore, γ -interferon (IFN- γ) expressed as a transgene induces severe lung inflammation and destruction associated with the induction of a number of proteases [71], while over-expression of TNF- α leads to increases in lung volumes and pulmonary hypertension [72], confirming the role of inflammation.

The integrated cellular function of neutrophils is essential for protection against a wide range of infectious agents. Their bacteriostatic and bactericidal function is mediated by

a powerful armamentarium of cidal molecules including hydroxyl radicals, singlet oxygen, oxygen halides, hydrogen peroxide [73] and nitrating agents together with antimicrobial peptides and, to some extent, proteases [74]. While these molecules are critical for protecting against infectious agents [75], they also have considerable potential for damaging the host. The capacity of neutrophil proteases, stored within azurophil granules in large amounts at millimolar concentrations [76], to cause acute lung damage is exemplified by diseases where they are released extracellularly in amounts in excess of available natural inhibitors. The presence of high concentrations of active neutrophil elastase in the sputum of cystic fibrosis patients can account in a number of ways for the extensive lung damage in this disease [38,77]. In acute exacerbations of Goodpasture syndrome [78], haemorrhagic immune complex-induced vasculitis results from gross destruction of alveolar basement membranes. This damage is probably mediated by the directed local activity of neutrophil serine proteases such as elastase, cathepsin G and PR3 following stimulation by engagement of Fc receptors by immune complexes formed in basement membranes [79,80]. This is consistent with inhibition of haemorrhage associated with immune complex formation in the lung by selective neutrophil elastase inhibitors [81]. This indicates how the persistence or release of proteases in inappropriate microenvironments in interstitial tissue, which excludes inhibitors, can rapidly lead to major tissue damage. It is noteworthy that patients with glomerulonephritis associated with Goodpasture syndrome are more likely to experience pulmonary haemorrhage if they smoke [82].

The potential of neutrophil serine proteases to cause catastrophic tissue damage is great. It is therefore all the more remarkable that the critical structures of the lung and other tissues are protected so well against these enzymes. Approximately 10¹⁰ neutrophils are released into the circulation every day and these cells spend half of their time in the pulmonary circulation with an even slower transit time during cigarette smoking [83]. These cells are efficiently cleared from the body with few emerging into extravascular tissues. In blood, α_2 -macroglobulin and α_1 -antitrypsin provide an excess of inhibitory capacity for any enzyme that may be released. This is indicated by the presence of α_1 -antitrypsin elastase complexes as well as specific cleavage products of plasma proteins as exemplified by the A α (Val³⁶⁰) neoepitope exposed on a 42-kd fragment of fibrinogen [84], even in plasma of healthy individuals. These markers are elevated in a variety of inflammatory diseases [84,85]. Interstitial tissues have their own complement of inhibitors for any released neutrophil proteases [62]. Also, there are very effective mechanisms in place for removal of neutrophils by macrophages that are specifically programmed to recognize and remove apoptotic cells

[86] to prevent further enzyme release if the cells were to disintegrate.

The alveolar macrophage removes ageing and damaged cells by various scavenger receptors such as CD36 and the phosphatidylserine receptor [86,87], which remove neutrophils before their proteases are released. This is important because neutrophil elastase cleaves the phosphatidylserine receptor [87] and inhibits the phagocytosis of apoptotic cells by alveolar macrophages. If, as suggested here, the role of the neutrophil to remove toxic constituents of cigarette smoke is not essential then containment and timely removal of its protease content is critical. The more efficiently that this end is achieved the less likely it is that the products of activated macrophages and neutrophils become misdirected against the host. It is significant that some of the same cytokines, such as TNF- α , IL-1 β , IFN- γ and granulocyte-macrophage colony-stimulating factor (GM-CSF), that macrophages use to enhance the bactericidal activity of neutrophils are also strong inhibitors of apoptosis. These effects are mediated through a factor originally described as a growth factor for early stage B lymphocytes [88]. Decreased neutrophil apoptosis is seen in septic patients and a similar trend has been claimed in patients hospitalized with acute exacerbations of COPD [89] as well as in patients expressing the antiapoptotic molecule survivin in their neutrophils [90]. In view of this, mechanisms by which macrophages limit the recruitment of neutrophils to sites of inflammation and facilitate their removal may be important in limiting tissue damage. For example, the induction of CD36 function in alveolar macrophages by peroxisome proliferator activated receptor γ (PPAR γ) agonism [91,92] could be a significant pharmacological target for enhancing clearance of apoptotic neutrophils.

Elucidation of the role of proteases in COPD

Robust surrogate markers of relevant activities of individual proteases in COPD are not available. While there have been many documented examples of elevated protease activity in the lung of COPD patients [93–97], these have not been definitively linked to degradation of critical substrates that lead to disease. The definition of the role of individual proteases in COPD would be greatly aided by the availability of proximal markers of their activity. Ideally, these would be unique soluble fragments (generated by the endogenous activity of a specific protease) that are readily measured in blood or urine. An alternative would be non-specific markers of the degradation of relevant substrates as exemplified by desmosine as a marker of elastic tissue damage. Failure to consistently detect specific breakdown products of elastin is not surprising given the relative paucity of this

substrate together with its longevity in the lung [35]. This is reminiscent of the difficulty in developing markers of cartilage breakdown in osteoarthritis [98]. This disease is characterized by the breakdown of type II collagen which, like elastin in the lung, is laid down only once and cannot be replaced in a fully functional form if damaged. Systemic measures of enzyme activation are seen with neutrophil elastase in a variety of diseases including cystic fibrosis and Acute Respiratory Distress Syndrome (ARDS) [85] but not reproducibly seen in COPD although this does not negate the role of the enzyme in the lung. Systemic measures of the consequence of ongoing local inflammation such as acute phase proteins have been used extensively in other diseases including atherosclerosis [99]. In COPD, robust increases of C-reactive protein levels are associated with exacerbations of diseases associated with infection [100] but are lower and highly variable in stable disease [101]. A possibility that remains to be fully explored is the generation of long-lived soluble neopeptides measurable in plasma as exemplified by cleavage products of fibrinogen by neutrophil elastase [84] (see below).

Utility of animal models to study the role of proteases in COPD

The original protease-antiprotease concept led to widespread use and investigation of animal models of COPD based upon intratracheal administration of tissue-degrading enzymes [102], particularly elastases. In these models, immediate damage occurs, including the destruction of vascular basement membranes with consequent haemorrhage. A non-specific inflammatory response ensues, leading to damage resembling some aspects of emphysema. The initial effects of proteases lead to secondary changes which contribute to indices of subsequent alveolar destruction [70]. These models have utility for defining the pharmacodynamic properties of protease inhibitors [103]. However, they do not reflect the intricacies of damage caused by ongoing activity of multiple proteases in the microenvironments of the lung inflamed by cigarette smoke and have not been useful in delineating the role of individual proteases in COPD.

The development of technology to allow sustained exposure to and inhalation of cigarette smoke by mice [32] and other species [104,105] has allowed a more detailed evaluation of events leading to chronic pathological changes. Exposure of several animal species to cigarette smoke induces changes resembling emphysema-like loss of alveolar structural integrity and functional elasticity [104]. These studies have provided a much clearer understanding of how the innate immune response and its constituent proteases can mediate the irreversible changes brought about by loss of elastic tissue. A picture has

emerged indicating a number of interdependent functions of macrophages and neutrophils involving their respective proteases in the inflammation and tissue destruction seen in this model.

The observation that deletion of the gene for MMP-12 in mice greatly reduces their susceptibility to cigarette smoke [32] led to a fundamental change in thinking about the protease–antiprotease hypothesis. This change continues as new observations are made in mice with specific genetic modifications related to protease function [19,28,29, 106–108]. Not only is the development of emphysema abolished in the smoke-exposed MMP-12 null mouse, but the recruitment of macrophages and neutrophils to the lung is also inhibited [32].

The decrease in experimental emphysema also observed in mice lacking neutrophil elastase has been attributed to multiple consequences of the absence of the enzyme [31,109]. These include inhibition of neutrophil recruitment, together with reductions in the inactivation of tissue inhibitor of metalloprotease 1 (TIMP1) and activation of the 55-kd latent precursor of MMP-12. In addition, higher levels of α_1 -antitrypsin are present in lung tissue extracts from MMP-12 null mice exposed to cigarette smoke. This is attributed to lack of MMP-12 mediated degradation of the serine protease inhibitor. Alternatively, this could result from diminished consumption as a result of decreased release of elastase from activated neutrophils despite their recruitment in similar numbers as seen in MMP-12 sufficient mice. The failure of MMP-12 null macrophages to generate TNF- α , which in turn activates neutrophils to release elastase, would be consistent with this [110]. As commented on elsewhere [111,112], a series of studies by Churg *et al.* on the sequential events in the lungs of mice exposed to cigarette smoke have provided considerable insights into the phenotypes of the MMP-12 and neutrophil elastase null mice. Acute inhalation of cigarette smoke results in the recruitment of neutrophils [113], which is dependent both on MMP-12 [113,114] and TNF- α [110,114]. It is to be noted that the C57BL/6 mice used in these studies produce more TNF- α than the 129 strain used by Hautamaki *et al.* [32]. The acute damage is inhibited by α_1 -antitrypsin [115,116], and in a similar model in guinea pigs, synthetic inhibitors of neutrophil elastase protect partially against emphysema development [105].

The relevance of these findings in humans remains to be clarified. The different activities of macrophage metalloelastases in the two species [24] raises significant questions regarding the role of MMP-12 compared with MMP-7 and MMP-9 in humans. Neutrophil elastase remains a target, with the potential role of PR3 [117] less clearly defined. Concerns remain, however, regarding the role of neutrophil serine proteases in host defence based on findings in

gene-deleted mice for elastase [118], dipeptidyl peptidase 1 (DPP1) [119] and the phenotype of Papillon–Lefèvre patients defective in DPP1 function [120]. All these studies suggest that strategies to regulate neutrophil elastase activity completely could be counterproductive.

Further insights into the potential function of individual proteases have been obtained when the genes for these molecules are conditionally up-regulated by cytokines and other endogenous molecules. In these instances, changes resembling COPD occur in the absence of an inducing stimulus in transgenic mice where molecules regulating protease activity are deleted or overexpressed. For example, the transgenic overexpression of IL-13 [121,122] results in aberrant expression of metalloproteases such as MMP-9 and MMP-12 and the cysteine proteases cathepsins K, L and S. Removal of the critical regulatory function of the integrin αv - $\beta 6$ [33] results in specific aberrant expression of MMP-12. Endogenously generated lung destruction can be induced by host defence mediators including cytokines such as IL-13, TNF- α and IFN- γ . Chemokines are also active in this respect as is illustrated by the significant protection of the IL-13 transgene-induced lung damage when present in mice lacking the chemokine receptor CCR2 [123] and CCR1 [124]. The phenotypes of these mice provide independent indications of the potential importance of alveolar macrophages to mediate lung destruction. Thus, intervention in pathology with protease inhibitors should not be targeted at endstage destructive processes alone. Consideration should also be given to the ability of proteases to generate biologically active molecules, or to degrade regulatory molecules, that contribute to inflammation and hence pathology. A summary of this work is provided in Table 68.2.

However, these findings cannot be directly extrapolated to humans. Overexpression of inducers of inflammatory cascades as exemplified by IL-13 will distort the natural inflammatory process by exaggerating the pattern of expression of pro-inflammatory proteases and anti-inflammatory protease inhibitors. This, together with differences in gene expression in humans compared with animal species, means that the molecular details of the pathogenic mechanisms of COPD in humans will be quite different from those being elucidated in mice and other species. This is the case for cystic fibrosis where deletion of the cystic fibrosis transmembrane conductance regulator (CFTR) channel is not sufficient for the development of lung disease in mice [143]. Comparative gene profiling should provide useful information and the basis for this is underway with the comparison of the human and murine degradomes [5]. Profiling of various sites of the inflamed lung at successive stages of disease progression in smokers, be they mice or men, will provide much information regarding the potential use of protease inhibitors.

Table 68.2 Genetic manipulation of protease genes and functions. Potential implications for pathogenesis of COPD.

