Preface

What is Immunosenescence?

The number of elderly people is steadily increasing in most countries. Concomitantly, the number of age-related diseases is unfortunately also increasing. One of the leading causes of death in the very elderly is infection, with cardio-vascular diseases and cancer less prevalent than in younger elderly. All three major pathologies are to some extent related to the immune system due to its well-known but still imperfectly investigated deregulation during aging.

Thus, the large amount of data accumulated during the last decade or more has allowed a better but still incomplete understanding of all the complex alterations affecting the immune system with aging. Although we do not know everything, we feel that it is important for the scientific community to become more acquainted with the corpus of knowledge recently generated in this domain, presented in a manner providing a critical evaluation of the current status of research. Many accepted ideas have changed during the last decade, such as the effect of aging on the innate immune system, antigen presentation, the cytokine imbalance and low grade inflammation. If not exactly a paradigm shift, the time seems ripe to present this critical evaluation and update of the state-of-the-art in these different areas. We perceive a great need to assemble this current knowledge in one volume by collecting contributions from the most eminent researchers in the field from all around the world. In this way, we aim to facilitate a synthesis of the different aspects of the disparate disciplines in ageing research to focus on immunosenescence for the first time (basic and clinical, molecular, cellular, biochemical, genetics). We hope this multidisciplinary approach from the aging, immunity and inflammation community will also be important for future innovative research in this domain.

Thus, this book will have as its main themes Aging, Immunity and Inflammation, with an emphasis on studies in humans. However, as data are not always available in this species, work in experimental animals will be also treated as appropriate. A large number of colleagues responded enthusiastically to our proposal and contributed with very high quality chapters. We begin with a description of Methods and models for studying immunosenescence. We continue with Cellular immunosenescence, treating most specifically T cells, B cells, neutrophils, antigen presenting cells

and NK cells. We then proceed to mechanisms. In this context, receptor signaling, the role of mitochondrial activity, the proteasome, cytokine status and the neuro-endocrine-immune netweork are treated. The important but very challenging area of the Clinical relevance of immunosenescence for disease states is covered next by the individual treatment of infections, autoimmunity, cancer, metabolic syndrome, neurodegeneration and frailty. Finally, and even more challengingly, the last part of the book is devoted to possibilities for eventual intervention and modulation. We particularly emphasise nutritional aspects, lipids and experimental interventions. In this way we feel that we cover the whole range of areas from models, through basic molecular mechanisms to the clinical relevance and finally eventual modulation.

One of the main objectives of this book is to present in a systematic way our current knowledge in the field of the immunology related to aging. So do we now know what immunosenescence is? It is still difficult at answer this question, but we hope even the most specialist investigator in the field will find concepts and ideas within the book which will help him or her to approach an answer to this important question more closely than before. We would therefore sincerely like to hope that we have created an authoritative, innovative and thought-provoking book dedicated for the first time to this topic alone. We also like to hope that this volume will help to attract a new generation of researchers to the field of immunosenescence as an expanding and vital research arena.

Tamas Fulop — Quebec, Canada
Claudio Franceschi — Bologna, Italy
Katsuiku Hirokawa — Tokyo, Japan
Graham Pawelec — Tübingen, Germany

Contents

Cellular Immunosenescence - B Cells

Cellular Immunosenescence - Neutrophils

Cellular Immunosenescence - Antigen Presenting Cells

Cellular Immunosenescence - NK and NKT Cells

Methods and Models for Studying Immunosenescence

The Immune Risk Profile and Associated Parameters in Late Life: Lessons from the OCTO and NONA Longitudinal Studies

Anders Wikby, Jan Strindhall and Boo Johansson

Contents

Abstract: The OCTO Immune Longitudinal Study is a population-based study of ageing in a sample of 102 Swedish octogenarians with the aim to explore age changes of the immune system using a sample selected for good health. Data collection was performed in 1989, 1990, 1991 and 1997. An Immune Risk Profile (IRP) associated with increased mortality was characterized by high CD8+, low CD4+ T-cell counts and a poor T-cell proliferative response, inversion of the CD4/CD8 ratio and evidence of persistent cytomegalovirus infection was identified. The subsequent NONA Immune Longitudinal Study of 138 Swedish nonagenarians was performed in 1999, 2001, 2003, and 2005, not excluding individuals due to compromised health. The overall aim was to examine predictive factors for longevity and to further investigate in greater depth the immune risk profile identified in the OCTO Immune Study in the context of functional and disability parameters also examined

in the NONA. The immune panel included the analysis of T-cell subsets, inflammatory markers, virus serology, cytokines, TCR clonotype mapping, and functional and phenotypic analysis of virus specific CD8+ cells by HLA/peptide multimers, in collaborations between participants of the EU funded T-CIA project.

The present chapter report findings from the longitudinal studies of Swedish octo-nonagenarians with focus on IRP and its associations with persistent virus infection, CD8+ T-cell differentiation, cytokines, cognitive functioning, inflammatory activity, virus specific CD8+ cells, CD8+ T-cell clonal expansions and longevity. It also reports on low grade inflammation processes of importance in predicting longevity in the very late life.

Keywords: Immune risk profiles • Immunosenescence • Longitudinal studies • T-cells

1 Introduction

The very old constitute the fastest growing age segment in developed countries. From a societal and population perspective, this demographic trend is also accompanied by an increase in the number of very old individuals with compromised health and significant requirements for service and health care. From a physiological perspective, the robustness of the immune system is particularly important in this age segment, considering the fact that the incidence of death due to infection diseases seems to continue to increase although mortality related to cardiovascular disease and cancer may level off in many populations (Vasto et al. 2007).

Immune studies of elderly populations, however, so far have mainly been conducted on individuals in their 60s and 70s. Few studies have focused on samples over 80 years and still fewer have employed longitudinal designs that allow studies of intra-individual change (Pawelec et al. 2005). In the Swedish OCTO and NONA Immune Longitudinal Studies (Wikby et al. 1994, 2002), we deliberately examined individuals in very late life because of the substantially elevated risk for compromised health, morbidity, and mortality. The overall aim was to provide better understanding of processes and mechanisms related to intra-individual change in various parts of the immune system regulation in very late life. An aim was also to identify presumptive predictors for subsequent mortality and clinical parameters related to the substantial morbidity/comorbidity observed in late life. From a clinical perspective detection of predictive markers may enable interventions that could assist in various improvements of quality of life for individuals in this rapidly growing age segment.

The OCTO Immune Longitudinal Study is a population-based study of ageing and the immune system in a sample of Swedish octogenarians (Wikby et al. 1994). It was started in 1989 in Jönköping, Sweden, as a collaboration between researchers at the Institute of Gerontology and the Department of Natural Science and Biomedicine, School of Health Sciences, Jönköping University, the Department of Micro-

biology, Hospital of Ryhov, Jönköping and the Department of Veterinary Science, Penn State University, USA and ended in 1997 when the vast majority participants were deceased. The subsequent NONA Immune Longitudinal Study of nonagenarians was initiated in 1999 to extend and refine findings from the OCTO Immune Longitudinal Study identifying an Immune Risk Profile (IRP) associated with an elevated mortality rate (Wikby et al. 2002). The NONA immune also became part of the EU supported programs *Immunology and Ageing in Europe, ImAginE,* (Pawelec, Caruso 2003) and *T cell immunity and ageing, T-CIA,* (Koch et al. 2005) creating collaborations between the NONA immune researchers and several European laboratories participating in these networks. The OCTO-NONA Immune Longitudinal Studies have investigated predictive factors for longevity with focus on immune risk profiles in a context of functional and disability health parameters of importance in late life. The present review summarizes some of the main findings and lessons learned from these studies.

2 Methodological Design and Sampling Considerations in Ageing Studies

2.1 Design Considerations

First we address the significant design and sampling considerations that directed our research. The two methods used in population-based studies of ageing are the cross-sectional and longitudinal designs (Wikby et al. 2003). The most common design is the cross-sectional, in which two or more age groups are compared at a single occasion. Age changes are typically inferred from the observed age differences in mean values. This design provides a procedure that is logistically easy and fast and less expensive than the longitudinal design. However, great caution is necessary in the interpretation of cross-sectional data since age differences may be confounded by the fact that birth-cohorts have been exposed to various environmental exposures and socio-cultural influences (Wikby et al. 2003; Pawelec 2006). Another confound that become more of an issue with age is that of selective mortality (Wikby et al. 2003). As a study population ages it becomes gradually more selected, since deaths do not occur at random. For example, if a high value in a variable is deleterious, death is likely to occur first in individuals with high values and last in individuals with low values. In a cross-sectional study an observed difference in mean values between age groups may be incorrectly interpreted as a real age change rather than as an effect of selective mortality. Many studies have characterized changes in the immune system with age, but a number of these have yielded conflicting results, partly due to the fact that the vast majority of these studies are cross-sectional (Wikby et al. 2003).

In a longitudinal design (Wikby et al. 2003) individuals are followed across time, usually with a number of years in between measurement occasions. This allows

the detection of intra-individual change and minimizes many of the confounding artefacts likely to emerge in the cross-sectional design. Although the longitudinal design represents the superior alternative for conducting ageing research, the use of this design has been very limited, particularly in studies of the immune system. The main reason is that such studies are expensive and require considerable effort, financial support, and commitment of personnel. In addition, longitudinal studies require careful coordination, standardised procedures, and control of studied panels to avoid dropouts. A main caution to note in the use of a longitudinal design is the involvement of a possible confounding between age and time of measurement effects. Time of measurement confounding includes numerous factors, such as the motivation and interest of the participating subjects, experimenter effects including changes in personnel and their motivation, and in the methods, techniques and essays used across time. Many of these problems can be compensated for by including a younger group for comparisons across measurement occasions. The immune system changes that occur across times of measurement will then be negligible in the healthy young people compared to the very old. Also, restricted time periods between the measurements and the use of identical methods will prevent time of measurement effects.

2.2 Sampling Considerations

Advancing age is typically accompanied by an increased prevalence of compromised health and diseases (Jeune 2002). This is one of the primary problems in the selection and definition of a sample in population-based studies of ageing. To overcome this problem, most studies have used various selection schemes to exclude individuals with underlying diseases from participation in studies of the immune system. The stringent *SENIEUR* Protocol (Ligthart et al. 1984) represents an example of a widespread application of a set of exclusion criteria used to select individuals in good health, to be able to distinguish between age changes caused by *primary ageing* and *secondary ageing*, i.e. by diseases. Noteworthy, the exclusion of *non-SENIEUR* individuals will, however, result in a study of less than 10% of a population among individuals aged over 80 years and older (Pawelec et al. 2001). Another way to diminish confounding between primary ageing effects and disease has been to employ exclusion criteria tailored to the experimental situation (Hallgren et al. 1988), i.e. in immune studies to exclude individuals that have immune related diseases or who use drugs that affect the immune system. Such a strategy was used in the OCTO Immune Longitudinal Study but will also generate a select sample. In our case, about 50% in a population aged over 80 years were excluded (Wikby et al. 1994).

A way to overcome some of the selection problems is to examine a population-based sample, combined with careful continuous evaluation of individual health parameters (Nilsson et al. 2003). This was the approach taken in the NONA Immune Longitudinal Study. The clinical variables needed for the evaluation of

individual health and morbidity are then of considerable value in the comparison of findings from the application of various protocols and in the categorization of individuals into subgroups according to their health status (Nilsson et al. 2003). Thus, the significance of a change in health status is included rather than excluded as an important consideration in these aging studies.

3 The OCTO and NONA Immune Longitudinal Studies

3.1 The OCTO Immune Study

The OCTO Immune Longitudinal Study was an integrated part of the OCTO Longitudinal Study of biobehavioral ageing, in Jönköping, Sweden. The municipality of Jönköping has 122 000 inhabitants and is situated in South-central part of Sweden. The aim of the OCTO immune was to explore age changes in the immune system in Swedish octogenarians relative to an array of medical, biobehavioral, and social variables (Wikby et al. 1994).

Census data was used to identify octogenarians living in Jönköping and born in 1897, 1899, 1901, and 1903. A non-proportional sample that composed of 100 persons in each of the birth-cohorts was recruited. From these 400 individuals, 324 were examined in the first wave in 1987/1988 of the OCTO study. The persons were then at the ages of 84, 86, 88, and 90 years old. At the second wave of the study, the OCTO Immune Longitudinal Study was initiated. Of the 324 examined at baseline of the OCTO, 96 were deceased before the start of the second wave of this study. Another 15 declined to participate, giving a total number of potential participants of 213 for the OCTO immune.

Exclusion criteria were set to diminish confound between ageing, disease, and medications and to secure reliable psychosocial self-reports. Potential candidates were included if they:

- Were noninstitutionalized
- Had normal cognition according to neuropsychological tests (Johansson et al. 1992)
- Were not on a drug regimen that may influence the immune system.

These exclusion criteria were similar to those of Hallgren et al. (1988). Of the potential 213 individuals, 110 met inclusion criteria. Of these, 102 individuals participated in the first wave. Sixty-nine individuals were available throughout the three waves in the longitudinal analysis and 23 participated in the longitudinal analysis over all four time-points, T1 (1989), T2 (1990), T3 (1991), and T4 (1997) (Table 1). Nonparticipation at the various measurement occasions was mainly due to mortality in the sample. Fourteen healthy middle-aged volunteers (39 years SD±5.8) of men and women working in the laboratories at Ryhov Hospital in Jönköping were included across the measurement occasions for comparative reasons.

Table 1 Characteristics of individuals included in the OCTO Immune Longitudinal Study

Occasion (Time)	Year	Number of individuals investigated	Age (years)	
			Mean	Range
1	1989	102	88	86–92
2	1990	83	89	87–93
3	1991	69	90	88–94
4	1997	23	95	94–100

The very old individuals were examined in their place of residence. Blood samples were drawn in the morning between 8:00 and 10:00 (a.m.). The following immune system parameters were investigated:

- Complete blood cell count
- Differential WBC count
- Antibody defined T and B cell surface molecules using three colour flow cytometry
- Proliferative response of PBMC using a mitogen stimulation assay with ConA in cell culture
- Interleukin 2 production
- Cytomegalovirus (CMV) and Herpes simplex serology.

3.2 The NONA Immune Study

Findings from the OCTO Immune Longitudinal Study constituted the background for the subsequent ongoing NONA Immune Longitudinal Study of nonagenarian individuals also living in the municipality of Jönköping (Wikby et al. 2002). The NONA immune is an integrated part of the NONA Longitudinal Study initiated to examine the disablement process in late life. The overall aim in the NONA immune is to examine predictive factors for longevity in the very old and to further investigate in greater depth the immune risk profile identified in the OCTO immune. The aim is also to consider immune data in the context of functional and disability parameters examined in the overall NONA. The overall study includes measurements of the following functional and disability domains:

- Physical and mental health
- Cognitive functioning
- Personal control/coping
- Social networks
- Provision of service
- Care and everyday functioning capacity.

The NONA immune examines a population-based random sample without excluding individuals due to compromised health, but to include a continuous evaluation of various individual health parameters (Nilsson et al. 2003). Individuals

were drawn from the population (census) register of Jönköping. A nonproportional random sampling procedure was employed, including all individuals permanently residing in the municipality, with the goal to have individuals aged 86, 90, and 94 years old. The sampling frame was defined on the available census information in September 1999. As the number of available subjects in the oldest birth cohort was limited, a few subjects were also included from the birth cohorts of 1904 and 1906. Blood samples for the immune system analysis were drawn in 138 individuals, of whom 42 belonged to the oldest birth cohort, 47 were 90-years, and 49 86-years old. Data collections were made using two-year inter-occasion intervals in 1999, 2001, 2003, and 2005.

The mean age of the sample at baseline was 89.8 years with a total proportion of women of 70%. While about 60% of them lived in an ordinary housing, 40% resided in a sheltered housing or in institution. A comparison between individuals who participated in the in-person testing part of the NONA study (n=157), and those who accepted that blood was drawn (n=138), indicated no significant differences for demographics or overall ratings of physical and mental health. In the second wave, 61% of individuals participated, at the third 40%, and at the fourth only 22%. Nonparticipation at the various measurement occasions was mainly due to mortality. A younger group of 22 healthy middle-aged men and women working at the Ryhov Hospital in Jönköping participated (mean age 44.7, SD=8.9 at baseline) across measurement occasions for the sake of comparison. Characteristics of the individuals participating in the NONA Immune Longitudinal Study are summarised in Table 2.

Health was defined based on medical records and from clinical chemistry data, supplemented with information gathered in a health interview that focused on diagnosed illness, current symptoms, and use of medications (Nilsson et al. 2003). The neuropsychological battery used to identify cognitive impairment included the Mini-Mental State Examination (MMSE) and the Memory-In-Reality (MIR) test (Folstein et al. 1975, Johansson 1988/1989). MMSE is a screening device used in epidemiological studies to identify cognitive impairment. The MIR test comprises of a naming condition for 10 common real-life objects, followed by showing a three-dimensional model of an apartment. The participants are then asked to place the objects in the different rooms according to personal preferences. Following a distraction, a recall test is administered, followed by a recognition task for items not recalled. In the NONA Immune Longitudinal Study we used the following three

Table 2 Characteristics of the subjects participating in the NONA Immune Longitudinal Study

Occasion (year)	No. of subjects investigated	Proportion of women (%)	Age (years)	
			Mean	Range
1999	138	70	89.8	86–95
2001	84	69	91.6	88–97
2003	55	69	93.2	90–99
2005	31	81	94.7	92–101

cognitive status categories: 1) cognitive intact, 2) mild cognitive dysfunction or questionable cases (MCD, evidence of compromised memory/cognition, not fully meeting DMC-IV criteria for dementia, APA, 1994), and dementia (according to DMS-IV criteria, APA 1994). The two latter diagnostic categories were pooled under the category of "cognitive impairment" and compared with those rated as cognitively intact.

Subjects were examined in their place of residence by trained Registered Nurses with extensive experience of working with the elderly. The tests and interviews took about 3 hours, including breaks, for individuals who were able to participate in all parts. The blood samples were drawn in the morning between 09:00 and 10:00. The following immune and clinical components are studied in the NONA Immune Longitudinal Study:

- Complete blood cell count
- Differential WBC count
- Proteins, albumin, transthyretin, C-Reactive Protein, orosomucoid, haptoglobulin,
- IgG, IgM, IgA, urea, cystatinC, creatinine as indicators of malnutrition, inflammation or kidney disease
- Antibody defined T-cell surface molecules of T, NKT, NK cell populations, using three colour flow cytometry
- Secretion of cytokines, IL-2, IL-6, IL-10, interferon-gamma
- CMV, EBV and Herpes simplex serology
- MHC/peptide tetramers to analyze the number of CMV and EBV specific CD8+ cells
- TCR clonotype mapping with Denaturing Gradient Gel Electrophoresis (DGGE), including RNA extraction, cDNA synthesis and amplification by use of a primer panel amplifying the 24 BV region families covering a majority of TCR's. The resulting DNA fragments are separated by DGGE and expanded clones are identified as distinct bands on a gel (thorStraten et al. 1998).

4 Results and Discussion

4.1 The OCTO Immune Study

In the OCTO Immune Longitudinal Study we were able to identify an immune risk profile by multiple comparisons of individuals grouped by homogeneity of certain combinations of adaptive immune system parameters (Ferguson et al. 1995). These cluster analysis use profile similarities to group individuals when the number and nature of the groups are not known in advance, ideal in the exploration of complex systems like the immune system. The analysis was employed to determine groups based on immune functioning and T-cell subpopulations using the mitogen response to Concanavalin A, and the percentages of CD3, CD4, CD8, and CD19 positive cells. The groups identified by cluster analysis were then compared with respect

to their impact on survival-non-survival by chi-square analysis. This analysis of immune data at baseline revealed an Immune Risk Profile (IRP) predictive of subsequent 2-year mortality (Ferguson et al. 1995). An IRP cluster, designated cluster 1, was characterized by immune parameters that consisted of high levels of CD8+ T-cells, low levels of CD4+ and CD19+ T-cells, and poor proliferative mitogen response to ConA (Table 3). No such association could be found using common methods for univariate analysis.

The result demonstrated that additional individuals developed the IRP by increases in the CD8+ cells as well as decreases in the CD4+ cells and CD4/CD8 ratio between baseline and a 2-year follow-up (Wikby et al. 1998). At that time the IRP individuals again were found to have increased subsequent 2-year mortality. Interestingly, we found that the IRP could be defined by using only the inverted CD4/CD8 ratio, since this sole marker was strongly associated with the IRP defined by the cluster of parameters (Wikby et al. 1998).

The results also showed that 31% individuals out of the 102 participating either had at baseline (16%) or developed (15%) an Immune Risk Profile during the 8-year longitudinal period of the study (Olsson et al. 2000). Noteworthy, individuals who belonged to the IRP category at baseline or moved into that category over the 8 years never moved out from this elevated mortality risk group (Olsson et al. 2000).

Although the significance for changes leading to a skewed CD4/CD8 ratio in the IRP was not well understood at the time of our initial exploration, the relationship observed between a reduced functional immune response and mortality had indeed been described in several previous studies. It was reported in humans that with age the lack of a response to three mitogens: the T-cell mitogens concanavalin A, phytohemagglutin, and the T-dependent B-cell mitogen, pokeweed, were associated with increased mortality (Murasko et al. 1987). In another study of individuals older than 80 years of age, it was found that anergic aged individuals had a 2-year mortality rate of 80% compared to 35% in those who were nonanergic (Roberts-Thomson et al. 1974). A third study examined the relation between anergy and all cause mortality in healthy individuals above 60 years of age (Wayne et al. 1990). The study showed that anergy, defined as a decreased delayed type hypersensitivity (DTH) response in a skin test to four common recall antigens, was associated with nonsurvival.

Since our study at baseline did not analyse subsets of CD4 and CD8 T-cells on the basis of other phenotypic markers, the changes in the CD4/CD8 balance in IRP individuals was not well characterized. In 2000 various subsets of CD4 and

Table 3 Statistical description of variables used in the formation of a three cluster solution

Cluster (n)	Mitogen response/DPM	CD3+/%	CD4+/%	CD8+/%	CD19+/%
1 (14)[a]	11077 (8413)[b]	62.6 (14.8)	30.8 (4.3)	43.3 (8.9)	5.5 (2.6)
2 (36)	16915 (11491)	75.6 (7.6)	47.9 (12.1)	26.5 (5.9)	8.4 (4.1)
3 (39)	29681 (14427)	54.5 (12.3)	42.4 (9.8)	20.5 (6.9)	12.5 (7.1)

[a] IRP cluster predicting non-survival
[b] Mean (SD)

CD8 were therefore included in the study (Olsson et al. 2000). The results indicated immune system changes that suggested a loss of T-cell homeostasis, as reflected by a substantial increase in the number of CD8 cells with parallel decrease in the number of CD4 cells in individuals with an inverted CD4/CD8 ratio. The changes were apparent in a number of T-cell subsets, with significant increases in the levels of CD8+CD28- cells, in particular, demonstrating that differentiated effector/memory CD8+ cells are disproportionately represented in this cell population. These cells has been shown by others have shortened telomers, suggesting an extensive history of replication (Effros 2007). Initially it was surprisingly found that these homeostatic T-cell changes associated with an inverted CD4/CD8 ratio was associated with persistent CMV infection, prevalent (90%) in the very old (Olsson et al. 2000). Importantly, our studies showed no evidence of a relationship of these T-cell changes and other viruses, Herpes simplex and Epstein Barr viruses, indicating an unique impact of CMV on the immune system. This result was unexpected since the carriage of CMV had long been considered to be quite harmless to individuals with a functional immune system. The finding thus suggested that the changes in the T-cell balance among IRP subjects at least partly is produced by the generation of CD8+ effector/memory cells against persistent CMV infection and subsequent homeostatic decreases in the CD4+ and CD4/CD8 ratio. This conclusion was supported by tetramer technology demonstrating significant expansions of CD8+ T-cells specific for the CMV_{NLV} peptide in HLA-A2 individuals to be associated with both age and the IRP (Ouyang et al. 2004).

4.2 The NONA Immune Study

Results from the OCTO Immune Longitudinal Study provided the basis for the subsequent Swedish NONA Immune Longitudinal Study (Wikby et al. 2002) and potentials to further advance and refine our knowledge about various predictive factors for longevity but still with special focus on the Immune Risk Profiles (IRP's). The NONA sample provided a broader set of functional and disability parameters, including morbidity, cognitive impairment and chronic viral infection, to be examined in relation to longitudinal changes in inflammatory parameters, the CD8+ T-cell phenotype and differentiation, and CD8+ T-cell clonal expansion.

4.2.1 Immune Parameters and Morbidity

Studies of the immune system in very old individuals are most commonly performed on highly selected samples by the use of selection protocols excluding individuals with conditions that influence the immune system (Nilsson et al. 2003). Among a great variety of protocols the SENIEUR protocol represent the most commonly used and accepted with a comprehensive set of health and laboratory criteria for sample selection aiming at the distinguishing between ageing per se and

those associated with morbidity (Lighthart et al. 1984). Another selection protocol used in the studies of ageing and the immune system, used in the Swedish OCTO Immune Longitudinal Study, is that proposed by Hallgren et al (1988). This protocol excludes individuals with diseases and other conditions known to affect specifically the immune system to tailor the study to its particular purpose. In the NONA Immune Longitudinal Study a slightly modified SENIEUR and Hallgren protocol were used to characterize the sample according to health status (Nilsson et al. 2003). This permitted us to distinguish subgroups of very healthy, moderately healthy and frail individuals for various immune system parameter comparisons.

The modified SENIEUR protocol excluded 90.6% of the NONA immune sample at baseline, indicating that only 9.4% were rated as *very healthy*. The use of the original protocol, suggesting additional laboratory analysis for exclusion, would probably have excluded even more individuals, demonstrating the need for using less stringent criteria in studies of the immune system in later life to avoid studies of only highly selected, nonrepresentative samples. Thirty-eight (27.5%) participants, selected from those being not very healthy and defined as *moderately healthy*, met the criteria used in the previous OCTO Immune Longitudinal Study of not residing in an institution, not being demented, and not using medication known to affect the immune system. The remaining sample (63%) comprised *frail* individuals not meeting the above health criteria (Nilsson et al. 2003).

Applying the five most common exclusion criteria, cardiac insufficiency, medication, laboratory data, urea and malignancy, the modified SENIEUR protocol excluded 87% of the original sample (Nilsson et al. 2003). When the OCTO Immune protocol was applied, medications was found to be the most common criterion, excluding 43%, institutionalisation the second, excluding 39%, and cognitive dysfunction the third, excluding 14%. Among various diseases conditions cardiac insufficiency (51%), malignancy (15%), dementia (14%), chronic obstructive pulmonary disease (12%), diabetes mellitus (11%), rheumatoid arthritis (9%), hypothyroidism (6%) and pernicious anaemia (6%) constituted the eight most prevalent diagnoses. These figures demonstrate the considerable prevalence of morbidity and comorbidity in a representative sample of very old individuals (Nilsson et al. 2003).

A comparison of the number of T-cells across the subgroups of very healthy, moderately healthy and frail indicated no group differences for subsets characteristic of the immune risk profile, previously identified in octogenarians (Nilsson et al. 2003). Interestingly, the IRP might thus serve as a significant biomarker of ageing, independent of overall health status. This is further confirmed by results demonstrating that clusters of immune markers can predict longevity in noninbred mice independently of health conditions (Miller 2001).

4.2.2 Immune Risk Profile, Cognitive Impairment and Mortality

Prevalence and incidence of cognitive impairment and dementia become substantial in very old people. Studies have shown that compromised cognition is significantly related to proximity of death by a twofold increased mortality risk among demented

octogenarians and nonagenarians (Johansson and Zarit 1997; Wilson et al. 2003). There is also considerable evidence suggesting interactions between the nervous and innate immune systems, in which cytokines have a central role as communicators (Wilson et al. 2003). Studies have suggested that higher levels of interleukin 6 (IL-6) are significantly associated with poorer cognitive function and predict future cognitive decline among the elderly (Marsland et al. 2006). In pathological conditions such as ischemia and Alzheimer's disease, microglia cells in the brain seem to respond to injury by producing increased levels of particularly the proinflammatory cytokines interleukin 1 (IL-1) and the multifunctional IL-6 (Tarkowski 2002).

Analysis of mortality in the very old NONA immune individuals (n=138) confirmed our previous findings in the OCTO Immune Longitudinal Study of an approximately twofold mortality rate in the 22 (16%) individuals with an IRP, i.e. showing a significantly higher relative 4-year mortality (77%) than those who were non-IRP individuals (43%), a finding suggesting that the IRP concept could be generalized to the more broadly defined NONA sample (Wikby et al. 2005). The findings was also in line with the Healthy Ageing Study in the Nottingham/Cambridge area in the UK in which it was found that an inverted CD4/CD8 ratio is predictive of nonsurvival in older adults (Huppert et al. 2003).

Our results also supported previous findings in samples of octogenarians and nonagenarians of a twofold elevated mortality risk in individuals with cognitive impairment (Wikby et al. 2005). Among the NONA Immune individuals (n=138), those who were categorized as cognitively impaired (29%) also showed a significantly higher 4-year mortality (75%) compared with cognitively intact individuals (39%). Moreover, the results showed that the two conditions of IRP and cognitive impairment independently predicted survival also when age, sex and various kinds of prevalent diseases and comorbidity were controlled for (Wikby et al. 2005). This provided further support for the previous findings that IRP constitute a major predictor of nonsurvival in very late life independently of morbidity. Only 9% of the NONA Immune individuals conformed to the SENIEUR criteria for optimal health (Nilsson et al. 2003).

4.2.3 Allostatic Load

The concept of allostatic load was proposed by McEwen and Stellar as a measure of dysfunctions across multiple physiological systems, suggesting that the cumulative dysfunctions may have more than an additive impact on overall health and survival (McEwen and Stellar 1993). Allostatic load derives from the concept of allostasis which in turn is derived from homeostasis (McEwen 2003). Allostasis, however, focus more specifically on the challenges upon the specific regulatory nervous, immune and endocrine systems in order to adapt to maintain balance though changes in various psychosocial or physical situations, like stress, in life (Karlamangla et al. 2002). Although such processes may be adaptive in the short term, they are likely to be damaging when becoming excessive in duration, frequency and magnitude (McEwen 2003). This line of thinking correspond to the growing interest to identify

more comprehensive measures that incorporates multiple risk factors that may predict subsequent health and survival (Karlamangla et al. 2006).

In the NONA Immune Longitudinal Study we identified a small sample (n=8) with both IRP and compromised cognitive status at baseline (Wikby et al. 2005). A Kaplan-Meier survival analysis revealed that these individuals showed a significantly higher annual mortality rate (42%/year) compared with those with one of the conditions (15%/year) as well as with those having none (8.5%/year), corresponding to relative mortality rates of 5:2:2:1 (Fig. 1). These observed mortality effects indicates immune and central nervous system interactions, and were integrated into the general framework of allostatic load, since survival data suggested that the cumulative dysfunctions across the nervous and immune systems had more than an additive impact on survival (Wikby et al. 2005).

The allostatic load in IRP individuals with cognitive impairment was associated with changes in the levels of the cytokines IL-2 and IL-6 (Wikby et al. 2005). Cytokines in general are considered to have a central role in the mediations of allostasis by communications between the nervous, immune and endocrine systems (McEwen 2003). A suppression of the T-cellular function in IRP individuals is supported by our finding of poorer IL-2 responsiveness in those individuals compared with non-IRP's (Wikby et al. 2005). A further decline of this responsiveness in IRP individuals with cognitive impairment support the existence of an interaction between the nervous and peripheral immune system dysfunctions with a further down-regulation of the T-cellular response in these persons. Excessive increases in the plasma levels of the proinflammatory cytokine IL-6 did also represent changes characteristic of an allostatic load in the individuals and might have contributed to the T-cellular suppression by acting as an immunosuppressant via the hypothalamic-pituitary-adrenal axis (Wikby et al. 2005).

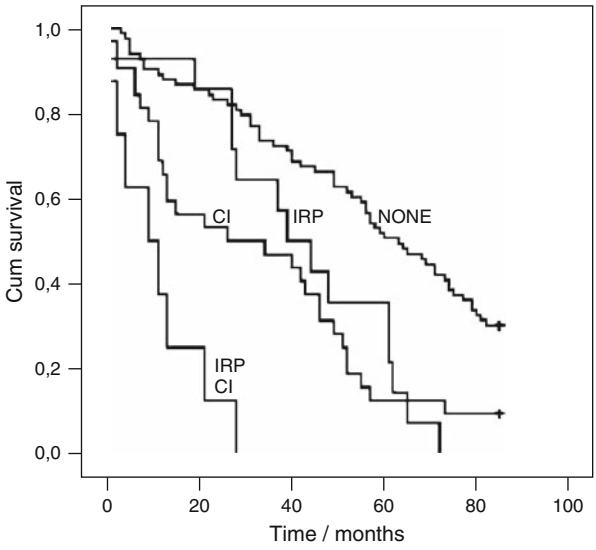

Fig. 1 Kaplan Meier survival curves for NONA individuals in subgroups created by IRP status combined with cognitive status. The subgroups were: "IRP, CI" (IRP, cognitively impaired); "CI" (cognitively impaired, non-IRP); "IRP" (IRP, cognitively intact); "NONE" (non-IRP, cognitively intact). Test for equality of survival distribution for the subgroups showed, p<0.001

4.2.4 IRP, T-cell Differentiation and Persistent Viral Infection

Baseline results also confirmed findings from the OCTO immune study that showed an association between the IRP and the prevalence of persistent CMV infection (Wikby et al. 2002). As for the OCTO immune study, the NONA study demonstrated a CD3+CD8+CD28-phenotype as markedly expanded for IRP and CMV-positive individuals. This led us to examine the T-cell differentiation in more detail, using the CD45RA+, CCR7+, CD27+ and CD28+ markers in a sequential model, suggesting a positive expression for naive cells, gradual losses of the markers in the various memory stages and negative expression for lately differentiated effector/memory cells (Appay et al. 2002, Akbar, Fletcher 2005). A final differentiation step occurs by reversion of CD45RO+ to CD45RA+ to obtain CD27-CD28-CCR7-CD45RA+ terminally differentiated cells of effector type (Wallace et al. 2004).