Gene target	Phenotype	Challenge phenotype	Ref.
<i>Serine proteases</i>			
PMN elastase – deletion	Normal	Impaired cigarette smoke induced lung inflammation and emphysema Decrease in neutrophil recruitment, inactivation of TIMP, activation of MMP-12 precursor Decreased susceptibility to LPS Impaired host defence	[31] [109] [125] [118] [126]
Cathepsin G – deletion	Normal	Decreased susceptibility to LPS	[125]
PMN elastase/cathepsin G – deletion	Normal	Decreased susceptibility to LPS Diminished bacterial clearance	[125] [119]
SLPI – deletion	Normal	Increased susceptibility to LPS and sepsis – enhanced innate immune responses	[127]
<i>Metalloproteases</i>			
MMP-1 Overexpression under haptoglobin promoter	Enlarged airspace – not clear whether developmental		[128] [129]
MMP-2	Normal	Impaired allergic inflammation but increased susceptibility to asphyxiation Impaired tumour angiogenesis and growth	[130] [131]
MMP-7		Impaired wound healing and host defence Impaired chemokine mobilization and neutrophil migration	[132] [133]
MMP-9		No change in disease induction after cigarette smoke inhalation Decreased airspace enlargement in IL-13 transgenic mice Impaired cellular infiltration and hyperresponsiveness after allergen Diminished aortic aneurysm Decreased dendritic cell recruitment	[34] [121] [134] [41] [135]
MMP-12	Normal	Abolition of cigarette smoke induced emphysema Macrophages fail to penetrate basement membranes	[32] [136] [137,138]
MT1-MMP	Defect in skeletal development, dwarfism, osteopenia		
TIMP 3 $\alpha\gamma\beta 6$	Spontaneous airway enlargement	Increased airspace enlargement. Specific increase in MMP-12 expression	[139] [33]
Surfactant D	Increased MMP activation and emphysema		[140]
<i>Cysteine proteases</i>			
Cathepsin S		Decreased airspace enlargement in IL-13 transgenic mice Diminished vascular wall inflammation when crossed with LDL receptor null mice	[121] [141]
DPP1	Normal	Decrease in experimental arthritis Decreased susceptibility to caecal ligation induced sepsis Increased bacterial load	[45] [142] [119] [119]

DPP1, dipeptidyl peptidase 1; IL, interleukin; LDL, low-density lipoprotein; LPS, lipopolysaccharide; MMP, matrix metalloprotease; PMN, polymorphonuclear neutrophil; SLPI, secretory leucoprotease inhibitor; TIMP, tissue inhibitor of metalloprotease.

Endogenous regulation of protease activity

While the profusion of information emerging from the studies described above gives an indication of the potential of these individual enzymes to cause tissue damage, it does not provide a clear picture of their role in human disease. This potential is governed by complex regulatory processes that limit protease activity. Prominent among these are the diverse families of natural protease inhibitors which regulate the function of proteases in various body compartments such as blood and in the microenvironments of cells and their pericellular environment in interstitial tissue and other extravascular sites. These inhibitors are diverse in their structure, specificity and mechanism. Each of the major families of the degradome have well-characterized inhibitors of varying specificity as exemplified by the serpins [144], cystatins [145] and TIMPs [6]. In addition, α_2 -macroglobulin has a more global function as a pan-inhibitor of most proteases from every class [6]. Often, these inhibitors do not completely inactivate their target enzymes as is the case with α_2 -macroglobulin and enzyme-inhibitor complexes may have distinct biological activities not seen with either free enzyme or inhibitor. This is exemplified by the chemotactic activity of α_1 -protease inhibitor (α_1 PI) which has been inactivated by mouse macrophage elastase [146]. The deficiency of α_1 PI provides the most widely studied example of how the lack of a single inhibitor with considerable specificity has a clear association with increased susceptibility to COPD. The extensive experience with replacement therapy with this inhibitor is discussed in Vogelmeier *et al.* [147]. More limited experiences with replacement therapy with other serine protease inhibitors [147] will not be discussed further here. The clinical efficacy and usefulness of replacement therapy remains to be fully established [148].

Defects in metalloprotease inhibitors have not been widely described in humans. Genetic ablation of TIMP3 in mice leads to spontaneous airspace enlargement early in life with shortened life span [139]. Inflammation is not prominent in the lungs of these animals but they contain increased MMP activity as detected by zymography. It is therefore reasonable to consider the development and evaluation of protease inhibitors that not only replace deficient function of natural inhibitors but which will give qualitatively different profiles of activity. Such properties have the potential to be double-edged swords; on the one hand they can have beneficial effects on protease activity which drives pathology but on the other may interfere with essential biological functions of the protease themselves or their complexes with their natural inhibitors.

The complexities of the function of natural inhibitors and the consequences of their modification in the lung are illustrated by studies of natural inhibitor function in murine

strains with defined differences in α_1 PI function [149,150]. In the pa+/pa+ pallid mouse a nonsense mutation in the gene for a pallidin results in a 50% decrease in syntaxin13, a molecule with which it interacts to mediate vesicle docking and fusion to early recycling endosomes. This is associated with an inability to export α_1 PI into the circulation and a decreased elastase inhibitory capacity. Significant differences in both the rate of onset and nature of smoking-induced emphysema are seen in these mice when compared with congenic C57 mice. In the pallid mouse, emphysema is panlobular but in congenic mice it is centrilobular in location, emphasizing the different function of the natural inhibitor in different regions of the lung. The onset of changes in pallid mice is more rapid and while increases in mean linear intercept are eventually seen in congenic mice, they are not accompanied by the changes in lung compliance seen in the pallid mice. This suggests that pathogenic mechanisms may differ in various parts of the lung, as may be the case with COPD patients with deficient and normal α_1 PI phenotypes, a consideration to be borne in mind when studying novel therapeutics with specific mechanisms of action.

These multiple regulatory controls ensure that the activities of these proteases have stringent temporal and spatial restrictions for their activity. It is when these finely tuned regulatory mechanisms are disrupted that it becomes more likely that protease activity with potential for inducing pathology occurs. Examples where this is acute and potentially catastrophic in nature is exemplified by exacerbations of Goodpasture syndrome [78] where formation or deposition of immune complexes in basement membranes lead to the activation of complement, the recruitment of neutrophils and the release of their potent tissue destructive serine proteases.

Cell biological approaches to the definition of the role of proteases in COPD

The extracellular environment into which cellular proteases are released and activated differs greatly from the intravascular compartment to extravascular domains and, relevant to COPD, the lumen of the lung. It is only from the latter space that free active enzyme can be recovered in purulent sputum and fluids of cystic fibrosis [77] and acutely infected patients with bronchitis and pneumonia. However, in most instances, aberrant protease activity will be transient and spatially constrained as extracellular inhibitors gain access to the enzyme, making it difficult to quantify the extent and duration of enzyme activity.

The capacity of neutrophils to cause tissue damage is well established [79,151,152] based on the exocytosis of the proteases stored in active form at high concentrations in their granules. Cell biological systems have been developed

that allow the demonstration and measurement of these activities. Campbell *et al.* [153] have used morphological approaches at the single-cell level to demonstrate the proteolysis associated with degranulation of neutrophils onto appropriately labelled substrates. They generated micrographical images of this phenomenon at the level of single cells. The quantal nature of the release of enzyme concentrated in the azurophil granules of the neutrophil [76,154–156] results in a concentration and time-defined transient proteolysis as the released enzyme is diluted and fluid phase inhibitors gain access to the cloistered pericellular environment. Subsequently, quantitative analyses of these striking images were made at the level of individual azurophil granules [76]. These established the dynamics of this rapidly changing environment to the point of equilibrium with extracellular inhibitors as exemplified by α_1 -antitrypsin, α_2 -macroglobulin, secretory leucocyte protease inhibitor and the small molecule elastase inhibitor ICI 200,335. In the presence of a physiological concentration of protease inhibitor, degradation of fluorescent labelled fibronectin occurred over an area approximately eight-fold that of the individual neutrophils under observation. Appropriate specificity controls with inhibitors and antioxidants as well as cells from chronic patients with granulomatous disease indicated that this process was specific for elastase and not dependent upon oxidative inactivation of inhibitors. This approach has allowed calculation of the extent and duration of enzyme activity [76,157] with the demonstration of increased activity when extracellular inhibitor activity is compromised as exemplified by PiZZ plasma [153].

The serine proteases of neutrophils constitute by far the highest level of circulating cellular proteases. For example, elastase is estimated to achieve millimolar concentrations in the azurophil granule [157] which is a hundred-fold that of its plasma inhibitors. When neutrophils are degranulated in human blood their serine proteases are complexed by α_1 -antitrypsin and α_2 -macroglobulin, which are present in approximately a thousand-fold excess (the volume of azurophil granules, the repository of the serine proteases, is tiny compared with that of plasma in blood). However, transient activity of these proteases, before they are sequestered by inhibitors, is demonstrable based on the cleavage of plasma substrates and generation of specific neoepitopes. The use of neoepitope specific antibodies has provided a novel way of measuring the transient catalytic activity of a protease before its inhibition by natural inhibitors. Nossel *et al.* [158] pioneered this approach with the development of an antibody specific for the C-terminus of fibrinopeptide A, a 16-residue fragment of the A α chain of fibrinogen generated by thrombin. Weitz *et al.* [159] used this antibody for an indirect assay of the A α (1-21) fragment of fibrinogen generated by neutrophil elastase.

This provided an opportunity to seek robust and specific direct assays for various degradation products of elastase. Mumford *et al.* [84,160] developed an antibody specific for the C-terminus of the A α (1-21) peptide and used it to demonstrate the activity of elastase released from neutrophils degranulated in blood [161]. Stimulation with granule-releasing agents resulted in peptide formation in the face of the high amounts of natural inhibitors. As would be expected, this signal is considerably amplified in blood from PiZZ patients and is normalized by reconstitution of the patients with α_1 -antitrypsin [162].

The claim that A α (1-21) is elevated in plasma from PiZZ patients [163] has not been confirmed by others. Based on the rapid clearance of A α (1-21) *in vivo* it is unlikely that these elevations are represented by this neoepitope. However, this approach has great potential to seek markers of *in vivo* activity when applied to neoepitopes with long *in vivo* half-lives. A systematic evaluation of fibrinogen in this respect yielded a number of cleavage sites to include one at the Val³⁶⁰-Ser³⁶¹ of the A α chain of fibrinogen [84]. This releases a 250 residue C-terminal peptide leaving a 42-kd molecule with the A α (Val³⁶⁰) associated with the β and γ chain of fibrinogen. A specific antibody to this new C-terminus long-lived molecule of high molecular weight showed it to be present in the plasma of healthy individuals at approximately 4 nmol/L concentration and elevated in the plasma of cystic fibrosis patients up to 1000 nmol/L as well as in rheumatoid synovial fluid [84]. Thus, healthy individuals express neutrophil elastase activity sufficient to maintain circulating levels of this cleavage product. The significance of these products in health is unknown but their elevation in disease provides a sensitive and specific method for exploring the systemic activity of proteases such as neutrophil elastase. Evaluation of the levels of these long-lived neoepitopes in PiZZ and COPD patients will be informative. This approach also provides a sensitive and specific pharmacodynamic method for monitoring the activity of elastase inhibitors in various environments, both *in vitro* and *in vivo*.

These cell biological findings highlight the consideration of whether the design of a pharmacological inhibitor should allow the introduction of properties that inhibit enzymes under circumstances where endogenous inhibitors fail to do so. Pharmacological inhibitors have the potential to be effective in the presence of endogenous inhibitors which are often present in gross molar excess over their target enzymes. Assays that measure enzyme activity over brief periods of time in restricted spatial environments provide optimal demonstration of these activities. Such agents would supplement natural inhibitors that are either in deficit or inactivated (e.g. by oxidants or overwhelmed by abnormal release and activation of proteases).

Individual proteases implicated in COPD are in some

instances derived from more than one cell type, as exemplified by the presence of serine proteinases associated primarily with neutrophils in monocytes with a pro-inflammatory phenotype [66,67]. The complexities of establishing the role of individual proteases in COPD is exemplified by studies on the role of MMP-9, also known as gelatinase B, in lung remodelling [34]. This enzyme is present not only in macrophages (secreted as an inactive precursor), but also in a number of lung cells including epithelium, Clara cells, alveolar type II cells, fibroblasts and smooth muscle as well as neutrophil from which it is released as an active complex with lipocalin [34]. It has a wide range of natural substrates, including elastin, relevant to the inflammation and tissue damage of COPD. However, its genetic ablation does not change the susceptibility of mice to cigarette smoke [34], although the airspace enlargement seen in IL-13 transgenic mice is decreased in its absence. Its activation by MMP-3 and its ability to inactivate serine protease inhibitors [44] suggests that its contribution to tissue damage will be greatly influenced by multiple factors in its environment and that these are probably as important as its intrinsic activity in determining its contributions to pathology. This is illustrated by its interaction with MMP-2 in the development of aortic aneurysms [164].

As the role of individual enzymes in cell-based elastolysis is elucidated by various approaches in animal species, it is clear that these mechanisms are not necessarily of the same qualitative or quantitative relevance in humans. A premium is placed on the study of human cells by these species differences in the degradome [5,165] and phenotypic differences in integrated expression of multiple protease activity. For example, a defect in MMP-2 in humans causes severe osteolysis and arthritis [166] not seen in null mice [36,130].