Our results suggested major decreases in the number of naive cells in the very old, changes that were even more pronounced in IRP individuals (Fig. 2). The results also showed significant increases in the number of CD8+CD27-CD28-CCR7-perforin+ effector/memory and effector cells in IRP individuals (Fig. 2) and since a majority of these cells also were CD45RA+, data confirmed that the IRP is strongly associated with increases in the number of terminally differentiated effector cells. Recent evidence suggests that increased proportions of terminally differentiated CD8+ cells possess characteristics of replicative senescence, including telomere shortening and apoptosis-resistance (Effros 2007). The inclusion of high proportions of senescent T-cells in the IRP may for the first time provide clinical confirmation of the Hayflick Limit theory of human ageing (Effros 2004). The clinical relevance for the prevalence of large amounts of senescent CD8+ T-cells has also been demonstrated by three independent studies performed on different elderly populations (Goronzy et al. 2001; Saurwein-Teissl et al. 2002; Trzonkowski et al. 2003. These studies showed consistently that a diminished antibody response to influenza vaccination is significantly associated with having high proportions of a population of CD8+ cells that lack expression of the costimulatory molecule CD28.

Evidence for a major impact of CMV in generating terminally differentiated CD8+ cells was demonstrated in the OCTO subjects by tetramer technology and was also confirmed in the NONA Immune Study (Reker-Hadrup et al. 2006). We found CMV_{NLV} specific expansions, mainly composed of terminally differentiated cells, in the range 1–20% of total CD8+ cells, similarly to findings in the OCTO Immune Study. Increases in the CMV_{NLV} percentages were associated with decreases in the IFN-γ responsiveness, suggesting that the accumulation of CMV-specific T-cells is a result of compensatory mechanisms to control CMV to balance the compromised functionality that occur with increasing age (Reker-Hadrup et al. 2006). Recent findings have indicated a failure in this control by indicating that the aged immune system is unable to control CMV and EBV, supporting the view that the expansion of virus-specific CD8+ T-cells might be due to increased herpes virus reactivation and replication (Stowe et al. 2007).

The NONA immune results also support the suggestion that besides CMV infection, persistent EBV infection plays a role as bystander associated with the

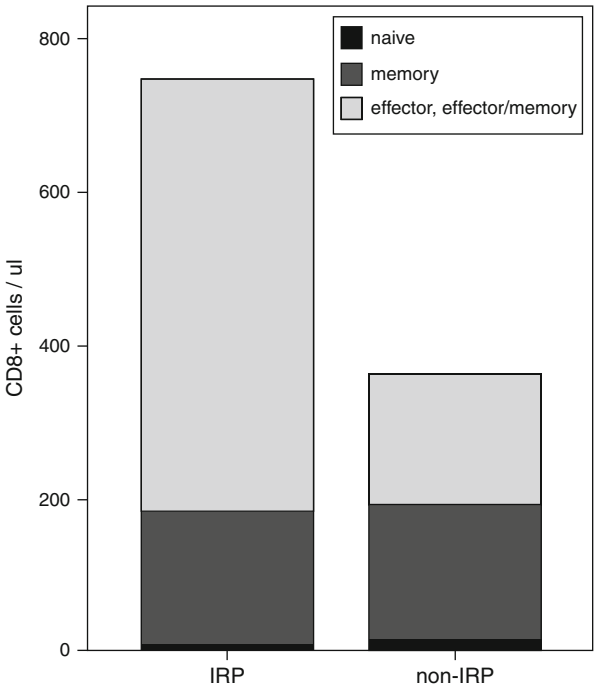

Fig. 2 Mean number of CD8+ T-cells (per µl) and subsets of CD8+ differentiation in IRP and non-IRP NONA individuals. Naïve cells were identified as CD8+CD45RA+CCR7+ cells, memory cells as CD8+CD28+CD27+ CD45RA-, CD8+CD28+ CD27-, CD8+CD28-CD27+ cells, and effector, effector/memory cells as CD8+CD28-CD27-CCR7- cells. The number of effector, effector/memory cells was significantly ($p<0.001$) higher in IRP individuals compared with non-IRP individuals

IRP (Wikby et al. 2005). IRP individuals were in all cases double sero-positive, suggesting that chronic viral load in the very old might contribute to the development of an IRP. Increased numbers of lately differentiated CD8+ cells, characteristic of the IRP, was also found particularly in double sero-positive individuals, to a less but significant extent in those being infected with CMV only, and to a low extent in individuals only infected with EBV (Wikby et al. 2005). In line with this we found significant expansions of EBV_{GLC} specific CD8+ cells; although their frequency was tenfold lower than for the CMV-specific cells (Ouyang et al. 2003).

4.2.5 TCR Clonotype Mapping

Clonal expansions have been detected in healthy old individuals and accumulating evidences suggest that that these expansions are associated with chronic antigen stress induced by persistent viral infections (Khan et al. 2002). We analysed the CD8+ T-cell clonal composition in NONA immune (n=39) and middle-aged (n=9) individuals using TCR clonotype mapping (Reker-Hadrup et al. 2006). The method combines RT-PCR and denaturing gel electrophoresis (DGGE) for rapid detection and characterization of T-cell clonal expansions by use of specific primers covering a vast majority of TCRBV 1–24 variable regions (thor Straten et al. 1998). With a polyclonal T-cell population a nondistinct smear in the denaturing

gradient gel is seen while, in contrast, a population of clonally expanded TCR is seen as a distinct band. The clonal expansion were quantified by staining with anti-TCR-BV mAbs showing that for an individual CMV_{NLV} specific clone to be detected as expanded, the clone exceeds at least 1% of the CD8+ repertoire Reker-Hadrup et al. 2006).

The mean number of expanded clones was significantly higher in nonagenarians compared with the middle-aged (Fig. 3), suggesting a considerable impact of CD8+ clonal expansions in the very old (Reker-Hadrup et al. 2006). Importantly, these clonal expansions were also found to be stable across a two-year period of time. The results also showed a very strong association between the number of expansions and persistent CMV infection (Fig. 3), suggesting that a vast majority of CD8+ clonal expansions in the elderly are derived from CMV. Direct evidence for this was also demonstrated, since the sorting of CMV_{NLV} specific cells and subsequent TCR clonal mapping revealed that this specific T-cell population was oligoclonal with a mean number of six CMV related clone types (Reker-Hadrup et al. 2006). These results are comparable with findings showing that when a broad range of CMV epitopes was studied by tetramer technology, the aggregated percentages of the specific cells were more than 10% and as high as 50% of the total number of CD8+ cells (Moss and Khan 2004). Such substantial accumulations of CMV specific cells in a limited number of clones may reduce the available space for T-cells with other specificity, which may be lost through competition and result in a reduced clonal diversity and immune protection capability, particularly relevant for IRP's (Akbar and Fletcher 2005). A demonstration that clonal expansions of specific T-cells can compromise the response to other antigens by a mechanism through competition was given in mice (Messaoudi et al. 2004). The

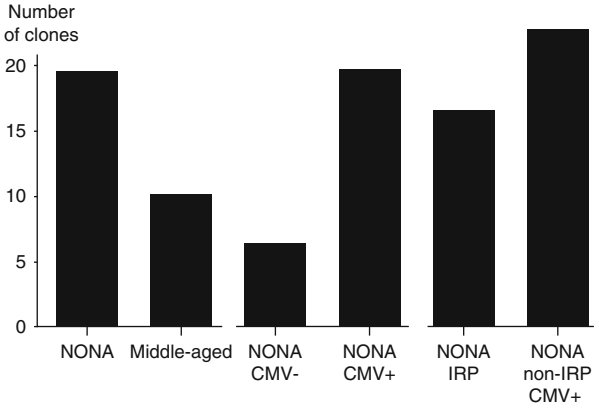

Fig. 3 The mean number of clonal expansions in the CD8+ repertoire determined by DGGE in subgroups of individuals. NONA individuals showed significantly ($p<0.01$) higher mean number (19.4, $n=39$) compared with middle-aged (10.1, $n=9$). CMV positive NONA individuals showed significantly ($p<0.001$) higher mean number (22.6, $n=31$) compared with CMV negative NONA individuals (7.4, $n=8$). CMV-positive NONA IRP individuals showed significantly ($p<0.05$) lower mean number (15.0, $n=8$) compared with non-IRP CMV+ individuals (25.2, $n=23$)

observations that infection with CMV can reduce prevailing levels of immunity to EBV (Khan et al. 2004) also support this hypothesis. Similarly to the CD8+ T-cell expansions, it has been shown for the CD4+ T-cells that the CMV-specific response expands considerably with age altering the CD4+ repertoire (Pourgheysari et al. 2007), and that VZV-specific populations (Fletcher et al. 2005) are significantly decreased when CMV-specific CD4+ cells expand.

Surprisingly, however, we found that among sero-positive individuals, the IRP individuals showed a significantly lower number of expanded clones than the non-IRP's (Reker-Hadrup et al. 2006, Fig. 3). We also found that a decrease in clone numbers among IRP individuals was associated with increases in the inflammatory activity by elevated plasma IL-6 as well as with shorter survival times. This suggests that increased numbers of clonal expansions is beneficial to the individual, indicating an increased clonal expansion diversity and immune protection capability. It also support the hypothesis that when a critical point is reached, clonal exhaustion leads to shrinkage of the clonal expansion repertoire, detrimental to immune capabilities both for unrelated antigens and for CMV itself (Reker-Hadrup et al. 2006).

4.2.6 Low-Grade-Inflammation

There is considerable evidence of age-associated changes in immune capabilities resulting in increased morbidity and mortality due to altered function of the innate immune system (Krabbe et al. 2004). Low grade inflammation increases in the level of the inflammatory markers TNF-α, IL-6, and CRP and decreases in the levels of albumin in plasma have been shown to be significant predictors of mortality in population studies in the elderly (Evrin et al. 2005; Bruunsgaard et al. 2003; Reuben et al. 2002). Many studies have focused on the multi-factorial cytokine IL-6 and suggest that ageing independently of any particular disease is associated with two- to four-fold low grade increases in the plasma levels of this inflammatory mediator. Studies have shown that low-grade increases in IL-6 levels are related to increased amounts of fat tissue and loss of muscle mass, strength, functional capability and weight that occur with normal ageing. CRP is considered as a surrogate marker of IL-6, because CRP is produced by IL-6 induction in the liver (Krabbe et al. 2004). Increases in IL-6 are also associated with many age-related diseases such as cardiovascular disease, arthritis, osteoporosis and Type-2 diabetes (Forsey et al. 2003), which represent major morbidity classes and causes of death in the very old.

Using data from the second and third waves of the NONA immune study, we were able to confirm results from other studies that have demonstrated that ageing is associated with low-grade inflammation and that inflammatory markers are significant predictors of mortality in the very old (Wikby et al. 2006, Table 4). Logistic regression analysis also revealed that the IRP and low-grade inflammatory activity, defined by the marker IL-6, were independently predictive of 4-year survival, an outcome that remained when CRP and albumin were entered as covariates (Wikby et al. 2006). The independent main effect predicted 57% of nonsurvival

Table 4 Inflammatory parameters in plasma at Time 2 in very old individuals that had survived (survivors) and not survived (non-survivors) at Time 3 of the NONA Immune Longitudinal Study

Parameter	Survivor	Non-survivor	p<
IL-6 (pg/ml)	4.9 (61)[a]	9.2 (21)	0.001
CRP (mg/ml)	1.4 (60)[a]	3.6 (22)	0.05

[a] Median (*n*)

and, impressively, 97% of survival, showing that IRP and IL-6 are better predictors of survival than of subsequent mortality. These parameters are consequently strong candidates as significant markers of healthy ageing. IRP and IL-6 were predictive of mortality and not significantly affected by eight prevalent diseases, including Alzheimer's, cardiovascular disease and Type-2 diabetes, controlling for age and gender (Wikby et al. 2006). These results are in agreement with findings demonstrating that low-grade inflammation (Krabbe et al. 2004) and IRP (Nilsson et al. 2003) can predict mortality independently of disease and comorbidity. While the IRP reflects changes in the adaptive T-cell system primarily associated with lifelong persistent CMV infection, the increases in IL-6 seem to reflect innate immune system changes, including a wide range of alterations associated with overall devitalisation and frailty. This is supported by our findings of changes in the plasma levels with decreases in albumin and increases in acute-phase proteins (Wikby et al. 2006).

The above results may at first seem contradictory to our baseline findings of elevated IL-6 plasma levels specifically associated with cognitive impairment and mortality. This association was not seen at second wave follow-up (Wikby et al. 2006). However, cognitively impaired individuals who survived until the follow-up or who became incident cases were more likely to be in their early stages of the disease process compared with those who showed manifest cognitive impairment already at baseline with higher subsequent mortality rates. Thus, it is likely that sample composition variously reflect reasons for survival or selective mortality in late life (Pawelec et al. 2005).

A comparison of the inflammatory markers IL-6 and CRP at baseline, and two years later (wave 2) for IRP survivors and nonsurvivors four years after baseline, was performed in the NONA study. The result demonstrated only a minor inflammatory activity in the subgroups at baseline, indicating that the IRP is not associated with inflammation per se (Wikby et al. 2006). Increases in the inflammatory activity found between baseline and wave 2 among nonsurvivors, however, show that IRP individuals develop such an activity by increases in IL-6 and CRP in a terminal decline stage (Wikby et al. 2006). The results suggest a linkage between adaptive T-cell and innate immune system changes for IRP individuals that begins with acquisition of CMV infection in earlier life and is followed by an expansion and accumulation of senescent CD3+CD8+CD28-T-cells, the development of an IRP and finally an activation of the innate immune system in a terminal decline stage late in life (Wikby et al. 2006), including low-grade inflammatory processes with the secretion of proinflammatory cytokines like IL-6 and TNF-α (Zanni et al. 2003).

4.2.7 IRP Movement

In the NONA Immune Longitudinal study only 5 individuals (4%) moved into the category at risk by changes in the CD4/CD8 ratio, which was a significantly lower percentage as compared to the previous OCTO Immune Study (30%). Intriguingly and contrary to findings in the OCTO Immune Study, however, we have found that a few NONA individuals (n=3) actually moved out of the IRP category (Wikby et al. 2006). The changes found were associated with increases in IL-6, IL-10, neutrocytosis and lymphopenia, suggesting that IL-6 may induce an antiinflammatory rather than a proinflammatory effect in association with enhanced IL-10, neutrocytosis and lymphopenia to limit the potential injurious effects of sustained inflammation in these particular and rare individuals (Steensberg et al. 2003).

4.2.8 Longitudinal Changes

To follow a population of very old individuals over time in a longitudinal study offers unique opportunities to examine intraindividual changes as well as to test various factors predictive of longevity. Throughout the 20th century a remarkable increase in lifespan has taken place in humans and the increased number of centenarians in recent decades is considered to mainly be due to a dramatic decline in the mortality rate among those above 80-years of age (Jeune 2002), that is individuals exclusive focused upon in our studies. There is evidence that infectious disease become more important in the very old and that the immune system thus may be considered decisive for successful ageing and longevity in humans (Delarosa et al. 2006). In the NONA Immune

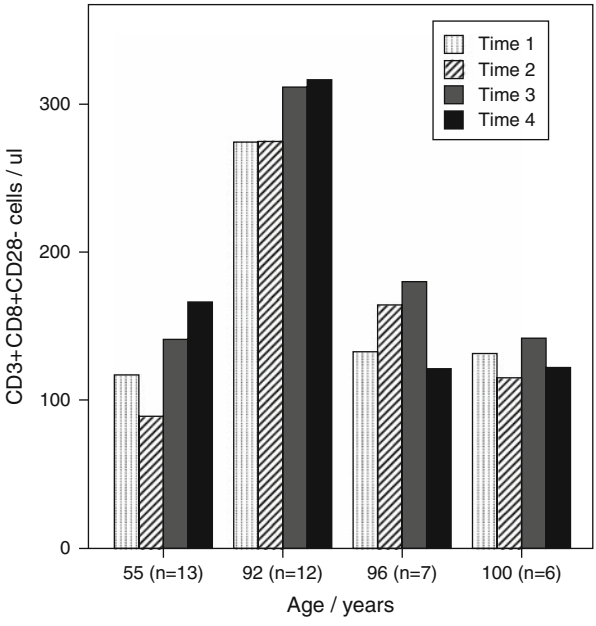

Fig. 4 Longitudinal data for the number of CD3+CD8+CD28- cells in subgroups of middle-aged and very old surviving through time 1 (1999), time 2 (2001), time 3 (2003) and time 4 (2005). Multivariate analysis of variance indicated significant differences between the age groups (p<0.05) with greater number of CD3+CD8+CD28-cells for the 92 year group as compared with other age groups. The analysis showed no significant change across time or group by time interaction effects

study, considering that the oldest cohort had become centenarians, commonly taken as a paradigm for "successful ageing" a question of significant interest was weather the "successfully aged" might be exceptional in their avoidance of the IRP.

Blood was drawn at baseline from 138 individuals with 42 belonging to the oldest 94-year old cohort, 47 to the 90-year cohort and 49 to the 86-year cohort. After 6 years, 99 individuals (72%) were deceased and another 8 declined to participate at this forth wave, giving a total number of 31 participants for the 6-year follow-up study. At baseline, 22 individuals resided in the IRP category and none of those had survived at 6-year follow-up. During the 6 year longitudinal study, five individuals developed an IRP by increases in the number of CD8+ and decreases in the number of CD4+ cells. Of these 4 were deceased at the 6-year follow-up, leaving only one individual with an IRP at 6-year follow-up (Strindhall et al. 2007).

At the 6-year follow-up, significant cross-sectional differences were found in the various T-cell subsets as well as in the CD4/CD8 ratio between age groups, differences not seen at baseline (Strindhall et al. 2007). The results suggest age-related changes but longitudinal data, however, revealed no significant changes at all across the 6-year period in any of the T-cell subsets (Figs. 4 and 5). These findings support the interpretation that the observed differences in the 6-year cross-sectional mean values are an effect of selective mortality. Individuals surviving until the age of 100 years did not display any T-cell changes associated with the Immune Risk Profile, i.e. they retain low numbers of CD8+CD28-cells and high CD4/CD8 ratio (Figs. 4 and 5), also predominant when these "successfully aged" people were younger, while among ten cases close to the CD4/CD8 cut-off of 1.00 (range 0.8–1.6), nine (including the one single IRP individual) belonged to the youngest age group (92 years old), and one to the 96 year old group (Strindhall et al. 2007). An effect of selective mortality is also

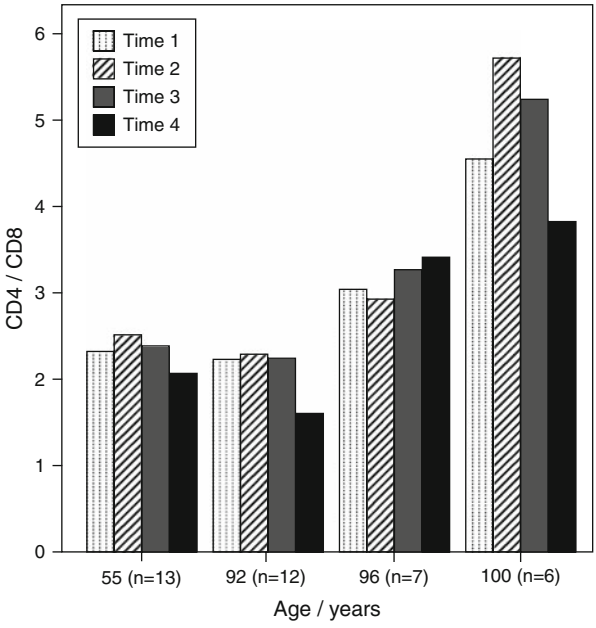

Fig. 5 Longitudinal data for the CD4/CD8 ratio in subgroups of middle-aged and very old surviving through time 1 (1999), time 2 (2001), time 3 (2003) and time 4 (2005). Multivariate analysis of variance indicated significant differences between the age groups ($p<0.05$) with the 96 and 100 year groups indicating higher ratio as compared with other age groups. The analysis showed no significant change across time or group by time interaction effects

supported by the fact that the prevalence of IRP decline from 16% at baseline to 3% at 6-year follow-up, when individuals in the NONA sample had become 95 years old on average.

The results also support the view that centenarians, although being "successfully survivors", they are not healthy (Jeune 2002). In the NONA Immune sample three quarters of the individuals were in fact classified as frail and at most 5% conformed to the SENIEUR criteria for being quite healthy (Wikby et al. 2006). The IRP, however, was shown to be predictive of mortality independently of the health status of the very old (Nilsson et al. 2003) and the absence of an IRP in centenarians therefore indicate a well preserved adaptive immune system, that helps to account for their survival in spite of substantial morbidity and co-morbidity.

5 Conclusions and Future Direction

Immunosenscence is the term used to describe the acquired dysfunctional immunity in old people and is characterized by changes in the T-lymphocyte system in particular. The changes become manifest as increasing numbers of lately differentiated T-cells that previously was exposed to antigens (memory and effector cells), and a decreasing number of cells being able to recognise and combat new antigens (naïve cells) that invade the human body (Akbar and Fletcher 2005). In the OCTO and NONA studies we have identified and examined a T-cellular IRP showing the above outlined characteristics of *immunosenscence*, i.e. the accumulation of dysfunctional terminally differentiated CD8+ cells with a CD3+CD8+CD27-CD28-CD45RA+CCR7-perforin+ phenotype and the depletion of the number of CD8+CCR7+CD45RA+ naïve cells (Wikby et al. 2005). Extensive analysis to search for associations between this IRP and various parameters including the psychosocial domains of physical and mental health, cognitive functioning, personal control/coping, social networks and everyday functioning capacity, clinical laboratory parameters, various diagnosed diseases and medication revealed that the IRP was associated only with evidence of persistent CMV infection (with EBV as a bystander). This result may indicate that CMV has a more insidious impact on the immune system than previously believed and also compared with other herpes viruses examined in these studies. The accumulation of large numbers of CMV-specific CD8+ T-cells as well as the finding that a majority of clonal expansions in the very old are associated with CMV has given additional information supporting the hypothesis that CMV greatly contribute to the development of an IRP and thus contributes to the development of *immunosenscence* in the elderly. Characteristics of the IRP identified in the OCTO and NONA studies are summarised in Table 5.

In the NONA Immune Longitudinal Study the IRP was studied in the context of low-grade inflammation, previously identified as a predictor of mortality in the old (Wikby et al. 2006). The IRP and low-grade inflammation were independently found to be main predictors of survival. This outcome was not significantly affected by individuals' health status, suggesting that the physiological ageing

Table 5 Characteristics of the Immune Risk Profile

Increased CD8+ and CD3+
Decreased CD4+ and CD19+
CD4/CD8 ratio < 1
Increased lately differentiated CD8+CD28-CD27- cells
Depletion of naïve CD8+CD45RA+CCR7+ cells
CMV-seropositivity
Clonal expansion of CD8+ cells carrying receptors for CMV
High proportion of dysfunctional cells among the CMV-specific CD8+ cells

processes of T-cell immunosenescence and low-grade inflammation are of crucial importance in late life survival (Wikby et al. 2006). The results also suggest a sequence of stages for IRP individuals (Fig. 6) that probably begins in early life with CMV infection, followed by the generation of large CD8+CD28-effector cell expansions to control lifelong persistent infection, homeostatic T-cell changes and a gradual change towards an IRP, that might be associated with a failure of the T-cell capability to control CMV. These individuals show decreased numbers of the CD8+ cell clonal expansions associated with increases in levels of plasma IL-6 and shorter survival, suggesting a stage in ageing where clonal exhaustion may lead to shrinkage of the clonal expansion repertoire detrimental to immune capabilities (Reker-Hadrup et al. 2006). It ends in a terminal decline stage with a low-grade inflammatory process that occurs in late life (Wikby et al. 2006,

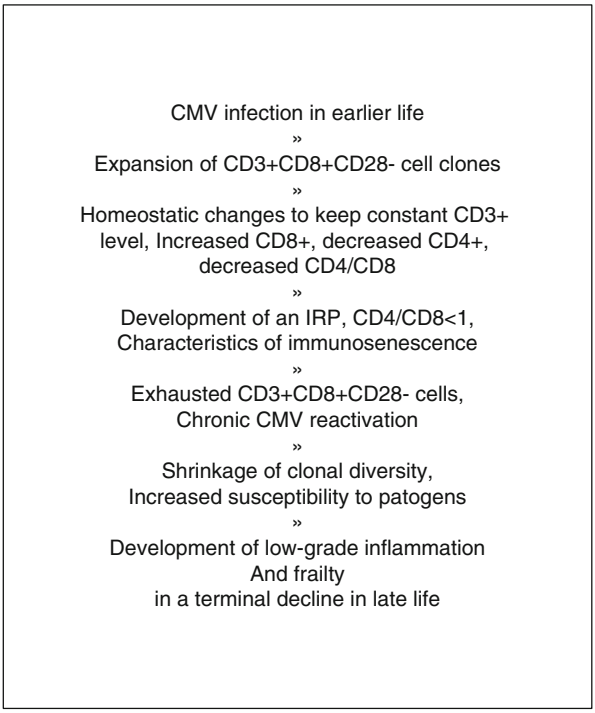

Fig. 6 Processes in a sequence of stages in the human life span of importance for late life survival in IRP individuals
The sequence is based on findings in the OCTO and NONA immune longitudinal studies and supports the inflamm-ageing hypothesis (Franceschi et al. 2000)

Fig. 6). This supports the inflamm-ageing hypothesis in human ageing suggesting that age-associated chronic inflammation causes frailty and that immunosenescence is driven by a chronic antigen load, associated with CMV infection, that induces a progressive expansion of compromised poorly functional CD8+CD28- effector T-cells (Franceschi et al. 2000; Fulop et al. 2005). The CD8+CD28- cells are able to secrete pro-inflammatory cytokines like IL-6 and TNF-a that may compensate for the defective T-cellular function, and/or amplify an ongoing inflammatory process (Zanni et al. 2003).

In future studies it will be important to investigate why only a certain fraction of CMV sero-positive individuals reside in or move into the category of risk. It is also urgent to further characterize those exceptional individuals that move out of the category of risk, allowing insight into clinical intervention approaches for those who remain in the IRP category until death. It is important to specifically study the phenomena of clonal expansion regarding frequencies and specificities of cells for various clones and to gain a better understanding of the nature of the link between CMV infection, phenotypic T-cell changes and changes in proinflammatory cytokines associated with the IRP. We should also study the relevance of the IRP more comprehensively in relation to age and gender. Future research also need to be multidisciplinary and include more detailed medical and biobehavioral evaluations of risk individuals to more fully understand the complex immune alterations that are associated with the major IRP marker.

Acknowledgment The authors acknowledge the considerable support from the EU project "T-cell immunity and ageing" T-CIA, contract no QLK6-CT-2002-02283, the Research Board in the County Council of Jönköping and the Research Council in the Southeast of Sweden (FORSS) for funding these projects. We also acknowledge Länsjukhuset Ryhov for provision of laboratory resources for the completion of these studies. The authors are also indebted to our coworkers Sture Löfgren, Bengt-Olof Nilsson, Jan Ernerudh, Jadwiga Olsson, and Per-Eric Evrin for their important contributions to these studies. We particularly would like to thank the nursing staff including Annica Andersson, Inga Boström, Gerd Martinsson, Agneta Carholt, Lene Ahlbäck, Lena Blom, Monica Janeblad, Gun Karlsson and Lena Svensson for their efforts in obtaining the blood samples used. We are particularly indebted to Frederick Ferguson, Roberta Valeski, Florence Confer, Margaret Kensinger, Penn State University, United States, and Andrea Tompa, Gunilla Isaksson, Inger Johansson, Cecilia Ottosson, Helen Olsson, Lisa Stark Jönköping, Sweden, for secretarial and technical assistence. We finally acknowledge Graham Pawelec, Qin Ouyang, University of Tubingen, Germany, Yvonne Barnett, Paul Hyland, Owen Ross and colleagues, University of Ulster, Northern Ireland, Julie Thompson, Unilever, UK, and Per thor Straten, Sine Reker-Hadrup, Tania Kollgaard and Tina Seremet, Danish Cancer Society, Copenhagen, Denmark, for successful cooperation.

Contents

Abstract: Several cell subsets participate to the immune response, and their close interplay is fundamental for the successful elimination of harmful pathogens. In addition, a tight regulation of the immune response has to occur in order to avoid excessive inflammation and potential autoreactivity towards self components. In the last years, the discovery and the characterization of new lymphocytes subsets, including regulatory T (Treg)-cells and Natural Killer T (NKT)-cells allowed a better understanding of how an effector immune response is induced and therefore down-modulated. During the ageing of the immune system, a process termed immunosenescence, these subsets undergo a profound remodelling, both in phenotype and function. In this chapter, we will describe the essential features of lymphocyte populations in centenarians and the differences that occur with unsuccessfully aged people.

1 Introduction

The progressive lengthening of the mean life span and the consequent growth of the elderly population has focused the attention of the scientific community on human longevity. Aging is a complex process characterized by a general decline in physiological function with an increasing morbidity and mortality. The specific causes of aging are not known. Several studies suggest an association between changes in immune function and longevity, and indicate that the deterioration of the immune function, termed "immunosenescence", could be the cause of the increased susceptibility to cancer, autoimmune and infectious diseases which characterize elderly. However, a common bias in the studies on immunosenescence has been the confusion between ageing and age-related diseases and the difficulty to study the immunology of the physiological ageing and not the immunology of the age-associated diseases. Centenarians have been proposed as model to study immunosenescence in physiological conditions, being exceptional individuals who have reached the extreme limit of human life escaping the major age-related diseases [1]. Many of them, the so called "healthy centenarians", have resulted free of diseases typical of ageing, such as cancer, dementia, diabetes, cardiovascular diseases and osteoporosis.

One of the most important characteristics of successful ageing is the ability to fight efficiently infective agents. An efficient immune response requires the coordinated action of several components, and is mainly due the presence of a consistent number of continuously renewed T- and B-cells that are equipped with a clonotypic receptor recognizing virtually every potential antigen. The immune system must have the ability to expand efficiently the adequate antigen-specific clone(s) and the ability of producing and maintaining memory cells that, during a following infection by a pathogen that has been recognized in the past, mount a more efficient response.

Immunosenescence is characterized not only by a simple deterioration of the functionality of the immune system, but also by a complex modification of several components. As a result, some immune parameters tend to diminish with ageing, while some others remain constant or even increase [1]. At the cellular level, features of immunosenescence are the constant decline in the number of naïve T-cells, the reduction of new B-cell precursors, and the tendency to expansion of T- and B-clones in the periphery, reflecting in a diminished capacity to recognize antigens [2, 3]. Indeed, at the molecular level, the expansion of antigen-specific clones is paralleled by a restriction of the T-cell repertoire, that defines the amplitude and diversity of the molecules that form the T-cell receptor (TCR) [4]. This is also accompanied by the restriction of the B-cell repertoire, and indeed the presence of clonal B-cell expansions that give origin to monoclonal gammopathies is relatively common in aged individuals, accompanied by a decline in peripheral blood B-cell count [5, 6].

2 An Overview on the Immune System

In order to cope with all possible antigens that can be encountered in the course of human life, T-cells have the capacity to generate theoretically 10^{15} different TCR, that form a really large T-cell repertoire. It has been estimated that, in a young healthy adult, about 10^8 different TCR are present in every moment [7]. T-cell compartment is generated and maintained by the production and output of new T-lymphocytes, naïve for their antigen, from the thymus. Such production tends to decline with age of about two orders of magnitude, and is considered the leading force of immunological ageing. Thymic activity is extremely efficient during childhood, but very low in the elderly. This is likely due to the fact that the immune system has to cope very early with an environment full of infectious agents, and thus has to be extremely strong and maximally functional in the first period of life, *i.e.*, during childhood.

In parallel with the decline of thymic acticvity, an increase in the number of circulating memory T-cells exists during ageing because of the differentiation and maturation of naïve T-cells, and/or the expansion and maintenance of memory cells that continuously encounter the same (persistent or recurrent) antigen. The contribution of these two components to the circulating T-cell pool changes with age. As thymic output declines (while the number of possible encounters with infective agents obviously increases with age), the relative importance of the reexpansion of "old" but experienced memory cells becomes more relevant than the differentiation of naïve T-cells. This age-related accumulation of memory cells can represent a response to the reduced number of naïve T-cells, required to fill the so-called "immunological space", or conversely a cumulative effect of the expansion of cells, likely due to persistent, subclinical infections [8–10]. It is not still clear which is the precise dynamics of the functional decline of the immune system, and at which age the generation of T-cells in the thymus is eventually exhausted. Some authors, based on the rate of reduction of the thymopoietic tissue, have estimated a complete loss of thymopoiesis at 105 years [11], but this estimation was clashed by the observation that active thymic tissue can be found even later [12]. Moreover, a recent study revealed the existence of a second organ that produces T-cells in mice, but this evidence still lacks in humans [13].

The pool of naïve T-cells can be maintained throughout life by a mechanism called "homeostatic proliferation", induced by cytokines such as interleukin (IL)-7 and IL-15. Small amounts of these molecules can maintain a small rate of T-cell proliferation, and thus keep the system alerted. After stimulation with these cytokines, naïve T-cells from elderly subjects can show a reduced capability to differentiate and proliferate. This seems to indicate that naïve T-cells that have undergone homeostatic proliferation are not fully functional, probably because an intrinsic reduction of their proliferative potential, and so a full immunological response cannot be generated [14].

The role of another key population, that of "naturally occurring" CD4+ regulatory T-cells (Treg), is currently under analysis. This is a population of T-cells with suppressor capacity, that regulate a wide variety of immune responses [15–18], including the activity of self-reactive T-cells that can potentially cause autoimmune disease. Treg exert their suppressive function in different manner, either by contact or production of inhibitory molecules, and preferentially express high levels of CD25 (the low affinity chain of the IL-2 receptor), the winged-helix family transcription factor forkhead box P3 (FoxP3) [18], the ectoenzymes CD39 and CD73 [19–21], and lack the interleukin-7 receptor α-chain (CD127) [22, 23]. Controversial data exist on the role and amount of this cell subset with age, and it is unclear whether and how these cells are altered, or in some way related to the immune dysfunction in the elderly [24]. It has been reported that the thymic output of Tregs may decrease when there is a significant loss of its capacity to generate new T-cells, and thus the homeostasis of Tregs has to be sustained by alternative pathways, *i.e.* the generation of Tregs in the periphery [25, 26]. Scanty data actually exist on this aspect of immune regulation, and further studies are needed.

The occurrence of modifications in the production and release of growth factors (such as G-CSF, SCF) or interleukins (such as IL-2, IL-7, IL-9, IL-13, IL-15) and chemokines (such as CXCL12, sCXCL10 and sCCL2) has been described either in the thymus or in the periphery, along with changes in the production of haematopoietic cells and of other components, including cells forming the microenvironment where lymphocytes and monocytes are produced and activated. The cytokine network undergoes profound modifications with age, and several authors have shown the relevance of such a phenomenon [27–32].

Centenarians provide the best example of successful ageing and are an excellent model to understand the complex modifications of the aforementioned processes. They are exceptional individuals who have reached the age of 100 years in a relatively good state of health, from many points of view (cognitive, physical, endocrinological, biochemical and immunological) [33–35]. Studies on their immune system have revealed parameters that follow the degenerative trend often present in aged people (eg, reduction of B- and T-lymphocytes, reduction of proliferative capability), whereas other parameters are well preserved (natural killer cell activity, chemotaxis, phagocytosis) or even increased (production of proinflammatory cytokines) [33, 34]. In this chapter we will discuss the main features of lymphocyte subsets from centenarians in order to identify an "immunological signature" which is responsible for their difference with the entire elderly population.

3 B-cells in Centenarians

During ageing several changes in the B-cell compartment, in terms of new B-cell generation, homeostasis, repertoire and functionality, can occur. Peripheral B-cells and their progenitors can be classified in different subsets on the basis of phenotypic, anatomic and functional parameters. Most B-cells originate from bone

marrow, where common lymphoid precursors are committed to specific lineage commitment, with rearrangement of immunoglobulin (Ig) genes and subsequent expression of surface IgM (sIgM). After B lineage commitment, cells rearrange the Ig heavy chain genes in a stage defined "pro-B-cell". Successful rearrangement initiates pre-B-cell stage, where cells express a pre-B-cell receptor (BCR) together with Igα and Igβ transmembrane signalling molecules. After a brief proliferation, the Ig light chain genes are rearranged, and cells express a complete surface receptor, defined as the BCR, characteristic of immature B-cells.

Immature B-cells complete their differentiation in the periphery, in a series of stages collectively defined as "transitional stages", classified as T1, T2 and T3 on the basis of surface expression markers. Cells that successfully complete differentiation join to peripheral pools; the large majority becomes mature follicular B-cells (the so-called B2-cells), which include precursors of primary antibody forming cells as well as memory cells, and represent more than 80% of B-lymphocytes [36]. Others cells join the marginal zone pool of lymph nodes, where they play a major role in response to T-cell independent antigens, or in the very early phase of T-cell dependent response. Even if the exact mechanism driving the differentiation in follicular or marginal zone B-cells is not fully clear, it is clear that BCR signal strength plays a crucial role in such a process [37, 38].

The last compartment of B-cells is formed by B1-cells (mostly CD5+), the first that appear during development, which is maintained by self renewal. B1-cells were originally identified as CD5+ B-cells participating in autoimmunity, and sharing similarities with those causing human chronic lymphocytic leukaemia [39, 40]. In humans, B1-cells are normally about 1–5% of the total B-cells, and are found in a variety of tissues including the spleen, peritoneal cavity, pleural cavity and intestines. B1-cells can be further divided in B1a or B1b using surface markers CD19, CD45 (B220), and CD5. B1a-cells are CD19+, CD45+ and expresses high levels of CD5, while B1b are CD19+, CD45+ and express low to almost-absent levels of CD5 [41].

Concerning naïve and memory B-cell subpopulations, a series of studies have shown that human B-cell subpopulations can be distinguished on the basis of CD27 expression and have striking characteristic features [42–45]. In particular, it is possible to identify three main subsets: CD19+, IgD+, CD27- (naïve B-cells), CD19+, IgD+, CD27+ (memory cells that underwent somatic hypermutation, and express high affinity IgM), and CD19+, IgD-, CD27+ (memory cells that switched Ig class) [44, 45].

The expression of CD27 on B-cells increases gradually with age: cord blood B-cells do not express CD27, whereas approximately 40% of adult peripheral blood B-cells are CD27+ [46, 47]. These two subpopulations are different: indeed, CD27+ B-cells are large cells with abundant cytoplasm, whereas CD27- B-cells are smaller and have a scanty cytoplasm [48].

Studies on the B-cell compartment in centenarians were not as accurate as those regarding T-cells. As in the case of T-cells, it is widely accepted that the maintenance and renewal of the B-cell pools are subjected to a complex network of homeostatic processes which undergoes to substantial modifications with ageing. During the

‘90s, several studies have shown a significant modification in the pattern of B-cells subpopulations (reviewed in [33, 34]). It was shown that the proportion of B-cells in the peripheral blood usually decreases in elderly persons, including centenarians [6]. Moreover, age-related increase of the serum level of immunoglobulin classes (IgG and IgA but not IgM) and IgG subclasses (IgG1, 2 and 3, but not IgG4) was detected [49].

Conversely, less attention was paid to modifications of the B-cell compartment during ageing, and only a few studies have analyzed B-cells subsets in centenarians [50–52]. These studies have shown an age-dependent decrease in the absolute number of CD5+ and CD40+ B-cells, and a slight, even if not significant decrease of CD19+, CD27+ cells. The changes in absolute counts were mainly due to the decrease of the absolute number of B-cells. The percentage of CD19+, CD27+ B-cells increased significantly with age, reflecting increase in memory cells and decrease in naïve B-cells; centenarians did not escape from this trend. It was observed that the percentage of IgD+, CD27+ memory cells increases until 30–40 years, and then declines, with a secondary deficiency in IgM production in elderly subjects. The shift observed towards memory cells, as in the case of T-cells, can mirror the continuous exposure to foreign antigens throughout life [50, 51].

Similar results were obtained by other authors, who analyzed changes in B-cells with ageing, in a population of healthy subjects 21-99 years old, and demonstrated a rapid increase in the absolute number of memory B-cells (either IgD+ or IgD-) in the first three decades of life, and then a slight decrease of IgD-, CD27+ B-cells, and a marked decrease of IgD+, CD27+ elements. Concerning the percentage of these subset among B cells, CD27+ B cells increase during childhood and adulthood and then decline, the most marked decline regarding IgD+, CD27+ cells. The percentage of naïve B-cells increased with age. Again, extremely old people fit perfectly the trend observed in “normal” people [52]. Functional studies have shown that memory B-cells in the elderly have remarkable diminished production of Igs after stimulation, and that induction of plasma cell differentiation was decreased in elderly persons compared with that in adults [52]. These observations are in complete agreement with the reduction of clonotypic response to new antigens, accompanied by the progressive expansion of monoclonal B-lymphocytes observed in the elderly and the consequent increase in monoclonal immunoglobulin (MIg).

MIgs are known to appear with a high frequency during ageing and indeed about 20% of elderly humans have serum MIg; there are direct evidences that, in the mouse model, cells producing MIg derive from expansion of single clones [53]. About 1% of elderly subjects transform these alterations into myeloma, and perhaps chronic lymphocytic leukaemia, a lymphoid malignancy that appears with a relative frequency in advanced age [54]. The shift in the specificity of antibodies from foreign to autoantigens observed with ageing is mirrored by the specificities of serum MIg, according to data indicating that approximately 50% of MIg reacts with autoantigens [55]. Indirect evidence from studies performed in mice suggests that cells that secrete MIg derive from the CD5+ B-cell population, even if also CD5- monoclonal B-lymphocytes can be present in humans [56].

Such modifications of B-cell subsets with ageing, and in particular the progressive increase in memory B-cells and the reduced capability to cope with new antigens, as well as with recurrent encounters with the same antigen, is clearly reflected in deep changes in the production of antibodies. The concentration of natural and antigen-induced antibodies specific for foreign antigens decline with age, as well as specific antibody responses to almost all vaccines [57]. Despite this defect in the antibody response to foreign antigens, the level of serum Ig does not decline during ageing [57], a paradox that can be explained by an age-dependent increased serum concentration of autoantibodies [58]. Thus, ageing is associated with alterations in the B-cell repertoire with respect to the ratio of antibodies specific for the nominal versus self antigen. The autoantibodies detected at increased concentrations in the serum of elderly people are specific for autoantigens such as DNA, immunoglobulins, thyroglobulin, and are found at high concentrations in patients with systemic lupus erythematosis, rheumatoid arthritis or hypothyroidism. However, it is interesting to note that centenarians are characterized by a striking absence of organ specific autoantibodies, whereas nonorgan specific autoantibodies increase in healthy aged donors, as well as in centenarians [6, 33, 34, 59].

The serum concentration of IgM, IgA and IgG also increases with age [60] although the concentration of IgD decreases in elderly people, including centenarians [61]. The preferential loss during ageing of IgG and high affinity antibody, the most protective antibodies against bacterial and viral diseases, can be related to the increased susceptibility and severity of infections and a lower efficacy of vaccines in elderly people.

4 General Features of T-cells in Centenarians

The fine analysis of the phenotype of peripheral T-lymphocytes is crucial for a better comprehension of the T-cell homeostasis during ageing. Not only this allows to determine T-cell dynamics, but also to deeply investigate the role of specific T-cell subsets. One of the most age-related changes within the T-cell population is the progressive accumulation of memory cells in spite of the naïve T-cell pool [62–65]. It is to note that in the past years several studies, including ours, have used the expression of CD45 isoforms, CD45RA and CD45R0, to define naïve/unprimed and memory/experienced T-cells, respectively [62]. As a consequence, it was reported that a well preserved number of naïve T-cells can be still present in people with advanced age, included centenarians [33, 62]. Few years later the publication of such studies it was shown that CD45RA+ cell population was quite heterogeneous, includes terminally differentiated T-cells, and that several different memory subsets are present in the peripheral blood, which can be recognized by the simultaneous use of anti-CD45RA, anti-CCR7 and anti-CD62L monoclonal antibodies [66]. Interestingly, a particular subset of memory cells, the so-called TEMRA (T effector memory RA+) subset, more frequent in the CD8+ than in the CD4+ compartment, is formed by terminally differentiated memory cells that are capable of reexpressing the CD45RA

isoform, but are incapable of recirculating in secondary lymphoid organs. These CD45RA+ revertant cells have been definitely demonstrated to behave as memory cells [67].

The advent of polychromatic flow cytometry (PFC) has increased the capacity to analyze several antigens in the same cell and, as a consequence, has allowed a better definition of T-cell differentiation state. As evidenced in Figs. 1 and 2, multiple subsets can be identified in the peripheral blood by the simultaneous analysis of differentiation (*i.e.* CD45RA, CCR7, CD95), activation (*i.e.* CD38) and survival (*i.e.* CD127) markers. PFC led to demonstrate that the use of only one or two markers is not sufficient for the definition of naïve T-cell [68, 69]. PFC has been recently used by our group to analyze T-cell differentiation in centenarians, and we have found that in these subjects true naïve T-cells are extremely rare [70]. Indeed, a small proportion of CD4+ and CD8+ T-cells coexpress CD45RA and CCR7 [71], but further analysis of these "naïve" T-cells reveals that most of them also express CD95 (typically present on memory cells). Several questions still await an answer, such as where do these cells come from and where are they going (in terms of which lymphoid site is their final destination), do they represent an intermediate subset between naïve and memory cells, or are they terminal effector cells with the capability to recirculate to lymphnodes and spleen. It is to note that, in the elderly, the majority of CD45RA+ cells lack the costimulatory molecules CD27 and CD28 [64, 72], express CD57 and KLRG1 [73, 74] and produces IFN-γ upon stimulation [64], suggesting that these cells are part of the memory pool.

Both repeated exposure to antigens for more than a century and reduced thymopoiesis can account for the striking accumulation of memory T-cells in centenarians. It has been estimated that thymopoiesis declines over 80% after the age of 60 years and minimal or no thymic activity can be predicted after 100 years, due to the progressive loss of thymic epithelial space [75]. T-cell receptor rearrengement excision circles (TRECs), which are indicative of thymic activity [76], are practically undetectable in these subjects, although in our experience about 15% of centenarians (4 out of 25) displayed detectable levels of TREC+ lymphocytes [71]. It is thus likely that external factors such as the activity of homeostatic cytokines could contribute to the maintanance of the few naïve T-cells in old age [75]. However, competition with memory cells for those factors could compromise naïve T-cell survival and maintenance (see below).

IL-7 and IL-15 have been widely described as important cytokines for the regulation of T-cell homeostasis [77]. In particular, IL-7 plays a pivotal role in determin-

Fig. 1 Polychromatic flow cytometric analysis of peripheral blood T-cells from a centenarian and a young donor (23 years old) **(a)** Lymphocytes were first gated on the basis of forward (FSC) and side (SSC) scatter, then T-cell subsets were selected by gating on CD3+, CD4+ or CD3+, CD8+ cells. Further analysis of the expression of CD45RA and CCR7 allowed the identification of naïve (TN: CD45RA+, CCR7+), central memory (TCM: CD45RA-,CCR7+), effector memory (TEM: CD45RA-,CCR7-) and CD45RA+ terminal effector (TEMRA: CD45RA+, CCR7-) cells (b, c) Analysis of the expression of CD38 and CD95 in naïve and memory subsets of (b) CD4+ and (c) CD8+ T lymphocytes. Fig. 2 Analysis of CD127 expression on naïve and memory subsets of CD4+ (upper panels) and CD8+ (lower panels) T-cells In each panel, upper histogram indicates CD127 expression in a young donor (Y), while lower panels are referred to a centenarian (C)

ing the survival of naïve T-cells and their proliferation in lymphopenic conditions. For naïve cells, IL-15 seems to be less important, since IL-15$^{-/-}$ and IL-15R$\alpha^{-/-}$ mice display only slightly reduced levels of naïve CD8+ T-cells, which could be due to modest defects in thymic production, or to effects on the survival and/or proliferation of naïve CD8+ T-cells [77–79]. It is noteworthy that CD4+ T-cells, which express higher levels of IL-7Rα than CD8+ T-cells, appear to be more dependent on survival signals mediated by IL-7 signals. IL-7 is also important for the maintenance of memory CD4+ T-cells while memory CD8+ T-cells mainly rely on IL-15 signals. Recently it has been reported that CD8+ T_{EMRA} cells from elderly subjects (>65 years old) display altered expression of CD127 and reduced responsiveness to IL-7 in vitro [80]. Differently, we recently demonstrated that centenarians do not undergo a remodeling of the IL-7/IL-7 receptor system, as it is in the elderly, suggesting an active role for this cytokine in very old age [71]. We found that plasma IL-7 levels were unmodified throughout life, and the same was observed for CD127, both at the mRNA and protein level [71]. However, more detailed analysis of T-cell subsets by PFC revealed that slight modifications regarding CD127 expression can be found in certain subsets after analysis of T-cell flow cytometric profile by novel bioinformatic approaches (see below) [70].

IL-15 may also play a role in regulating T-cell homeostasis in centenarians. IL-15 level is increased in these subjects [81] and may itself contribute to the accumulation of memory cells. IL-15 has also a potent capacity to induce peripheral T-cell expansion and, together with IL-7, may compensate loss of thymic activity by driving homeostatic turnover. The idea that aged subjects are characterized by a higher T-cell turnover than young subjects is supported by several experimental evidences: i) old people have nearly twice Ki67+ T-cells in the periphery in comparison to young donors [82]; ii) studies using the deuterated glucose technique revealed an accelerated turnover of the CD8+,CD45RA+ subset in the elderly population [83]; these cells, that in old people are probably part of the so-called T_{EMRA} subset, can

be generated, at least in vitro, by the proliferation of central memory T (T_{CM}) cells in response to hoemostatic cytokines rather than by the direct expansion of T_{EMRA} cells themselves [84]; iii) TREC+ cells, which are not only influenced by thimic activity but also by the rate of immune activation and proliferation occurring in the periphery, are undetectable in most centenarians [71]. As a consequence, it is possible to speculate that the expanded memory pool, which is a predominant feature of centenarians, may compete with naïve T-cells for IL-7 and IL-15 availability, thus limiting naïve T-cell survival and proliferation.

5 T-cell Function in Centenarians

There is large agreement that T-cell function is in part compromised during ageing, and it affects both CD4+ and CD8+ T-cells at the level of antigen-specific immunity [85]. These alterations regard many aspects of cellular function such as proliferation, intracellular signalling, cytokine production and effector function.

CD4+ T-cells display age-related reduced helper capability. Studies in aged mice revealed that effector CD4+ T-cells generated from naïve CD4+ T-cells are characterized by a reduced expression of differentiation and activation markers such as the CD40 ligand (CD154) and CD25 [86, 87]. As a consequence, reduced B-cells response was observed due to a defective helper activity [87], which is mainly ascribed to reduced IL-2 production [86]. Decreased production of IL-2 and impaired response to this cytokine have been documented in aged humans as well. However, altered production and utilization of this cytokine can be potentiated by exposing cells from aged donors to low frequency-pulsed electromagnetic fields, suggesting that these altereations are reversible and can be positively modulated [88].

Age-related defects in naïve CD4+ T-cells are likely due to the chronologic age of the CD4+ T-cells rather than to the chronologic age of the individual [14]. In fact, newly generated naïve CD4+ T-cells in old mice exhibit normal effector function *ex vivo* and *in vivo*. These data indicate that long-term maintenance of the naïve T-cell pool by homeostatic mechanisms may result in the alteration of T-cell activity. On the other side, restoring or boosting thymic activity may help in reducing immune defects in the elderly.

In addition to IL-2, alterations in the production of several cytokines have been detected such as decreased production of IL-4 by CD4+ T-cells from aged mice after stimulation with anti-CD3 antibody [89], or increased production of TNF-α from aged humans after stimulation with PMA/ionomycin [90]. By contrast, the production of TNF-α was not modified in centenarians [90]. Increased inflammation exerted by CD4+ T-cells could reflect the proinflammatory status which is often observed in the elderly but not in centenarians [10].

Reduced effector function has also been observed for CD8+ T-cells by analyzing antigen-specific immune responses. For example, CMV-specific CD8+ T-cells from >65 year old people are highly expanded in CMV carriers but they are impaired in IFN-γ and IL-10 production after CMV stimulation [91]. By contrast, secretion

of IFN-γ was observed after stimulation with mitogens. Surface receptor analysis revealed a highly differentiated effector-memory (CD45RA- CCR7-) or terminal effector (CD45RA+ CCR7-) phenotype and lack of CD28 and CD27 molecules but high levels of the KLRG-1 receptor, which is associated to end-stage differentiation and apoptosis resistance [91]. The same authors reported that CMV-specific CD8+ T-cells from HLA-A2+ centenarians were not so highly expanded and displayed lower KLRG-1 expression, suggesting earlier differentiation and normal mechanisms of apoptosis [91]. However, other authors reported that CMV-specific CD8+ T-cells for a HLA-B7-restricted epitope can occur at very high frequency in centenarians as well [92]. Differently, EBV-specific CD8+ T-cells response remains constant with ageing but it is interesting to note that in CMV-seronegative donors, the response to EBV increases significantly with age [93].

Modifications in the proliferation of peripheral blood lymphocytes (PBLs) from centenarians have been detected but they were not unidirectional. In fact, full capability of PBL proliferation has been observed in response to anti-CD3 antibody, pokewood mitogen and phorbol esters, while proliferation in response to PHA, IL-2, autologous and allogenic mixed lymphocyte reaction is reduced [94]. However, it is to be noted that, after PHA stimulation, PBLs from centenarians showed a delayed peak of thymidine incorporation but the overall thymidine incorporation was comparable to that of young donors [95]. Analysis of telomeres revealed an inverse correlation between age and telomere length, indicating that centenarians do not escape the phenomenon of telomere erosion. Interestingly, in fibroblasts from centenarians telomere length is indistinguishable from those from young donors [96, 97]. Thus the general idea is that lymphocyte proliferation in centenarians is in part preserved. As defects in the production of and response to IL-2 have been proven in human ageing, by contrast lymphocytes from centenarians are fully capable of binding IL-2 [33]. IL-2 could certainly sustain lymphocyte proliferation but it remains to be determined whether IL-2 production is critically modified in these subjects. Genetic analysis of the IL-2 promoter revealed that the IL-2 high-producer genotype is less frequent in centenarians than in young people [98]. These data contrast with what has been reported above but it is to be noted that an increase of IL-2 production characterizes the Alzheimer's disease serum profile. Moreover, people carrying the IL-2 low-producer genotype have a lower CD8 cell count in comparison to those carrying the IL-2 high-producer genotype. These data together suggest that the genetic background could not be a bystander factor in determining the so-called "immune risk phenotype" (IRP). Longitudinal studies identified the IRP phenotype as a composition of parameters which includes CMV seropositivity, a CD4:CD8 T-cell ratio of <1 due to increased CD8+ T-cells, an expansion of CD8+ CD28- T-cells with features of terminally differentiated T-cells, the presence of CD8+ T-cell clonal expansions, and elevated levels of proinflammatory cytokines in serum [99–101]. It has been also demonstrated that the IRP strongly influences the survival of people above the age of 80 [99, 100].

CD8+ T-cell clonal expansion is very common in aged people and has been also reported in animals [102]. In humans, a strong correlation exists between

age and the incidence of CD8+ T-cell clonal expansions, with one-third of adults over the age of 65 years developing CD8+ clonal expansions [103]. However, the occurrence of such a high number of monoclonal CD8+ T-cells does not seem to be pathological since CD8+ T-cell lymphomas do not develop in these subjects, suggesting that CD8+ T-cell clonal expansion is still under homeostatic control. Antigen may play a predominant role in the occurrence and maintenance of this phenomenon. In particular, CMV infection seems to drive CD8+ T-cell clonal expansion. By using MHC tetramers bearing CMV antigen, authors found that a T-cell clone specific for a single CMV antigen can account for a high proportion of the entire CD8+ T-cell pool in the elderly population [93, 104]; however, at the moment, it is still unclear whether this occurs also in the centenarian cohort [91, 92]. Persistent CMV infection is thought to actively contribute in the definition of the IRP; however, little is known on how CMV strongly influence subjects' survival in advanced age and how clonal expansion of CMV-specific CD8+ T-cells is driven, as these subjects did not display any reactivation of CMV infection [92]. Some authors hypothesized that such a high oligoclonal expansion of CMV-specific T-cells in the elderly population may shape the T-cell repertoire, fill the immunological space and compete for survival and growth factors [105]. For this reason, memory CD8+ T-cells specific for other antigens than CMV could be impaired [93] or lost through competition, resulting in the exposure of elderly people to otherwise silent infections.

Compared with a sample of very old, the prevalence of IRP and the associated increase of CMV specific T-cells might decline in a sample of centenarians by selective mortality, because survival in those aged 80–95 years occurs preferably in the non-IRP individuals [10].

6 Regulatory T-cells in Centenarians

It was supposed, since many years, that effector immune response should be tightly regulated in order to avoid excessive inflammation and, subsequently, tissue damage. This hypothesis and further experimental evidences suggested the existence of a subset of cells involved in the suppression of the immune response. Extensive research in the past decades led to the identification of suppressor T-cells as subsets of the CD4+ T-cell lineage. In particular, in 1995, Sakaguchi and colleagues reported that "activated" CD4+ CD25+ T-cells, now defined naturally-occurring regulatory T (Treg) cells, were able to maintain immunologic self-tolerance [106] while, in 1997, Roncarolo and colleagues identified an inducible subset of CD4+ T-cells capable of suppressor function [107]. These cells, therefore defined Type-1 T-regulatory cells 1 (Tr1), differed from Treg cells because they were not naturally present in the circulation but could be induced by prolonged treatment with IL-10 in vitro and responded after recognition of cognate antigen [107]. Further research confirmed that Treg cells originated from the thymus and constitute a different lineage from Tr1 cells and conventional CD4+ T-cells [108]. Treg cells constitutively

express the forkhead box transcription factor FoxP3, which acts as a key control gene of their development and function [109]. Differently, Tr1-cells and other subsets of suppressor/regulatory T-cells later identified, such T-helper Type-3 (T_H3) cells, are inducible and can develop from conventional CD4+ T-cells when exposed to specific stimulatory conditions such as the blockade of costimulatory signals, deactivating cytokines or different drugs [110].

Naturally occurring Treg cells constitute the 1-8% of total CD4+ cells in healthy adults. This large imprecision in the determination of their number could be due to the different criteria used for their identification (defined either CD4+, $CD25^{high}$ or CD4+, $CD25^{high}$, FoxP3+) or to the limited number of subjects studied. In fact, the definition of Treg cells solely based on the expression of high levels of CD25 (CD4+, $CD25^{high}$) could overestimate their number, since the CD25 antigen is also upregulated in activated T-cells. This raises several doubts on the reliability of CD25 as a unique marker of CD4+ Treg cells, expecially in the contest of chronic immune activation, such as HIV infection, autoimmune diseases and ageing itself, where an increased number of activated T-cells in the peripheral blood has been described [33]. Additional markers, possibly in combination and in the same cells, should be investigated for this purpose, such as FoxP3 [109], CD127 [22, 23] or CD39 and CD71 [19–21].

Whether the amount of Treg cells in peripheral blood is dependent on age is still a matter of debate. Many independent groups studied large cohort of subjects and positive correlations between age and the number of Treg cells were reported or not [24]. However, people with advanced age (>80 years) were considered only in a few studies and none of them were centenarians. Thus, up to now, no data are present on the number and function of Treg cells and other regulatory T-cell subsets in centenarians. Adding to this, controversial data are available on the influence of the ageing process on the function of Treg cells. A study reported the decline in the suppressive function of Treg cells by almost 90% with age over 50 years [111], but others reported equivalent function of Treg cells between young and old donors [112, 113].

Animal studies suggest that phenotipic and functional modifications can occur in this subset with ageing. In aged mice, high accumulation of CD4+, CD25+, FoxP3+ Treg cells has been observed in the spleen [114, 115] and lymph nodes [114], and these cells retained suppressive capability [114, 115]. Removing these cells by anti-CD25 monoclonal antibodies restored effector CTL response and anti-tumour immunity [114]. However, major suppressor activity was found in a subset of CD4+, CD25- cells [116], which have been later demonstrated to harbour intracellular FoxP3 [115]. Thus, it is possible that other subsets rather than only CD4+, $CD25^{high}$ cells are able to regulate effector responses. It remains to be determined whether these CD25- suppressor cells were $CD25^{high}$ Treg cells in origin, or have been generated from conventional CD4+ T-cells under particular conditions of stimulation. In any case, further experiments, including the analysis of multiple Treg markers together with functional studies, are required to clarify the role of the ageing process on this CD4+ lineage.

7 γδ T-cells in Centenarians

In addition to conventional αβ T-cells in blood and in peripheral tissues, a second subset of T-cells bearing a different T-cell receptor, composed of γ and δ chains, can be identified. These γδ T-cells represent only 5% of total T-cells in peripheral blood but are enriched in many organs containing epithelia such as skin, lung, intestine, and genitourinary tract [117]. Since multiple γ and δ genes are available, different combinations of γ and δ chains are possible, thus generating different families of γδ T-cells. Intriguingly, γδ T-cells in different epithelial tissues use distinct Vγ/Vδ chains; for example, in the intestinal epithelium and lamina propria, γδ T-cells, which represent 30% and 5% of total T-cells, respectively, are mostly Vγ8/Vδ1, while in the peripheral blood Vγ9/Vδ2 are found [117]. These data suggest that different subsets of γδ T-cells may recognize specific antigens and may play different roles during the immune response.

Despite a strong similarity with conventional αβ T-cells dictated by the presence of a TCR and αβ surface markers, γδ T-cells exibit cytolitic activity by a major histocompatibility complex (MHC) antigen-unrestricted mechanism [118]. Thus, γδ T-cells are not activated by peptides presented by antigen-presenting cells (APC) but by nonpeptidic compounds of low molecular weight and cell-cell contact is needed for γδ T-cell activation to occur [117, 119, 120]. So far, their most potent activator is (E)-4-hydroxy-3-methyl-but-2-enyl pyrophosphate (HMB-PP), an intermediate of the microbial nonmevalonate pathway of isopentenyl pyrophosphate (IPP) biosynthesis [121, 122]. Other ligands than phosphoantigens can be recognized by γδ T-cells, including MHC-class I like molecules, such as T10 and T22 in mice and MICA and MICB in humans, and an ATP synthase F1-apolipoprotein A-I (AS-ApoA-I) complex [123]. The role of these cells in immunity is still to be clarified but γδ T-cell response is nowadays considered foundamental in tumor surveillance and in infectious diseases.

In several microbial infections in humans, such as tularemia, salmonellosis, brucellosis and ehrlichiosis, γδ T-cells are expanded up to 48-97% of total T-cells [124]. Increased levels of circulating γδ T-cells have been also described in infections with protozoal parasites (malaria, toxoplasmosis, leishmaniasis) and mycobacteria (*M. avium* and *M. tuberculosis*) [124]. Recent studies in nonhuman primate models concerning the major subset of γδ T-cells, *i.e.,* that expressing the Vγ9/Vδ2 TCR, revealed that γδ T-cells may play an active role during the early phases of the immune response [125]. In macaques, the expansion of γδ T-cells was detected 2–3 weeks after inoculation of *M. Bovis* BCG, and was observed in the lung and intestine, but not in lymphoid organs [125]. Accumulation of γδ T-cells at infection sites but not in lymph nodes has been also described in murine infections. Moreover, γδ T-cells specific for the murine MHC class Ib molecule T22 harboured Vγ4 and Vγ1 in the spleen and Vγ7 in the gut epithelium [126]. These data together suggest that this lymphocyte population acts locally in a tissue-specific, and not antigen-specific, manner and is excluded from secondary lymphoid organs.

However, contrasting data have been reported. CCR7 and CD62L receptors, which are able to mediate the homing to secondary lymphoid tissues, are not expressed on the majority of Vγ9/Vδ2 T-cells. The phenotype of these cells resembles that of conventional effector T-cells, *i.e.* CD45RA-, CD45R0+, CD27-, CD11a^{bright} [127], which are preferentially localized to nonlymphoid tissues [128]. However, upon activation with cognate ligand, γδ T-cells can acquire an APC phenotype, by inducing the expression of HLA-DR, CD80 and CD86 costimulatory molecules together with CCR7. These cells are able to present antigens to conventional αβ T-cells, thereby activating the adaptive immune response [117, 129].

Due to the difficulty to obtain specimens from different anatomic sites, the majority of studies conducted in humans concerns peripheral blood γδ T-cells. Recent data reported a prominent role of these lymphocytes in regulating intestinal homeostasis [120], and thus it would be interesting to check whether this sort of protection is maintained in the elderly or, if altered, could be responsible for immune pathologies of the gastro-intestinal tract.

Different subsets of γδ T-cells are affected by age in a different way. In fact, while the absolute number and percentage of Vδ2 T-cells progressively diminishes with age, that of Vδ1 remains rather constant throughout life [130, 131]. This obviously leads to a subversion in the Vδ2/ Vδ1 *ratio*, that is more prominent in centenarians than in old donors, despite the total γδ T-cell count does not differ between the two groups [130]. Ageing did not change the proportion of γδ T-cells as regards to αβ CD3+ T-cells, suggesting common mechanisms of depletion [130]. It is thus possible that thymic involution and peripheral expansion may play a role in regulating the homeostatis of γδ T-cells. However, these aspects need further elucidation.

Interestingly, γδ T-cells were not impaired in their cytolitic potential in old age, despite an age-dependent decrease in proliferative capability in response to isopentenyl diphosphate (IPP), which was completely ascribed to the Vδ2 subset [130]. Increased production of TNF-α, but not IFN-γ, by γδ T-cells has been observed in centenarians in comparison to young donors [130]; moreover, γδ T-cells from centenarians displayed higher tendency to undergo apoptosis after treatment with TNF-α and anti-CD95 monoclonal antibody [131]. Higher percentage of CD95+ γδ T-cells in centenarians may reflect the accumulation of effector memory-like T-cells, which are known to be highly sensitive to activation-induced cell death mediated by signals passing through CD95/Fas. Milder alterations in the γδ T-cell population have also been described in old people [130, 131]. This suggests that a progressive loss of γδ T-cell activity is observed with age and, as for αβ T-cells, centenarians do not escape this phenomenon.

Whether γδ T-cells play a role during immune responses in old age is still a matter of debate. Many papers confirmed a continued, protective role of this subset in adult animals [132, 133], including humans [134–136] but recent studies in mice revealed a largely redundant role in the presence of a fully mature and expanded αβ T-cell compartment [137].

Sex-dependent phenotypic and functional differences have been described in γδ T-cells. In particular, the number of V 9/V 2 cells and their effector capacity remain constant with age in females, while drop in males [138]. It would be inter-

esting to confirm these data in old people and centenarians in order to determine whether this cell subtype could influence the female predominance in the centenarian population.

8 NK-cells in Centenarians

NK-cells are lymphocytes that can recognize and kill virus-infected as well tumor cells without antigen-presentation or MHC-restriction. NK and T-cells share a common precursor, that expresses FcγRIII, but can develop independently of the presence of the thymus, as shown in athymic mice [139]. NK-cells do not rearrange immunoglobulin (Ig) or T-cell receptor (TCR) genes and therefore neither Ig nor the TCR/CD3 complex is expressed at the cell surface, except for the ζ chain [140]. In humans, these cells are characterized by the expression of CD56, an isoform of the neural cell adhesion molecule (N-CAM), CD16, the low-affinity IgG Fc receptor (FcgRIII-A), CD57, an oligosaccharide antigenic determinant, and CD2, an adhesion molecule that appears to be correlated with the acquisition of Fas ligand-mediated cytotoxicity [141]. They also express inhibitory receptors that interact with MHC class I molecules and prevent unwanted destruction of the target cells. Thus the function of NK-cells results from a balance between activating and inhibitory signals delivered by specific membrane receptors and NK cell activation requires the interaction of activating NK receptors with their ligands on the targets and also the lack of inhibitory signals initiated by the interaction of NK inhibitory receptors with target MHC class I molecules.