The macrophage expresses an extensive repertoire of extracellular protease during tissue remodelling, cellular clearance after apoptosis and the débridement of injured tissue. Major species differences exist in the effector molecules for these functions. The up-regulation of proteases exemplified by MMP-12 in the mouse results in direct elastolysis as well as the generation of chemotactic stimuli and cytokines leading to pathology. As is discussed here and elsewhere, MMP-12 has been shown to have prominent activity, not only as an elastase, but in other aspects of the inflammatory process in the smoking mouse. These include the induction of TNF- α synthesis in the macrophage and subsequent activation and involvement of the neutrophil in the smoking mouse model of emphysema [110,114]. However, the demonstration of the elastolytic activity of this enzyme by human monocytes has been problematical despite clear evidence of its presence and activity [167–169]. Early studies showed that human

alveolar macrophages have considerable elastolytic activity when cultured in the presence of human serum [170,171], which was ascribed predominantly to cysteine proteases. Human blood monocytes can be cultured under conditions where they display elastolytic activity orders of magnitude greater than initially described [24]. Key to this finding is the mediation of elastolysis by plasmin-dependent activation of matrilysin (MMP-7), which does not occur in mouse macrophages. Human monocytes cultured in autologous serum show a 10-fold enhancement of elastin degradation in the presence of urinary plasminogen activator. This activity is mediated by a metalloprotease based on its sensitivity to inhibition by the non-specific MMP inhibitor BB94. Plasmin-dependent enhancement of elastolysis is not apparent when the cells are cultured on an extracellular matrix derived from MDCK cells, emphasizing how the matrix in which cells find themselves influence their secretion of proteases. Enzyme activity can also be up-regulated as illustrated by the induction of gelatinase B by substrate [172]. Under these conditions, the synthesis of matrilysin (MMP-7) is also suppressed but the elastolytic activity of the culture medium of these cells is reconstituted by addition of exogenous active enzyme without further enhancement by either MMP-9 or MMP-12. The activity of MMP-7 under these conditions is further enhanced by cysteine proteases such as cathepsins L and S [173], but probably not K [174], as indicated by studies with cells in which this gene has been inactivated. The activity of the cysteine proteases is probably restricted to the cell-substrate interface within an acidified vacuole dependent on H⁺-ATPase activity. These findings suggest that human monocytes are dependent on members of several classes of proteases for their optimal elastolytic activity – the serine protease plasmin, the MMP matrilysin and a subset of lysosomal cysteine proteases – leading to the conclusion that ‘therapeutics aimed at select members of both (cysteine/MMP) gene families might be necessary to ameliorate elastolytic effects *in vivo*’ [24]. The same conclusion is probably applicable to the role of proteases and other processes that sustain the inflammation in COPD. Matrilysin has a number of other significant properties which imply that it could contribute to the chronic inflammation in COPD. It is a product of healthy epithelium and in mice its deficiency results in significant defects in wound healing [40]. Moreover, it has a significant role in facilitating neutrophil egress during acute lung injury through cleavage of the heparin sulphate proteoglycan syndecan1, which forms chemotactic gradients by binding the chemokine KC [133].

Cell biological studies will therefore continue to provide insights on the complexities of protease function in health and disease and should provide a critical bridge in establishing the efficacy of protease inhibitors [175].

The development of protease inhibitors as drugs for chronic inflammatory diseases

An expert panel convened by the National Institutes of Health (NIH) in 2002 to consider the needs and opportunities for clinical research in COPD [176] suggested six potential new therapeutic approaches. The first advocates direct inhibition of protease activity. Several of the other approaches could have an impact on disease progression involving aberrant protease activity. These include the following:

- The inhibition of recruitment of inflammatory cells.
- Enhancement of the antioxidant capacity of the lung to prevent loss of activity of molecules that down-regulate protease activity in various ways [177] including the reduction of the inhibitory capacity of α_1 -antitrypsin [178].
- Inhibition of apoptosis of pulmonary cells associated with the development of emphysema [97]. This process is critically dependent on the activity of the caspase family of cysteine protease [179].
- Inhibition of mucus secretion by goblet and glandular mucosal cells because neutrophil serine proteases are potent mucus secretagogues [37].

There are important examples of the successful use of protease inhibitors in the treatment of human disease. Angiotensin-converting enzyme (ACE) inhibitors have been used extensively to treat cardiovascular disease, while the introduction of inhibitors of the aspartyl protease of HIV has made major contributions to the treatment of AIDS [180]. Attempts to discover and develop protease inhibitors for the therapy of COPD have been guided by insights into the role of proteases in the pathogenesis of the disease. The original protease-antiprotease hypothesis led to extensive efforts on neutrophil elastase as a target [13]. Matrix metalloprotease inhibitors active against the endoproteolytic activity of a number of enzymes have been extensively evaluated for the treatment of a range of chronic diseases including cancer [181] and arthritis [6]. As it has become clear that some of the same enzymes may be significant mediators of the pathology of COPD, efforts have been initiated in this direction [7,10,29]. There have been no compelling therapeutic breakthroughs in the therapy of cancer and arthritis, suggesting that the understanding of the role of metalloproteases in these diseases remains to be elucidated.

Criteria for the design of low molecular weight protease inhibitors

While the search for protease inhibitors has yielded agents of great intrinsic potency and specificity, much less attention has been given to the requirements for these agents to

be effective in the complex environment in which proteases function in health and disease. The intrinsic activities of proteases are extensively regulated in a variety of ways. These include sequestration in intracellular compartments, often as inactive precursors. Once synthesized and processed to an active form, functional latency can be maintained through storage in granules as exemplified by the high concentrations of serine proteases present in the specialized azurophilic lysosomes of myeloid leukocytes. When released from cells, these proteases face an environment containing specific and extremely potent natural inhibitors. This is exemplified in blood, which contains molar excesses of both α_2 -macroglobulin and other more specific inhibitors for their target enzymes. The extracellular catalytic activity of the major classes of proteases have different functional requirements. Metalloproteases exist as pro-enzymes with specific activators. These activators are still not well defined and may be induced in pathological situations. Cysteine proteases act most effectively in an acidic environment created by exocytosis of lysosomes and lose activity with adjustment of pH towards physiological levels. Neutrophil serine proteinases are active within azurophilic granules. In blood, their extracellular environment contains very large molar excesses of inhibitors such as α_1 -antitrypsin and α_2 -macroglobulin, albeit at lower concentrations than that of the enzyme in granules, hence the brief activity seen in blood when cells are degranulated. It is possible that this activity can be further modulated by cytokines to increase the activity of neutrophil membrane associated enzyme [182, 183]. The synthesis and activity of natural inhibitors may be down-regulated during pathology. Indications of this are exemplified by the decrease in α_1 -antitrypsin gene expression in IL-13 transgenic mice [123] and its inactivation by oxidative stress [177]. It is therefore critical that these requirements for activity be considered for inhibitor design.

Development of mechanism-based neutrophil elastase inhibitors exemplifies the demonstration of the biological activity of synthetic inhibitors in the presence of excess of natural inhibitors

The search for and development of protease inhibitors has been very much influenced by progress in the understanding of the biology of their target enzymes. This is illustrated by the series of lactam-based inhibitors of neutrophil elastase (Fig. 68.1) [85,103,184,185] culminating in the introduction into humans of a cell penetrant inhibitor L694458 (DMP 777) which provides long-lasting inhibition of the body load of the enzyme [16]. At the outset, such a compound was viewed as unlikely to be safe for introduction into humans because the physiological functions of neutrophil elastase were largely unknown. Subsequent biology has provided some insights in this respect, based both on gene knockouts in mice [45,118,125,126] and the

Figure 68.1 Some properties of three representative lactam-based inhibitors of polymorphonuclear neutrophil (PMN) elastase. (a) Cephalosporin. Active by aerosol administration to inhibit PMN elastase-mediated lung damage in rats and hamsters. Not active systemically after oral administration. (b) Acidic monocyclic. Orally bioavailable in a number of species and systemically active to inhibit PMN elastase-mediated lung damage. (c) Cell-penetrant inhibitor which is orally bioavailable in a number of species. Causes rapid and long-lasting inhibition of PMN elastase in peripheral PMN in primates.

discovery of a genetic defect in humans of DPP1 [120], an enzyme that activates precursors of myeloid cell serine proteases [186] as they are packaged into storage granules in neutrophils, mast cells monocytes and natural killer (NK) cells. The development of the lactam-based inhibitors of neutrophil elastase shown in Figure 68.1 was initiated by a serendipitous observation with an inhibitor of a bacterial enzyme. Clavulanic acid is an acylating inhibitor of bacterial serine proteases but does not affect mammalian serine proteases. Doherty *et al.* [184] showed that the benzyl ester of clavulanic acid, while inactive against the bacterial enzyme, inhibits neutrophil elastase and other mammalian serine proteases. This provided a starting point for the development of a series of increasingly specific and potent lactam-based inhibitors [85,103].

The cephalosporin L658758, which by present-day standards is a modestly potent inhibitor of human neutrophil elastase, inhibits human neutrophil elastase-induced lung haemorrhage after intratracheal instillation to hamsters. The compound is not orally active because of metabolic instability. At the time of its development, it was already established that immune complexes cause degranulation of neutrophils [79] and it was thought that proteases such as elastase contributed to the damage seen in immune complex diseases. L658758 inhibited the haemorrhage associated with a reverse passive Arthus reaction in the rat lung. It prevented destruction of blood vessels associated with the basement membranes where immune complexes are deposited without significant effects on neutrophil recruitment [81]. Thus, the low molecular weight inhibitor was supplementing the activity of natural inhibitors of the target neutrophil serine proteases.

The studies of Owen *et al.* [156,182] lent a clear rationale for developing compounds that would be effective against

the local and transient activity of enzyme present at high concentration in exocytosed azurophil granules. Subsequent efforts sought orally active compounds and led to the development of more potent monolactam-based inhibitors of elastase as exemplified by L680833 (see Fig. 68.1) [103], which inhibited tissue damage by both exogenous and endogenous elastase. The availability of sensitive and specific neopeptide assays allowed the potency and activity of this family of compounds to be assayed in biological systems and it became clear that these agents inhibited the activity of elastase that escaped natural inhibitors [103,161]. The great intrinsic potency of L680833 against elastase [103] is considerably attenuated in the presence of physiological concentrations of natural inhibitors in blood. Approximately 10 $\mu\text{mol/L}$ L680833 is required to inhibit by 50% the fibrinopeptide formation occurring when neutrophils are degranulated in the presence of 100 $\mu\text{mol/L}$ or more of $\alpha_1\text{PI}$ and $\alpha_2\text{-macroglobulin}$ in blood [103].

Further enhancement of this potency was achieved by changing the physical properties of the inhibitors to allow them to penetrate into azurophil granules and inactivate the enzyme intracellularly. This is illustrated by the properties of L694458, which under the code name DMP 777 has been advanced to Phase II clinical studies in cystic fibrosis [16]. This compound inhibits the cellular pool of neutrophil elastase with an inhibitory concentration 50% (IC_{50}) close to the overall blood concentration of 100–200 nmol/L of the enzyme, indicating a very high efficiency of inhibition approaching unit stoichiometry. The detailed mechanism of action of this class of agents has been delineated with the identification of the precise nature of the complex and products of inactivated enzyme with parent inhibitor [187–190]. Using a combination of electrospray ionization mass spectrometry and two-dimensional nuclear magnetic

Figure 68.2 The potent and efficient inhibition of polymorphonuclear neutrophil (PMN) elastase by L694458.

resonance (NMR) techniques, the precise molecular weights of enzyme–inhibitor complexes were determined with subsequent specific identification of reaction intermediates. With this information in hand, it was possible to develop a specific antibody to a substituted urea reactivation product (bottom right-hand side of monocyclic molecules in Fig. 68.1) that is uniquely derived from the stable enzyme–inhibitor complex [191]. Because the antibody has minimal cross-reactivity with parent inhibitor or enzyme, it is possible to measure formation of enzyme–inhibitor complexes in biological fluids containing excesses of either active enzyme or inhibitor. Figure 68.2 illustrates some of the general principles underlying this technology [191–197] using L694458 as an example. The compound is a very fast and efficient inhibitor of elastase, requiring only 1.13 mol to inhibit each mole of enzyme forming a complex of 25 560 Da with release of a 361-Da C2 leaving group (phenoxy group at top right part of the molecule, Fig. 68.1). This occurs extremely rapidly with a second-order rate constant, k_{inact}/K_i of 3 800 000 mol/s. The complex is stable with a $t_{1/2}$ of 15 h, which is well in excess of the half-life of circulating neutrophils. Slow reactivation of this complex, which can be accelerated to more rapid completion at elevated temperature, yields the substituted urea, which is not generated from the parent inhibitor [191].