They can kill target cells by the secretion of specialized lysosomes, containing pore-forming protein perforins [142], or by the induction of programmed cell-death pathways [143]. Some cytokines (such as IL-2, IL-12, IL-15, IL-18 and IFN-α/β) can induce NK cell proliferation and activation, migration and production of IFN-γ, TNF-α and GM-CSF (for review see [144]). NK-cells can produce also cytokines and chemokines that directly participate in the elimination of pathogens or activate other cellular components of immunity.

Several alterations have been described in NK cell function with ageing both in animals and humans. In humans, the different selection criteria of the elderly populations have produced contrasting data. Some authors reported a decrease in cytotoxic function of the circulating NK-cells of elderly subjects [145] which is associated with an increased incidence of infectious diseases [146, 147]. Indeed, there is an increase of mortality risk of 3 times in people more than 85 years with low numbers of NK-cells respect those with high NK cell numbers [148]. Several pathologies usually associated with ageing are associated with low NK cell activity in the elderly, such as atherosclerosis [149]. On the contrary, high NK cytotoxicity is associated with lower incidence of infections of the respiratory tract and with a better development of protective antibody in response to influenza vaccination [150].

Indeed, in centenarians, NK cell number, as revealed by analysis of CD56 expression on PBMCs, and functionality are not modified in comparison to young

donors while a partial loss of NK cell cytotoxic activity can be found in middle-age subjects, despite the CD57+ and CD16+ populations, which are capable of rapid cytotoxic activity, increased as in centenarians [151]. Further studies revealed a preferential expansion of the terminally differentiated $CD56^{dim}CD16+$ subset while minor modifications were found in the $CD56^{bright}CD16-$ subset [152].

Whereas NK cell activation mediated by CD16 is not affected by aging [144, 148, 149, 153], poor data exist on the function of other NK receptors and probably other NK activating or inhibitory receptors are defective in the elderly. It was reported that the expression of HLA-specific killer receptors is not significantly affected in NK-cells from elderly [154], but more recent studies have shown that NK-cells display an age-related increase in KIR expression and a reciprocal decrease in CD94/ NKG2A expression, although the CD94/NKG2A inhibitory signaling pathway is intact [153].

The killing activity mediated by perforins is not modified in people with advanced age and no significant decrement of these molecules has been observed in NK-cells from young and old donors [155]. Interestingly, a greater decline of perforin expression is present in elderly men if compared to elderly women [156]. This could be a further element to understand the typically higher percentage of females among centenarians [157].

NK-cell activity and phenotype can be affected by the differential presence of cytokines between the young and the old population, as well as centenarians. In fact, a reduced production of cytokines involved in NK-cell activation, i.e, IL-2, IL-12, IFN-α and IFN-γ, is observed with increased age [158]. Accordingly, IFN-γ secretion by NK-cells in response to IL-2 [159] and chemokine secretion in response to IL-12 or IL-2 decrease in elderly [160]. In aged mice and humans the response of NK-cells to IFN-α/β is decreased and could be related to the delay in virus clearance observed in aged mice [159]. The decrease of NK-cell secretion could lead to an impaired adaptive immune response that could contribute to age-related diseases.

The functionality of the immune system is strongly influenced by the presence of certain hormones in a circuit that is called “neuroendocrine immune system” [161], which undergoes profound remodelling with increasing age [162]. NK-cells, as other immune cells, express some hormone receptors on their surface. As a consequence, certain hormones of the hypothalamic–pituitary–gonadal axis as well as thyroid hormones, dehydroepiandrosterone (DHEA), insulin-like growth factor (IGF)-1, melatonin or insulin regulate their function. Moccheggiani *et al.* showed that hormonal treatments with T3, T4, melatonin, GH or IGF-1 in old mice can restore NK-cell cytotoxicity and IL-2 and IFN-γ production [163, 164]. In healthy nonagenarians and centenarians, NK cell number and/or cytolytic activity was positively associated with serum levels of vitamin D, while T3 and i-PTH hormones were associated only with NK-cell number, suggesting a positive role of these molecules in regulating NK-cell homeostasis [165]. Preserved NK-cell functionality in these subjects, *i.e.,* NK-cell cytotoxicity and IFN-γ production, was also associated with good zinc ion bioavailability which, by contrast, is reduced in old animals and humans, but not in centenarians [165–167].

9 NKT-cells in Centenarians

The term "NKT" includes more than one subset of T-lymphocytes that have different phenotype, functional capacities and tissue distribution and that express NK-associated receptors (NKR) [168], historically CD161 in humans [169] and NK1.1 in mice [170].

The large number of studies regards the so-called "classical" or "invariant" NKT-cells (iNKT) expressing a semi-invariant T-cell receptors (TCR), characterized in most cases by Vα14/Vβ8.2 in mice [171] and by Vα24/Vβ11 in humans [172, 173]. iNKT-cells TCR can recognize CD1d (a monomorphic class Ib molecole) [174] and bind endogenous glycosphingolipids and α-glycuronosylceramide (present on the microbial cell wall), suggesting a role in the protection from bacteria that are not detected by classical pattern recognition receptors [175–178].

iNKT-cells can be divided at least in three subset on the basis of the expression of CD4 or CD8 coreceptor and on their cytokine production. iNKT-cells that express CD4+ produce Th1 and Th2 cytokines, while CD4- NKT-cells primarily produce Th1 cytokines. CD4- NKT-cells can be further divided into CD4-CD8- (double negative; DN) and CD8+ NKT-cells, which predominantly express the CD8αα dimer instead of the CD8αβ form present on conventional cytotoxic T lymphocytes [179–181]. Indeed, it has been shown that iNKT-cells express CD45RO but lack CD62L. It was hypothesized that this effector memory phenotype probably derives from the endogenous self ligands recognition [182]. A minority of iNKT-cells are classified as central memory (CCR7+CD45RO+), while most Vα24CD4+ and CD4- NKT-cells could be defined as effector memory cells (CCR7-CD45RO+)[183].

There is evidence that CD1-restricted NKT-cells represents a thymus-dependent population. They are absent in nude mice, do not develop in thymectomized mice and first appear in the thymus slightly later than most other T-cell subsets. There is also convincing evidence that NKT-cells segregate from conventional T-cells at the stage of double positive (CD4+CD8+, DP) thymocyte in the thymic cortex [184]. Indeed, it seems that they acquire a relative resistance to activation-induced apoptosis in the late stage of intrathymic development [185].

iNKT-cells play an important role in host defense and immunoregulation, including the prevention of tumor development and metastasis, suppression of allergic responses and protection against viruses, parasites, bacteria and their products [171, 173, 186]. The most striking property of NKT-cells is their capacity to secrete large amounts of cytokines (IFN-γ, IL-4, IL-2, IL-5, IL-10, IL-13, GM-CSF and TNF-α) within minutes after TCR stimulation. Activation of NKT-cells also leads to upregulation of CD40L, resulting in IL-12 production by dendritic cells upon CD40 triggering [187]. Upon TCR engagement, NKT-cells have cytotoxic activities through the release of perforins and granzymes and by the expression of membrane-bound members of the TNF family (such as FasL) [188]. Activation of NKT-cells leads to subsequent activation of other cells, such as NK-cells, B cells, DC, macrophages, and conventional T-cells in mice as well as humans [189, 190]. Thus, they can affect the acquired immune system by activating pathogen-specific

CD4 Th1 cells as well as CD8 T-cells, suggesting an important role in conferring protection against microbial pathogens, like malaria. Moreover, they have been shown to play a crucial role in interfering with the initiation, growth and metastatic spread of tumours. NKT-cell-derived Th2 cytokines, such as IL-4, can downregulate immune responses and have been shown to contribute to protection against the development of autoimmune diseases (reviewed in [191]). Consequently, NKT-cell activation results in a cascade of immune reactions, providing a possible explanation for their regulatory effects.

Human iNKT-cells can be identified either by their invariant TCR formed by Vα24 and Vβ11 gene segments, or by CD1d-tetramers loaded with α-galactosylceramide (α-GalCer), a marine sponge-derived glycolipid able to selectively activate iNKT-cells in a CD1d-dependent manner [171, 192]. In human peripheral blood, however, classical CD1d-restricted NKT-cells are typically less than 0.1%.

Besides iNKT-cells, a different subset of conventional CD1d-independent α/β T-cell, called "NKT-like" or "nonclassical NKT"-cells, can express several NKR, such as CD16, CD56, CD57, CD161, CD94, NKG2A. The majority of NKT-like-cells likely belongs to nonclassical subpopulation and are mostly CD8+. The nonclassical NKT-cells can account for 5-20% of total T-cells in human peripheral blood [193, 194].

A limited number of studies investigated the role of peripheral blood NKT-cells in aged people. Studies on iNKT frequency in peripheral blood of centenarians from Okinawa were performed by Miyaji *et al.* who analyzed the so-called "extrathymic T-cells", characterized by the expression of CD3 and CD56 or CD57. They found a higher frequency of these cells compared to middle-aged subjects but no differences were detected between males and females [194]. Thus, these authors confirmed that the proportion and the absolute number of NKT-cells (CD56+ or CD57+ T-cells expressing Vα24+) were highly increased in the blood of centenarians, along with the proportion of IFNγ-producing cells among NKT-cells [166].

Other studies showed an effect of age on the homeostasis and function of circulating NKT-cells but elderly subjects rather than centenarians were considered. DelaRosa et al. found a decreased percentage of Vα24+ T-cells in elderly when compared with young controls and, within Vα24+ T-cells, a significant increase in the percentage of Vα24+CD4−CD8+ T-cells, while the percentage of Vα24+ within CD3+CD28+ was similar [195]. In accordance with that study, an age-related decrease in the percentage and absolute count of Vα24+Vβ11+ iNKT-cells has been shown in healthy individuals, although their functional capacity to respond to α-GalCer was not altered [196]. Indeed, a decline of 3.4% per year was evaluated in Vα24+Vβ11+ iNKT-cells with age [197], which involved both their absolute levels and their proportion as to the total T-cell compartment. In addition, they found a gender-related difference in the frequency of circulating iNKT-cells, that was lower in males than in females, and decreased faster with age in the formers than in the latters [197]. Similar results were obtained by Peralbo *et al.* who also reported a decreased proliferative potential of Vα24+Vβ11+ iNKT-cells in reponse to α-GalCer in healthy elderly compared to young subjects [198]. A decrease in the frequency of iNKT-cells in the elderly has been also reported by Jing *et al.* which

was also associated with an alteration in the iNKT-cell subset compositions, that is an increase in the proportion of the CD4(+) subset and a decrease in the proportion of the CD4/CD8 DN subset [199]. In addition, iNKT-cells from aged people produced predominantly Th2 rather than Th1 cytokines [199].

Whereas iNKT-cells are characterized by the expression of a semi-invariant TCR that interact with CD1d loaded with glycolipids, ''NKT-like'' T-cells are NKR-expressing conventional T-lymphocytes which display an oligoclonal TCR repertoire able to recognize classical MHC molecules loaded with peptides [200]. Most of NKT-like cells have an effector memory phenotype and contain high levels of perforin and granzymes [201]. NKR-expressing T-cells expand with aging and centenarians do not escape this phenomenon, as revealed by the increased expression of CD56 on T-cells [151].

Little is known about the function of NKT-like cells but the general belief is that their accumulation is primarily driven by a chronic inflammatory environment, as it is in the elderly population as well as in patients with persistent viral infections, rheumatic diseases and autoimmune diseases, in which a chronic stimulation of the immune system occurs [201]. In particular, the expansion of NKT-like cells accompanies the loss of CD28 expression on T-cells after antigenic stimulation in vitro and is associated with the accumation of $CD28^{null}$ T-cells *in vivo* [202].

In summary, several studies have demonstrated age-related effects on iNKT-cells, a diminished proliferative functionality, a shift from Th1 to Th2 response and a modification in the iNKT subset ratio. However, only one study investigated the frequency of these cells in centenarians.

All these findings may contribute to highlight the role of NKT in the general deterioration of the immune response in the elderly. Considering the importance of these cells in the recognition and elimination of Gram-negative bacteria [178], these defects could be involved in the increased morbidity and mortality due to bacterial infection associated to ageing. The age-dependent alterations in NKT-cells might also reflect the thymic involution, as conventional T-lymphocytes [203–205]. Molling *et al*. suggested that iNKT-cells decrease could affect an efficient tumor immunosurveillance in aged donors, representing a risk factor for tumour development [197]. Furthermore age-dependent alterations in iNKT cytokine production might contribute to the dysregulation of the cytokine network shown in the aged people [206, 207].

10 Bioinformatics Tools for the Analysis of Cellular Dynamics in Centenarians

As described above, a huge number of lymphocytes subsets exists in human peripheral blood. The fine analysis of these subtypes is of extreme importance for a better understanding of the cellular dynamics during physiological processes such as the ageing of the immune system. So far, the simultaneous analysis of multiple parameters at the level of single cell can only be performed by polychromatic flow

cytometry [208, 209]. A huge amount of data can be generated by such a technology which is, however, difficult to manage. In fact, several functional different populations can be identified by combining the positive and negative expression of each antigen (typically 2^n, where *n* is the number of parameters analyzed). Thus, using 8 fluorochromes coupled to 8 different monoclonal antibodies, it is thus possible to identify 256 lymphocyte subpopulations in 100 μL of blood.

T-cells from centenarians were recently studied by 8-colour flow cytometry in our laboratory. By combining the expression of CD45RA, CCR7, CD127 (IL-7rα), CD95 and CD38 (whose expression can be further distinguished between *dim* and *bright*), we were able to identify up to 48 subpopulations both for CD4+ and CD8+ T-cells (Fig. 1). In order to uncover subtle differences among the three groups of subjects under investigation (20 years old donors, middle aged and centenarians) that otherwise could be missed by classical approaches, we used global approaches based on the Cluster Analysis (CA) and on the Principal Component Analysis (PCA), which are often used for microarray experiments [70]. In particular, the former is able to generate groups or "clusters" of variables on the basis of their similarities and differences, while the latter allows the dimensionality of a multidimensional dataset to be reduced, in order to obtain a new system of coordinates, *i.e.* the principal components. In this ideal space, subjects are plotted by considering all the variables, *i.e.* the T-cell subsets generated by boolean combination. These analyzes revealed that, in centenarians, CD4+ T-cells can be highly heterogeneous since it was not possible to cluster centenarians on the basis of the CD4+ T-cell flow cytometric profile. PCA of CD4+ T-cell subsets revealed the expansion of either CD95+ central memory or effector memory cells where the expression of CD127 could be retained or not. A different behavior was observed for CD8+ T-cells, where a striking expression of terminally differentiated effector (CD45RA+, CCR7-) T-cells with a preferential CD95+, CD127-, CD38- phenotype was detected. More detailed analysis by using different approaches for data pretreatment, such as data scaling, revealed that, for instance, that the same memory subset from young donors and centenarians differentially express CD127. These data thus suggest that, while the production of IL-7 remains constant throughout life [71], T-cells subsets from centenarians could be differentially regulated in terms of peripheral homeostasis [14, 80, 105, 210].

These approaches are very useful to identify cellular dynamics during the ageing process and to identify minimal difference among different ages or clinical conditions. More detailed analysis, in particular in larger cohorts, will reasonably lead to the identification of specific subsets with a possible protective role towards diseases of various origins.

11 Concluding Remarks and Future Directions

We have described some crucial modifications occurring in different lymphocyte subsets with ageing, and underlined that centenarians display some special features that are not shared by the entire elderly populations. Whether these components,

rather than genetic or environmental determinants, are responsible for reaching such an advanced age still remains to be determined. It is however general opinion that all of the aforementioned factors act in synergy. Until now, many studies investigated whether the function of a specific subset is maintained or modified in these individuals, but data are lacking on the interplay among different lymphocyte populations.

An efficient immune response is the result of the tight cooperation of many cell types, and the disfunction of one of them can lead to the persistence of the antigen (or the pathogen), and to the onset of a chronic inflammatory enviroment. Thus, it is needed to uncover specific interactions among cell types by using more global approaches such as systems biology, genome-wide analysis and bioinformatics. A complete and detailed picture of the immune system of centenarians can reveal potential targets for therapy and vaccination in the elderly.

Mouse Models and Genetics of Immunosenescence

Qing Yu, Jyoti Misra Sen and Dennis Taub

Contents

Abstract: Age-related changes in the immune system result in deterioration in the ability of elderly human beings to develop immunity after vaccination and to respond to infections. Thereby the quality of longer lifespan enjoyed by modern man is significantly compromised. Furthermore, higher mortality in the elderly from infections, autoimmune disease and cancer is associated with decline in the immune function. The use of rodent models has yielded critical knowledge of mechanisms by which immune cells develop and function. In this chapter, we focus on several mouse models that have provided significant data on the changes in immune system with advancing age. A greater understanding of many of the age-related changes in immune function, recently defined as immunosenescence, may provide important insight into the development of clinical strategies and interventions for the maintenance of adequate immune system as human beings age.

Keywords: Immune system • Thymic involution • Immune aging • Mouse models • Immunosenescence

1 Introduction

In mammals, adaptive immunity complements the more primitive innate immunity resulting in a more comprehensive protection from infection and neoplasms. Cells of the adaptive immune system, T-cells and B-cells are activated by the antigenic stimulation provided by the pathogen in combination with various growth factors and

immunomodulatory molecules of the innate immune system (e.g., cytokines). The mammalian immune system undergoes significant changes throughout the animal's lifespan. Aging has been associated with immunological changes (immunosenescence) including thymic involution, lower number of naive T-cells, decrease in several cell immune functions and increase in others, and poor vaccination response to new antigens. At each stage of immune development over a lifespan, complex changes have been observed involving multiple cell types and molecular events, making it unlikely that we will be able attribute the age-related changes to a single gene or signalling pathway. Therefore, it has become imperative to understand not only the development and function of individual cell types that participate in normal immune responses and age-associated immunosenescence but also the interactions between various cells and signalling mediators and growth factors.

Many of the early efforts to examine age-associated immune dysfunction have centered on possible loss or alterations in the number of circulating lymphocytes, more specifically T-cells (Taub and Longo 2005). The focus on T-cells makes sense given the fact that T-cells are produced by the thymus, which is known to involute with advancing age resulting in a significant loss in its capability to generate new T-cells for export into the peripheral T-cell pool. Interestingly, this age-associated loss in thymic output does not result in any significant change in the total peripheral number of T-cells. It is believed that peripheral T-cell numbers with aging are maintained by a homeostatic compensatory process involving the peripheral thymus-independent expansion of mature T-cells. Given that T-cells have a limited replicative lifespan, the continued proliferation of T-cells with age is believed to lead to an accumulation of replicative-senescent T-cells possessing a diminished capacity to respond to new or recall antigens and activation stimuli. This homeostatic expansion of peripheral T-cells results in a significantly limited T-cell receptor (TCR) repertoire with age (Taub and Longo 2005). Moreover, while a number of additional age-associated alterations including effects on TCR and growth factor signaling, loss of bone marrow and thymic activity and output, alterations in cytokine and hormone expression and deficits in accessory cell function have been reported, the literature contains a number of contradictory findings describing age-related alterations in immune function suggesting significant variability in the immune aging process. Such variability hinders the identification of a central factor(s) responsible for the loss of immune function. Therefore, with the involvement of so many distinct processes within the aging immune system, the development of potential therapeutic interventions and strategies to reverse the aging process and rejuvenate the immune system has been hindered. Given that the loss in thymic function is one of the earliest and most consistent steps in the progression to immune dysfunction, strategies that target the involuting thymus are the focus of many interventions with the specific goal to reverse thymic atrophy and restore thymopoiesis and T-cell export. Increases in the numbers of new and functional T-cells in the circulating pool may extend and expand the peripheral T-cell repertoire as well as the individual's ability to mount a response to new or recall antigens.

In addition to the age-associated decline in T-cell function, the number of B-cells generated also decline with age resulting in a paucity of naive B-cells. Diminished immune responses to novel antigens in the elderly are the cumulative

effect of fewer newly generated naïve T- and B-cells and a decline in B-cell function and proliferative capacity. This decline in B-cell generation results from the deterioration of the hematopoietic stem cells (HSC) as well as the inability of the older bone marrow environment to support lymphopoiesis. This has lead to increasing interest in the study of HSCs and the local lymphoid environment and their ability to survive, expand and mature during the aging process. Moreover, apart from age-associated defects observed in the adaptive immune system, a number of immunological defects have also been observed in cells of the innate immune system including dendritic cells (DCs), natural killer (NK) cells, monocytes and macrophages, neutrophils, eosinophil, basophil and mast cells. The innate immune system forms the first line of defence in a host with phagocytes (macrophage, DC, granulocytes) engulfing microbes and particulate antigens, killing microbes and tumor cells and presenting processed antigens to T-cells. Defects in many of the established functions of innate immune cells have been reported (Taub and Longo 2005). Thus, it would appear that aging has an impact on many of the immune cell subsets and together may impact our ability to respond to antigens, microbial challenges and tumors with advancing age. Thus, increasing our understanding of the potential mechanisms believed responsible for age-related immunosenescence should yield valuable insight into the development and optimization of interventional strategies aimed at restoring thymic and bone marrow function and boosting the responsiveness of adaptive and innate cell subsets.

Animal models are commonly utilized in aging research to obtain data on specific tissue and organ systems that are difficult to obtain directly from humans. In addition, given the significantly shorter life span of animals and ethical issues with performing certain treatments in human volunteers or patients, it is much easier to examine the impact of genetic, hormonal, nutritional and physiological changes in these models than in humans. For example, one can easily examine the impact of caloric restriction in mice and rats over their 2–3 year life span compared to similar studies in human, which would be nearly impossible to perform from birth to death. Moreover, in mice, various genes can be manipulated and modified to generate gene hyper-expressing or deficient animals to examine the influence of a single gene pathway on life span or various physiological functions. A number of animal model systems have been established examining the age-associated defects in immune function and specific pathways that have been shown to be altered, accelerated and/or influenced by normal or pathological aging. These immunosenescence models include mice with alterations in telomerase activity, tumor suppressor function, oxidative stress, hormone expression and various other molecules associated with immune development and differentiation as well as longevity. A number of unique findings have been made in these models regarding basic immune function and the relationship between various pathways associated with longevity and immune function. Many of these models can be divided into several categories including those mouse models demonstrating a shorter life span, an extended lifespan and little to no significant differences in life expectancy. In this chapter, we have reviewed and consolidated the available data on many of these established mouse model systems that have been utilized to study alterations in innate and adaptive immune function and their relationship to age-related immunosenescence and clonal exhaustion.

2 Mouse Models Demonstrating a Shorter Life Span

A. Klotho Mice. Klotho gene is the first gene to be documented that accelerates aging and shortens life span upon disruption and extends life span when overexpressed (Kuro-o et al. 1997; Kurosu et al. 2005). The Klotho protein is a 130kD single-pass transmembrane protein, but the extracellular fraction of the protein is shed and secreted into the blood and body fluids and thus it is now believed to function as a hormone or cytokine. The Klotho protein inhibits intracellular insulin and IGF-1 signalling, which is a major mechanism for Klotho's effect on preventing aging (Kurosu et al. 2005). Klotho mice, which bear an insertional mutation of Klotho gene, have demonstrated various disorders resembling human aging as well as a significantly shortened life span (Kuro-o et al. 1997). Klotho mice have dramatically accelerated age-related thymic atrophy (Kuro-o et al. 1997) and significantly accelerated age-related decline in B-lymphopoiesis (Okada et al. 2000). The defective B-lymphopoiesis is not cell autonomous and thus Klotho may exert its effect by influencing hematopoietic microenvironment, which includes IL-7 gene expression by bone marrow stromal cells (Okada et al. 2000).

B. Senescence-accelerated Mouse (SAM). The SAM series were generated in 1980s from the breeding of AKR/J mice when the researchers found that certain litters of mice had an accelerated senescence in an inherited manner. To date, the SAM series includes nine SAMP strains with accelerated aging and three SAMR strains with normal aging, and each SAMP mouse shows various strain-specific and age-associated phenotypes (Higuchi, 1997; Hosono et al., 1997; Takeda et al., 1991; Takeda et al., 1981). The genetic changes in SAMP mice await extensive investigations, although alterations in the expression of apolipoprotein A-II (Apo A-II) has been identified in these strains (Higuchi 1997). SAMP mice demonstrate age-associated early decline in various immune functions, including decline of antibody production to T-independent antigens and NK cell activity; decline in antibody response to T-dependent antigens as a result of impaired T helper cell activity for antibody response and early onset of autoantibody production (Haruna et al. 1995; Hosokawa et al. 1987a; Hosokawa et al. 1987b; Hosono et al. 1997; Yoshioka et al. 1993).

C. Terc Deficient Mice. Telomerase is the protein complex that synthesizes telomeres and thus preventing telomere shortening during cell division and the consequent chromosomal instability and cell cycle arrest or apoptosis. Telomerase consists of two basic components, telomerase reverse transcriptase (Tert) and telomerase RNA component (Terc), which provides the RNA template for the telomeric DNA repeats (Collins 2000; Nugent and Lundblad 1998). Mice that are deficient for Terc are initially normal, but after 5–6 generations both females and males are sterile and demonstrate certain premature aging phenotypes and shorter life spans (Blasco et al. 1997; Lee et al. 1998). These mice also exhibit an impaired ability to regenerate hematopoietic cells after ablation of these cells by 5-FU, decreased antibody responses and germinal center formation to a T-dependent antigen and reduced T and B-cell proliferation after activation in vitro. These

results confirm that telomere shortening can influence immunoresponsiveness, although the precise mechanisms by which this occurs remains unknown (Herrera et al., 2000; Lee et al., 1998).

D. Tumor Suppressor Mouse Models. A number of genes that are involved in tumor suppression, DNA repair and cell cycle checkpoint also regulate aging and life span. The direct studies on effect of tumor suppressor P53 have been hampered by the early onset of tumor in $p53^{-/-}$ mice and failure of embryonic development in mice overexpressing p53 (Donehower et al. 1992; Tyner et al. 2002). However, mice expressing two types of truncated forms of p53, p24 and p44 (that bestow enhanced activity to endogenous full-length p53), show early onset of aging, a range of aging phenotypes and significantly decreased life span (Maier et al. 2004; Tyner et al. 2002). Disruption of Wip1, Brca1, Atm, Ku86, K70 or XPD all lead to shortened life span by modulating p53 activity (Barlow et al. 1996; Cao et al. 2003; Choi et al. 2002; de Boer et al. 2002; Li et al. 2007; Vogel et al. 1999). In $p53^{-/-}$ mice, apart from the development of thymic lymphoma, peripheral CD4+ T-cells demonstrate traits of immune senescence such as accumulation of memory type cells and defective proliferative response upon activation (Clarke et al. 1993; Donehower et al. 1992; Lowe et al. 1993; Ohkusu-Tsukada et al. 1999). In mice deficient for Wip1, a serine/threonine phosphatase that inhibits p53 activity, T-cell and B-cell proliferation response to mitogen stimulation is reduced and the immune system also manifest some other changes indicating of immune senescence (Choi et al. 2002). In $Ku86^{-/-}$, $K70^{-/-}$ and $Atm^{-/-}$ mice, development of T- and/or B-cells are severely impaired due to the critical requirement of these genes for recombination of antigen receptor genes and the incidence of lymphoma development is dramatically increased, both of which prevent a thorough study of the effect of these genes on immune aging (Gu et al. 1997; Li et al. 1998; Li et al. 2007; Matei et al. 2007; Matei et al. 2006; Nussenzweig et al. 1996; Zhu et al. 1996). The development and aging of the immune system in other interesting aging models, $p53^{+/m}$ mice, p44-Tg mice and TTD ($XPD^{-/-}$) mice remains to be thoroughly investigated.

E. Reactive Oxygen Models. Reactive oxygen species (ROS) are involved in pathology of aging and cancer and therefore molecules that provide defences against oxidative stress and ROS are important in preventing aging. Peroxiredoxin is a family of small antioxidant proteins that scavenge peroxide and play a role in the cellular response to ROS. Peroxiredoxin-$1^{-/-}$ mice have a shorter life span due to hemolytic anemia and develop several types of cancer including T- and B-cell lymphomas (Neumann et al. 2003). The mice have impaired innate immune systems with decreased number of NK-cells that express activation receptor Ly49D and decreased NK-cell cytolytic activity as well as reduced NK-enhancing activity in RBCs. The impaired NK-cell activity may be one of the factors responsible for increased tumor development in these mice (Neumann et al. 2003).

F. Hormonal Models. Growth hormone/insulin-like growth factor 1 (GH/IGF-1) signalling pathway has long been associated with the aging process and has been demonstrated to negatively affect life span, primarily by decreasing cellular antioxidative capacity and increasing cell apoptosis (Bartke 2005; Everitt 2003; Quarrie and Riabowol 2004). Transgenic mice expressing GH demonstrate various

Table 1 Mouse Models Demonstrating a Shorter Life Span

Strain name (reference)	Molecular description	Immune system	References (immune system)
Klotho mice (Kuro-o et al. 1997)	Mice with an insertional mutation of Klotho gene Novel membrane protein and aging suppressor, 20–40% sequence homology to bacteria and plant β-glucosidases and mammalian lactase glycosylceramidase. Function as a hormone and inhibits insulin and IGF1 signaling Multiple disorders resembling human aging Life span: decreased significantly	Significantly accelerated thymic atrophy with thymus normal early after birth but barely detectable at 6–9 weeks of age Markedly decreased B-cells in bone marrow, spleen and blood Reduced IL-7 responsive B-cell precursors Decreased IL-7 gene expression in bone marrow stromal cells but injection of IL-7 does not rescue the defective B-lymphopoiesis HSCs have normal capacity of B-lymphopoiesis in vitro and in normal hosts Normal B-cell development in neonates and young KO mice before 2 weeks of age that have no aging phenotypes	(Kuro-o et al. 1997) (Okada et al. 2000)
SAMP mice (Takeda et al. 1991) (Takeda et al. 1981)	Senescence-accelerated mice, naturally occurring mutant mice (AKR/J background) Accelerated aging Life span: decreased by 27%	Age-associated early decline in immune function Early onset of regression in Ab production to T-independent Ag (DNP-Ficoll) and NK-cell activity Profound defect in Ab response to T-dependent Ag (sRBC), due to the impaired T-helper-cell activity for Ab response Early decline of stimulatory activity in DCs and B-cells Earlier production of autoantibodies against DNA and collagen Type II Some cellular immuneresponses, such as mix lymphocyte reaction, CTL response and DTH reaction are normal	(Hosono et al. 1997) (Hosokawa et al. 1987a) (Hosokawa et al. 1987b) (Yoshioka et al. 1993) (Haruna et al. 1995)

Table 1 (continued)

Strain name (reference)	Molecular description	Immune system	References (immune system)
TERC$^{-/-}$(mTR$^{-/-}$) (Blasco et al. 1997)	Target knockout of telomerase RNA template (mTR) Later generation TERC$^{-/-}$ mice have shorter life span and some phenotypes of accelerated aging	Normal initial development of lymphocytes and other hematopoietic lineages, impaired ability to regenerate hematopoietic populations after 5-FU treatment Reduced proliferative response of T- and B-cells in vitro Decreased T-cell dependent humoral response in vivo, including decreased Ab response and germinal center formation	(Herrera et al. 2000) (Lee et al. 1998)
P53$^{-/-}$mice (Donehower et al. 1992)	Target knockout of P53 gene Tumor suppressor, induces DNA repair, cell cycle arrest and apoptosis Increased incidence of early death, mostly not due to tumor	Thymocyte development initially normal, but develop thymic lymphoma Thymocytes and B-cells are resistant to DNA damage induced apoptosis Accelerated aging of immune system Accelerated age-related accumulation of memory like CD4 T-cells Increased cytokine production and decreased proliferation of CD4 T-cells upon activation in adult mice	(Donehower et al. 1992) (Clarke et al. 1993) (Lowe et al. 1993) (Ohkusu-Tsukada et al. 1999)
P53$^{+/m}$mice (Tyner et al. 2002)	Transgenic mice expressing N-terminus truncated P53 protein Early onset of various aging phenotypes. Effects dependent on wild-type P53 Life span decreased by 17–19%	Significantly enhanced age-associated lymphoid atrophy	(Tyner et al. 2002)

Table 1 (continued)

Strain name (reference)	Molecular description	Immune system	References (immune system)
pL53 mice (Tyner et al. 2002)	Transgenic mice expressing temperature sensitive mutant P53 protein Early onset of aging phenotypes Life span: not documented		
P44-Tg mice (Maier et al. 2004)	Transgenic mice expressing P44, the shorter isoform of P53 Early onset of aging phenotypes Life span: decreased by 40–50%		
Wip1$^{-/-}$mice (Choi et al. 2002)	Knockout of Wip1 (wild-type P53-induced phosphatase1) Serine/threonine phosphatase induced in a P53-dependent manner by DNA damaging agents. Inhibits P53 activity by inhibiting P38 phosphorylation Life span: dramatically decreased in males	Enhanced susceptibility to pathogens Increased inflammation and skin ulcerations Abnormal lymphoid histopathology Decreased T-cell and B-cell proliferative response to mitogenic stimuli	(Choi et al. 2002)
Brca-1$^{-/-}$P53$^{+/-}$ (Cao et al. 2003)	Targeted knockout of Brca-1 gene plus heterozygote knockout of P53 gene. Protein that has been implicated in many normal cellular functions such as DNA repair, transcriptional regulation, cell-cycle checkpoint control Brca-1$^{-/-}$ mice are embryonic lethal, Brca-1$^{-/-}$ P53$^{+/-}$ mice are viable but show dramatic aging phenotypes and significantly shorter life span compared to P53$^{+/-}$ mice

Strain name (reference)	Molecular description	Immune system	References (immune system)
Atm$^{-/-}$mice (Barlow et al. 1996)	Target knockout of Atm (ataxia-telangiectasia mutated) Protein kinase that coordinates DNA damage monitoring and repair pathways. Phosphorylates and activates effectors that mediate cell-cycle checkpoint responses Life span: death before 4.5 month due to thymic lymphomas	Decreased generation and survival of DP thymocytes undergoing TCRα gene recombination Severely reduced number of mature CD4+ and CD8+ single positive thymocytes Develop aggressive thymic lymphoma, causing death before 4.5 months	(Barlow et al. 1996)(Matei et al. 2007)(Matei et al. 2006)
Ku86$^{-/-}$mice (Vogel et al., 1999) (Li et al., 2007)	Target knockout of Ku86 Important component of DNA-dependent protein kinase (DNA-PK) that's required for repairing DNA double-strand break (DSB) by nonhomologous end-joining (NHEJ) Early onset of senescence in multiple tissues and organs Life span: decreased by 61–66%	Severe immune deficiency due to early arrest of T- and B-cell development, resulting from failure in VDJ recombination Early onset of age-associated acute and chronic immune reactions in multiple organs, sometimes resulting in sepsis	(Zhu et al. 1996)(Nussenzweig et al. 1996)
Ku70$^{-/-}$mice (Li et al. 2007)	Target knockout of Ku70 Important component of DNA-dependent protein kinase (DNA-PK) that's required for repairing DNA double-strand break (DSB) by nonhomologous end-joining (NHEJ) Early onset of senescence in multiple tissues and organs Life span: decreased by 66%	Deficiency of mature B-cells or serum immunoglobulin Severely decreased thymocytes and peripheral T-cells due to severe impairment in VDJ recombination Significant incidence of $CD4^+CD8^+$ Significant incidence of $CD4^+CD8^+$ thymic lymphoma and disseminated T-cell lymphomas at a mean age of 6 months	(Gu et al. 1997)(Li et al. 1998)

Table 1 (continued)

Strain name (reference)	Molecular description	Immune system	References (immune system)
TTD mice (de Boer et al., 2002)	Target mutation of XPD gene DNA helicase involved in DNA repair and transcription Exhibit many premature aging symptoms Life span: decreased by >50%	Lower NK-cell activity reported in TTD patients	(Mariani et al. 1992)
GH-Tg mice (Palmiter et al. 1992) (Selden et al. 1989) (McGrane et al. 1988) (Bartke 2003)	Transgenic mice expressing growth hormone (GH) under mouse metallothionein I (MT) promoter or rat PEPCK (phosphoenolpyruvate carboxykinase) promoter Transgenic GH is expressed in multiple tissues, such as liver and kidney Exhibit multiple premature aging symptoms Life span: significantly decreased	Increased numbers of migrating cells in laminin-coated transwells Increased CXC chemokine ligand 12 (CXCL12)-driven migration Increased recent thymic emigrants in lymph nodes	(Smaniotto et al. 2005)
Peroxiredoxin$^{-/-}$ mice (Neumann et al. 2003)	Target knockout of peroxiredoxin Small antioxidant proteins, scavenge peroxide and are involved in cellular response to reactive oxygen species (ROS) Life span: significantly decreased	Decreased NK cell cytolytic activity, decreased frequency of NK-cells expressing activation receptor Ly49D Significantly reduced NK-enhancing activity in RBCs from KO mice Development of B- and T-cell lymphomas	(Neumann et al. 2003)

premature aging phenotypes and have drastically decreased life span (Bartke 2003; McGrane et al. 1988; Palmiter et al. 1992; Selden et al. 1989). The development and aging of the immune system in these mice remain poorly studied and await more detailed examination.

3 Mouse Models Demonstrating an Extended Life Span

A. Caloric Restriction Models. Caloric restriction (CR) (limiting food intake without causing nutritional deficiencies) has been the most potent environmental factor that results in consistent extension of life span. The mechanisms responsible for the effect of CR include reducing oxidative damage, lowering GH/IGF level and triggering an innate beneficial response to low-level stressors (Masoro 1996; Merry 2000; Quarrie and Riabowol 2004; Sohal and Weindruch 1996; Weindruch and Walford 1982). CR is also the most extensively studied factor that leads to potent and consistent delay or prevention of immune senescence processes. CR results in delay or reversal of age-related reduction in naïve T-cells, decline of T-cell proliferative response to mitogens and decline in anti-viral immune response, increase in occurrence of tumor and autoimmune diseases and increase in production of inflammatory cytokines (Chen et al. 1998; Effros et al. 1991; Hobbs et al. 1993; Hursting et al. 2003; Spaulding et al. 1997a; Spaulding et al. 1997b; Walford et al. 1973; Weindruch and Walford 1982). Together, these data suggest that overall the immune system benefits from CR. However, in vivo immune responses to pathogens have not been studied to determine if infected CR mice fare better than age-matched mice on ad libitum diets. These studies will provide critical support to the hypothesis that CR benefits immune function.

B. Hormonal Models. A large group of mouse models that have extended life span involve reduced pituitary GH/IGF-1 function (Quarrie and Riabowol 2004). Among these models, the Ames dwarf and Snell dwarf mice have mutate Prop1 gene and Pit1 gene, respectively, both of which result in lowered GH/IGF-1 levels that account for both an extended life span and dwarfism (Bartke et al. 2001; Brown-Borg et al. 1996; Flurkey et al. 2001). Little mice have mutation in Ghrhr gene that encodes GH-releasing hormone receptor and the Laron mice have targeted mutation in growth hormone receptor (GHR) and GH binding protein. The p66shc$^{-/-}$ mice lack the downstream effector of GH/IGF-1 signaling and the IGF-1R$^{-/-}$ mice lack the receptor for IGF-1 (Coschigano et al. 2000; Flurkey et al. 2001; Holzenberger et al. 2003; Lupu et al. 2001; Migliaccio et al. 1999; Zhou et al. 1997). All of these mice have demonstrated extended life spans presumably due to their defective GH/IGF-1 axis. The studies on immune function in these animals are much less extensive than that done with CR mice and many results remain controversial. Among them, the immune senescence of Snell dwarf mice has been the more thoroughly investigated and results show that multiple immune senescence processes are delayed or reversed in these mice (Flurkey et al. 2001; Taub and Longo 2005). These include

Table 2 Mouse Models Demonstrating a Longer Life Span

Strain name	Molecular description	Immune system	References
Klotho-Tg mice (Kurosu et al., 2005)	Transgenic mice expressing Klotho gene under the control of human elongation factor 1α Life span: increased by 20–30% in male, and around 19% in female		
CR mice(Masoro 1996) (Merry 2000) (Sohal, Weindruch 1996) (Weindruch, Walford 1982)	Mice with caloric restriction (limiting food intake without causing nutritional deficiencies) Life span: significantly increased	Delayed or reversed immune senescence, which include age-associated decrease in naïve CD4+ and CD8+ T-cells, decline in T-cell proliferation to mitogenic stimuli, increase in incidence of tumor and autoimmune disease, decrease in anti-viral immunity, increase in production of inflammatory cytokines	(Chen et al. 1998) (Walford et al. 1973) (Weindruch and Walford 1982) (Hursting et al. 2003) (Effros et al. 1991) (Hobbs et al. 1993) (Spaulding et al. 1997a) (Spaulding et al. 1997b)
Ames Mice (Brown-Borg et al. 1996) (Bartke et al. 2001)	Mutation of Prop1 gene Transcription factor in embryonic development of anterior pituitary Life span: increased by 40–50%	Decreased thymocyte numbers	(Duquesnoy 1972)
Snell mice (Brown-Borg et al. 1996)	Mutation of Pit1 gene Pituitary-specific transcription factor Life span: increased by 40–50%	Delayed or reversed immune senescence The age related increase in splenic memory CD4+ T-cells and memory CD8+ T-cells is almost completely prevented, so is the increase in CD4+ and CD8+ T-cells that express cell surface P-glycoprotein The age related decrease in CD4+ and CD8+ T-cell function reflected by IL-2 production and generation of cytotoxic effectors is also near completely prevented	(Flurkey et al. 2001)

Table 2 (continued)

Strain name	Molecular description	Immune system	References
Little mice (Flurkey et al. 2001) (Lupu et al. 2001)	Recessive mutation of Ghrhr (GH-releasing hormone receptor) Life span: increased by 23–25% when maintained on low fat diet		
Laron Mice (Zhou et al. 1997) (Coschigano et al. 2000)	Target knockout of GHR (growth hormone receptor) and GHBP (GH binding protein) Life span: increased by 37–55%		
p66shc$^{-/-}$mice (Migliaccio et al. 1999)	Target knockout of P66shc Downstream effector of IGF-1R Life span: increased by 30%	T-cells are less susceptible to apoptogenic stimuli, and have enhanced proliferation in response to TCR stimulation in vitro	(Pacini et al. 2004)
IGF-1R$^{+/-}$mice (Holzenberger et al. 2003)	Heterozygous for the IGF-1R gene (IGF-1R$^{-/-}$ is lethal) Life span: increased by 26% overall, 33% in female, 16% in male mice and not statistically significant	Decreased T-cell-independent B-cell response by in vivo assay	(Kelley et al. 1998)
TRX-Tg mice (Mitsui et al. 2002)	Transgenic mice expressing thioredoxin driven by human β-actin promoter Small thiol-mediated redox-active protein Enhanced resistance to a variety of oxidative stresses Life span: increased by 35%	Tg mice sustain the Th1 skewed status of Th1/Th2 balance during aging, in contrast to the gradual polarization to Th2 in WT mice Tg macrophages retain the phenotype of reductive macrophages with the ability to produce IL-12, and produce increased amount of NO and reduced amount of IL-6 and IL-10 during aging	(Murata et al. 2002)
FIR-KO mice (Bluher et al. 2003)	Conditional knockout of insulin receptor (IR) in adipose tissues Life span: increased by 18%		
uPA-Tg mice (Miskin, Masos 1997)	Transgenic mice expressing uPA (urokinase-type plasminogen activator) in the brain Reduced food consumption, body size and weight Life span: increased by 16%		

an age-related increase in memory T-cells and a decrease in IL-2 production and generation of cytotoxic CD8+ T-effector-cells (Flurkey et al. 2001).

4 Mouse Models Demonstrating a Normal or Undocumented Life Spans

A. Wnt-β-catenin-TCF signaling models. Wnt-β-catenin-T Cell Factor (TCF) signalling pathway has been shown to regulate thymic involution. TCF-$1^{-/-}$ mice have decreased thymocyte cellularity as early as during embryonic development, resulting from impairment at early stages of thymocyte development (Verbeek et al. 1995). In these mice, thymic involution becomes increasingly severe with age such that by 6 months of T-cells are essentially depleted (Schilham et al. 1998). Mice expressing stabilized form of β-catenin, a partner of TCF-1 for activating target gene transcription, also show enhanced thymic involution with decreased number of all thymocyte subpopulations (Xu and Sen 2003). Thus, increased Wnt signalling, as seen in transgenic mice expressing β-catenin, or decreased Wnt signalling documented in TCF-1-deficienct mice both promote thymic involution. While the precise molecular mechanisms involved in these processes remains under investigation, a balanced Wnt-β-catenin-TCF signalling pathway appears to be essential to maintain thymic function.

B. Ghrelin Infusion and Knockout Mouse Models. Recent studies have demonstrated important roles of Ghrelin in promoting thymopoiesis during aging (Dixit et al. 2007). Ghrelin is a peptide hormone mainly produced by enteroendocrine cells in the stomach in response to negative energy balance. Ghrelin binds to the GH secretagogue receptor (GHS-R) and stimulates growth hormone (GH) secretion from the pituitary. Both ghrelin and GHS-R are expressed by resting and activated human T-cells and exert anti-inflammatory effects on immune cells and systemically in mice (Dixit et al. 2004; Dixit and Taub 2005). Ghrelin and GHS-R expression declines within the thymus with age (Dixit et al. 2007). Mice deficient for ghrelin or GHS-R demonstrate enhanced age-associated thymic involution and decreased numbers of lymphoid progenitor cells in the bone marrow and thymus. Conversely, infusion of ghrelin into old mice significantly improves age-associated changes in thymic cellularity, the number of ETP, CLP, LSK and RTE and improves the TCR diversity of peripheral T-cells (Dixit et al. 2007). Thus, ghrelin emerges as an important factor to promote thymopoiesis during aging.

C. Cytokine Models. Cytokines, particularly IL-7, have been found to be associated with preventing age related thymic involution. IL-7, produced mainly by thymic and bone marrow stromal cells, is a critical trophic factor for both T- and B-cell progenitors, and deficiency of IL-7, its receptors (IL-7Rα and γ_c) and its downstream signalling molecule Jak3 all lead to severe defects in early T- and B-cell development and thus thymic involution and lymphopenia. IL-7 mRNA levels in the thymus decreases 15-fold by 22 months of age (Alves et al. 1995; Andrew and Aspinall 2002; Ortman et al. 2002). Effect of IL-7 administration on

Table 3 Mouse Models Demonstrating Normal or Undocumented Life Span

Strain name	Molecular description	Immune system	References
TCF$^{-/-}$ mice	Target knockout of TCF-1 Transcription factor downstream of Wnt signalling pathway, binds DNA and forms a complex with β-catenin which activates gene transcription	Dramatically decreased thymic cellularity starting from embryonic stage and throughout life; incomplete block at DN1, DN2 and ISP stage of thymocyte development in young mice and complete block at DN1 stage in older mice	(Verbeek et al. 1995) (Schilham et al. 1998)
CAT-Tg mice	Transgenic mice expression stabilized β-catenin under proximal Lck promoter Mediator of Wnt signalling pathway, pairs with TCF-1/LEF-1 to activate gene transcription	Enhanced thymic involution Decreased number of all the thymic subpopulations No drastic reduction in splenic T-cells	(Xu and Sen 2003)
Ghrelin$^{-/-}$mice	Target knockout of Ghrelin Peptide hormone mainly produced by stomach Also expressed by thymocytes and T-cells	Enhanced age-associated thymic involution with reduced thymopoiesis Infusion of ghrelin into old mice significantly improves age-associated changes in thymic cellularity, number of ETP, CLP, LSK and RTE and improves the TCR diversity of peripheral T-cells	(Dixit et al. 2004; Dixit and Taub 2005; Dixit et al. 2007)
GHS-R$^{-/-}$mice	Target knockout of GHS-R (growth hormone secretagogue receptor) G-protein coupled receptor, receptor for Ghrelin	Enhanced age-associated thymic involution with reduced thymopoiesis and diminution of bone marrow and peripheral LSK hematopoietic stem cell population	(Dixit et al. 2004) (Dixit and Taub 2005) (Dixit et al. 2007)
Lurcher mice	LC mutation, autosomal semidominant mutation of glutamate receptor (GluRδ2) gene Selectively expressed on Purkinje cells and LC mutation causes their apoptosis by a high glutamate concentration LC/LC mice die early after birth	LC/+ mice show significant reduction of DP thymocytes and thymic involution by 3 month of age due to enhanced cell death, while peripheral T-cell number is normal compared to control mice	(Mandakova et al. 2005) (Mandakova et al. 2003) (Mandakova et al. 2003)

Table 3 (continued)

Strain name	Molecular description	Immune system	References
Dnmt1$^{+/}$mice	Target knockout of Dnmt1 (DNA methyltransferase 1) Enzyme responsible for maintaining DNA methylation through mitosis	Delayed immune senescence, reflected by significantly delayed age-associated increase in memory-like CD4 T-cells, decline of CD4 T-cell proliferative response and IL-2 production Delayed development of autoimmunity	(Yung et al. 2001)
IL-7$^{-/-}$	Target knockout of IL-7	Severe T- and B-cell lymphopenia resulting from severe impairment of early T- and B-cell development	(von Freeden-Jeffry et al. 1995) (Moore et al. 1996)
IL-7Rα$^{-/-}$ γc$^{-/}$mice	Target knockout of IL-7 receptor alpha (α) chain and the common gamma (γ) chain	Severe T- and B-cell lymphopenia resulting from severe impairment of early T- and B-cell development	(Peschon et al. 1994) (Akashi et al. 1998) (Cao et al. 1995)
Jak3$^{-/}$mice	Target knockout of Jak3 Jak family Tyrosine kinase mediating IL-7 receptor signal	Severe T- and B-cell lymphopenia resulting from severe impairment of early T- and B-cell development Severe defects in NK-cell development	(Nosaka et al. 1995) (Thomis et al. 1995) (Baird et al. 2000)
Lck-IL-7-Tg mice	Transgenic mice expressing IL-7 under proximal lck promoter	Low level IL-7 expression: increased thymocyte number, increased DP and SP thymocyte number Medium level IL-7 expression: no significant changes in thymocyte number High level IL-7 expression: decreased thymocyte number due to impaired proliferation of DN thymocytes	(El Kassar et al. 2004)
IL-7Rα-Tg mice	Transgenic mice expressing IL-7Rα under human CD2 promoter	Normal thymocyte number at birth, rapid decline in thymocyte number with age	(Munitic et al. 2004)

Table 3 (continued)

Strain name	Molecular description	Immune system	References
IL-12β$^{-/-}$mice	Target knockout of IL-12β IL-12 p40 subunit is produced by APCs and regulates function of T-cells and NK-cells.	Accelerated thymic involution due to increased thymocyte apoptosis Accelerated degeneration of thymic structures with decreased cortex/medulla ratio No defect in thymocyte development in young mice No age-associated decrease in IL-12 level produced by APCs in normal mice	(Hsu et al. 2005; Li et al. 2004)
CD11c-Bcl-2-Tg mice	Transgenic mice expressing human BCL-2 under CD11c promoter, in DC cells	Increased frequencies and numbers of DCs, increased turnover/survival (longevity) of DCs Enhanced humoral and cellular immune response in vivo, including enhanced IgG production, T-cell proliferation and cytotoxic activity	(Nopora and Brocker 2002)
CD2-Fas-Tg mice	Transgenic mice expressing Fas under CD2 promoter, in T-cells. Surface molecule that is critical for apoptosis and stimulation during T-cell development	Prevent age-associated decrease in ligand-induced apoptosis and proliferation as well as changes in IL-2, IL-10 and IFNγ production in T-cells; decrease in density of cell surface lipid raft elements possibly influencing cell death or activation	(Zhou et al. 1995)

thymopoiesis and thymic output has been controversial because some reports did not demonstrate significant effects (Fry and Mackall 2002), while others showed that IL-7 increases recent thymic emigrants in periphery without enhanced thymic function and restores immunity in athymic T-cell-depleted hosts (Chu et al. 2004; Fry et al. 2001; Mackall et al. 2001). IL-12, produced mainly by dendritic cells, is another factor that's required for preventing thymic involution during aging process. Aged IL-12$\beta^{-/-}$ mice, but not young IL-12$\beta^{-/-}$ mice, demonstrate accelerated thymic involution compared to age-matched wild type mice. IL-12 enhances the proliferation of thymocytes from aged IL-12$\beta^{-/-}$ and wild type mice in response to IL-2 and IL-7. Thus, IL-12 enhances IL-7 and IL-2 signalling in thymocytes from aged mice and thus may compensate for the age-associated reduction in IL-7 and IL-2 expression and signal, and thereby inhibiting thymic involution in older mice (Hsu et al. 2005). Thus, cytokines can enhance T-cell generation as well as regulate thymic function and peripheral T-cell activity. Additional work is required to define challenges in administrating cytokines to therapeutically enhance T-cell output in older humans.

5 Conclusions

The selection of an animal model for aging or immunosenescence research is dependent on the specific cells, pathways and interventions being considered or studies by an investigator and how such models may physiologically relate to normative aging and immune function. The loss or gain of immune function in a transgenic, knockout or mutant mouse does not necessarily reflect the physiological role of the manipulated molecules within a normal immune response. However, such manipulation does permit one to examine the impact of a pathway or system on life span, aging, immunity and immune development and interactions between various organ systems. Information from these animals can then lead to further examination under physiological conditions and eventually to the development of strategies to manipulate these same systems for possible therapeutic benefit. To date, only a few systems have been examined in the context of aging and much more work is needed. Many of the model systems discussed in this chapter have provided valuable new information on both aging and age-associated immunosenescence, which have lead investigators to initiate more detailed studies on specific molecules and signalling systems as well as the development of additional mouse models to further examine the interrelationships and interactions between these various ligand and signalling pathways. Moreover, some of these studies have even lead to the development of clinical trials in human subjects, such as in several hormonal administration trials. With the completion of the human genome project, we can expect the development of many additional mouse models and our need to understand the role of these molecules in the context of aging, age-related pathologies and immunosenescence will be required.

Acknowledgments This research was supported in part by the Intramural Research Program of the National Institute on Aging, National Institutes of Health.

Insect Models of Immunosenescence

Jeff Leips

Contents

Abstract: For the past few decades invertebrates have been used extensively as models for understanding the general process of senescence (see reviews by Partridge and Gems 2002; Grotewiel et al. 2005; Keller and Jemielity 2006; Houthoofd and Vanfleteren 2007) and since the 1920's as models for understanding the genes, signaling pathways and cellular processes involved in innate immunity (Brey 1998). These two fields of study have begun to merge as invertebrate models, chiefly terrestrial insects, are increasingly being used to understand both the causes and consequences of age-related changes in immunocompetence. Invertebrates are ideally suited for such studies as they generally have short generation times, short life spans and can be raised in large numbers which improves statistical power for detecting the effects of genetic and environmental influences on functional measures of the immune response. In addition, recently completed genome sequences of invertebrates (e.g., *Caenorhabditis elegans*: C. elegans Sequencing Consortium 1998; *Drosophila melanogaster:* Adams et al. 2000; *Anopheles gambiae*: Holt et al. 2002: *Bombyx mori:* Xia et al. 2004) reveal that many of the genes regulating the innate immune response have homologous genes in vertebrates. Molecular genetic studies have also revealed extensive homology between invertebrates and vertebrates in the signaling pathways that are activated to fight infection (Hoffmann and Reichhart 2002). Thus, the use of invertebrate models is likely to contribute a great deal to our

understanding of the genetic influences on immunosenescence in a wide range of organisms, including humans.

Keywords: Immune response • survival • bacterial clearance • *Toll* • IMD • JNK • phenoloxidase • phagocytosis • encapsulation • hemocyte • aging

1 Introduction

One complication in translating what we learn about immunosenescence in invertebrates to vertebrate organisms is that invertebrates rely solely on an innate immune response and lack the components of the adaptive immune system found in vertebrates. While there is some evidence to suggest that invertebrates have immunological memory (Sadd and Schmid-Hempel 2006; Pham et al. 2007), this ability is not well understood. Our current understanding suggests that immunological memory in invertebrates results from remodulation of existing cells to enhance their ability to phagocytize previously encountered pathogens. As such, this is fundamentally different from immunological memory that stems from the use of the B- and T-cells of the adaptive component of the immune response. Looked at in another way however, the lack of the adaptive component of the immune response can be considered an advantage because it allows us to examine the effect of age on the innate immune response without the complications of interactions between the adaptive and innate immune systems. Given the similarity among organisms in the many components of the innate immune response, studies of immunosenescence in invertebrates are likely to provide insight into the effect of aging in the innate immune system in all metazoans, including humans.

This chapter begins with a brief review of the immune system of invertebrates, drawn largely from information on the invertebrate with the most extensively studied immune response, *Drosophila melanogaster.* Those wishing to explore this topic further should consult the many excellent reviews on this topic (e.g., Hoffmann et al. 1996; Tzou et al. 2002; Hultmark 2003; Kurz and Ewbank 2003; Brennan and Anderson 2004; Cerenius and Söderhäll 2004; Christophides et al. 2004; Loker et al. 2004; Gravato-Nobre and Hodgkin 2005; Kim and Ausubel 2005; Mylonakis and Aballay 2005; Schmid-Hempel 2005; Evans et al. 2006; Lemaitre and Hoffmann 2007; Royet and Dziarski 2007; Uvell and Engström 2007). The next section summarizes what we have learned about age related changes in the immune system in invertebrates and includes a discussion of the various techniques used to study this phenomenon. The final section outlines some future directions for the use of invertebrates as models of immunosenescence, highlighting both the challenges and the promise that these organisms provide for a more complete understanding of the causes and consequences of age-related deterioration of the innate immune function.

2 Invertebrate Immunity

There are three general components of the innate immune system shared by most invertebrates: i) a wound response which involves proteolytic cascades and melanization to limit the spread of infection and kill pathogens, ii) cellular responses which involve phagocytosis and/or encapsulation of the invading organism, and iii) local and systemic synthesis and secretion of antimicrobial proteins. Age-related deterioration in any of these components is likely to reduce the effectiveness of the immune system.

2.1 Immune Response Activation

The immune response is typically induced following recognition of nonself by the host. In most invertebrates pathogen recognition is accomplished by pattern recognition receptors circulating in the hemolymph or embedded in the cell membranes of hemocytes (Khush and Lemaitre 2000; Hoffmann and Reichhart 2002 Hultmark 2003; Leulier et al. 2003; Royet and Dziarski 2007). These receptors recognize and bind evolutionarily conserved molecular structures that are unique to the surfaces of different types of microorganisms such as the peptidoglycan components of gram-positive and gram-negative bacteria, β-1,3 glycan in fungi, and phosphoglycan of parasites (Kimbrell and Beutler 2001; Janeway and Medzhitov 2002; Hultmark 2003). Invertebrates produce several classes of these pattern recognition receptors such as peptidoglycan receptor proteins (Royet and Dziarski 2007) and C-type lectins (Nicholas et al. 2004; Ao et al. 2007; O'Rourke et al. 2007), many of which have shared homology with vertebrate receptors (Kang et al. 1998; Khush and Lemaitre 2000; Chaput and Boneca 2007; Griffiths et al. 2007). This shared homology suggests that the general strategies for pathogen recognition are evolutionarily conserved.

In most invertebrates studied to date, the binding of recognition receptors to pathogens initiates a series of proteolytic cascades that result in coagulation of blood and in many species the localized production of melanin (Hoffmann and Reichhart 2002; Cerenius and Söderhäll 2004; Theopold et al. 2004). Interestingly, *C. elegans* is an exception in this case as genes regulating the proteolytic pathway leading to melanization in other invertebrates do not appear to have homologues in the worm genome (Ewbank 2002). Binding of these receptors also initiates signaling pathways to produce antimicrobial peptides (discussed below). The melanization reaction requires the activation of phenoloxidase by prophenoloxidase enzymes which typically reside within particular cell types (the names of these cells vary depending on the organism, Lavine and Strand 2002) and are released following cell disruption. Release of prophenoloxidase enzymes initiates a series of reactions leading to production of melanin (Cerenius and Söderhäll 2004). Deposition of melanin at wound sites contributes to wound healing and the toxic reactive compounds produced during melanin formation are thought to act as disinfectants (Bogdan et al. 2000; Nappi and Ottaviani 2000; Nappi et al. 2000; Cerenius and Söderhäll 2004).

2.2 Cellular Response

The cellular immune responses consist of phagocytosis (engulfment of small pathogens by single cells), nodulation (binding of multiple cells to bacterial aggregations), encapsulation (binding of cells to form a capsule surrounding foreign bodies too large to be phagocytized), and participation in clot formation at wound sites (Lavine and Strand 2002). While phagocytic cells appear to be present in most invertebrates, hemocytes of *C. elegans* do not appear to have phagocytic capabilities (Ewbank 2002). In *Drosophila*, three blood cell types are recognized that participate in various aspects of the immune response: plasmatocytes, crystal cells and lamellocytes (Meister 2004). Plasmatocytes are the phagocytic cells, comprising the largest fraction of the hemocytes in larvae (> 95%, Williams 2007) and are the only blood cell type in adults. Crystal cells are smaller cells containing enzymes for initiation of the phenoloxidase cascade. Encapsulation and nodulation of particles too large to be phagocytized appears to be a unique feature of invertebrates and cell types most often involved in these cell aggregates are plasmatocytes and granulocytes (Jiravanichpaisal et al. 2006). In *Drosophila* encapsulation is carried out only in larvae by lamellocytes which are produced by the differentiation of larval plasmatocytes (Evans et al. 2003).

Phagocytosis involves a complex set of cellular changes involving binding of the pathogen, reorganization of the plasma membrane, induction of cytoskeletal changes and processing of the ingested organism by the phagosome. The use of model genetic organisms, primarily *Drosophila*, combined with large scale genomic studies are beginning to reveal the genes that regulate this process (e.g., Wu et al. 2001, Brennan et al. 2007). Several families of receptor proteins have been implicated as important for the first step in this process, the binding of plasmatocytes to microorganisms. Known receptor families include the *Drosophila* homologue of the mammalian CD36 family of scavenger proteins (Philips et al. 2005), genes in the scavenger receptor class C Type-1 family (Rämet et al. 2001), peptidoglycan receptor proteins (Rämet et al. 2002), proteins with EGF-like repeats (*Eater*: Kocks et al. 2005; *Nimrod*: Kurucz et al. 2007), integrins (Moita et al. 2006) and *Dscam*, a protein with an immunoglobulin domain (Watson et al. 2005; Dong et al. 2006). *Dscam* is of particular interest as this gene has four alternatively spliced exons, different combinations of which can result in the production of over 18,000 different transcripts in *Drosophila* (Watson et al. 2005) and over 30,000 transcripts in *Anopheles* (Dong et al. 2006). This potentially allows recognition and discrimination of a wide diversity of pathogens and may even provide a mechanism for immunological memory in invertebrates. Hundreds of genes appear to be required for internalization and processing of microorganisms as has been revealed by genome wide RNAi analysis (Rämet et al. 2002; Philips et al. 2005; Agaisse et al. 2005; Stroschein-Stevenson et al. 2006) and combined proteomic and RNAi analyses (Stuart et al. 2007). A great deal of research remains to be done to understand how this complex genetic network is organized to regulate phagocytosis.

Invertebrates also produce complement type proteins that act as opsonins to enhance phagocytosis. In the mosquito *Anopheles gambiae,* a circulating thiol-ester

protein (aTEP-1) binds to gram-positive and gram-negative bacteria and stimulates phagocytosis by blood cells (Levashina et al. 2001). The *Drosophila* genome encodes at least four TEP-like genes, three of which are up-regulated after immune-challenge, and one of which seems to be up-regulated by the JAK/STAT signaling pathway (Lagueux et al. 2000; De Gregorio et al. 2001; Agaisse and Perrimon 2004). Proteins encoded by the TEP genes have significant similarity with vertebrate complement proteins of the C3/α_2-macroglobulin superfamily (Levashina et al. 2001, Nonaka and Yoshizaki 2004). This lends support to the idea that the general function of these proteins to promote phagocytosis has been conserved during evolution.

2.3 Humoral Response

The third component of the immune response is the humoral response which results in the local and systemic production of antimicrobial peptides (AMPs). In *Drosophila*, the systemic response of AMPs primarily results from two signaling pathways that regulate NF-κB transcription factors in the cells of insect fat bodies (the functional equivalent of the mammalian liver). Comparative genomic studies have shown these pathways to be generally conserved in most insects (Christophides et al. 2002; Evans et al. 2006; Luna et al. 2006; Cheng et al. 2007). In addition, functional genetic studies and genomic sequence comparisons indicate that the genes regulating the intracellular steps in these pathways are remarkably similar to those regulating the innate immune response in mammals (Hoffmann and Reichhart 2002; Minakhina and Steward 2006).

In *Drosophila*, two pathways regulate the production of up to 20 different AMPs, the *Toll* pathway and the immune deficiency (IMD) pathway (Lemaitre and Hoffmann 2007). The *Toll* pathway, which is similar to the mammalian toll-like receptor (TL-R) signaling pathway, is activated through the binding of the growth factor-like cytokine Spätzle to the *Toll* receptor. *Toll* is a transmembrane receptor first identified as a necessary component for dorsal-ventral patterning (Wu and Anderson 1997). Signaling through this pathway results in the translocation of the transcription factors DIF and Dorsal to the nucleus and upregulation of AMPs such as drosomycin and defensin which act directly on fungi and gram-positive bacteria respectively. The IMD pathway, which exhibits similarity to the mammalian tumor necrosis factor receptor (TNF-R) pathway, is thought to be regulated by the binding of a transmembrane peptidoglycan receptor protein (PGRP-LC) to gram-negative bacteria (Gottar et al. 2002; Choe et al. 2005; Tanji and Ip 2005). Signaling through this pathway results in the translocation of the NF-κB transcription factor Relish to the nucleus and subsequent expression of a number of AMPs generally targeting gram-negative bacteria, although some downstream targets of both pathways are effective against gram-negative and gram-positive bacteria. Recent evidence also suggests that signaling through the IMD pathway also activates the Jun N-terminal kinase (JNK) pathway which contributes to the production of AMPs by the fat body (Delaney et al. 2006). Although the *Toll* pathway is triggered primarily by infec-

tion from fungi and gram-positive bacteria (Ligoxygakis et al. 2002; Lemaitre et al. 1996) and the IMD pathway primarily triggered by gram-negative bacteria, it has been known for quite some time that there is cross talk between these pathways and this provides some level of redundancy in the immune response to infection by these organisms (Lemaitre et al. 1997). A recent model developed by Delaney et al. (2006) proposes that this cross talk results in part from the activation of the JNK pathway whereby the downstream transcription factors of the JNK pathway upregulate AMPs normally targeted by the transcription factors of the *Toll* and IMD pathways. *Toll* and IMD have also been shown to act synergistically, jointly contributing to the upregulation of representative target genes of both of these pathways. This synergism appears to result from the fact that the transcription factors of each pathway can bind to different domains of the promotor regions of these target genes leading to higher levels of expression than expected by the additive effect of each pathway when considered alone (Tanji et al. 2007).