Several complementary assays can be used to assay the potency of this type of inhibitor in neutrophils in blood or isolated from blood. These assays are useful for *in vitro* studies or for *in vivo* evaluation of compounds. They include:

- Hydrolysis of conventional synthetic substrates by neutrophils lysed after isolation from blood and washed to remove plasma inhibitors.
- LC-MS/MS quantitation of parent compound and C2 leaving group in blood and plasma to concentrations below 1 nmol/L.
- Immunoassay of specific fibrinogen cleavage products such as Aα(1-21) and Aα(Val³⁶⁰) formed in the presence of endogenous inhibitors after degranulation of neutrophils in blood.
- Immunoassay of α₁-antitrypsin–elastase complexes formed during the activation of neutrophils in blood. In the presence of inhibitor, lesser amounts of this natural complex are made.
- Immunoassay of the substituted urea leaving group derived from enzyme–inhibitor complex.

The diagram in Figure 68.3 illustrates how these assays can be used in one sample of human blood to characterize enzyme inhibition. In intact blood with no perturbation of neutrophils, the addition of inhibitor results in concentration-dependent release of equimolar amounts of the C2 leaving group and formation of complexes yielding the substituted urea. Close to maximum yield (in the range of several hundred nanomolar) of these require only approximately fivefold excess of parent compound, which is not detectable by LC-MS (less than 1 nmol/L) until this maximum is achieved, suggesting complete sequestration by intracellular enzyme. Neutrophils separated and lysed show the expected loss of activity against synthetic elastase substrate.

Figure 68.4 L694458 inhibits polymorphonuclear neutrophil (PMN) elastase *in vivo* rapidly and with great potency in chimpanzees. This figure shows an intravenous infusion (0.5 mg/kg) of L-694 458 (DMP 777) to a chimpanzee.

Inhibitor is totally consumed up to concentrations required to inhibit enzyme fully; the IC_{50} being approximately 100 nmol/L. Degranulation of neutrophils in blood allows access of elastase to substrates such as fibrinogen and high levels of 30–50 μmol of $\alpha_1\text{PI}$. Catalytic activity against fibrinogen is evident by the formation of $\text{A}\alpha(\text{Val}^{360})$ [84] as is the formation of $\alpha_1\text{PI}$ –elastase complexes as the inhibitor gains access to the released enzyme. In the presence of L694458, formation of both fibrinopeptide and $\alpha_1\text{PI}$ –elastase complexes is inhibited with equal potency with IC_{50} of several hundred nanomolar [84]. This activity reflects the intracellular inhibition of enzyme.

Preclinical *in vivo* studies with L694458 are complicated by the fall in potency against elastase across species with second-order rate constants dropping from 2.4 to 1.6, and 0.059×10^6 mol/s from the chimpanzee, to the rhesus to the rat respectively. This necessitated the use of chimpanzees to model the *in vivo* pharmacodynamic properties of this compound. The potency of the compound predicted from *in vitro* studies is apparent *in vivo* (Fig. 68.4). A slow infusion of 0.5 mg/kg of L694458 over a period of approximately 20 min resulted in rapid inhibition of elastase in blood taken at various times after initiation of drug delivery. Within 10 min, with a total of 0.25 mg/kg of drug administered, complete inhibition was seen. Total inhibition of intracellular enzyme is achieved with plasma concentration of drug of 10 nmol/L as the drug rapidly penetrates cells and associates with intracellular enzyme. Based on the calculation of the amount of enzyme present in the body, only a 10- to 20-fold molar excess of drug is required to achieve this level of inhibition. Because the enzyme is sequestered in azurophil

granules, which form only a tiny fraction of blood/whole body volume, the extreme tropism of L694458 for its target is again apparent.

These potent pharmacodynamic properties, combined with its good pharmacokinetic properties and safety profile, have provided the opportunity to evaluate the properties of L694458 (DMP 777) in humans [16]. Initial studies showed that these pharmacodynamic properties are observed in short-term studies in cystic fibrosis patients and controls. Close to full inhibition of elastase in lysates of neutrophils from patients receiving drug at single and multiple doses with inhibition of enzyme correlating with pharmacokinetic parameters including C_{max} and area under the curve (AUC). It is therefore clear that the combination of the extraordinary potency, amounting to almost stoichiometric inhibition of the enzyme, the ability to access intracellular enzyme and excellent pharmacokinetic properties allows this agent to inactivate the body load of elastase in humans.

The ability of the compound to prevent pathology in animal models has been demonstrated in the reverse passive Arthus in the rat, despite its far poorer potency ($k_{\text{inact}}/K_i = 59\,000$ mol/s) against elastase in this species. The compound has not been evaluated in the smoking mouse model. This should be possible based on the safety and efficacy in shorter term models in the mouse, despite relatively poor activity against the elastase of this species. The profile of the compound as compared with the elastase null mouse is not predictable. Confounding variables include possible effects on PR3 [185,192] which causes lung damage characteristic of other elastolysins [193] and functions that may not require catalytically active enzyme [74].

Another neutrophil elastase inhibitor, ZD 0892, an orally active trifluoromethyl ketone inhibitor, reduces cigarette smoke-induced emphysema in guinea pigs [105]. This agent inhibits both acute inflammation and chronic lung destruction. It effectively abolished increases in the chemokines MCP1 and MIP2 as well as reducing elevated plasma levels of $\text{TNF-}\alpha$ seen after 2 h exposure to cigarette smoke. On a longer term basis, decreases in desmosine, hydroxyproline and neutrophils in lung lavage fluid are observed while also reducing airspace enlargement by 45%. These findings were not complemented by measurement of surrogate markers of neutrophil elastase activity nor was there any information on the pharmacokinetics of the compound. However, if the effects were mechanism based then they give a clear indication that the neutrophil as well as $\text{TNF-}\alpha$ have significant roles in the inflammation and tissue damage seen in this model. Similar findings have been made with human α_1 -antitrypsin administered to mice tolerized to this molecule by low level expression of a transgene for the human molecule [116].

What are the concerns regarding inhibition of elastase and other neutrophil serine proteases? The sophisticated

biological mechanisms that regulate the extracellular activity of proteases *in vivo* place strict temporal and spatial restrictions on their activity. Yet it is clear that they allow these enzymes to be active against a wide range of endogenous substrates, including those that are targeted in destructive inflammatory diseases such as COPD. These activities are likely to mediate physiological tissue turnover and repair in many instances, particularly in the case of macrophages and connective tissue cells, probably less so in the case of the neutrophil. The boundary between these beneficial activities and aberrant activities that lead to pathology remain to be clearly defined and make it difficult to predict possible side-effects of inhibitors. This is particularly true if these agents also affect intracellular protease activity. The phenotype of mice in which individual serine proteases such as elastase and cathepsin G have been ablated give indications of specific defects in defences against some, but not all microorganisms [118,125,126]. Neutrophil elastase knockout mice have mild defects in host defence against specific infectious agents but animals appear phenotypically normal in the sheltered environment of protected animal housing. The realization that DPP1 (or cathepsin C) processes the precursors of serine proteases found in a number of myeloid cells including NK cells, mast cells and neutrophils and its deletion in mice [45] provided a broader perspective on the consequences of genetic ablation of not only neutrophil elastase but a number of other serine proteases. These findings have now been complemented by the discovery that the genetic defect underlying the juvenile periodontitis and plantar hyperkeratinization in Papillon-Lefèvre and Haim-Munk syndromes is caused by a loss of function of DPP1 [120]. The details of this genetic defect remain to be fully elucidated but the rare cases that have been described are characterized by early-onset periodontal disease, a phenomenon associated with other types of neutrophil dysfunction, but individuals with this defect survive into adulthood. Mice in which this gene is ablated appear to be normal in their protected environment and recent studies in a model of cecal ligation show that there is some protection to be derived from ablation of this gene [119]. This was associated with the loss of tryptase as a regulator of IL-6 and, while lethality was reduced, the clearance of the systemic bacterial load in these mice may have been hindered based on the increased bacterial count [119], which is consistent with the defects in certain aspects of host defence against specific organisms in neutrophil elastase knockout mice. These observations give an indication of the concerns about host defence that need to be registered about pharmacological inhibitors of this family of enzymes, particularly agents that give extensive coverage and are active against intracellular pools of these enzymes.

Other concerns regarding inhibition of extracellular

neutrophil elastase have been expressed [194,195] based on the exacerbation of lung damage seen in some pharmacodynamic models of elastase-induced lung haemorrhage used to evaluate competitive inhibitors that form reversible complexes with neutrophil elastase [196]. It was suggested that these reversible complexes are transported to sites where reactivated enzyme is not readily accessible to natural inhibitors [194,195].

A lack of neutrophil function has long been associated with marked defects in host defence function. Genetic defects in adhesion molecules such as CD18 and in the NADPH oxidase system have life-shortening consequences [73]. On the other hand, defects in the serine proteases have not been apparent until recently. Disordered intracellular trafficking of elastase has been associated with severe congenital neutropenia [197] while the cleavage by elastase of the fusion protein PML-RAR α formed as a result of a chromosomal translocation in acute promyelocytic leukaemia has been associated with increased incidence of leukaemia [39]. In this instance, an elastase inhibitor has a beneficial effect on a transgenic mouse with a functional PML-RAR α fusion protein [39]. Possible consequences of the pharmacological loss of function for neutrophil elastase on myelopoiesis in humans have not been determined.

Ohbayashi [13] has extensively reviewed neutrophil elastase inhibitors that are in development and the current status of a number of compounds brought forward into the clinic. At this time there is no documentation of the activity and clinical utility of these inhibitors. In many instances there is no demonstration that these inhibitors inactivate elastase that escapes inhibition by endogenous inhibitors. It is clear that while elastase on its own is not going to be solely responsible for the complex protease-mediated pathology in COPD, its interactions with other proteases, most notably cysteine and metalloproteases, will make the evaluation of its inhibition useful to determine whether it has a non-redundant role in the ongoing pathogenesis of COPD.

Matrix metalloproteases

The challenges for the development of MMP inhibitors for the therapy of chronic disease are reflected by the experiences in the cancer and arthritis fields [7,9,198]. Based on their up-regulation at affected sites, there is circumstantial evidence for a role of MMPs in tumour metastasis and in cartilage destruction in the arthritides. Clinical investigation of MMP inhibitors over the last 15 years has not yielded any conclusive evidence of clinical benefit. A number of issues stand in the way of gaining clear-cut knowledge and understanding of the potential of these agents. The complexity of the MMP family adds to the

difficulty of designing specific, pharmaceutically and clinically acceptable compounds. Musculoskeletal side-effects, which are speculated to be mechanism based [198], have been observed with a number of non-specific inhibitors, such as the Roche MMP inhibitors [198] which have been taken forward to Phase II–III evaluation in arthritis. It is not clear whether any of these effects reflect the severe osteolysis and arthritis associated with MMP-2 deficiency in humans [166]. Development of more specific inhibitors such as prinomastat and tanomastat has not resolved these problems. Moreover, the complexity of the metalloprotease families with the emergence of the ADAM and ADAM-TS families makes it very difficult to evaluate broad-based specificity of inhibitors. Preclinical studies of MMP inhibitors have shown that the non-specific compound CP-471,474 attenuates the acute inflammation and emphysematous changes seen in guinea pigs exposed to cigarette smoke [199]. It is not clear which enzyme(s) is the target of the inhibitor.

The difficulty in developing MMP inhibitors is compounded by the lack of reliable biomarkers for MMP activity in disease. This has been a long-standing problem for COPD where reliable assays even for specific degradation products of elastic tissue are not available to allow development of markers of either individual proteases or as a collective indicator of accelerated elastic tissue turnover and degradation.

MMPs are maintained in a latent form until activated by physiological triggers or inappropriate signals at sites of pathology. Their activity is restricted to the pericellular environment by the activity of natural inhibitors. While increased levels of individual enzymes have been detected in lung fluids, good markers for their catalytic activity are not available. Unlike the serine proteases from neutrophils, which have well-validated markers such as specific cleavage products and their complexes with α_1 PI, the metalloproteases are only available in small amounts which often serve physiological functions in the target tissue. Accordingly, direct catalytic activity is extremely difficult to measure. Local sampling for specific degradation products is also difficult and their release into the circulation results in their catabolism and/or dilution to undetectable levels so that they cannot be assayed in blood and urine.