While the fat body of most insects is the primary tissue involved in the systemic response to infection, epithelial surfaces of the epidermis, gut, reproductive system and respiratory tract are also responsible for the constitutive and inducible production of antimicrobial agents to limit microbial growth (Brey et al. 1993; Tzou et al. 2000; Ha et al. 2005; Pinheiro and Ellar 2006, Shapira et al. 2006). Interestingly, production of AMPs at wound or infection sites does not rely solely on the activation of NF-κB pathways, but instead on tissue specific transcription factors and local production of reactive oxygen species (Ferrandon et al. 1998; Ryu et al. 2004; Han et al. 2004; Ryu et al. 2006).

Much of the work in invertebrates has focused on understanding the immune response to bacterial and fungal pathogens; however there is a great deal of recent interest in understanding the immune response to viruses. A major mechanism thought to regulate the response to viral infection is by RNA interference (RNAi), an evolutionarily conserved mechanism for silencing the translation of RNA (Meister and Tuschl 2004). Functional genetic analysis in both *Drosophila* and *C. elegans* indicates that this is also a conserved and effective way to fight viral infection (Schott et al. 2005; Wilkins et al. 2005; Cherry and Silverman 2005; Fritz et al. 2006; van Rij et al. 2006). In addition, expression studies of *Drosophila* artificially infected with the Drosophila X Virus suggest that the *Toll* and JAK/STAT pathways are also involved in mediating an immune response to viral infection (Dostert et al. 2005; Zambon et al. 2005).

3 Invertebrates as Models of Immunosenescence

Many different aspects of immunosenescence have been measured in invertebrates including assessment of the age-specific ability to clear and survive infection and measurements of functional changes in the components of the immune response. Age-specific survival measurements have been obtained either by pricking individuals with a septic needle (Burger et al. 2007), microinjecting individuals with a

standard concentration of bacteria (Adamo et al. 2001; Hillyer et al. 2005), or exposing individuals of different ages to a pathogen (Laws et al. 2004). Typically a large number of individuals of each age group are infected and the subsequent number of deaths scored daily to identify differences in mortality rates following infection. Age-specific abilities to clear bacterial infections are carried out by either pricking or microinjecting individuals of different ages with a standard concentration of bacteria, allowing 24–48 hrs for individuals to clear the infection, and then homogenizing or perfusing individuals and plating aliquots of the solution on agar plates (Kim et al. 2001; Hillyer et al. 2005; Lesser et al. 2006). The resulting number of colony forming units on the plate is an estimate of the ability of that individual to clear the infection. Both age-specific survival and clearance assays provide no functional information on the causes of age-specific changes in the immune response. Functional changes in age-specific components of the immune system that have been measured include age-related changes in expression of immune response genes following infection (Hillyer et al. 2005; Zerofsky et al. 2005), age-specific changes in hemocyte counts (Adamo et al. 2001; Doums et al. 2002; Amdam et al. 2004, 2005; Hillyer et al. 2005), age-specific phagocytic ability of hemocytes (Hillyer et al. 2005), age-specific phenoloxidase activity (Adamo et al. 2001), age-specific encapsulation and melanization ability (Doums et al. 2002) and even age-specific changes in the quantity of fat (used as an indicator of the size of the fat body, the major site of lipid storage and the tissue most responsible for secretion of antimicrobial peptides, Doums et al. 2002).

While it is clear from these studies that the ability to survive and clear a bacterial infection declines with age, the data so far indicate that the underlying causes of immunosenescence differs among species. Adamo et al. (2001) studied various indicators of immunosenescence using a population of crickets, *Gryllus texensis*, that had been collected in the wild but maintained for several generations in the laboratory. They measured sex-specific changes in phenoloxidase (PO) activity (based on an in-vitro enzyme assay with cricket hemolymph that measures the rate of conversion of L-dopa to quinone), counts of hemocyte numbers and survival following injection of *Serratia marcescens* at four ages spanning prereproductive maturity to 4 weeks of age. Males and females were similar in the various immune response indicators up to the age at which males began to display sexual behavior. Sexually mature males had lower phenoloxidase activity and higher mortality following infection compared with younger males and same aged females. This was interpreted by the authors as males trading off immunity for reproduction although the functional connection between PO activity and mating behavior is unclear. The relationship between PO activity and survival following infection was weak however, as 2 week old females had higher PO activity compared to earlier and later ages, but exhibited higher mortality following infection compared with prereproductive ages. The authors speculate allocation of energy toward reproduction offsets the increased protection that would have resulted from higher PO activity, producing a trade-off between reproduction and survival following infection. This hypothesis could potentially be tested with age-matched virgins to minimize the survival cost of reproduction. Unlike PO activity, there was no age-specific change in hemocyte

number and no correlation between hemocyte number and the ability individuals to survive infection at any age. Both males and females had a reduced ability to survive infection with increasing age but were also more likely to die from a sham injection of saline with age. This increase in mortality following sham injection suggests that older individuals may have a reduced ability to withstand the stress imposed by the injection and also possibly a reduced ability to repair a wound site.

An interesting contrast is provided by the work of Hillyer et al. (2005) on the mosquito, *Aedes aegypti*. This study examined age-associated changes in a number of traits including changes in hemocyte numbers, the phagocytic ability of cells, the production of antimicrobial peptides, the ability to clear infection and mortality during the first five days following eclosion. They observed age-related reductions in hemocyte number, a reduction in the ability to clear an artificial injection of bacteria, and an increase in mortality rates following infection. They found no change in the production of antimicrobial proteins following infection at different ages and no decline in the phagocytic ability of hemocytes with age. In this case, age-specific decline in clearance ability and the age-specific increase in mortality rates following infection may be largely explained by a decline in hemocyte number with age. As mosquitoes, like most insects, are not known to produce new hemocytes as adults (either by hematopoiesis or by mitosis, Hillyer et al. 2005) the rate of change in immunocompetence with age may largely depend on the total number of blood cells produced during the larval and pupal periods and the age-specific rate of loss of hemocytes as adults. These conclusions are of course based on observation of correlated changes with age and the causal relationship between hemocyte number and age-specific immunocompetence needs to be further tested. One caveat with this study is that the age-associated changes observed may not reflect senescence per se, as this species can live between 2 weeks to over a month in the laboratory. Further assessment of immune function at later ages, perhaps concurrently with other indicators of senescence such as age specific mortality rates will determine if the interrelationship between immunocompetence and hemocyte number is consistent as the organism ages.

3.1 Implications for Social Influences on Immunosenescence

Comparisons of different species of social insects reveal the potential for age-specific hormonal control of immunosenescence. Doums et al. (2002) implanted workers of two different species of bumblebees (*Bombus terrestris* and *Bombus lucorum*) with nylon filaments at two different ages to measure the age-specific ability to encapsulate and melanize a foreign object. Encapsulation and melanization ability declined in both species with age. In an effort to provide a physiological explanation they measured age-specific changes in the size of the fat body and the number of circulating hemocytes in one species, *Bombus terrestris,* and found only a slight reduction in the size of the fat body and no change in hemocyte number with age. Their conclusion was that the age-related decline in encapsulation and melanization

ability could not be attributed to changes in hemocyte number and the size of the fat body. Of course, this leaves open a number of possibilities yet to be explored to explain their results including age-related changes in the phagocytic ability of the hemocytes. Using a different species of hymenoptera, the honey bee *Apis mellifera*, Amdam et al. (2004) found that immunosenescence is cued by a change in social status as hive workers shift to foragers when they reach 18–28 days old (Winston 1987). This change in social status from hive bee to forager leads to higher levels of juvenile hormone (JH), a reduction in vitellogenin production, a decrease in hemocyte numbers and an increase in the number of pycnotic hemocytes which are not phagocytic. As vitellogenin is an important carrier of zinc the increased pycnosis in hemocytes probably results from low zinc availability. Phagocytic ability of the nonpycnotic cells did not change with age. Interestingly, when foragers are forced to revert to hive duties, juvenile hormone titers are reduced leading to an increase in vitellogenin, increased hemocyte numbers and a reduced number of pycnotic cells (Amdam et al. 2005). The source of these new hemocytes is unclear but may result from hematopoiesis, cell division or mobilization of previously sessile cells. Thus, immunosenescence in this aspect of the cellular component of the immune response in honeybees appears to be under social control and so is reversible, at least temporarily. The fact that *Bombus* do not exhibit age-specific changes in hemocyte number while *Apis* does, may reflect the different social biology of these organisms. *Apis* have a very defined schedule of changing tasks and social status as they age, while *Bombus* are much less regimented, performing both hive and foraging duties for their entire life. As such, JH titres in *Bombus* adults may not change in the manner seen in *Apis* and so the resultant change in hemocyte number is not seen in this organism. A comparative study using these species, and indeed other social invertebrates, in which similar immune response traits are examined with age (combined with changes in survival and clearance ability following infection) would elucidate the general importance of social behavior and hormonal influences in regulating immunosenescence.

3.2 Genetic Basis for Immunosenescence

While the studies discussed above are aimed at understanding the cellular and physiological causes of immunosenescence another set of studies has aimed at understanding the potential genetic contributions to age-related changes in immunocompetence. Kim et al. 2001 were the first to document the existence of an age-related decline in the immune response in an invertebrate system. They used *Drosophila melanogaster* to test the effect of age on the ability to clear an infection of *E. coli.* They used a wild type strain and a strain containing a mutation in *xanthine dehydrogenase* (*XDH*), a gene that influences the production of uric acid, a scavenger of reactive oxygen species and so is a candidate gene for aging. Reactive oxygen species and nitric oxide levels were substantially higher in the mutants and mutants had a significantly higher rate of mortality compared to wild

type flies. Interestingly, in the wild type strain they found a dramatic reduction in their ability to clear bacterial infection as the flies aged, with approximately 60% reduction in this ability from 2–80 days of age. Flies with the mutation were extremely limited in their ability to clear infection and did not show any age-related decline. This is may be due to the fact that the immune response of mutant flies had very little scope for an age-specific decline in immune-response as infection levels were over 25 times higher in mutants than in wild type flies at all ages. Their results suggest that generation of high levels of reactive oxygen is deleterious to all physiological systems, including the immune response. It does not imply that *XDH* directly plays a role in regulating the immune-response or immunosenescence in *Drosophila.*

As the term immunosenescence itself implies age-specific changes in immune function, studies of age-related changes in gene expression are more likely to be useful for understanding genetic influences on immunosenescence than studies using mutants. Microarray studies of flies and mammals have identified a number of age-related changes in the expression of immune response genes a consequence of general aging. In fact, genes known to be involved in the immune-response exhibit some of the most dramatic changes in gene expression with age compared to genes involved in other processes such as metabolism, and growth regulation (Pletcher et al. 2002; Seroude et al. 2002; Landis et al. 2004). Of interest is that immune response genes are typically upregulated with increasing age. This likely reflects a higher pathogen load in older individuals (as demonstrated in *Drosophila* by Ren et al. 2007) and not the age-related deterioration in the control of transcription in general. Another possibility is that older individuals are hyperresponsive to pathogens, and as a consequence show higher levels of transcription following infection compared with younger individuals. This last hypothesis was tested in the experiment described below.

Zerofsky et al. 2005 used changes in transcript levels of the antimicrobial peptide diptericin following artificial infection at different ages as an indicator of age-specific immune function. In their study virgin females of different ages were infected by pricking the cuticle with a needle containing a mixture of bacteria (*E. coli* and *Micrococcus luteus*) that were either live or killed. They found that older females had higher background levels of diptericin than younger females before the artificial infection, reflecting the findings of microarray studies on aging flies. They also found that when flies are infected with live bacteria older females had a higher and more sustained level of diptericin transcription than younger flies. The authors interpreted this as an indication that older flies were less able to clear the infection and so continually maintained production of high levels of diptericin. Unfortunately the bacterial load was not measured in old and young flies and so this conclusion awaits confirmation. When infected with killed bacteria, younger females had higher and more sustained production of diptericin than older flies. Older flies upregulated diptericin production during the first six hours following infection, matching the production of the young flies, but then diptericin transcripts gradually declined. These results suggest that older individuals are not hyperresponsive to infection. Combining the results of this study with observation of higher transcript levels of

immune response genes in older flies implies that older flies carry higher pathogen loads and so have elevated transcription of immune response genes.

The nematode *Caenorhabditis elegans* is an emerging invertebrate model for studying evolutionarily conserved responses to infection (Kurz and Ewbank 2003) and recent work has begun to identify some interrelationship between immunocompetence and longevity. The utility of *C. elegans* for understanding the cellular and physiological processes of immunosenescence may be limited by the fact that many components of the innate immune system common in other invertebrates are missing in this species. As discussed above however, there may be a limited number of such features that are generally responsible for immunosenescence across taxa, even within species. However, given the genetic utility of this species, understanding the genetic basis of immunosenescence in this organism may provide key insights not provided by other insect models. It is clear that *C. elegans* experience higher age-specific mortality when exposed to pathogens (Kurz et al. 2003; Laws et al. 2004). While there is some indication of a connection between genes regulating the immune response and longevity in *C. elegans* (Kurz and Tan 2004; Troemel et al. 2006) additional research is necessary to determine if these same genes act to influence immunosenescence.

3.3 Understanding Natural Genetic Variation Underlying Immunosenescence

In a seminal paper Lazzaro et al. (2004) found that natural populations harbor extensive genetically based variation in the ability to clear infection and indentified single nucleotide polymorphisms in candidate genes associated with this variation. This study has opened up an exciting new direction to identify genes that regulate age-specific changes in immunocompetence. Lesser et al. (2006) used a modified assay developed by McKean and Nunney (2001) to demonstrate a genetic basis for age-related changes in immunocompetence. Using twenty five genetically distinct lines derived from a natural population of *Drosophila* they found that only five lines exhibited an age-related decline in clearance ability (measured at 1 and 4 weeks of age) while eleven lines showed an improved ability to clear an infection with age. The clearance ability of the remaining nine were unaffected by age. They also found no genetic correlation in the ability clear the infection between the two ages. This lack of a genetic correlation in immunocompetence across ages suggests that different genes are responsible for producing the phenotypic variation in clearance ability at different ages. Identification of the genes controlling these age-related changes in the ability to clear infection is an important priority.

4 Future Directions

As highlighted above, many of the age-related changes in the components of innate immunity appear to be species-specific. This undoubtedly reflects the evolutionary divergence in the innate immune system among lineages, the different nature of infective agents faced by these organisms in their particular ecological setting, and also differences among species in the strength of selection to maintain immune function with age. As invertebrates have only recently been used as models to explore the causes and consequences of immunosenescence, perhaps more generalities will be revealed as more species are examined. Much could be gained by a systematic study of age-related changes in key components of the immune response in closely related taxa to establish the extent to which changes in particular components of the immune system (e.g., hemocyte count, phagocytic ability) are unique to particular lineages and which might be generally conserved across taxa. Shared features of the innate immune response that show age-specific decline in function among invertebrates are those most likely to be shared across broader taxonomic groups including vertebrates.

An exciting future goal is to use a combination of techniques for assessing age-specific changes in the immune response in invertebrates to gain a more wholistic view of the mechanisms that underlie immunosenescence. These should include assessing the concentration and identity of pathogen recognition proteins, the levels and killing ability of antimicrobial peptides, measurements of hemocyte numbers and age-specific phagocytic ability. Combining these measurements with age-specific abilities to survive and clear infection will provide the key to understanding which components of the immune response change with age and which have functional consequences for the survival and fitness of the organism.

Shirasu-Hiza and Schneider (2007) have also suggested that we pay more attention to physiological changes in other aspects of the host following infection to identify the causes of mortality when it occurs. As they point out, when humans get sick we measure many physiological indicators that reflect their health and which ultimately contribute to the ability of the individual to survive the infection. They rightly suggest that we expand our understanding of the pathology of infection to monitor changes in aspects of organisms that are not necessarily part of the immune response when experiments are done on model organisms. Additional traits that may be influential include changes in feeding or reproductive behaviors, changes in energy allocation to storage or reproduction, and changes in basic metabolic processes like respiration and the rate and quality of waste produced. As these behavioral, life history and metabolic processes normally change with age, understanding the interrelationship between these physiological characteristics and immunocompetence in the aging organism will provide a more complete understanding of age-related changes in the pathology of infections.

Finally, technological advances are likely to greatly facilitate our understanding of the genetic contribution to age related changes in immunosenescence. Whole genome microarray and proteomic studies are likely to reveal a number of genes that exhibit age-related transcriptional changes prior to and following infection. The key to interpreting these data and identification of important genes will be

to directly test the effect of changes in transcript and/or protein expression with functional tests of immunocompetence. This is perhaps where the real advantage of using invertebrate model systems like *Drosophila* lies. During the past decade there have been a number of tools developed to control the expression of candidate genes in an age—and tissue—and even cell type specific manner in both *Drosophila* and *C. elegans* (e.g., Roman et al. 2001; McGuire et al. 2004; Johnson et al. 2005; Dietzl et al. 2007; Qadota et al. 2007). Controlled up- and down-regulation of candidate genes at different ages prior to and following infection, combined with measurements of survival, bacterial clearance efficiency, or the efficacy of particular components of the immune response (e.g., phagocytic ability) will allow direct tests of the importance of candidate gene expression on age-specific immune function.

Genetic mapping techniques such as quantitative trait loci (QTL) mapping have proven useful for identifying genomic regions that contribute to natural variation in age-specific phenotypes (e.g., Leips et al. 2006) and continued development of these techniques should allow us to rapidly identify the actual genes that contribute to age-specific changes in immune response (Lai et al. 2007). In addition, as age-specific transcriptional controls are likely to contribute to age-specific immunocompetence, the continued use and improvement of expression QTL mapping methods (e.g., Alberts et al. 2007; Jia and Zu 2007) holds great promise for identifying the genes that regulate age-specific expression of those genes that directly contribute to immunosenescence.

Acknowledgment I am grateful to Tashauna Felix and Adrienne Starks for thoughtful discussions of immunosenescence. Also, I owe a great deal of thanks to Tashauna Felix, Mary Kaminski, Adrienne Starks and Louisa Wu for their critical comments on this manuscript. This work was supported by a research grant from the National Institutes of Health (NHLBI R01HL080812).

Clonal Culture Models of T-cell Senescence

Graham Pawelec, Jürgen Kempf and Anis Larbi

Contents

Abstract: Studying human T-cell senescence is mostly limited to investigations on peripheral blood ex vivo or on cultured cells in vitro. In both cases, single cell analysis is challenging and many age-associated alterations described are the result of changes in the proportions of the ever-increasing numbers of different T-cell subsets rather than changes to the cells per se. One model avoiding this problem utilises monoclonal populations cultured long-term in vitro. Such T-cell clones (TCC) can be maintained without oncogenic transformation by intermittent antigen restimulation in the presence of growth factors. However, TCC possess finite lifespans (which vary greatly from clone to clone). This TCC model can be used to investigate many aspects of the processes of clonal expansion and contraction essential for adaptive immunity, including biomarker discovery at the genomic, proteomic and functional levels, and to test interventions of possible clinical utility. This chapter describes techniques for the production and maintenance of human TCC in vitro, the impact of culture conditions and oxygen levels on lifespan, and the application of genomic and proteomic analyses in this model.

Keywords: Chronic antigenic stress • Immunosenescence • In vitro culture model • Physiological oxygen level • T-cell clones

1 Introduction

Long-term propagation of human T-cells became possible after the discovery of "T-cell growth factor", enabling single T-cells to be isolated and cultured for extended (Gillis et al. 1978) but not indefinite periods (Effros and Pawelec 1997). All TCC culture systems relied on the presence of "feeder cells" to facilitate T-cell growth via ill-defined mechanisms of cell contact and cytokine secretion. Nowadays, T-cells can be cultured with defined factors such as the common γ-chain cytokines IL 2, IL 7 and IL 15, together with nanoparticles presenting antibodies to stimulatory surface molecules, commonly the T-cell receptor (TCR) CD3 component and the costimulatory receptor CD28, or together with TCR-cognate antigen and antigen presenting cells (APC) or particles. Notwithstanding all these variations, the basic principles remain the same: to propagate T-cells in vitro it is necessary to provide them not only with exogenous growth factors but also to stimulate them intermittently via their cell surface receptors, most usually the TCR. TCC cultured in this way provide a model for reactivity against antigens which cannot be eliminated by the immune system, i.e. certain parasites, viruses and commonly cancer. When confronted with acute infection, adaptive immunity develops effector responses to clear the antigen; thereafter, excess effector cells are purged from the system and memory cells retained for any future challenges. However, antigens from persistent viruses, notably Herpes viruses, as well as immunogenic cancers, are not cleared, but continuously stimulate specific T-cells. The number of different, mostly CMV-specific, T-cell clonal expansions quantified in vivo first increases and then decreases with age; in the very elderly, the number of remaining clones correlates closely with residual survival time (Hadrup et al. 2006). Thus, chronic antigenic stress (mostly CMV antigens in this case) causes clonal exhaustion and attrition, with clinical consequences. We hypothesize that similar phenomena can occur in younger people harbouring different sources of chronic antigen, especially cancer (Pawelec et al. 2006). The process of T-cell clonal expansion and eventual attrition can be modelled in vitro in tissue culture. We can hope to learn how to modulate this process in vivo by improving and studying the model in vitro.

2 T-cell Cloning

As with fibroblasts, early data on T-cells suggested that clonal lifespan in culture was influenced by age of the donor from whom the starting population was obtained. Thus, clones derived from neonates averaged a larger number of population doublings (PD), than those from adults, especially the elderly (McCarron et al. 1987). Our own more extensive results, collected over many years from multiple cloning experiments, do not support this finding. Individual TCC do have very

varied lifespans, but the overall patterns for T-cells of quite different origins and donors of different ages are remarkably similar, as we have previously reported (Pawelec et al. 2002); thus, clonable T-cells from a centenarian or from a young adult behave similarly, implying that the former have not been functionally compromised. This is consistent with the main age-associated alteration in human T-cells being the changed distribution of T-cell subsets, reflected most prominently in the decreased proportion of naïve cells and the increased proportion of memory cells of different subtypes.

The process of clonal attrition is striking in this in vitro model (Table 1). After 20 PD, representing a clone size of 10^6 cells, about half of the clones originally obtained in each experiment have already been lost. By 30 PD, another half of these is lost, so that only one quarter of the originally clonable cells is still present. By 40 PD (which now represents a very large clone size of 10^{12} cells, at least theoretically if no daughter cells ever die at each cell division), although more clones have been lost, 15% of the original starting clonal population does still remain. These results reflect a steady attrition of T-cell diversity at the clonal level, but with retention of something like 5% of the original CD4 repertoire up to 40 PD and with retention of very rare clones for much longer (some at least to 70 PD). Although difficult to establish, similar clonal attrition probably occurs in vivo as well, at least in infectious mononucleosis, perhaps with quite similar distributions of clonal longevities (Maini et al. 1999). Similar considerations concerning cells from other sources predict that any T-cell, if clonable under these conditions, will behave in a very similar way to any other. This is borne out by the finding that T-cells generated in situ from $CD34^+$ hematopoietic progenitors and those from cancer patients do not manifest greater or lesser average and maximum longevities, respectively (Table 1).

Table 1 Longevities of human T-cell clones under standard culture conditions

Origin	%CE	Clones/ Expts	Percentage of clones reaching:			Max. longevity
			20 PD	30 PD	40 PD	
CD3 (young)	47	1355/15	47	24	15	70
CD3 (old)	52	298/7	48	26	16	77
CD3 (cent)	38	52/3	41	23	17	80
CD3 (CML)	49	35/1	60	35	14	51
CD34 (periph)	55	533/6	31	17	6	60
CD34 (cord)	43	94/2	29	15	5	57

CE, cloning efficiency (calculated from percentage of wells positive in cloning plates). Longevity is expressed as a percentage of established clones (ie. those counted as positive in calculating the CE) which survive to 20, 30 or 40 PD. Origins: CD34+, positively-selected hematopoietic stem cells from peripheral or cord blood; CD3+, normal peripheral T cells; young, apparently healthy donors under 30 yr.; old, healthy donors over 85 yr.; cent, centenarians; CML, a middle-aged donor with chronic myelogenous leukemia in chronic phase treated with interferon.

3 Changes in Behavior over the TCC Life Cycle

The 15–35% of TCC surviving for prolonged periods can be followed longitudinally over their finite lifespans regarding surface molecule expression, activation, signal transduction, cytokine secretion, cytotoxicity, and many other parameters. A typical growth curve of such a clone is shown in Fig. 1 (in this case, a CD4+ clone derived from an octogenarian donor). Growth is well-maintained until 40–50 PD, after which it slows, and the clone is lost at around 55 PD. This slow-down and demise is caused by increasing susceptibility to CD4+ TCC to apoptosis caused by activation-induced cell death, rather than changes to cell division rate. Age-associated alterations discovered in this way over the lifespan of the TCC can be used to screen for similar changes ex vivo in order to validate biomarkers of immune ageing, and they can also be used to test interventions in vitro aimed at preventing or reversing deleterious changes.

3.1 Changes of Surface Phenotype and Function

Bearing in mind the constraints of the cloning procedure, "early passage" TCC will have already undergone at least 22 or 23 PD before sufficient cells are available for analysis and further propagation of the clone, but as mentioned above, at this point there is still a good representation of the original repertoire. TCC can be

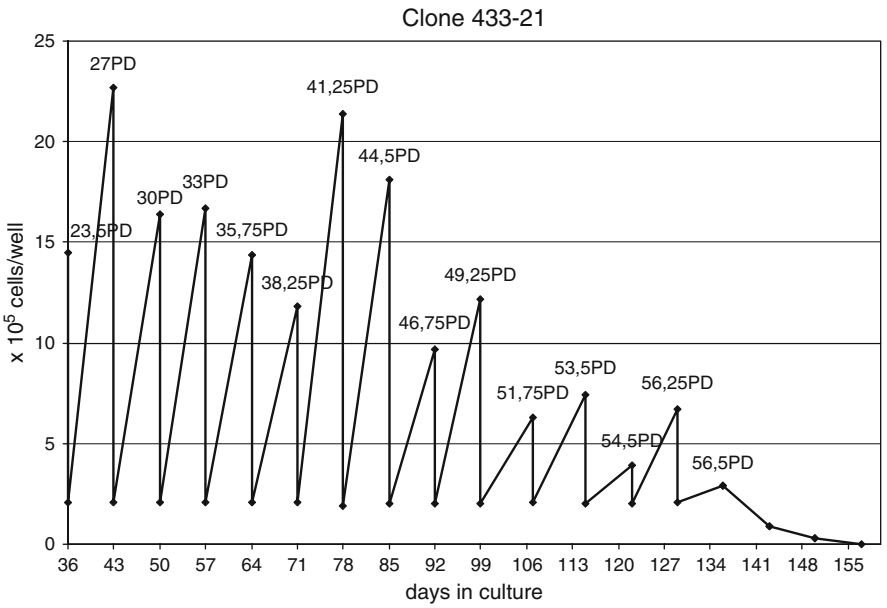

Fig. 1 Growth characteristics of TCC 433-21, showing days in culture plotted against the number of cells per culture well and giving the CPD estimated at each subculture

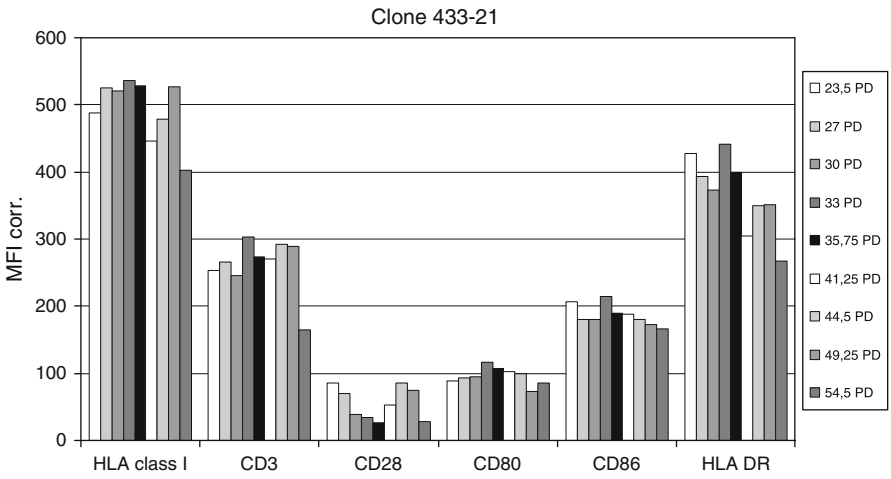

Fig. 2 Surface marker expression of TCC 433-21 giving the CPD estimated at each subculture

analyzed by flow cytometry for changes to expression of an ever-increasing number of monoclonal antibody-defined cell surface molecules, many with important known functions for T-cell responses. A common but not universal age-associated reduction in the level of expression of the costimulatory receptor CD28 has been documented (Pawelec et al. 1997), whereas the level of TCR remains more stable (Fig. 2). This suggests that these cells retain the ability to recognise and respond to antigen but may lack full costimulation, which may contribute to the changes observed in the patterns of cytokines secreted, commonly resulting in decreased levels of IL 2 and increased levels of IL 10 (Pawelec et al. 1997). When comparing the growth curve and the surface marker expression of the same clone, there was a correlation between CD28 expression and the capacity of the clone to grow. CD28 expression is decreasing from 27 to 35 PD and is then re-expressed and finally lost at the end-stage of the clone's lifespan (Fig. 2). This perfectly correlated with the number of cells obtained at each PD (Fig. 1). Nonetheless, other factors certainly play a role in the varied age-associated changes seen in different individual clones. Because T-cell functions are triggered by intracellular signaling via a multitude of surface receptors in addition to the TCR and CD28, any alterations impinging on the membrane (early events) through the cytoplasm (intermediate events) to the nucleus (late events) will influence the final outcome of each encounter with APC for each individual T-cell. This suggests that stochastic events may drive heterogeneity within clonally expanding T-cell populations, a hypothesis for which some evidence does exist.

4 Genomic and Proteomic Analysis

We recently undertook a first global gene expression analysis of early and late passage TCC derived from an octogenarian donor, one of which is shown in Fig. 1. This screening approach allows the hypothesis-free identification of potentially impor-

tant age-associated changes which can be usefully followed up at the protein and functional levels. Array analysis has thus revealed a wide range of differentially expressed genes, including those encoding proteins involved in signal transduction, inflammation, apoptosis, and other processes implicated in senescence (Mazzatti et al. 2007b). Of particular note may be the age–associated upregulation of genes encoding various proinflammatory molecules, considered an important factor in physiological ageing and development of frailty. A similar approach applied at the proteome level may also assist in the discovery of biomarkers of relevance in vivo. Thus, using SELDI-Tof-MS protein profiling, we have identified several protein/peptide peaks which could be associated with T-cell senescence (Mazzatti et al. 2007a). One protein identified through this analysis, profilin-1, hitherto unsuspected in the context of senescence, has important roles in cellular survival, cell division, cytoskeleton remodeling and motility, and may contribute to immunosenescence or possibly cellular senescence in general.

5 Interventions

5.1 Culture Conditions

Interventions that we have tested in the in vitro longitudinal T-cell ageing system described here include culturing TCC in different cytokine cocktails, supplementing with factors such as zinc, attempting to block apoptosis in various ways, and culturing in lower levels of oxygen. The basic culture conditions have remained the same: use of an excess of feeder cells usually consisting of irradiated PBMC pooled from many different healthy donors, culture medium containing human serum or more recently serum free (X-Vivo 15, Lonza, Basel, Switzerland), and a source of growth factors. Briefly, of the many different variants that we have tested, relatively few have had much impact on the growth characteristics and longevities of the TCC. One of these, neutralisation with antibodies of the TNF-α secreted into the culture medium by essentially all TCC, resulted in an increased cumulative PD (CPD) of 10-15 PD (Pawelec et al. 2006). This can translate to a very large number of cells at later passages, and could be used in vivo, since agents that neutralise TNF are licensed for use in humans in diseases such as rheumatoid arthritis. The only other manipulation which has had an impact on TCC longevity, also increasing CPD by 5-15 PD, is to culture the cells in a more physiological level of oxygen, as described in the next section.

5.2 Physiological Oxygen

All of the above-mentioned studies, and indeed most cell culture experiments in any context, are performed at 37°C in humidified incubators gassed with 5% CO_2

but otherwise containing air. This equates to a hyperoxic environment with 20% O_2, not applicable in vivo. We are therefore embarking on experiments in which TCC are cultured in lower oxygen environments. Earlier experiments using 4 different TCC suggested that oxidative DNA damage measured in TCC by a modified Comet assay increased with increasing PD in culture in air. Reducing the oxygen level to 5% led to a marked reduction in accumulated oxidative DNA damage, but contrary to expectations did not lead to an increased longevity of the TCC (Duggan et al. 2004). However, more recent experiments reducing the level of oxygen further to 2% suggest that while some TCC do not show increased longevity under 2% compared to 20% oxygen, the majority does (Fig. 3). Changes in expression of inducible heat shock proteins and other parameters parallel the growth and signal transduction modulations observed in TCC cultured in what we believe approximates a more "physiological" oxygen tension than air. Thus, the interpretation of data derived from the usual type of in vitro culture in air must be treated with caution, and ideally experiments repeated at lower oxygen levels not only in the context of TCC but essentially all other culture-based systems.

5.3 Telomerase Induction

Expanded TCC loss of CD28 expression is associated with reduced telomerase activity and thus telomere length. Transferring the human telomerase reverse tran-

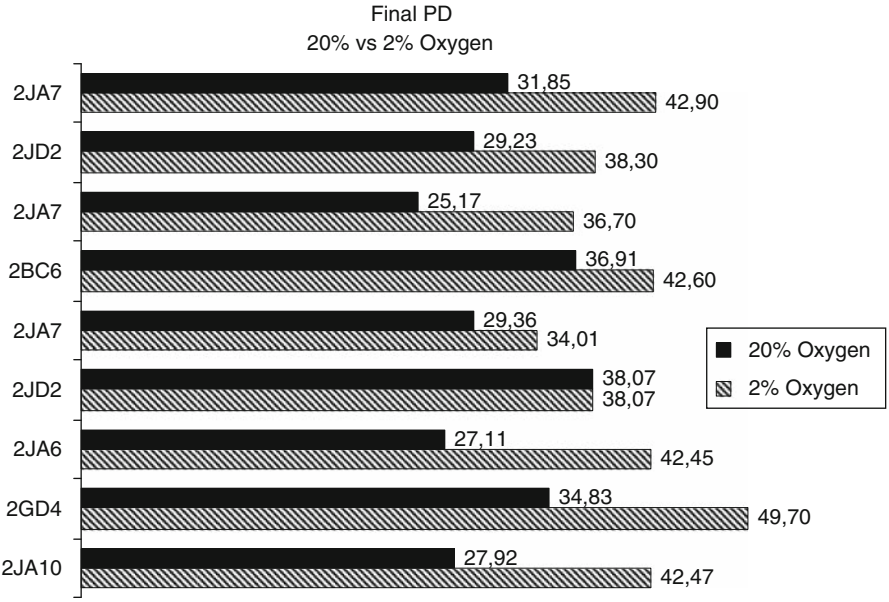

Fig. 3 Longevity of TCC cultured in air or at 2% oxygen. CPD are given for each of 9 individual TCC

scriptase (TERT) gene into T-lymphocytes can increase their lifespan (Rufer et al. 2001). T-cell clones with high levels of telomerase maintained or increased their telomere lengths for extended periods of time. Thus, enforced telomerase expression can increase T-cell longevity.

5.4 Autoantigen-specific T-cell Cloning

The cloning of autoreactive T-cells is more difficult. On early attempts to do so, we concluded that factors other than cytokines including IL 2, IL 4 and IL 7 were required for the expansion of these cells. Mannering et al., recently used CFSE-stained cells, a known cell tracker dye used to assess proliferative capacity of cells, to pre-select responding clones. After stimulation with the auto-antigen acid decarboxylase-65 for 7 days, propidium iodide-negative CD4+CFSE^{dim} cells could be cloned. The cytokine cocktail included IL 2, IL 4 and IL 7 but also IL 15 (5 ng/ml). This resulted in a cloning efficiency averaging from 10 to 15%. IL 15 may therefore be the crucial factor (Mannering et al. 2005).

6 Conclusions

Human T-cell clones can be maintained for extended but finite periods without transformation in tissue culture but eventually cease proliferating at time points up to the Hayflick limit. This remains the case even when known inhibitory factors such as TNF-α are neutralized and when more physiological oxygen tensions are applied, which can increase lifespan but not indefinitely. Only enforced expression of telomerase may greatly extend the lifespan, but this probably also fails to immortalize the cells. The changes which can be investigated longitudinally over the lifespan of the TCC and which reflect in vivo alterations make this a good model for studying human T-cell immunosenescence.

Acknowledgments We thank Ms A. Rehbein and K. Hähnel for maintaining the TCC and Dr. H. Eltschig for use of the low oxygen work station. Mouse Models of Influenza

Ian C. Brett and Bert E. Johansson

Contents

Abstract: Influenza is an enveloped, segmented negative sense RNA virus capable of infecting epithelial cells lining the human respiratory tract. Influenza A and B are important causes of disease in humans. Transmitted via aerosol, the virus possesses two major surface, hemagglutinin (HA) and neuraminidase (NA). HA has binding specificity for sialic acid, and allows viral attachment and entry into the cell. NA cleaves sialic acid residues off glycoproteins or mucoproteins, which aids new progenitor virions in eluting from the cell. The primary method of reducing influenza disease burden has been through vaccination.

Keywords: Influenza • murine • pulmonary titers

1 Introduction

Many different animal models of influenza infection have been used throughout the years, including ferret, mouse, rabbit and swine. However, the mouse is the preferred model for infection because of its ease of breeding, handling and relative low-cost. Importantly the mouse model can be a good predictor of the human response to

infection and vaccination. Mouse models have been useful in developing and testing vaccine formulations and pharmacological treatments, as well understanding the pathogenesis of the virus and the dynamics of the host antiviral response. Recent studies have sought to delineate the changes in response to influenza infection or vaccination with age. Studying vaccine efficacy and immune responses in this population is especially important given that the elderly typically show decreased immune response and vaccine efficacy.

This chapter will cover the most widely used mouse strains, discuss gene knockout models, host response to infection and practical aspects of experiments involving mice to provide a starting point for new investigators interested in utilizing mouse models for studying influenza.

2 Inbred Mouse Strains

Investigators requiring mice for research can choose subjects from a large number of inbred and random-bred lines. As part of selecting the ideal murine strain for an experiment, the investigator must choose the genetic state that makes the model a valid representation of the target population. This may include, but is not limited to: selection of histocompatiblity antigens (H2 haplotype), T-helper 1 or 2 skewing of the immune response, or predilections for particular disease states (Table-1). An inbred line consists of a population of great genetic homogeneity, and experiments performed within such a population can test the treatment variability, which in the haphazardly bred mouse might be confounded with genetic variability.

The development of inbred lines of mice in biological research is equivalent to the development of measurement standards and the preparation of reagent and

Table 1 Common Mouse Strains used in Influenza Studies

Strain	Source	H2 Haplotype	Comments
BALB/c	221 (BALB/cJ); 235 (BALB/cByJ) inbred generations	d	Th_2 Skewed; nonaggressive strain; very large reticuloendothelial system
C57BL/6	226 inbred generations	b	Th_1 skewed; High mammary tumor incidence; high mortality in chloroform exposure; low erythrocyte & leukocyte counts; poor LPS response; aggressive strain
Nude (*nu*)	BALB/c-*nu*/+97 inbred generations	d	T-cell deficient, intact B-cell immune system

analytical grade chemicals and serological reagents. The "reagent grade" animal, the result of carefully controlled inbreeding, permits design and repetition of experiments requiring fine discrimination within an animal species. The inbred mouse line is a population of animals that has attained homozygosis at nearly every locus through the use of a mating system that reduces the number of genetically dissimilar ancestors [44]. Traditionally, the most common practice is rigid brother-sister mating over many generations.

The history of the inbred laboratory mammal is actually the history of the use of the mouse in cancer studies. In order to attain repeatable and controlled systems for studying factors affecting tumor transplantation and for providing insight into why cancer develops, Little and Tyzzer [36] began to breed mice to obtain the necessary genetic homogeneity. Many of the early inbred strains of mice originated from a small number of stocks [12]. This relatively restricted gene pool accounts for the similarities and differences in the classic inbred lines. The history of each inbred mouse line is included in the listing of *Standardized Nomenclature of Inbred Strains of Mice* [54] published regularly. We strongly recommend that the most recent publication of the list of inbred strains be consulted.

The *inbreeding coefficient*, F, is a useful theoretical measurement of the progress of inbreeding, which has retained its usefulness with the experimental use of transgenic animals. It is defined as the probability that both alleles at a locus are identical by descent. It therefore indicates the proportionate decrease of heterozygous loci in the inbred individual relative to those in a representative individual of the starting population. F increases at different rates, depending on the amount of ancestry shared by the mated individuals. F should be used with caution, it is a theoretical value calculated from a pedigree, and not only does it ignore mutational effects, it also ignores effects of selection favoring heterozygotes [12, 53]. Once inbred lines are established, they can be genetically manipulated to establish yet other strains with special attributes for genetic analysis and control. Namely, these are: the *congenic* lines, the *coisogenic* lines, and the *recombinant-inbred* line. A *congenic* line is an inbred line genetically identical to an already established inbred strain except for a short chromosomal segment that bears a distinctive gene of interest. The congenic line is created by crossing the established inbred strain with an individual mouse bearing the distinctive gene of interest; a gene introduced either by breeding or molecular biological techniques. By repeatedly crossing selected carriers of the distinctive gene back to the established inbred strain, in time all introduced genes except the distinctive gene and closely linked genes will have been purged [53]. The locus at which the distinctive gene resides is known as the *differential* locus, the linked genes carried along on the introduced segment are called *passenger* genes, and the original established inbred strain is termed the *partner* or *background* strain. Congenic lines are used (i) to compare effects of genes without the interference of genes in the background, (ii) to easily identify, by the congenic line in which they are carried, individual genes that have similar phenotypic effects, such as histocompatablity genes, and (iii) to assist in linkage studies. In contrast, to the congenic line, a *coisogenic* line is one that differs from its partner strain at a single locus, as a result of a mutation, random or introduced, in an established

inbred line. A *recombinant-inbred* (RI) strain is derived from a cross of two already established highly inbred strains (the progenitor strains), followed by systematic inbreeding as for any other inbred strain. This procedure, with no conscious selection pressure applied, allows the reassortment and fixation of genes from the two progenitor lines [12, 53].

Inbred mice lack the genetic and phenotypic variation seen in outbred mouse populations. The H2 allele is the region that codes for the major histocompatibility complex (MHC), the proteins responsible for processing and presenting processed antigen peptides to T-cells for immune system activation. There are several H2 alleles in circulation in mouse populations, but inbred mice only possess one of these alleles (*e.*g., BALB/c has the $H2^d$ allele). These alleles may vary in the number of different MHC proteins that can be expressed by an organism, or by variation in the protein sequence of amino acids in the cleft that binds and presents processed peptide. However, studies in inbred mice strains infected with *Rickettsia* [2] and murine cytomegalovirus (MCMV) [38] failed to establish a clear role for H2 haplotype in determining susceptibility or resistance to these pathogens. It is likely that several alleles persisted in the population because having the ability to bind a greater number of antigens or having the ability to bind certain antigens conferred some evolutionary advantage to the mouse and allowed persistence of these genes. Therefore, the use of inbred mice homozygous at this locus may skew the results of experiments in an unanticipated manner by artificially restricting the number or type of antigens that can be processed and/or presented by the organism's immune system. Conversely, experimental results may be better than seen in a genetically diverse population. One must be careful in interpreting results and extending generalizations to genetically diverse populations.

3 Specific Inbred Strains

BALB/c is the most common inbred mouse strain used in influenza vaccine studies, developed by HJ Bagg in 1913 (*B*agg *alb*ino). Many substrains of the original BALB/c mouse are now in general use (e.g., BALB/cJ and BALB/cByJ). The substrains share a high degree of genetic identity, but do differ at least one locus [46] and have behavioral and breeding dissimilarities [21]. BALB/c mice have a skewed Th2 immune response; characterized by CD4+ cell expression of IL-4, IL-5, IL-6 and IL-10, cytokines that correspond to activation of the humoral response to infection. IFN-γ and IL-2 correspond to the cell-mediated response. Several studies have demonstrated the BALB/c mouse's skewed Th2 immune response to infection with various pathogens or vaccination [18, 20, 38]. With respect to influenza infection and vaccination, primary infection or primary immunization with different vaccines [20, 16] causes a Th1 immune response in this mouse model, whereas a secondary response to vaccine [16, 55] induces a Th2 type immune response.

The *C57BL/6* mouse is opposite of its BALB/c cousin. This mouse is much more aggressive than the comparatively docile BALB/c. The immune response is skewed toward a Th1 response, which explains the phenotype of resistance to pathogens such as HSV-1, Sendai virus, *Leishmania* and *Rickettsia* [2, 6, 18, 45]. Though this strain has been used to study influenza infection and vaccination, it is usually used experimentally in conjunction with BALB/c mice as a comparison [3].

Nude mice are substrains of BALB/c and C57BL/6 mice homozygous for the *nu* allele carried on chromosome 11, which contains a nucleotide deletion in the *Foxn1* gene. This results in an athymic and hairless animal [19]. The *Foxn1* gene encodes a transcription factor (Forkhead Box) controlling development of the thymic epithelium, important for providing the correct environment for T-cell education [11]. The advantage of an athymic animal model is the ability to study immune responses that require T-cell participation. Sullivan et al. [54] studied infection with A/PR/8/34 (H1N1) found that nude mice had a lower rate of sero-conversion and lower geometric mean titers to virus challenge, indicating that to mount an effective humoral immune response, an intact T-cell immune system is required. However, the mean time to death for nude mice was increased versus BALB/c mice, suggesting that the immunopathology seen in animal models is due in part to Type-1 cell-mediated immunity.

4 Outbred mice

The advantage of using outbred mice for experiments involving infection or vaccine testing is, outbred mice are genetically and phenotypically dissimilar, and therefore a more heterogeneous population. Theoretically, experimental results from studies in such a population may better represent actual results of similar studies in humans. Studies directly comparing influenza infection in outbred models to inbred models are lacking, but studies performed with other pathogens provide data to elucidate differences and similarities of immune responses. Outbred mice have been used for the biological characterization of flavivirus *Alfuy* infection [39], *Coxsackievirus B4 E2* viral spread post-infection [23], Sendai virus infection [45], *Neospora caninum* infection [49] anthrax vaccine studies [14], and a DNA-based FMDV (foot and mouth disease virus) vaccine [4]. In another case [5], outbred mice failed to mount an immune response to vaccination with a plasmid expressing F1 antigen from *Yersinia,* while BALB/c mice demonstrated a robust antibody response. The arsenal of outbred mouse strains to choose from is extensive, however, the Swiss-Webster mouse, its derivative the ICR mouse, are the most used for influenza infection and vaccine studies, though CD-1 and NIH/S mice have been used as well.

Typically, differences between inbred and outbred models were seen in susceptibility or resistance to infection or in response to vaccination, indicating that genetic heterogeneity, likely at multiple loci, is an important consideration for these types of studies. Therefore, based on all studies mentioned in this section, knowledge of the

model chosen for study is essential, and extrapolation of experimental results must be done with extreme caution, and may not be possible in all cases.

5 Transgenic Animals

A transgenic animal is one that carries a foreign gene that has been deliberately inserted into its genome. The foreign gene is constructed using recombinant DNA methodology. In addition to a structural gene, the DNA usually includes other sequences to enable it to be incorporated into the DNA of the host and to be expressed correctly by the cells of the host. Transgenic mice have provided the tools for exploring many biological questions. Two methods of producing transgenic mice are widely used:

1. *The Embryonic Stem Cell Method (Method "1"):* Embryonic stem cells (ES cells) are harvested from the inner cell mass (ICM) of mouse blastocysts. They can be grown in culture and retain their full potential to produce all the cells of the mature animal, including its gametes.
2. *The Pronucleus Method (Method "2"):* Harvest freshly fertilized eggs before the sperm head has become a pronucleus, then inject the male pronucleus with your DNA. When the pronuclei have fused to form the diploid zygote nucleus, allow the zygote to divide by mitosis to form a 2-cell embryo. These embryos are then implanted in a pseudopregnant foster. Every cell in the offspring will contain the gene of interest.

5.1 Random vs. Targeted Gene Insertion

The early vectors used for gene insertion could, and did, place the gene (from one to 200 copies of it) anywhere in the genome. However, if you know some of the DNA sequence flanking a particular gene, it is possible to design vectors that replace that gene. The replacement gene can be one that restores function in a mutant animal or knocks out the function of a particular locus.

If the replacement gene is nonfunctional (a "null" allele), mating of the heterozygous transgenic mice will produce a strain of "knockout mice" homozygous for the nonfunctional gene (both copies of the gene at that locus have been "knocked out").

Knockout mice are valuable tools for discovering the function(s) of genes for which mutant strains were not previously available. Two generalizations have emerged from examining knockout mice:

1. Knockout mice are often surprisingly unaffected by their deficiency. Many genes turn out not to be indispensable. The mouse genome appears to have sufficient redundancy to compensate for a single missing pair of alleles.
2. Most genes are pleiotropic. They are expressed in different tissues in different ways and at different times in development.

6 Experimentally Infecting Mice with Influenza Virus

6.1 Viral Adaptation to Growth in a Mouse

Investigators utilizing murine models to study influenza virus must select or adapt an influenza viral strain suitable to address the experimental question. That is to say, does the murine model system and the infection induced accurately mimic real world phenomenon? In designing such experiments the investigator must address two questions: 1) Does the selected viral strain infect the mouse in a manner that is similar to a human infection in penetrance, viral replication, and replication kinetics? 2) Is the immunity engendered by an experimental vaccine or pharmacologic activity of a drug in the mouse mimic that in the human model? Investigators should be aware that the various immunogenic components of the influenza virus induce very different types of immunity easily reflected in a mouse model system. A more detailed discussion of the immune response to influenza virus can be found in reference [31]. Briefly, antibodies to HA neutralize viral infectivity [26]; antibody to the viral NA [26] and M2 [37] proteins are infection-permissive across a broad range of antibody levels (ie, no reduction in the number of infected subjects) but result in the reduction of pulmonary virus titers below a pathogenic threshold. Antibodies to M1 and NP can be found in the sera of animals immunized with whole virus vaccines, purified protein preparations and after infection. These studies failed to demonstrate a significant role for these antibodies in the amelioration of disease [25]. Despite evidence that live and inactivated influenza vaccines induce cross-reactive T-cells in humans [34] and mice [41], reinfection with homologous or heterotypic virus occurs. The level of anti-influenza CTLs correlates with the rate of viral clearance but not alter susceptibility to infection or subsequent infection [41].

Adaptation of influenza virus by serial passage in new host invariably results in the selection of mutants better equipped to replicate and spread within the new host. Most influenza virus strains grow readily in the mouse lung or murine tissue culture; thus influenza viruses, which are inherently cytolytic, adapt or become more damaging to the animal host not by changes in capacity to infect (which they already must possess) but by mutational changes that permit attainment of higher titers in the host. A common feature of adaptation of both influenza A and B viruses to the mouse has been the emergence of virus characterized by a more rapid growth rate [56, 35] and the capacity to reach higher concentrations in the lung [50]. Adaptation has been studied in the laboratory for many years. Changes in viral phenotype have been noted concomitant with sequential passage of virus in mice [8, 9, 40]. Serial passage of influenza A viruses in the mouse lung has been associated with antigenic changes [15], increased resistance to mucoprotein inhibitor, and changed sensitivity of viral HA to thermal inactivation [31]. Co-variation of these phenotypic changes with attainment of mouse lung virulence has not been unequivocally established. Whether adaptation comprises a complex series of mutational events or primarily entails selection of preexisting viral variants is not clear. Mouse-adapted virus is characterized by both a faster

growth rate and the capacity to attain higher titers in the lung [13]; indicating that both selection of preexisting mouse lung replication mutants and their subsequent mutation occur.

There have been several studies examining the specific mutations and in which viral genes that confer a mouse-adapted phenotype. Adaptation of human influenza virus to mice by serial passage results in the selection of highly virulent variants that have acquired mutations in multiple genes [8, 9, 40]. Analyses of the genetic basis for virulence by using reassortants that possess mixtures of genes from virulent and avirulent strains have identified various groupings of genes, which in aggregate implicate all eight genome segments [9]. Brown et al. [9] demonstrated in H3N2 virus that a group of 11 mutations convert an avirulent virus to a virulent variant. Thirteen of the 14 amino acid substitutions (93%) detected among clonal isolates were likely instrumental in adaptation because of their positive selection, location in functional regions, and or independent occurrence in other virulent influenza viruses. Mutations in virulent variants repeatedly involved nuclear localization signals and sites of protein and RNA interaction, implicating them as novel modulators of virulence. Mouse-adapted variants with the same HA mutations possessed different pH optima of fusion, indicating that other viral genes can modulate HA fusion activity. Experimental adaptation resulted in the selection of three mutations that were in common with the virulent human H5N1 isolate A/HK/156/97 [9]. Similarly, adaptation of the A/FM/1/47 H1N1 strain to mice resulted in selection of a variant with increased virulence. Complete sequence analysis identified mutations in the PB1, PB2, HA, NA, and M1 genes; all five mutations were shown to control virulence but also the replicative capacity in the mouse. The HA, NA and M1 mutations increased yield in all three hosts whereas in combination the PB1 and PB2 mutations were host restrictive changing the virus to a mouse specific strain. However, the HA mutation increased virulence largely independent of increased growth indicating a change in pathological properties [8]. Serial passage of an initially avirulent influenza B virus, B/Memphis/12/97, resulted in the selection of a variant that was lethal in mice. Sequencing data suggested one change in the C-terminal domain of the M1 protein, an asparagine to a serine at position 221, was responsible for acquisition of virulence and lethality [40].

6.2 Practical Experimental Points

Viral strains suitable for adaptation to the mouse can be derived from wild-type [50–52], classic reassortant virus [24, 28–30] or products of reverse genetics [57]. Use of each method has distinct advantages and disadvantages. Use of wild-type strains can be a quick, simple and allows for opportunities to mimic wild-type antigenic exposures from both the internal and surface antigens. However, adapting the strain to mouse may prove laborious, difficult to standardize and low-yield growth in embryonated chick eggs may limit experimental choices. Whereas, use of the classic reassortant and reverse genetic techniques offers the advantage of placing the surface glycoproteins,

HA and NA of a wild-type strain onto a background of internal proteins derived from A/PR/8/34 (H1N1) virus, as done annually, in the production of conventional inactivated influenza vaccine. A/PR/8/34 has an optimal growth temperature of 39°C -the average body temperature of a BALB/c mouse [1], is permissive to growth in a variety of experimentally useful tissue culture cell-lines including Madin-Darby Canine Kidney (MDCK) [31] and there are many commercially available serologic and immunologic reagents compatible with this system. The disadvantage of reassortants and reverse genetics is the need to expand the virus in embryonated chicken eggs to obtain sufficient virus to do the experiment. Passage in chicken eggs leads to deadaptation to the mouse [24, 28– 30]. A reverse genetics plasmid kit containing genes encoding influenza internal proteins from a mouse adapted strain is not available; therefore viral products of reverse genetics will require adaptation passages.

Traditionally, influenza virus has been adapted to increased penetrance or viral growth by sequential passage of virus in mouse lungs [9, 31, 50], with limited passage for expansion in embryonated chicken eggs, which may select for virus less adapted to growth in the mouse lung [24, 50–52]. Passage in MDCK selects for and preserves mouse-adapted characteristics. However, the total amount of virus produced in tissue culture is less than in eggs. Both methods require purification of virions from the growth medium; simple centrifugation and sucrose gradient centrifugation can produce usable high yields of infectious virus [48]. There are commercially available affinity chromatographic methods. Irrespective of the selection method chosen for passing the virus close attention must be paid to dilution (concentration) of virus used in passage studies. Successful adaptation to the mouse lung can be achieved with a wide range of varying viral concentrations and multiplicity of infections (*moi*). Too low of a *moi* may be insufficient for productive infection, to high of a concentration may result in multiplicity interference. Often prior to an experiment the optimal range of viral dilutions is unknown therefore titration of the virus in mice using several dilutions is warranted. In both reassortment and selection of viral strains, one must be cognizant of the enormous mutation rate of influenza (and other RNA viruses) and their apparent requirement for high *moi* for maintaining fitness in a given host system [33, 43]. In other words, either the introduction of populations limited in genetic diversity or the attempt to clone high titer virus by limiting dilution may lead to the establishment of a less fit virus. If such a virus is then maintained by high dilution passage, it will never regain adapted vigor. This phenomenon is known as a genetic "bottleneck" or "Muller's ratchet" [10]. In our laboratory, we have observed the loss of rapid growth and viral titer in mice if passed too early at high dilution. The practical lessons are: pass at sequential low dilutions early; then after sufficient dilutions and passages to escape unwanted nonadapted genes, passage should be maintained at a dilution sufficient to assure a reasonable gene pool. If using A/PR/8/34 reassortants this is in the range of 10^{-4} to 10^{-5} egg infectious dose (EID_{50}). In general, following infection with influenza virus in the mouse peak viral replication is at 3–4 days post inoculation and peak pulmonary lesions are seen on day 7 postinoculation [28–31, 51, 52, 57]. Although, there are viral strains that can peak earlier, it is our opinion that any mortality among the mice prior to day 3 should be examined by assaying the lungs in a tissue culture based plaque assay.

6.3 Experimental Techniques for Infecting Mice with Influenza Virus

Influenza virus has been used to infect mice via several routes of entry including intracerebral inoculation [42, 47], discussion will be limited to the most common techniques: intranasal instillation and aerosol exposure.

Intranasal instillation: Mice should be lightly anesthetized with Metofane anesthesia (Mallinckrodt Veterinarian) or another non-ether, non-chloroform based anesthetic agent. Light anesthesia should induce a state where the animal is not in distress and is mildly hyperpneic. The animal should be firmly held behind its neck and in one hand between the thumb and forefinger, the tail can be held by the investigator's fifth digit. With the animal held supine, 50 µl of live virus or phosphate-buffered saline can be instilled intranasally by pipette or syringe [17, 24, 51, 52]. A range of viral dilutions is recommended.

Aerosol exposure: Shulman and Kilbourne described a technique [24, 50–52] utilizing a retired autoclave. By the use of air pumps the interior of the autoclave could be maintained at a steady negative pressure relative to the room. Dilutions of virus could be aerosolized under positive pressure via an air pump. The aerosolizing devices are delicate, fragile and expensive, which in part contributes to the popularity of intranasal instillation. No mouse-to-mouse transmission has been observed [24, 51, 52].

6.4 Measurement of Endpoints of Infection

When initiating an experimental protocol decisions regarding how endpoint of infection will be measured should be made *a priori.* The options are: measure virus pulmonary titers in plaque assay [32] or by PCR [57] at specific time points; calculation of mouse infectious dose 50 (MID_{50}), monitor mortality/lethality to calculate a lethal dose 50 (LD_{50}) [9, 50]; measure weight loss and recovery [27]. Serologic studies (e.g., antibody titers to HA, NA or other viral antigens) and cellular immunologic studies (e.g., B-cell, T-helper and CTL assays) can be easily included [28–30]. Briefly, these assays are:

1. *Mouse Infectious dose (MID)* is a measure of the amount of infectious virus in a given sample, not the number of virions but a functional assay of infectious capacity. MID_{50} is the calculated dilution of a viral preparation that is expected to infect 50% of the mice inoculated. Usually stated as units of MID_{50} i.e., 1 MID_{50}; 100 MID_{50}. For example if a 10^{-5} dilution infected 50% of the mice exposed then the MID_{50} is 10^{5}; 100 MID_{50} would be a 10^{-3} dilution. The same concept is true for EID_{50} and $TCID_{50}$.
2. *Mortality-lethality* is a measure of how many and when animals die post exposure. A *Lethal dose* (LD) is often used, as with MID, a lethal dose 50 (LD_{50}),

a dilution of virus inducing an infection lethal to 50% of the animals exposed can be calculated. Relative risk (RR) and odds ratios (OR) can be extracted from these data.

3. *Mean pulmonary titer (mPVT)* can be directly measured in hemagglutination assay of lung preparation, or to increase sensitivity, HA assay can performed after lung preparations are inoculated into chicken eggs. Tissue culture assays allow calculation of *viral plaque forming units (PFU)*. In monolayer cell cultures maintained under agar, it can be shown that influenza-virus induced plaques usually are initiated by single virions [31]. Therefore, counting the number of plaques in a given dilution of lung preparation provides an estimation of the pulmonary viral load [7].
4. *Pulmonary lesion/plaques* lungs can be removed from infected animals on day 7 post exposure and the distinct plum colored pulmonary lesions induced by influenza cytopathology can be measured and counted.
5. *Weight gain/loss* is a sensitive measure of illness in the murine model for influenza. Infected animals become less active, eat and drink less in the context of increased metabolic demands of an acute illness. Daily weighing accurately detects weight loss and recovery. Weight loss and lack of recovery are good predictors of mortality [27].

7 Conclusion

The murine model for the study of influenza is well established. Although the mouse is not an exact mimic of avian, equine or human influenza knowledge of the systems experimental strengths and flaws can produce valid and reliable data.

A Transgenic Dwarf Rat Strain as a Tool for the Study of Immunosenescence in Aging Rats and the Effect of Calorie Restriction

Isao Shimokawa, Masanori Utsuyama, Toshimitsu Komatsu, Haruyoshi Yamaza and Takuya Chiba

Contents

Abstract: Immunosenescence or dysregulation of the immune system may accelerate the aging process and shorten the lifespan in animals. Calorie restriction, a well-known nutritional intervention for longevity in laboratory animals, retards immunosenescence and modulates the immunosystem. These effects of CR could contribute partly to extending the lifespan. A transgenic (Tg) dwarf rat strain, in which the growth hormone (GH) axis is selectively suppressed, lived longer and exhibited several phenotypes similar to those in CR rats, suggesting an important role for the GH axis in the effect of CR. Here, we describe the longevity, pathology, thymic and splenic lymphocyte subpopulations and response to endotoxin in Tg rats in comparison with CR rats. The findings support the importance of the GH axis in the effect of CR on the immune system and, in particular, longevity. The Tg rats could be a useful tool to better understand the molecular mechanisms underlying the antiaging effect of CR.

1 Introduction

Innate and acquired immunity is important for animals not only to protect against infection of microorganisms but also to inhibit a number of diseases including cancers, which are prevalent in aged animals. The immune system is, however, a 'double-edged sword' as the inflammatory hypothesis of aging presumes [1]. Aging-related dysregulation of the immune system could accelerate the aging process and shorten the lifespan of animals by activating proinflammatory processes that lead to excess generation of reactive oxygen and nitrogen species that potentially injure cellular components.

Restriction of food intake with supplying essential nutrients for survival in laboratory animals, referred to as calorie restriction (CR), reduces morbidity and mortality [2]. This effect has been called 'anti-aging' because many laboratories also confirmed retardation or inhibition of the pathophysiological aging processes by CR, an effect first reported by McCay et al [3]. Although proper modulation of the immune system could be one of the main mechanisms by which CR affects aging and longevity in animals, our knowledge is incomplete.

Another line of studies in the biomedical gerontology have found that a single gene, if spontaneously mutated or genetically engineered, could prolong the lifespan of organisms. Although this evidence was initially limited to invertebrates, over 10 genes are now reported in laboratory rodents (Fig. 1). Many of these longevity genes are clustered into the signaling pathway of GH and subsequently insulin-like growth factor (IGF)-1 or insulin. Attenuation of these signaling pathways favors longevity. The GH-IGF-1/insulin pathway is important for understanding the mechanism underlying the effect of CR, because CR is also known to reduce plasma levels of IGF-1 and insulin in laboratory animals [4, 5]. Because GH and IGF-1 are known to modulate the immune system [6], we may hypothesize that CR exhibits the antiaging effect through suppression of the GH-IGF-1/insulin axis and thus modulating immune system.

In this study, we describe some traits of the transgenic dwarf (Tg) rat strain that we established as an aging research model [7, 8], in comparison with CR rats. Published data have indicated that Tg rats fed ad libitum had phenotypes similar to wild-type CR rats for body weight, food intake, fat content, glucose tolerance, insulin sensitivity, and adiopokines such as adiponectin and leptin [8-10]. Although, at present, the immunological findings of Tg rats are limited, this rat model could provide knowledge on the relevance of immunosenecence to aging and longevity. Similarily, data on immunosenescence in other longevity models are limited and, thus, future analyses of the immune system in these models are needed to explore the role for each gene or gene product in immunosenescence and aging.

2 Animal Husbandry and General Data

2.1 Transgenic Dwarf Rats and Husbandy

The Tg rats, with a genetic background of Jcl:Wistar (Japan Clea, Inc., Tokyo, Japan), were produced from founders created by introducing fusion genes into rat embryos [11]. The transgene consisted of four copies of thyroid hormone response

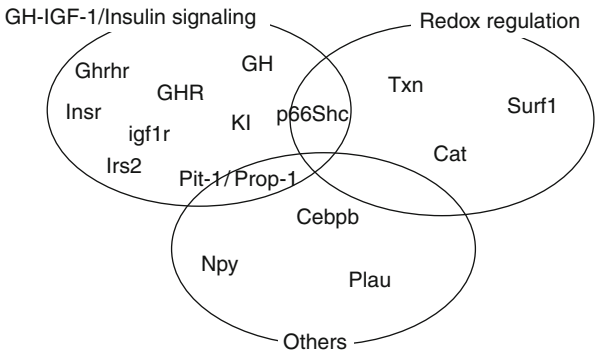

Fig. 1 Longevity genes in rodents. Genes that extend the lifespan of mice or rats, if spontaneously mutated or genetically engineered, are listed. The genes can be classified into three categories; genes that are associated with the GH-IGF-1/ insulin signaling pathway, redox regulation and other genes, although these categories are not mutually exclusive. ***Prop-1*** (spontaneously mutated mice for paired like homeodomain factor 1 gene; [15]): ***Pit-1*** (spontaneously mutated mice for POU domain, class 1, transcription factor 1 gene; [32]: ***p66Shc*** (knockout mice of src homology 2 domain-containing transforming protein C1 gene; [22]: ***Ghrhr*** (spontaneously mutated mice for growth hormone releasing hormone receptor gene; [32]: ***GHR*** (knockout mice for growth hormone (GH) receptor gene; [16]: ***GH*** (over-expression rats for antisense GH gene; [7]: ***igf1r*** (knockdown mice for insulin-like growth factor I receptor gene: [23]: ***Insr*** (mice for adipocyte-specific disruption of the insulin receptor gene; [33]): ***Txn*** (Overexpression mice for human thioredoxin gene: [34]): ***Cat*** (Mitochondria-specific overexpression mice for human catalase gene; [35]): ***Plau*** (brain-specific over-expression mice for urokinase type of plasminogen activator: [36]): ***Npy*** (overexpression rats for neuropeptide Y gene; [37]): ***Cebpb*** (knock-in mice for CCAAT/enhancer binding protein (C/EBP) beta gene; [38]): ***Kl*** (overexpression mice for klotho gene; [39]): Irs2 (whole body or brain-specific knockout mice for insulin receptor substrate 2 gene; [40]): ***Surf1*** (knockout mice for surfeit gene 1; [41])

elements, rat GH promoter, and antisense cDNA sequence for rat GH. The rat GH antisense gene was expressed in the pituitary gland of Tg rats as early as 3 weeks of age. Reverse transcription PCR analyses in Tg rats at 6 months of age confirmed that antisense GH-mRNA was expressed in the pituitary gland, spleen, and thymus, but not in the lungs, liver, heart, kidneys, and testis [7].

F1 hybrid rats were also generated at our laboratory animal center by mating female W rats with male Tg rats to moderate the reduced level of suppression of the GH-IGF-1 axis; the animals were referred to as tg/tg, tg/–, and –/– regarding the presence of the transgene.