Cysteine proteases

Cysteine proteases such as cathepsins L, S and K have been implicated in tissue injury and remodelling [20]. While cathepsin K is not obviously implicated in COPD, its genetic defect in humans [200] has provided a stimulus for seeking inhibitors that have beneficial effects on bone diseases. Cathepsin L and S both have significant elastolytic potency and there are indications that they may contribute to COPD

[20]. Design of inhibitors for cysteine proteases has proceeded the furthest with ICE, the IL-1 precursor processing enzyme [201]. Inhibitors for this enzyme have been taken forward to Phase II–III clinical studies in arthritis [202]. Other members of the ICE family, the caspases, have essential roles in apoptosis [179] and the progress in biology of this area may reveal rational targets in the context of cell death and removal that is such a critical part of lung host defence. Considerable interest in cathepsin S as a target has emerged, based on both its involvement in the immune response [47] as well as in vascular wall inflammation in genetically modified mice [141].

Conclusions

The clinical evaluation and development of protease inhibitors in COPD has only begun. The details of the proteome are now in hand [5] and intrinsically potent inhibitors of some of the individual enzymes are available. A handful of these have properties that have allowed their introduction into humans [13,16,17]. The rapidly evolving understanding of the biology of proteases in the healthy lung and in COPD will provide the basis for much further work in this area. This knowledge, together with the application of sensitive and specific tools for measuring the efficacy of candidate drugs against the irreversible damage to the lung, will provide the basis for determining whether they will be clinically useful.

Acknowledgements

We are grateful to Lorena Bennett for her assistance in the preparation of this chapter. We are appreciative of the many stimulating discussions with colleagues at Merck Research Laboratories regarding the subject matter of this chapter as well as their contributions to cited original work.

CHAPTER 69

Retinoids

Stephen R. Tudhope

Emphysema is caused by the destruction of alveolar walls leading to a loss of elastic recoil and small airway closure in addition to loss of alveolar surface area for gas exchange [1]. Emphysema, which is a component of chronic obstructive pulmonary disease (COPD), is thought to result from the action of proteases [2], reactive oxygen species and cytotoxic T lymphocytes [3]. While the majority of pharmaceutical research effort is currently focused on inhibiting the inflammatory response in COPD or targeting proteases involved in lung destruction, the 'holy grail' of therapeutics for the treatment of emphysema is undoubtedly an agent that will regenerate damaged lung tissue. Retinoids hold that promise.

The term retinoids refers to the natural and synthetic derivatives of vitamin A (retinol). While retinol is required for reproduction and its metabolite retinaldehyde for vision, it is another metabolite, all-*trans*-retinoic acid (ATRA) that is the focus of this chapter. The discovery that ATRA is a powerful and important morphogen involved in cell differentiation and branching pattern formation during embryonic development triggered the so-called 'retinoid revolution' of the 1980s [4]. ATRA was also found to be critical for the development of pulmonary alveoli and the discovery in 1997 that it could induce alveolar repair in an animal model of emphysema [5] appears to have triggered a new retinoid revolution.

This chapter reviews the role of retinoids in alveolar formation and models of emphysema as well as briefly considering some potentially related repair models. It also considers gene products that may be involved in retinoid-induced repair and assesses the clinical promise of retinoids for the treatment of emphysema.

Retinoid receptors

Retinoids exert their biological effects by directly regulating gene expression, their receptors belonging to the super-

family of nuclear hormone receptors. These include steroid, thyroid and vitamin D₃ receptors [6]. There are two major classes of retinoid receptors, retinoic acid receptors (RARs) and retinoid X receptors (RXRs), each with three subtypes (α , β and γ) and various isoforms arising from differential gene splicing. RARs and RXRs bind to specific DNA sequences known as response elements (RAREs and RXREs, respectively) (Fig. 69.1). These receptors typically suppress gene transcription in the absence of retinoids and induce it in the presence of retinoid agonists [7]. Although RARs and RXRs can homodimerize, heterodimerization increases the efficiency of binding to the response elements and generates combinatorial diversity [8].

The response elements usually consist of direct repeats of the sequence AGGTCA separated by a defined number of nucleotides, although palindromes and complex elements with little consensus structure have also been shown to bind. RARs usually associate with direct repeats separated by a spacer of five nucleotides, whereas RXRs generally bind to

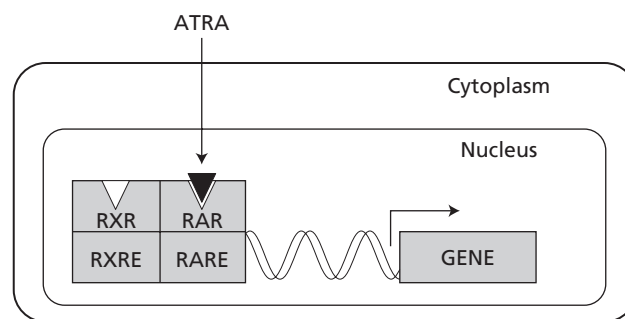

Figure 69.1 All-*trans*-retinoic acid (ATRA) signal transduction: The retinoic acid receptor (RAR) dimerizes with the retinoid X receptor (RXR) and associates with the retinoid response elements (RARE and RXRE) on DNA. ATRA activation of RAR induces gene transcription.

Compound	Structure	RAR selectivity
ATRA		α, β, γ
TTNPB		α, β, γ

direct repeats with a spacer of one nucleotide [9]. There is, however, a degree of promiscuity between the response elements such that a particular response element may be activated by more than one member of the nuclear receptor superfamily. In addition, there is some tolerance for nucleotide substitution in the consensus sequence, leading to a range of binding affinities and therefore potentially different levels of retinoid responsiveness for different genes [9].

ATRA is the physiological hormone for RARs, binding with approximately equal affinity to the three subtypes, but has low affinity for RXRs. An isomer of ATRA, *9-cis*-retinoic acid, which binds equally to RARs and RXRs, has been proposed as the physiological hormone for RXR activation, although this is still a matter of debate [10]. In the context of RAR/RXR heterodimers, activation is achieved by RAR agonists, although RXR agonists have been shown to enhance their effects in cellular assays [11,12]. RXRs also serve as heterodimeric partners to other nuclear receptors including the vitamin D, thyroid hormone and peroxisome proliferator-activated receptors (PPARs). Thus, RXRs are functionally

different to RARs and appear to act as a master partner for nuclear receptor signalling, albeit usually a silent one.

There is a remarkably high degree of conservation between mouse and human RAR subtypes, suggesting that each subtype may have important and distinct physiological roles [13]. In addition, the spatiotemporal expression pattern of the RAR subtypes in mouse and human is also highly conserved. In adult mice and humans, RAR α is ubiquitous, RAR β is highly expressed in the heart, lung and spleen, while RAR γ is confined to lung and skin [14–16]. This suggests that selective RAR agonists may provide a way to target specific tissues and minimize the side-effects associated with non-selective retinoids.

Through decades of retinoid research, mainly pioneered by companies interested in their dermatological and oncological effects, there are now many synthetic retinoids reported with varying degrees of selectivity for retinoid receptor subtypes. TTNPB, for example, is a synthetic retinoid activating all three RAR subtypes but not RXRs [17]. AM580 is selective for the RAR α receptor subtype [18], CD2019 preferentially binds to the RAR β receptor [19] and CD666 is RAR γ selective (Fig. 69.2) [20]. Antagonists have also been reported, such as AGN 193109, a pan-RAR antagonist [21] and the RAR α selective retinoid antagonist AGN 194301 (Fig. 69.3) [22]. Using such pharmacological tools, RAR subtype-specific effects are being identified.

Retinoids in alveolar formation

Studies utilizing vitamin A deficiency, RAR mutations and lung explants have demonstrated that ATRA is essential for

lung development [23]. During the pseudoglandular stage of lung development, retinoid signalling promotes formation of conducting airways and later promotes formation of the primary lung buds [24]. Retinoids also have a critical role in the development of alveoli by a process known as septation, where lung saccules constituting the gas exchange region of the immature lung subdivide to increase the available surface area for gas exchange. Septation mostly occurs postnatally in mammalian species beginning around the fourth postnatal day in rats and mice and completed by the fourteenth. In humans, the process begins during the last month of gestation and continues at least through the first few postnatal years.

There is a critical window for septation in rats and mice, which if inhibited – for example, by the administration of the synthetic glucocorticosteroid dexamethasone – prevents normal alveolar formation and the lung takes on a permanent emphysematous-like appearance [25]. The septation period in rats is associated with low serum levels of natural glucocorticosteroid hormones [26,27], an abundance of pulmonary lipofibroblasts (LIFs) [28] and high lung levels of a retinoid binding protein CRBP1 [29].

The LIFs appear to act as retinoid storage cells, containing abundant stores of retinol and ATRA prior to septation that are depleted post-septation. LIFs also secrete tropoelastin, the precursor to cross-linked elastin that provides the support and elasticity essential for lung function. Studies with rat fetal lung explants showed that inhibiting the metabolism of retinyl esters reduced elastin gene expression in culture, whereas supplementation with ATRA increased elastin gene expression [30]. Expression of RAR β and RAR γ was shown to increase in LIFs at birth, at the same time that these cells contain their maximal amount of ATRA. The RAR γ expression level declines again after the second postnatal day, as ATRA levels also decrease. These associations strongly implicate retinoids with the processes of septation and elastin synthesis.

Investigating the role of ATRA in septation, Massaro and Massaro [31] demonstrated that treatment of normal neonatal rat pups with ATRA induced the formation of additional septa compared with untreated animals. An increased rate of septation was also observed in RAR β knockout mice [32], suggesting that signalling through RAR β inhibited septation. This was confirmed by the use of an RAR β selective agonist [32]. McGowan *et al.* [33] discovered a decrease in the numbers of alveoli and alveolar surface area in RAR γ knockout mice, suggesting that RAR γ signalling is the trigger for septation. This proposal is supported by the finding that only RAR γ agonists stimulated elastin synthesis in pulmonary fibroblasts [34].

Although septation is the primary means to generate alveoli in the developing lung, there appears to be another, less understood process by which alveoli are formed during

post-neonatal lung growth. This process does not occur by subdivision of saccules [35] and appears to be regulated by RAR α signalling [36]. Taken together, these studies demonstrate a crucial role for retinoids in mediating alveolar formation, implicating RAR γ as the trigger for septation with RAR β acting as a brake to prevent excessive subdivision and RAR α mediating slower alveolar formation to synchronize with lung growth.

Retinoids in models of emphysema

Dexamethasone model

Treatment of neonatal rodents with dexamethasone during the critical period of septation results in an emphysematous-like lesion. However, as the alveoli have not yet formed and emphysema is defined as alveolar destruction, it is more correct to call this a model of impaired septation rather than emphysema. Nevertheless, the lungs do not spontaneously regenerate and adult animals have larger and fewer alveoli than untreated littermates (Fig. 69.4) [37,38]. Concomitant treatment with ATRA during the dexamethasone treatment period was found to reverse or block the inhibition of septation [31]. This effect could, however, be caused by inhibition of the steroid at a molecular level rather than overcoming its effect.

In adult rats with dexamethasone-impaired septation, ATRA induced the formation of smaller and more numerous alveoli [39], presumably by initiating septation, although the repair was only partial compared with control animals. This remarkable result has been confirmed in mice [40], demonstrating that ATRA can induce alveolar formation in adult animals at a time when alveoli do not normally form.

Elastase model

Many different proteases have been shown to induce an emphysematous condition when instilled into the lungs of animals. These include papain [41,42], neutrophil elastase [43] and trypsin [44], although the most frequently employed agent is porcine pancreatic elastase (subsequently referred to as elastase). A single administration of elastase has been shown to induce a condition that is functionally and morphologically similar to human panacinar emphysema [45].

Following their studies implicating ATRA in developmental alveolar formation, Massaro and Massaro [5] discovered that following elastase-induction of emphysema in rats, daily intraperitoneal injections of ATRA over 12 days resulted in a marked improvement in lung morphometry. This is consistent with formation of new alveoli by septation and the authors suggested that ATRA may have

Figure 69.4 Representative images of dexamethasone-impaired septation in rats. (a) Daily treatments from age 4 to 13 days with saline. (b) Daily treatments from age 4 to 13 days with 0.25 µg dexamethasone in saline. Lungs were harvested at age 60 days, fixed at a transpulmonary pressure of 20 cm H₂O, sectioned and stained with haematoxylin and eosin. Scale bars 200 µm.

Figure 69.5 Representative images of the effect of all-*trans*-retinoic acid (ATRA) on elastase-induced emphysema in rats. (a) Animals instilled with saline on day 0 and cottonseed oil daily from day 24. (b) Animals instilled with elastase (2 units/g) on day 0 and cottonseed oil daily from day 24. (c) Animals instilled with elastase (2 units/g) on day 0 and ATRA (0.5 mg/kg) in cottonseed oil daily from day 24. Lungs were harvested on day 37, fixed at a transpulmonary pressure of 20 cm H₂O, sectioned and stained with haematoxylin and eosin. Scale bars 200 µm.

‘turned back the clock’ to induce gene expression patterns associated with early lung development and the formation of alveoli in the immature lung. We have corroborated these findings and representative lung images are presented in Figure 69.5 [38].

A major question regarding this ATRA-induced alveolar regeneration was whether the newly regenerated lung was ‘normal’ and contributed to gaseous exchange. Using physiological measurements of lung function, Tepper *et al.* [46] demonstrated that treatment with ATRA reversed the elastase-induced increase in Pause (a measurement reflecting airflow obstruction) and the lung volume parameters TLC (total lung capacity) and RV (residual volume). This suggested that the ATRA-induced regeneration of alveoli in

the elastase model of emphysema resulted in the formation of normal functional alveoli.

These findings have been substantiated by Belloni *et al.* [47] who reported that ATRA induced a 50% reversal of elastase-induced lung damage in rats. Furthermore, in the same model, the RAR γ -selective agonist Ro444753 (see Fig. 69.2) induced lung repair by approximately 40% and improved some lung function parameters [48].

However, not all workers have been able to reproduce Massaro and Massaro’s findings. March *et al.* [49] found no significant effect of ATRA on Lm (a measure of alveolar size) in a rat model of elastase-induced emphysema and Lucey *et al.* [50] found the same lack of statistical significance in a mouse model. In both studies, however, ATRA

reduced the mean Lm by approximately 20%, which was similar to our own finding, although the data we obtained were statistically significant [38]. These contradicting results may stem from different techniques used to assess lung morphometry including their sensitivity to change [51] or from using different strains, species or dosing regimen [49,50].

Smoking model

It is well established that cigarette smoking can cause emphysema in humans [52]. In laboratory animals, cigarette smoke exposure has also been shown to induce emphysema in mice [53], rats [54] and guinea pigs [55].

In a rat model of smoke-induced emphysema, ATRA and Ro444753, administered daily for 1 month following the induction of emphysema, decreased elastin breakdown products and improved lung morphometry by 74% and 75%, respectively [56]. However, ATRA was found to be ineffective in guinea pig [57] and mouse [49] smoking models, although the guinea pig study was atypical as ATRA was administered during the smoke-induction of emphysema. The lack of effect of ATRA in mice, compared with the similarly conducted rat study, may result from differences in species, dosing regimen or the severity of emphysema [49].

Genetic models

Tight skinned (Tsk) mice [58], which contain a tandem duplication within the fibrillin-1 gene [59], fail to septate, resulting in an emphysematous-like condition [60,61]. Treatment of adult Tsk mice with daily injections of ATRA over 12 days was found to induce septation, resulting in 3.5 times more alveoli than on average were 2.7 times smaller compared with control animals [39].

The blotchy mouse is another example of disrupted lung matrix formation resulting in the development of an emphysematous-like condition [62]. In this case, altered copper transport effects lysyl oxidase activity [63] that is essential for the synthesis of mature cross-linked elastin [64]. The effect of retinoids in this model has yet to be reported.

Knockout models

The genetic models previously described suggest that defects in lung matrix deposition can lead to the inhibition of septation and altered lung morphology [65]. Elastin is possibly the most crucial of these proteins and its synthesis has been suggested to be the driving force behind alveogenesis [66–68]. Knockout mice lacking elastin die shortly after birth and display disruption of terminal airway branching

and fewer distal air sacs, indicating that elastin is essential for terminal airway development [69].

Mice lacking the growth factor PDGF- α survive birth and have normal lungs until the onset of septation [70]. Thereafter they develop an emphysematous morphology consistent with failed septation, undergo collapse of the lung parenchyma within a few weeks and die [71]. In these PDGF- α knockout mice, alveolar myofibroblasts fail to proliferate and spread, resulting in reduced elastin synthesis in the lung parenchyma. ATRA has been shown, *in vitro*, to stimulate postnatal rat lung fibroblast proliferation via a PDGF-mediated autocrine mechanism [72], suggesting that PDGF- α is a crucial downstream signalling molecule for ATRA-induced septation. These results also reinforce the central role of fibroblasts in lung septation.

A milder form of impaired septation is seen in a double knockout mouse model lacking the fibroblast growth factor receptors FGFR3 and FGFR4 [73]. However, in this knockout, elastin synthesis is apparently normal during the usual septation period although septation does not occur. The authors suggest that, besides elastin synthesis, a cellular differentiation step, blocked by the deletion of these receptors, is equally crucial for septation [73].

Angiogenesis models

Contrary to the widely held belief that the sole cause of emphysema is proteolytic injury to the lung extracellular matrix, Kasahara *et al.* [74] demonstrated that antagonism of the VEGF receptor VEGFR-2 induced emphysema in adult rats by an apoptosis-dependent mechanism with an absence of inflammatory cells. VEGF signalling through VEGFR-2 is necessary for maintenance of endothelial cells and angiogenesis. An antibody to PECAM-1, another effector of angiogenesis, was found to inhibit septation in rat pups, suggesting that angiogenesis also has an essential role in alveolar formation [75]. These novel findings revived the largely forgotten hypothesis of Liebow [76], which, based on histological examination of emphysematous lungs, proposed that vascular atrophy may initiate the loss of alveolar septa. Further support to this theory came from the observation that smokers with emphysema, but not healthy smokers, have decreased levels of VEGF, VEGFR-2 and increased lung endothelial and epithelial cell apoptosis [77]. This exciting new model of emphysema raises many questions, including whether or not the animals spontaneously repair following removal of the VEGFR-2 antagonist and whether ATRA can induce alveolar repair.

Hyperoxic lung injury

Exposure of neonatal animals to hyperoxic conditions during the period of septation inhibits the formation of alveoli

[78]. This inhibition of septation is similar to that seen with dexamethasone and is a feature of human bronchopulmonary dysplasia (BPD) seen in low birthweight infants supplemented with oxygen [79]. Although still a matter of controversy, treatment of vitamin A deficient, low birthweight infants with retinol has been reported to reduce the incidence of BPD [80], suggesting that retinol or a related metabolite may protect against the inhibition of septation caused by hyperoxia. Exposure of newborn rats to hyperoxic conditions and ATRA from age 3 to 14 days showed that unlike dexamethasone-impaired septation, ATRA had no effect on alveolar formation at this time [81]. However, following weaning to room air, examination of the lungs at age 42 days revealed that ATRA-treated animals had smaller alveoli and increased gas-exchange surface area relative to control hyperoxic lungs [82]. This suggests that ATRA protected against the hyperoxic-induced lung injury although the effect was only observed when a larger gas-exchange area was required for breathing normal air.

Calorific restriction

A possibly related model is that of calorific restriction, which supports a reversible link between lung architecture and an animal's oxygen demand [83]. In all mammals, there is a direct linear relationship between alveolar surface area and oxygen uptake [84]. During periods of starvation an animal's metabolic rate drops, lowering the oxygen demand [85] and in an apparent attempt to redress the balance between oxygen demand and alveolar surface area, calorific restriction results in an emphysematous morphology, which is returned to normal following refeeding [86]. This spontaneously regenerating model may throw new light on the natural mechanisms of alveolar destruction and regeneration, which could be involved in development of emphysema.

Associated models of regeneration

The mechanism of retinoid-induced alveolar regeneration may be related to the capacity of some species for compensatory organ growth and limb regeneration.

Compensatory lung growth

Spontaneous lung growth following partial lung resection has been documented in many species including dogs [87], ferrets [88], mice [89] and rats [90]. It also occurs in humans under the age of 4 years [91] and to a lesser extent up to the age of 20 years [92]. The rat model of compensatory lung growth post-pneumonectomy has been

extensively studied, where, following pneumonectomy, the remaining lung undergoes expansion and remodelling to compensate for the loss of lung capacity. The 'new' lung has normal morphology, implying that alveolar formation occurs together with lung growth [93]. This post-pneumonectomy lung growth is modulated by the hormonal status of the animal, proceeding more rapidly in adrenalectomized animals and can be inhibited by administration of adrenal corticosteroid [94]. It is tempting to speculate that dexamethasone may also inhibit post-pneumonectomy alveolar formation akin to inhibition of septation during development. In addition, ATRA has been reported to enhance lung growth following pneumonectomy [95], which further supports a link between neonatal alveolar development and compensatory lung growth.

Limb regeneration

Amphibians of the order Urodela such as the Axolotl have the remarkable ability to regenerate limbs and other large sections of body following wounding or amputation. The effect of retinoids is to enhance the process in a proximal manner. That is, following amputation of an Axolotl forearm and treatment with ATRA, a complete limb from the shoulder level onwards can regenerate from the forearm [96]. Frog tadpoles, which can regenerate tails following amputation, may be induced to regenerate hindlimbs from amputated tail stumps by treatment with ATRA [97]. This 'proximalizing' effect of ATRA has also been observed in developing mammalian lungs *in vitro* [98,99], where ATRA was found to suppress the development of distal epithelial buds in favour of proximal airways.

MRL mouse model

The MRL/MpJ strain of mice, originally bred for their susceptibility to autoimmune disorders, have the remarkable ability to heal ear hole punctures [100]. This repair of a through-and-through hole is more like tissue regeneration than wound healing, as it is associated with complete recovery of normal architecture and a lack of scarring. Their regenerative capacity is not limited to the skin, however, and has also been demonstrated in the hearts of adult MRL mice [101]. Scarless wound healing is a trait usually associated with fetal rather than adult animals and has been linked to the lack of development of the immune system, particularly T lymphocytes. However, analysis of the genetic trait responsible for the regenerative capacity of MRL mice showed no overlap with the autoimmune phenotype. Instead, the researchers found a number of genetic loci that in combination led to the healing phenotype. Candidate genes associated with these loci include

RARγ, *PDGF*, *FGFR4*, *TGFβ-3* and *hox8* amongst others [102]. This discovery demonstrates that far from being restricted to amphibians, spontaneous tissue regeneration is also possible in adult mammals and may require a multitude of factors.

Although there are obvious differences between limb regeneration, scarless wound repair, compensatory lung growth, alveolar development and alveolar regeneration, there are also some striking similarities, especially in the context of pattern formation and signalling pathways [103].

Retinoid-responsive genes

Some retinoid-responsive genes are listed in Table 69.1. Many of these are known to be involved in early lung branching morphogenesis, such as *Shh*, *Hox*, growth factors and matrix proteins [153]. Some of these genes are also likely to be required for alveolar formation. These include: matrix proteins, particularly tropoelastin, essential for the formation of alveolar septa; growth factors and their receptors such as EGF, PDGF and TGF-β, required for cell differentiation and proliferation; and proteases and cell adhesion proteins required for cell migration. ATRA also regulates genes associated with retinoid activity, such as retinoid receptors, binding proteins and catabolic enzymes that may have a role in retinoid self-regulation.

Table 69.2 lists some further gene products associated with developmental or regenerative models. Although these genes are not known to be directly regulated by ATRA, by association with these models they may be regulated by downstream factors following retinoid activation. The list again includes matrix proteins and growth factors, as well as enzymes and hormones. It seems likely that a conserved mechanism exists for the formation and regeneration of pulmonary alveoli and therefore comparing gene expression in the different models may lead to a better understanding of this process [165].

Retinoids in clinical development for emphysema

Retinoids are currently used in the clinic for treatment of skin disorders and particular forms of cancer [166]; however, only limited studies have been undertaken in emphysema. In 2002, a group from the UCLA reported the results of a pilot study to assess the effects of ATRA in human emphysema [167]. This small study of 20 patients with severe emphysema showed no clinical benefits on pulmonary lung function or by computerized tomography imaging following a 3-month cross-over treatment with ATRA. A larger, five-centre study, sponsored by the National

Heart, Lung and Blood Institute (NHLBI) using a 6-month treatment time followed by a 3-month crossover phase commenced in 1999 [168,169] and the results are expected in 2006.

Although ATRA was well tolerated in the UCLA study, mild side-effects including skin changes, transient headache, hyperlipidaemia and musculoskeletal pains were reported. Such side-effects may prove to be dose limiting. An alternative approach is to use selective retinoids targeting a single receptor subtype, which may have a more favourable therapeutic ratio. Roche [170,171] have released press reports on a selective *RARγ* agonist (R667), which is currently in phase II clinical development for the treatment of emphysema. The results of these clinical trials are expected in 2006.

Discussion

It has been demonstrated that retinoids not only promote alveolar formation during the neonatal period, but can also induce alveolar regeneration in adult emphysematous disease models. These include genetic dysfunction and protease or cigarette smoke induced lung destruction, although results in the latter models remain controversial and may be species or strain dependent.

Retinoids induce gene expression by activation of RARs and it is most likely that activation of specific RARs in particular cells underlie the effects discussed so far. Alternative mechanisms are inhibition of gene transcription by association with other transcription factors and indirect antioxidant effects; neither of which would appear to lend the required complexity to direct morphogenesis.

Although the exact mechanism of retinoid-induced alveolar formation remains a mystery, genetic models and knockouts have implicated a number of essential gene products in the process. These include the matrix proteins fibrillin-1 and tropoelastin; lysyl oxidase, to cross-link and produce mature elastin fibres; growth factor PDGF-α and fibroblast growth factors acting through FGFR3 and FGFR4. In addition, angiogenic factors such as VEGF and PECAM-1 may also have a pivotal role. That ATRA can induce alveolar formation and repair implicates it as a master morphogen, being able to initiate a cascade of controlled gene signalling resulting in coordinated lung growth.

Associated spontaneous repair models such as amphibian limb regeneration, mammalian compensatory lung growth, caloric restriction and scarless wound healing may also share repair pathways with the retinoids. Elucidating the mechanisms of these processes will enhance our understanding of natural tissue regeneration and may shed further light on retinoid mechanisms.

Conclusions

Until recently, there has been little optimism for finding therapeutic treatments to promote alveolar repair. However, the discoveries surrounding the effects of retinoids on lung morphogenesis are now changing the dogma that the adult mammalian lung is non-repairable. With clinical studies ongoing to test the efficacy of ATRA and selective retinoid agonists in human pulmonary emphysema, it will soon be known whether retinoids can deliver their promise. In addition, further work to understand the mechanism of retinoid-induced alveolar repair in animal models

may provide insight into alternative therapeutic approaches for the treatment of human emphysema.

Acknowledgements

The author would like to thank Mary Fitzgerald, Craig Fox and Sarah Lewis from Argenta Discovery and Guenter Benz from Bayer AG for kind permission to include unpublished work. Many thanks also to Mark Giembycz and Louise Donnelly from the Department of Thoracic Medicine, National Heart and Lung Institute, Imperial College and Craig Fox from Argenta Discovery for their critical review of this manuscript.

CHAPTER 70

Chemokines in COPD

Peter J. Barnes

Chemokines are small secreted proteins that have a key role in the trafficking and recruitment of inflammatory and immune cells to sites of disease and have become important new targets in the search for more specific anti-inflammatory treatments. Over 50 different chemokines are now recognized and they activate up to 20 different surface receptors [1]. Chemokine receptors belong to the seven transmembrane receptor superfamily of G-protein-coupled receptors and this makes it possible to find small molecule inhibitors, which has not yet been possible for classic cytokine receptors [2]. Some chemokines appear to be selective for single chemokine receptors, whereas others are promiscuous and mediate the effects of several related chemokines.

Four different families of chemokines are now differentiated, based on differences in the position of critical cysteine residues: CC, CXC, C and CX₃C chemokines are recognized. Each chemokine molecule binds to a single or several receptors expressed on target inflammatory cells, resulting in the activation of signal transduction pathways that then result in chemotaxis or other cellular activities that include proliferation, differentiation and survival. Chemokines appear to act in sequence in determining the final inflammatory response and so inhibitors may be more or less effective depending on the kinetics of the response [3].

Chemokines have a critical role in orchestrating inflammatory and immune responses by regulating the trafficking of inflammatory and immune cells to target organs [4]. Several chemokines are involved in the recruitment of inflammatory cells in COPD [5]. There is considerable interest in identifying the critical chemokines as small molecule chemokine receptor inhibitors are now in development for COPD [6,7].

The inflammation in COPD is characterized by a marked increase in numbers of macrophages, which are derived from blood monocytes, neutrophils and T lymphocytes with a predominance of cytotoxic (CD8⁺) cells over helper (CD4⁺) cells [8,9]. All of these cells are derived from the circulation and it is therefore likely that chemokines have an important

role in the migration of these cells into small airways and the lung parenchyma where the inflammation in COPD predominates.

CXC chemokines

Interleukin 8

The CXC chemokine interleukin 8 (IL-8) (CXCL8) is a potent chemoattractant of neutrophils and it is not surprising that it has been implicated in COPD as there is a marked increase in neutrophils in airway secretions. IL-8 levels are markedly increased in induced sputum of patients with COPD and correlate with the increased proportion of neutrophils [10,11]. The concentrations of IL-8 are even more elevated in patients with emphysema resulting from α_1 -antitrypsin deficiency [12] and during exacerbations [13]. Anti-IL-8 antibodies have an inhibitory effect on the chemotactic response to COPD sputum, indicating that IL-8 contributes to neutrophil chemotaxis into the airways [14,15]. The concentrations of IL-8 in induced sputum are further increased during acute exacerbations, which presumably contributes to the increased numbers of neutrophils and the increased purulence of the sputum [13,16,17]. There is a correlation between IL-8 concentrations and the bacterial colony count in sputum, indicating that bacterial infection may induce neutrophilic inflammation, at least in part, via induction of IL-8 release in the airways [18,19]. IL-8 is also increased in bronchoalveolar lavage (BAL) fluid of patients with COPD and correlates with numbers of neutrophils [20,21]. The concentrations of IL-8 are significantly higher in smokers with emphysema than in matched smokers without airflow limitation, whereas the concentrations of other CXC chemokines in BAL do not appear to discriminate between these groups [22].

The cellular source of IL-8 in COPD is not completely certain. Airway epithelial cells secrete IL-8 in response to

Figure 70.1 CXC chemokine receptors on neutrophils. Interleukin 8 (IL-8) binds with low affinity to CXCR1, resulting in adhesion and activation and to CXCR2 with high affinity resulting in chemotaxis. CXCR2 is also activated by other CXC chemokines, including growth-related oncogene α (GRO- α), β and γ , epithelial cell-derived neutrophil-activating peptide of 78 kD (ENA-78) and granulocyte chemotactic protein-2 (GCP-2). MPO, myeloperoxidase.

several stimuli, including tumour necrosis factor- α (TNF- α) and cigarette smoke extract [23–25]. IL-8 protein and mRNA are increased in bronchiolar epithelial cells of patients with COPD [26] and there is increased basal release of IL-8 from airway epithelial cells of patients with COPD [27,28]. Alveolar macrophages also secrete IL-8 in response to the same stimuli and cells derived from patients with COPD secrete more IL-8 than those from normal smokers, who in turn secrete more macrophages than normal non-smokers [29]. Neutrophils also release IL-8 and attract more neutrophils, so that a self-perpetuating inflammatory state may be established [30]. The secretion of IL-8 is regulated transcriptionally by several transcription factors, amongst which nuclear factor- κ B (NF- κ B) is predominant. NF- κ B is activated in alveolar macrophages of patients with COPD and is further activated during exacerbations [31,32].

Neutralization of IL-8 with a blocking antibody significantly reduces the neutrophil chemotactic activity of sputum from patients with COPD [15,17]. However, the reduction in neutrophil chemotactic activity is only of the order of approximately 30%, indicating that other neutrophil chemotactic factors are also involved and that blocking IL-8 alone may be insufficient as a therapeutic strategy to reduce neutrophil inflammation in the respiratory tract.

IL-8 acts via two receptors: CXCR1, which is a low affinity receptor that is specific for IL-8; and CXCR2, which has high affinity and is shared by other CXC chemokines (Fig. 70.1). It is likely that CXCR2 mediates the chemotactic response of neutrophils and monocytes to IL-8, whereas CXCR1 may mediate the effects of IL-8 on release of mediators and proteases. There is a marked up-regulation of CXCR2 in airway epithelial cells during acute exacerbations of COPD and this is correlated with the increased numbers of neutrophils in the airway [33].

Other CXC chemokines

GRO- α

Growth-related oncogene- α (GRO- α , CXCL1) is another CXC chemokine that is likely to be involved in COPD. GRO- α activates neutrophils, monocytes, basophils and T lymphocytes via CXCR2 [34]. The concentrations of GRO- α is markedly elevated in induce sputum and BAL of patients with COPD compared with normal smokers and non-smokers (Fig. 70.2) [35]. GRO- α selectively activates

Figure 70.2 Activation of the CXC chemokines interleukin 8 (IL-8) and growth-related oncogene α (GRO- α) via nuclear factor- κ B (NF- κ B) after stimulating with tumour necrosis factor α (TNF- α), bacteria and viruses. This results in chemotaxis of neutrophils and monocytes that differentiate into alveolar macrophages.

Figure 70.3 Elevated concentrations of: (a) growth-related oncogene α (GRO- α); and (b) monocyte chemotactic protein-1 (MCP-1) in induced sputum of patients with COPD. (From Traves *et al.* [35] with permission.)

CXCR2 and is chemotactic for neutrophils and monocytes. There is an increase in the monocytes' chemotactic response to GRO- α in COPD patients and this may be related to increased turnover of CXCR2 on monocytes of COPD patients [36]. It is possible that the increased chemotactic response of monocytes to GRO- α is one of the mechanisms leading to increased numbers of alveolar macrophages in the lungs of patients with COPD (Fig. 70.3) [37] and could be one of mechanisms of susceptibility to cigarette smoking.

ENA-78

Epithelial cell-derived neutrophil-activating peptide-78 (ENA-78, CXCL5) is derived predominantly from epithelial cells and also activates CXCR2, although monocytes do not appear to show an increased chemotactic response to this chemokine as they do to GRO- α [36]. ENA-78 is increased in BAL fluid of COPD patients compared with normal subjects, but there is no difference between patients with emphysema and normal smokers [22]. A marked increase in expression of ENA-78 has been reported in epithelial cells during exacerbations of COPD [33].

CXCR2 antagonists

The involvement of several CXC chemokines in COPD and the involvement of CXCR2 in chemotactic responses of neutrophils and monocytes indicates that CXCR2 antagonists may have therapeutic potential in inhibiting recruitment of monocytes and neutrophils. Potent small molecule inhibitors of CXCR2, such as SB 225002, have now been developed that block the chemotactic response of neutrophils to IL-8 and GRO- α [38,39]. This antagonist has a significant inhibitory effect on the chemotactic response to COPD sputum. Concentrations of GRO- α are also elevated in induced sputum of patients with COPD and this mediator has a chemotactic effect on neutrophils and monocytes [35]. CXCR2 antagonists may therefore also reduce monocyte chemotaxis and the accumulation of macrophages in COPD patients.

CXCR3

The mechanisms by which CD8⁺, and to a lesser extent CD4⁺ cells, accumulate in the airways and lungs of patients with COPD is not yet understood. However, homing of T cells to the lung must depend upon some initial activation then adhesion and selective chemotaxis. T cells in peripheral airways of COPD patients show increased expression of CXCR3, a receptor activated by γ -interferon inducible protein of 10 kDa (IP-10, CXCL10), monokine induced by γ -interferon (Mig, CXCL9) and interferon-inducible T cell- α chemoattractant (I-TAC, CXCL11). All three chemokines activate CXCR3, although I-TAC has the highest affinity [40]. CXCR3 is expressed on T lymphocytes, particularly of the CD8⁺ subtype. There is increased expression of IP-10 by bronchiolar epithelial cells and this could therefore contribute to the accumulation of CD8⁺ cells, which preferentially express CXCR3 [41]. It is of interest that γ -interferon (IFN- γ) stimulates dendritic cells to produce IP-10 and Mig which then enhances their ability to attract CD8⁺ cells [42]. Alveolar macrophages also have the capacity to produce IP-10 and Mig and result in attraction of CD8⁺ T cells [43]. Because CD8⁺ Tc1 cells produce IFN- γ this provides a potential feed-forward amplification loop. The role of CD8⁺ T cells in COPD is not yet certain, but as they have the capacity to produce perforins and granzyme B they might induce apoptosis in alveolar epithelial and endothelial cells, thereby contributing to emphysema [44,45]. This suggests that blocking CXCR3 might be beneficial in the treatment of COPD (Fig. 70.4).

CC chemokines

CCR2

Monocyte chemotactic protein-1 (MCP-1, CCL2) is a CC chemokine that activates CCR2 on monocytes and T

Figure 70.4 Chemotaxis of cytotoxic ($CD8^+$) T lymphocytes via activation of CXCR3 by the CXC chemokines γ -interferon inducible protein of 10 kDa (IP-10), monokine induced by γ -interferon (Mig) and interferon-inducible T-cell- α chemoattractant (I-TAC). $CD8^+$ cells may release perforins and granzyme B which may induce apoptosis in alveolar cells and release γ -interferon (IFN- γ), which in turn activates the release of these chemokines.

lymphocytes. CCR2 may have a role in COPD, as MCP-1 levels are increased in sputum, BAL fluid and lungs of patients with COPD (see Fig. 70.3) and MCP-1 is expressed in alveolar macrophages and epithelial cells [26,35,46]. MCP-1 is a potent chemoattractant of monocytes and may therefore be involved in the recruitment of macrophages in COPD. Indeed, the chemoattractant effect of induced sputum from patients with COPD is abrogated by an antibody to CCR2. Because macrophages appear to have a critical role in COPD as a source of elastases and neutrophil chemoattractants, blocking CCR2 may be a therapeutic strategy in COPD and small molecule inhibitors are in development.

CCR3

CCR3 are predominantly expressed on eosinophils and therefore have an important role in asthma. In COPD there is a small increase in eosinophils and eosinophil basic proteins in induced sputum and BAL fluid and an increase in eosinophils has been described in exacerbations of chronic bronchitis [10,47,48]. This suggests that eosinophil chemoattractants may play some part. RANTES (released by activated normal T cells expressed and secreted, CCL5) activates CCR3 and is strongly expressed in airway epithelial cells of patients with chronic bronchitis exacerbations [49]. Eotaxin (CCL*) and CCR3 show increased expression

in the bronchi of patients with exacerbations of chronic bronchitis and are correlated with increased numbers of eosinophils [50].

Other CC chemokine receptors

CCR4 and CCR8 are selectively expressed on Th2 cells and are activated by the chemokines macrophage-derived chemokine (MDC, CCL22) and thymus and activation dependent chemokine (TARC, CCL17) [51]. However, Th2 cells are not prominent in COPD so it is unlikely that these receptors are relevant.

CCR7 has a role in the migration of dendritic cells to regional lymph nodes and therefore blocking this receptor might suppress antigen presentation [52]. There is an increase in the number of dendritic cells in rat lungs exposed to cigarette smoke [53,54] and in the airways and alveolar walls of smokers [55,56], but the chemotactic factors involved have not yet been determined. MIP-3 α (CCL20), which acts on CCR6 that is expressed by immature dendritic cells, is potent chemoattractant of dendritic cells and is expressed by airway epithelial cells in response to IFN- γ [57].

CX₃C chemokines

The unique CX₃C chemokine fractalkine, which is tethered to cell surfaces, shows increased expression in human airway epithelial cells after stimulation with IFN- γ and may be involved in recruitment and adhesion of monocytes, T lymphocytes and natural killer cells to epithelial surfaces [58]. Whether fractalkine or its receptor CX₃CR1 are increased in COPD is not yet known.

Therapeutic implications

Chemokine receptor antagonists

Many new approaches to the treatment of inflammation in COPD are now under consideration [7]. Chemokine receptor antagonists are an attractive approach to the therapy of COPD because chemokines have a critical role in the recruitment of the key inflammatory cells, including macrophages (and monocytes), neutrophils and T lymphocytes. However, there is considerable redundancy in the system, so that blocking a specific chemokine receptor may not inhibit the chemotactic response as other chemokine receptors and other classes of chemotactic mediator also aid in recruitment. However, in COPD, a critical feature of the disease is an amplification of the inflammatory response seen in normal smokers, so that the aim of therapy is not

to abolish the inflammatory cells but to reduce them to the numbers seen in normal smokers. No chemokine receptor antagonists have so far been studied in COPD patients and it is only when clinical trials are conducted that the size of the clinical effect can be determined. Studies involving neutralization of IL-8 in sputum indicate that this chemokine accounts for only approximately 30% of the neutrophil chemotactic activity of sputum in COPD patients [15], and that leukotriene B₄ (LTB₄) accounts for a similar proportion, so that when these two chemotactic agents are blocked there is still approximately 50% of the chemotactic activity remaining. Whether this is sufficient to have an impact on clinical parameters such as exacerbation frequency or disease progression will only be determined by expensive clinical trials in relatively large numbers of patients.

Chemokine receptors are an attractive therapeutic target as small molecule inhibitors can be identified by screening and in the future by molecular design as each G-protein coupled receptor has a defined binding cleft for ligand interaction [2]. Several small molecule inhibitors have now been developed but so far none has reached the clinic. Another approach is the use of monoclonal antibodies directed at either the chemokine receptor (preferably) or the chemokine. An antibody to IL-8 has been developed [59] and has recently been in clinical trials in COPD, but the results have not yet been reported.

Chemokine synthesis inhibitors

Another approach to reduce chemotaxis is to inhibit the production of chemokines, although this approach is not specific. Corticosteroids inhibit the transcription of many chemokines through inhibiting the transcription factor NF- κ B. However, there appears to be a resistance to the anti-inflammatory effects of corticosteroids in patients with COPD, so that even high doses of inhaled or oral corticosteroids do not reduce the elevated concentrations of IL-8 in sputum [60,61]. Alveolar macrophages from patients with COPD are also steroid resistant and even high concentrations of corticosteroids do not inhibit the baseline or cigarette smoke-stimulated release of IL-8 [29]. The mechanism for this molecular resistance to corticosteroids is not yet certain, but there is a decrease in the expression of histone deacetylase-2, an enzyme that is critical for switching off inflammatory genes by corticosteroids [62–65].

Theophylline is a bronchodilator through inhibition of phosphodiesterases (PDE) in airway smooth muscle, but at lower concentrations acts as an anti-inflammatory agent through a novel molecular mechanism that involves activation of histone deacetylases [66]. This results in reduced expression of IL-8 in macrophages and epithelial cells. This also leads to increased responsiveness to corticosteroids,

raising the possibility that theophylline may reduce the apparent steroid resistance seen in COPD [67]. Theophylline in low concentrations reduces both neutrophil numbers and IL-8 concentrations in patients with COPD [68], indicating that unlike corticosteroids it has a useful anti-inflammatory action.

Selective inhibitors of PDE4 are now in development as anti-inflammatory therapy for COPD and are effective in inhibiting the synthesis of chemokines such as IL-8 in airway cells. PDE4 inhibitors markedly suppress IL-8 release from human neutrophils [69]. Unexpectedly, IL-8 release from epithelial cells and sputum cells from patients with COPD was not inhibited by a PDE4 inhibitor cilomilast that was effective in reducing TNF- α release [28], indicating that this therapy may not be effective in reducing chemokine expression. Indeed, a recent clinical trial of cilomilast in COPD showed no reduction in IL-8 expression in bronchial epithelial cells [70].

The p38 MAP kinase pathway is involved in expression of many chemokines, including IL-8 [71,72]. Non-peptide inhibitors of p38 MAP kinase, such as SB 203580, SB 239063 and RWJ 67657, have now been developed and these drugs have a broad range of anti-inflammatory effects [73], but they have not been tested in clinical trials in COPD. P38 MAP kinase inhibitors reduce IL-8 expression by epithelial cells by a post-transcriptional mechanism as they do not reduce its gene expression [74].

NF- κ B regulates the expression of IL-8 and other chemokines. NF- κ B is activated in macrophages and epithelial cells of COPD patients, particularly during exacerbations [31,32]. There are several possible approaches to inhibition of NF- κ B, including gene transfer of the inhibitor of NF- κ B (I κ B), a search for inhibitors of I κ B kinases (IKK), NF- κ B-inducing kinase (NIK) and I κ B ubiquitin ligase, which regulate the activity of NF- κ B, and the development of drugs that inhibit the degradation of I κ B [75]. The most promising approach may be the inhibition of IKK-2 by small molecule inhibitors which are now in development [76]. A small molecule IKK-2 inhibitor suppresses the release of IL-8 from alveolar macrophages [77] and might be effective in COPD when alveolar macrophages appear to be resistant to the anti-inflammatory actions of corticosteroids [29].

Resveratrol is a phenolic component of red wine that has anti-inflammatory and antioxidant properties. It has a marked inhibitory effect on IL-8 release from alveolar macrophages from COPD patients who show little or no response to corticosteroids [78]. The molecular mechanism for this action is currently unknown, but identification of the cellular target for resveratrol may lead to the development of a novel class of anti-inflammatory compounds. Resveratrol itself has a very low oral bioavailability so related drugs will need to be developed.

in cystic fibrosis 132
influenza 414, 416, 555
pneumococcal infection 555
and prevention of exacerbations 555
- vagus nerve in cough reflex 92–6, 97, 98, Plate 8.1
- vascular endothelial growth factor (VEGF)
in emphysema 280, 302–3
function 301–2
in lung development 321, 330
and pulmonary vascular changes 76, 111
in smokers 303, 305
as therapeutic target 112, 280
- vascular endothelial growth factor receptors 301, 302, 305, 330
animal models of blockade 343, 849
down-regulation 373
- vasoconstriction, hypoxic 75
- vasointestinal peptide in nasal secretions 514
- vasomotor rhinitis 516, 518
- vastus lateralis
capillarity 29
effect of hypoxia on 32
endurance 31
fibre types and size 28, 51, 462
mass 27
strength 30–1
structural alterations 30
- VATS 637
- VC in COPD 171
- VCAM-1 236–7
- VECAP 44
- VEGF *see* vascular endothelial growth factor
- venous thromboembolism (VTE) 528
clinical manifestations 529–30
and COPD 528–9, 535
electrocardiography 530
history-taking and physical examination 529
imaging 530–1
laboratory tests 530
management of unstable haemodynamics in massive pulmonary embolism 534
pathophysiology 528
prevention 534–5
prognosis 534
treatment 531–4
- ventilation
definition 16
distribution in COPD 15–17
during sleep 80
in COPD 81
in emphysema 16, 17
equations 65
increased demand in dyspnoea 21
measurement in CPET 44
response to exercise 47–8
wasted 15

- ventilation/perfusion (\dot{V}/\dot{Q})
 - in COPD 15–17
 - distribution, assessment by MIGET 102–3
 - during sleep 81
 - and gas exchange 15
 - high abnormality 15
 - low abnormality 15–16
 - matching 75, 313
- ventilation/perfusion mismatch (\dot{V}/\dot{Q} mismatch) 46, 102
 - assessment by MIGET 103
 - in bronchiolitis 109, 110, Plate 9.1
 - in COPD
 - exacerbations 105–8
 - measurement 171–2
 - stable mild to moderate 105
 - stable severe 104–5
 - effects of bronchodilators 108, 679–80
 - in emphysema 109, 110, Plate 9.1
 - in exercise 49, 627
 - and hypoxaemia 106, 624
 - in invasive ventilation 106–8
 - management 626
 - in non-invasive ventilation 106, 107
 - and pulmonary vascular changes 110–12, Plate 9.1
 - type H 104, 105
 - type H-L 104, 105
 - type L 104, 105
- ventilation/perfusion scanning in pulmonary embolism 531
- ventilatory capacity 44
- ventilatory dead space to tidal volume ratio, response to exercise 48
- ventilatory efficiency measurement in CPET 45
- ventilatory failure 63
 - in COPD exacerbations 559
 - in cystic fibrosis 129
- ventilatory rehabilitation units 602–3, 606
- ventilatory reserve (VR)
 - limitations to use 44
 - measurement in CPET 44
- versican 472
- video-assisted thoracoscopy 637
- vimentin 309
- viruses 408
 - childhood infections 412–13
 - classification 408
 - and COPD 546–7
 - in exacerbations 175, 414–16, 549, 730
 - relationship with inflammation and airway remodelling 552
 - role in development of 412–14
 - culture 410, 412
 - detection techniques 410–12
 - effect of *N*-acetylcysteine on 751
 - immunofluorescence 411, 412
 - infection, animal models 346
 - nucleic acid sequence based amplification 411–12
 - and obliterative bronchiolitis 148
 - polymerase chain reaction (PCR) 411, 412, 415
 - respiratory 408–10, Plate 35.1
 - secondary bacterial infection following viral infection 730
 - serology 410, 412
 - as therapeutic targets 416
- vital capacity in COPD 171
- vitamin A deficiency 321, 332
- vitamin C 368, 378, 748, 752
- vitamin D binding protein 442
- vitamin E 371, 376, 378, 748, 752–3
- VLA-4 236–7
- Vr 65
- VR *see* ventilatory reserve
- VRUs 602–3, 606
- V_T *see* tidal volume
- VTE *see* venous thromboembolism
- water brash in gastro-oesophageal reflux disease 503
- Wegener granulomatosis 515
- Westermarck's sign 530
- wheezing
 - in asthma 154
 - in COPD 168
 - in cystic fibrosis 128
 - in obliterative bronchiolitis 150
- Wnt- β -catenin pathway 329
- xanthine/xanthine oxidase system 369
- ximelagatran 533
- Young syndrome 515
- zafirlukast 290, 291
- zanamivir 416
- ZD0892 347, 836
- zileuton 289, 290, 291