At 4 weeks of age, weanling male rats were transferred to a barrier facility, housed separately, and maintained under specific-pathogen-free conditions. The animal husbandry is reported in detail elsewhere [7, 8]. Briefly, rats were provided a standard diet and tap water throughout the experiment (the AL group). The CR regimen in each rat group was initiated at 6 weeks of age. Rats in the CR group were provided 30% less food of the AL group by feeding them with two portions of food every other day 30 min before the lights were turned off.

Table 1 Characteristics of Tg and CR rats at 6 months of age

	(-/-)		(tg/-)		(tg/tg)	
	AL	CR	AL	CR	AL	CR
Body weight (g)	478.9 (34.1)	342.0 (16.9)*	316.6 (32.1)#	226.2 (15.4)*/#	199.1 (8.9)#	124.4 (10.5)*/#
Food intake (g/day)	21.6 (3.5)	15.9	17.0 (2.2)#	11.7	11.2 (1.3)#	7.9
Blood glucose (mg/dl)	126 (34)	112 (12)	106 (18)	90 (16)	106 (17)	n/a
Serum insulin (ng/ml)	102 (49)	15 (10)*	22 (18)#	20 (26)	21 (19)#	n/a
Plasma IGF-1 (ng/ml)	1094 (119)	864 (79) *	627 (90) #	346 (40)*/#	266 (23)#	170 (11)*/#
Plasma GH (ng/ml)	157.3 (55.0)	178.3 (26.7)	172.1 (44.1)	129.6 (35.9)	142.8 (33.9)	126.0 (46.0)
Pituitary GH-mRNA	1.00 (0.25)	0.81 (0.15)	0.34 (0.10)#	n/a	n/a	n/a

Values represent the mean (standard deviation) of 3–6 rats. (–/–); wild type rats. (tg/–); transgenic hemizygotic rats. (tg/tg); transgenic homozygotic rats. AL; ad libitum feeding rats. CR; 30% calorie-restricted rats. * $p < 0.05$ versus (vs) group AL in each rat group. #, $p < 0.05$ vs (–/–) of each diet group.

2.2 Characteristics of Tg and CR Rats at 6-Months of Age

The body weight and food intake in the AL condition decreased comparatively in tg/– and tg/tg rats, gene-dose dependently (Table 1). Following the 30% CR regimen for each AL group, the CR group showed 30~40% reduction in the body weight compared with the respective AL group. It should be noted that both the body weight and food intake in (tg/–)-AL rats were similar to those in (–/–)-CR rats for the first 24 months in the lifespan study [8].

Blood glucose levels under non-fasting conditions were slightly reduced in (tg/–)-AL and (tg/tg)-AL rats, while not significantly different between (tg/–)-AL and (tg/tg)-AL rats. CR also reduced the blood glucose level. The serum insulin level was significantly lower in (tg/–)-AL and (tg/tg)-AL. CR in (–/–) rats led to a significant reduction in the insulin level; there was no additional decrease by CR in (tg/–) and (tg/tg) rats.

The plasma IGF-1 concentration, an index for the degree of suppression of GH-IGF-1 signaling, decreased by 40% in (tg/–)-AL rats and by 75% in (tg/tg)-AL rats compared with (–/–)-AL rats. CR in each rat group further decreased the IGF-1 level; the level in (–/–)-CR rats was reduced to 80% of the level of (–/–)-AL rats. Thus the level was slightly lower in (tg/–)-AL rats than (–/–)-CR rats. The pituitary GH-mRNA level was also reduced by 20 and 66% in (–/–)-CR and (tg/–)-AL rats, respectively.

2.3 Longevity and Pathology

The lifespan at the 25th percentile point was increased by 10 and 11% in (tg/–)-AL and (–/–)-CR rats, as compared to (–/–)-AL rats (Figure 2); however, it was reduced

Table 2 Probable causes of death in Tg and CR rats

	(–/–)		(tg/–)		(tg/tg)	
	AL	CR	AL	CR	AL	CR
Total	30	26	30	30	39	17
Neoplastic (subtotal)	15	18	22	14	37*	11
Leukemia/lymphoma	0	1	2	3	21#	8
Pituitary adenoma	5	8	11	2#	1	0
Others	10	9	9	9	15	3
Non-neoplastic (subtotal)	15	8	8	16	2	6

Data represent the number of rats. The proportion of each category or disease was analyzed by χ^2 test or Fisher's exact test. * $p < 0.05$ versus (–/–)-AL rats. # $p < 0.05$ versus (tg/–)-AL rats.

by 9% in (tg/tg)-AL rats. Postmortem examination indicated that 50% of (tg/tg)-AL rats died of leukemia (Table 2); in contrast, only a few (tg/–) and (–/–) rats suffered from the disease. Furthermore, pituitary adenoma was less frequently in the cause of death in (tg/tg) rats. Our previous analysis indicated that moderate suppression of GH increased lifespan mostly due to the delay or inhibition of non-neoplastic causes; the effect on neoplastic causes was minor [7, 12].

Most of the rats that were considered to die of leukemia showed hepatosplenomegaly. Microscopic analysis and immunohistochemistry with an antibody for NK cells indicated that most of the cases were mononuclear large cell leukemia, which is frequently observed in inbread F344/N rats [13, 14]. Because this type of leukemia is not commonly observed in outbread Wistar rats and that the tg/tg rats were expanded from a pair of founder Tg rats, it is likely that this specific type of leukemia become tangible during the inbreeding process in (tg/tg) rats. Conditional survival analysis was performed to determine if the leukemic death was eliminated (Figure 2). However, the survival did not exceed that in (–/–)-AL rats.

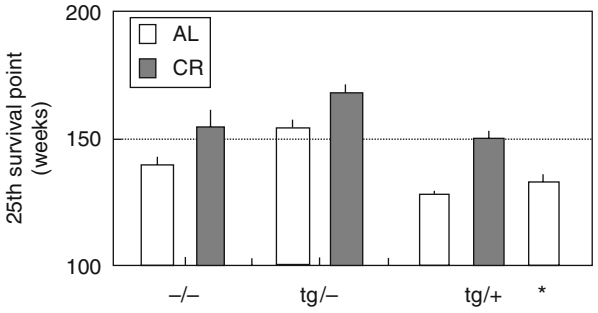

Fig. 2 Lifespan of transgenic dwarf rats: the effect of calorie restriction. Each bar represents the age (weeks) of 25th percentile survival point of lifespan (+ standard error). –/–, wild type rats. tg/–, hemizygotes for the transgene. tg/tg, homozygotes for the transgene. AL, a group of rats fed ad libitum. CR, 30% calorie-restricted rats. N = 30 for each group at the start of the study, with the exception of the (tg/tg)-AL group (N = 55) and (tg/tg)-CR group (N = 35). Survival data is described in more detail elsewhere [7, 8], except for the (tg/tg)-CR group. * Conditional survival if leukemia was excluded from the causes of death, i.e., leukemic death was considered to be the same censorship as random sacrifice of rats. The details of the procedure for the conditional survival are described elsewhere [42]

Thus, our data in dwarf rats suggest that moderate (but not severe) suppression of GH contributes to lifespan extension. This finding contrasts with those in long-lived mice whose GH signaling is almost deficient [15, 16].

CR increased the lifespan in all rat groups. Although CR decreased the plasma IGF-1 level in each rat group compared with the corresponding AL group, the reduced IGF-1 level alone is unlikely to contribute to the extended lifespan. As described above, the lifespan in (tg/tg)-AL rats was shorter than that in (tg/–)-CR rats, even if leukemic death was eliminated, while the plasma IGF-1 level was similar between the groups. Therefore, CR could have a GH-IGF-1 independent mechanism(s) for lifespan extension.

3 Subpopulation of Thymic and Splenic Lymphocytes

3.1 Thymic Lymphocyte Subpopulation

The weight of the thymus at 6 months of age did not differ significantly between rats or between diet groups, when normalized for body weight (Table 3). Flow cytometric analysis of thymocytes prepared from the 6-month-old rats illustrated that only double negative (DN; CD4– & CD8–) cells tended to increase in (tg/–) and (tg/tg) rats, particularly in (tg/–)-CR rats. However, there was no significant difference in double positive (DP; CD4+ & CD8+), CD4-single positive (SP4), or CD8-single positive (SP8) subpopulations among rats or between diet groups. Thus, the present data suggest that the suppression of GH or CR does not significantly affect the composition of thymocytes at least in the 6-month-old male rats.

The present data in Tg rats are in accord with the dwarf mice models in which pituitary GH, PRL, TSH are deficient or IGF-1-null mice, or hypophysectomized mice demonstrating no statistical difference in thymocyte subsets between the hormone-deficient mice and their normal littermates [6]. Neither GH nor IGF-1 is required for primary lymphopoiesis. However, possible aging-related changes in thymic cell subpopulations and functions in Tg rats need to be analyzed in future studies.

3.2 Splenic Lymphocyte Subpopulation and Mitogenic Response

The weights of the spleen did not differ between the rat groups when normalized for body weight (Table 4); the normalized weight was reduced by 4–9% by CR. The proportion of T-cells (CD3+/CD45R–) did not differ among rat groups, while it was slightly increased by CR, particularly in (–/–) rats. The B cell population (CD3–/CD45R+) was lower in (tg/tg) rats; CR significantly decreased the B cell population. Subsequently, the T/B cell ratio did not differ among rat groups, although it was increased in the CR group, particularly in (–/–) and (tg/tg) rats. The NK cell

Table 3 Subpopulation of thymocytes in the transgenic and calorie-restricted rats at 6 months of age

	(–/–)		(tg/–)		(tg/tg)		
	AL	CR	AL	CR	AL	CR	2-f ANOVA
Thymus	40.4 (4.4)	47.0 (4.8)	51.5 (6.6)	39.0 (6.6)	43.0 (3.2)	33.3 (1.4)	
DN	2.8 (0.4)	3.0 (0.6)	3.2 (0.7)	6.1 (0.6)*/#	4.5 (1.1)	4.4 (0.6)	Genotype effect, p = 0.0508
DP	73.6 (1.5)	75.7 (2.4)	76.4 (2.0)	72.9 (2.4)	76.5 (3.8)	75.2 (1.0)	
SP4	20.3 (3.0)	18.1 (1.4)	17.7 (1.5)	18.0 (2.0)	16.2 (2.4)	17.4 (1.3)	
SP8	3.3 (0.3)	3.2 (0.5)	2.7 (0.3)	3.0 (0.3)	2.8 (0.5)	3.1 (2.3)	

Values represent the means (standard error) of 5 or 6 rats. Thymus (mg/100g body weight); DN, DP, SP4, SP8 (% of total thymocytes). (–/–); wild type rats. (tg/–); transgenic hemizygotic rats. (tg/tg); transgenic homozygotic rats. AL; ad libitum feeding rats. CR; 30% calorie-restricted rats. * $p < 0.05$ versus (vs) the AL group in each genotype. # $p < 0.05$ vs (–/–) in each diet group.

(CD3–/NKR+) population and activity were decreased in (tg/tg)-AL rats compared with (–/–)-AL rats. The proportion of NK cell but not the activity of NK cells was increased in the CR group.

The naive T-cell (CD4+, OX22+) population was greatest in the following order; (tg/tg), (tg/–), and (–/–) rats. Memory T-cell (CD4+, OX22–) population was slightly reduced in (tg/tg) rats. CR also increased the proportion of naive T-cells, particularly in the (–/–) rats.

The mitogenic response of splenic cells, examined by the response to phytohemagglutinin (PHA), concanavalin (CON) A, and anti-CD3 antibodies did not differ significantly among groups (Table 5); responses to PHA and ConA tended to increase in CR groups.

Thus, it can be summarized as follows: 1) that reduction of GH does not affect the T and B lymphocyte populations except NK cells, 2) severe suppression of GH decreases the cell number and activity of NK cells, 3) CR increases the T-cell fraction and decreases B cells in splenic cells, 4) CR restores the NK cell function that was reduced by severe suppression of GH, 5) reduction of GH does not affect the proliferative response of splenic lymphocytes to stimulants, while CR tends to enhance this response.

Although our analysis is limited to 6-month-old rats, our results suggest that CR and suppression of GH affect the development of secondary lymphoid organs. The aged immune system is characterized by a decrease in T-cell function caused by an increase in the fraction of memory T-cells that are less capable of responding to mitogens or novel antigen stimulation [17, 18]; in contrast, the number or proportion of naive T-cells declines. Thus, we can speculate that the increased proportion of naive T-cells in the CR group and (tg/–)-AL rats is attributable in part to the prolonged lifespan. The restored NK cell activity and/or increased T-cell fraction by CR in (tg/tg) rats might also contribute to the extended lifespan in short-lived (tg/tg) rats, because these innate immune functions have important roles for the prevention of cancers [19].

Our analysis suggests that CR and moderate GH suppression exert similar beneficial effects on immune function, while severe suppression of GH may produce some adverse effects.

Table 4 Subpopulations of splenic lymphocytes

	(–/–)		(tg/–)		(tg/tg)

Values represent the means (standard error) of 5 or 6 rats. Proliferative response (stimulation index) of splenic cells to PHA, ConA, antibody to CD3 (aCD3), and lipopolysaccharide (LPS) was evaluated as previously reported {Utsuyama, 1997 #103}. (–/–); wild type rats. (tg/–); transgenic hemizygotic rats. (tg/tg); transgenic homozygotic rats. AL; ad libitum feeding rats. CR; 30% calorie-restricted rats. * $p < 0.05$ versus (vs) the AL group in each genotype.

4 Response to LPS-induced Inflammatory Challenge

CR protects laboratory rodents against a variety of stressors including inflammatory and toxic agents [20]. Many stressors damage cellular components through an increase in reactive oxygen and nitrogen species, i.e., oxidative stress, which are thought to cause or accelerate aging and diseases. Thus, resistance to stressors could be one of the essential mechanisms underlying the retardation of aging and prolonging the lifespan of organisms. Indeed, embryonic or skin fibroblasts prepared from long-lived mouse models have been shown to resist oxidative stress induced by UV light, hydrogen peroxide, paraquat, or heavy metals [21]. Some of the mice models also exhibit higher survival rates after paraquat administration [22, 23].

We analyzed the acute phase response of 6-month-old Tg and CR rats to lipopolysaccharide (LPS), a component of Gram-negative bacteria that elicits inflammatory processes. LPS initiates a cascade of cytokine mediators, i.e., successive waves of increments of the plasma concentrations of tumor necrosis factor (TNF)-α, interleukin (IL)-1, and IL-6 [24]. The initial step of activation of cytokines subsequently augments secretion and synthesis of interferon (IFN)-γ, an incremental increase in nitric oxide (NO) by induction of iNOS and platelet-activating factor in the plasma, and increased synthesis of acute phase reactants. In the activation cascade, monocytes and macrophages are functionally enhanced to eliminate invading bacteria; however, these processes also result in endothelial cell injuries, which, in turn triggers the coagulation process, and finally lead to hypoperfusion and ischemic injuries in peripheral tissues.

The procedure of LPS-induced inflammatory challenge was described in more detail elsewhere [25]. Briefly, a low dose of LPS (1.6 mg/kg body weight) administered intraperitoneally significantly increased the blood AST (aspartate aminotransferase) level, an indicator of tissue injury, at 4 and 8 h in control

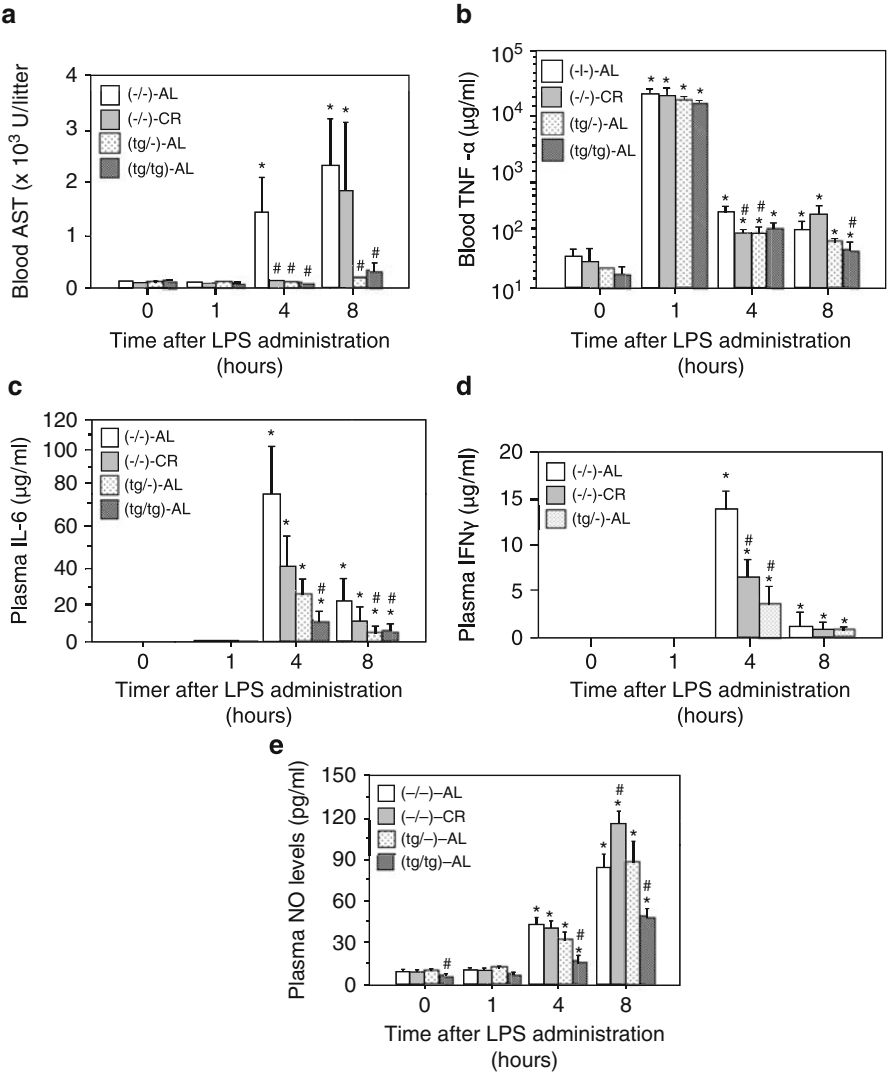

Fig. 3 **(a-e**) Response to LPS-induced inflammatory stress in CR and transgenic dwarf rats at 6 months of age. Values represent means + SE of 3–8 rats. * $p < 0.05$ versus 0 h in each rat group; # $p < 0.05$ versus (–/–)-AL rats at each time point. Blood or plasma samples were prepared for the following enzyme, cytokines, and nitric oxide assays (refer to Tsuchiya T et al [23] for further details) a) Blood levels of aspartate aminotransferase (AST), an index of tissue injuries after LPS administration. b) Tumor necrosis factor (TNF)-α, c) Interleukin (IL)-6, d) Interferon (IFN)-γ e) Nitric oxide (NO)

(–/–)-AL rats (Fig 3a). CR delayed the incremental increase in blood AST. In (tg/–)-AL and (tg/tg) rats, there was no significant increase. These findings indicate that either moderate or severe suppression of GH diminishes tissue injuries due to LPS

challenge. This effect seems to be stronger than that of CR. Since the degree of suppression of the GH-IGF-1 axis, indicated by the plasma concentration of IGF-1, was greater in (tg/–)-AL rats than in (–/–)-CR rats, the levels of AST correlated with the GH-IGF-1 levels.

The blood TNF-α did not differ between (–/–)-AL and (–/–)-CR rats at 1 h (Fig 3b); however, the TNF-α level at 1 h was low in (tg/–)-AL and (tg/tg)-AL rats. IL-6 was significantly increased at 4 h and reduced at 8 h (Fig 3c). This level was lower in the following order; (tg/tg)-AL, (tg/–)-AL, (–/–)-CR, and (–/–)-AL rats. The peak values of plasma INF-γ at 4 h was lower in the following order; (tg/–)-AL, (–/–)-CR, and (–/–)-AL rats (data for (tg/tg)-AL rats are not available), the finding was comparable to those of AST and IL-6. The level of NO was gradually increased between 0 and 8 h (Fig 3d). The level at 8 h was highest in (–/–)-CR rats and similar between (–/–)-AL and (tg/–)-AL rats, although the level was lowest in (tg/tg)-AL rats. These findings suggest that the suppression of GH attenuates the LPS-induced cytokine activating cascade and minimizes tissue injuries, and that CR also diminishes tissue injuries probably, in part, through the same mechanism, because CR modestly suppressed the GH-IGF-1 axis. The difference in severity of tissue injuries between the rat groups seemed to correlate with the degree of suppression of GH-IGF-1 axis. CR, however, could affect the LPS-initiated inflammatory cascade and related tissue injuries differently, because the NO level at 8 h was significantly higher in (–/–)-CR rats than in (–/–)-AL and (tg/–)-AL rats.

Previous studies indicate that GH primes phagocytes for an increased production of reactive oxygen intermediates [26, 27]. GH potentiates the biological activities of entotoxin, i.e., lethality, in the rat [28]. However, IGF-1 did not induce this effect, indicating that the enhancement of endotoxin effects by GH is via an IGF-1-independent pathway [29]. Priming rats by GH induced a further increased response to serum IFN-γ but not TNF-α to subsequent entotoxin challenge, suggesting that INF-γ rather than TNF-α is likely to be involved in this process [29]. In other words, the suppression of GH diminishes the propagation of the inflammatory cascade downstream of TNF-α and minimizes tissue injuries. In this context, we can conclude that lower levels of GH favors longevity in animals via minimization of activation of monocytes and macrophages that are provoked by inflammation at the molecular levels during the aging process.

The diminution of inflammatory cascade could sometimes be harmful in organisms particularly regarding the elimination of invading bacteria. GH-treated animals release more superoxide and TNF-α in response to the appropriate trigger stimuli and ingest Listeria monocytogenes better than macrophages from untreated animals [30, 31]. GH has also been shown to protect hypopituitary animals from lethal *Salmonella typhimurium* infections [31]. In nature, infectious challenges by microorganisms are frequent and, thus, enhanced innate immunity could be beneficial to increase survival, even if the enhanced immunity also damages host tissues and cells. Therefore, there could be optimal levels of the strength of innate immunity in animals to protect infectious agents but minimize host–tissue damage, depending on their living conditions.

5 Conclusion

If the GH levels in commercially available rats are set as control values, moderate suppression of GH favors longevity and exhibits few demerits in the immune system. Severe suppression of GH may have some adverse effects on innate immunity, e.g., the diminished NK cell activity and the attenuated cytokine activation cascade that may decrease survival probability under usual living conditions where animals are often exposed to a variety of infection agents. In other words, there could be optimal levels for GH to maximize survival of organisms, depending on living conditions. Under SPF conditions in the laboratory, the demerits of severe suppression of GH are masked and only the merit, minimization of host-tissue injuries caused by the self-defense system, is emphasized.

Tg and CR rats exhibited similar trends regarding the selected immune functions, suggesting that the GH signaling could mediate the effect of CR in part. In this sense, the Tg rat is an intriguing animal model to better understand the roles of the GH axis in the aging process and the anti-aging effect of CR. Because our analysis on the immune system in Tg rats is limited, future studies are required to further understand the role of immunosenescene in the aging process and the anti-aging effect of CR.

Mathematical Modeling of Immunosenescence: Scenarios, Processes and Limitations

A.A. Romanyukha, S.G. Rudnev, T.A. Sannikova and A.I. Yashin

Contents

Abstract: Mathematical modeling of immunosenescence is the new area of research emerging at the interface of the immunology, gerontology, and mathematics. In this paper we outline basic variables important for modeling aging immunity. We discuss the role of evolution in shaping pattern of aging in the immune system of modern humans. We investigate mathematical models of postnatal changes in the population of peripheral T-cells, effects of the antigenic load during development on the body growth, and contribution of immunosenescence to the old age increase in the risk of death from respiratory infections.

Keywords: Antigenic load • aging immunity • mortality from infections • body growth • population of T-cells

1 Introduction

There are two types of mathematical models applied to the life science problems. The objectives and methodology used in these models differ substantially. The first type of models deals with the problems of analysis and interpretation of the results

of a certain experimental study, or a series of such studies. The main objective of such modeling is the quantification of sensitivity of the phenomenon to changes in various factors. The results of modeling contribute to better understanding the roles of factors and mechanisms in the processes under study. The focus of the second type of models is systematization of knowledge and data in order to develop systemic view, obtain integral description of the results of heterogeneous experimental studies, and check consistency of such description with existing theories. The models of the second type deal with the description of the phenomenon: they assimilate results of different experiments, test their mutual compatibility, and correspondence to existing theories. Such models are an effective means of testing accumulated knowledge and can be used to predict effects of exposure to external factors on functioning of living systems, or changes in characteristics of the organism itself.

2 Modeling Immunosenescence

In this study we will investigate properties of the first type models of aging immunity. Such modeling is a relatively new area of research, emerging at the interface of immunology, gerontology, and mathematics. It studies regularities of aging related decline in functioning of the components of the immune system, as well as dynamic interaction among them during the aging process. To describe such nonlinear multidimensional aging related changes in the immune defense mechanism the dynamic mathematical and computer modeling of these phenomena is needed. An important step in such modeling is the selection of variables or "units" of the immunosenescence. These units suppose to reflect the basic features and processes of aging immunity. These variables include:

- The characteristics of the lymphocytes' aging (telomere length, the ability to respond to the antigenic and cytokine signals, intercellular cooperation;
- Population-wide characteristics of lymphocytes and other immune system cells (proportion of naïve and memory cells, the proportion of the various lymphocyte subpopulations, antigenic repertoire of lymphocytes);
- The characteristics of activity of the immune system (rate of lymphocyte formation in thymus and the bone marrow, the amount of active parenchyma in the lymphoid organs, the rate of lymphoid proliferation processes);
- The characteristics of the state of the organism (frequency and severity of infectious disease, activity of inflammatory process, probability of death and/or decrease of reproduction due to the deficiency of immune protection).

2.1 The Immune Life Histories

Thus, the units of immunosenescence should relate lymphocytes' characteristics to the processes developing in the aging body. These include infection, inflammation, tissue and organ aging, fertility and life span. These variables should relate the dynamics of lymphocyte populations and characteristics of individual fitness. The

age trajectories of these interrelated variables comprise the immune life history (McDade 2003). We will consider age-related changes in the: naïve cells concentration; memory cells concentration; replicative potential of lymphocyte subpopulations; antigen repertoire of lymphocytes; rate of the influx of immune cells from the thymus and bone marrow; incidence of infectious and, maybe, cardiovascular diseases; individual inflammatory status; antigenic load. All values, except the latter are characteristics of the immune system. The antigenic load is a measure of pressure of external and internal conditions at the immune system.

2.1.1 Antigenic Load

We define the antigenic load as the rate of the inflow of the alien, or modified antigens into the lymphoid tissue. The activity of the immune system and its rate of aging depend significantly on the level of antigenic load, because it affects the rate of division of the lymphocytes and their mortality risk. The antigenic load consists of the two components: alien antigens and modified self-antigens. Alien antigens may arrive from the external environment and reproducing in the host. They may also be located in the host and reproducing in certain circumstances.

The rate of inflow of infectious and noninfectious antigens from the environment must be proportional to the consumption of nutrients and the oxygen. Because such consumption is directly connected to the metabolic rate, it is reasonable to hypothesize that the level of external antigenic load is proportional to the metabolic rate.

A large proportion of modified self-antigens are formed due to action of free radicals; the rate of their formation is proportional to the metabolic rate as well. So we will assume that the rate of generation of self-antigens is proportional to the metabolic rate. Therefore, the total antigenic load largely depends on the intensity of metabolism.

The level of infectious component of the antigenic load is strongly influenced by the two factors, weakly dependent on the metabolic rate: the density of infectious microorganisms in the environment and the effectiveness of the immunity. Obviously, the high density of microorganisms in the environment increases the frequency of infections and, hence, the antigenic load also increases. On the other hand, in the presence of many memory cells, the infectious antigenic load will loosely depend on the microbial density or metabolic rate.

2.1.2 Antigenic Load and Immunosenescence

The intensity of metabolism declines with age. The effectiveness of the immune protection also varies with age: the frequency of infectious diseases is highest in the childhood, lowest in the intermediate age and increases in the old ages. Specific characteristics of the antigenic load affect the development of the immune system, its aging rate, and, hence, individual fitness. Consequently, many properties of the aging immunity, observed in modern humans, are formed by evolution during many thousands of years in the past. The principal objectives of the immune system are to ensure survival to reproductive age and provide maximum protection against infections during the reproductive period.

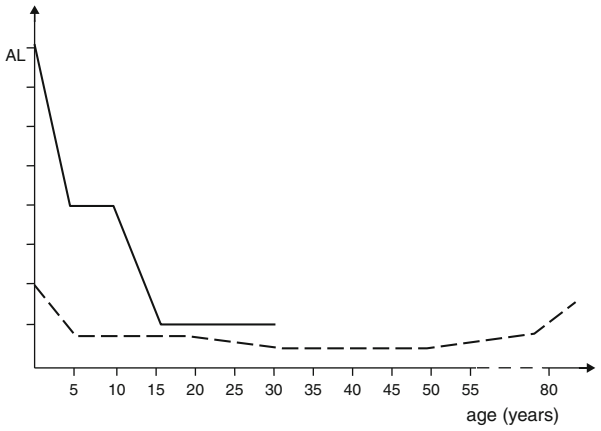

Fig. 1 Hypothetical scheme of life-long antigenic load dynamics for primitive (—), and contemporary man (— —), AL—antigenic load (in arbitrary units)

An important mechanism for ensuring effective protection involves adaptive immunity based on production of the immune memory cells. The more memory cell is formed after the primary immune response, and the longer they live; the more protected is the body from secondary infections of this type. Since the resources of the immune system are limited, there is a competition between the naïve cells and memory cells. The memory cells provide effective protection from a few known pathogens in current and future situations. The naïve cells are supposed to provide future protection from all possible pathogens. If the life expectancy is large and emergence of the new diseases is a likely scenario, it is beneficial to maintain more naïve cells and have active thymus, with less effective protection against endemic pathogens. In case of short life and low rate of emergence of the new diseases it is more profitable for an organism to produce less naïve lymphocytes and make higher investment to the memory cells. Thus, the fundamental property of the immunosenescence is its evolutionary coadaptation with antigenic load and other life history characteristics of the aging human organisms.

Figure 1 shows a hypothetical dynamics of antigenic load during life of primitive and modern man. It is important to understand how the immune system, evolutionary adjusted to the living conditions of primitive man, adapts to current environmental and living conditions. The main difference between the curves 1 and 2 involves significant reduction of the infectious burden, especially at the beginning of life and an increase of life expectancy in modern humans[1].

2.2 Scenarios of Immunosenescence

The differences in the current and prehistoric antigenic loads affect process of immunosenescence. The age related changes in the immune system of a primitive human were formed by high infectious load in the first years of life, where the immunity learning period is included in the child's growth interval. Short life and the relative isolation

[1] When creating the Fig. 1 we have assumed that the antigenic load of the modern humans is approximately equal to load by their self-modified antigens, and the antigenic load of the primitive humans was about an order of magnitude larger than of the modern ones.

from the new pathogens defined the replacement rate of the naïve cells by the memory cells, the rate of reduction of the naive lymphocytes production, the rate of reduction of replicative capacity of the memory cells with age. An exposure to the antigens during the growth period ensured training of the immunity for survivors, efficient use of the body resources and protection against antigens during the reproductive period.

Note that the high infant mortality rate observed in the past may indicate substantial variability in the antigenic load among survivors. Such scenario of developing immunity can be called **forced immunomaturation**. The essence of this scenario is the accelerated maturation and learning of the immune system. Reducing the antigenic load at this scenario improves the immunity condition in middle age. In modern conditions external antigenic load has much less impact on the aging immunity. The age decline of immunity is determined by the changes in the stem cell properties, lack of naive cells, a narrow repertoire of the memory cells, and reduced replicative ability of the memory cells. Thus, in modern conditions immunosenescence is largely defined by traits selected during the evolution of immunity (early decline of naive cell production, reduction of their replicative ability, etc.) as well as by traits depending on general properties of aging body (the aging of stem cell pool, increase of the self-modified antigen generation rate, etc.). Such scenario of age related changes in immunity can be called **inertial immunosenescence.** An important feature of this aging scenario is that the decline in the antigenic load, or slowing down of thymus involution has little impact on immunity in the older ages.

In this case in order to improve the immune function a combined influence on the immune system such as the rejuvenation of stem cells, thymus function enhancement, accelerated elimination of the old memory and naive cells, and accelerated immunity learning through vaccination is required. This procedure will be accompanied by a temporary decrease in the immune protection. Therefore, this process can not be conducted on the background of a strong decline in immunity, the optimal age is the border between medium and older age.In fact this is a repetition of immunity development and learning period in its reduced form. It can be assumed that in some individuals such events can occur as a result of natural events (starvation, severe stress, etc.).Hypothetical version of immune life history with such periodic recovering of the immune system can be called the **reciprocating immunorejuvenation** scenario.

2.3 Constraints of Adaptation

The adaptation responses develop in the presence of explicit or implicit limitations on the rate and the magnitude of physiological processes involved in such adaptations. For example, the total number of immune system cells should not change significantly during the adulthood. This restriction results in diminishing the memory cell life time, when the production rate of the naive cells by the thymus increases. An example of implicit limitation of the immune system adaptation is the need to coordinate the growth of the body size, growth of the immune system mass, and the rate of the immunity learning. If the new antigens presentation will delay an increase in the body mass the homeostatic proliferation of lymphocytes may lead to undesirable distortions in the immune cells' repertoire.

Mathematical modeling is a convenient method for studying such problems. Below we will consider examples of the use of mathematical models to study aging related changes in the immune system. They include postnatal changes in the population of peripheral T-cells, effects of the antigenic load during development on the body growth, and contribution of immunosenescence to the old age increase in the risk of death from respiratory infections.

First we investigate how the basic immunosenescence processes such as thymus decay, shortening of telomeres in the newly forming naive T-lymphocytes and shrinking of the peripheral lymphoid tissues interact depending on the antigenic load.

For description of these processes, we propose a mathematical model (1). It describes the balance of influx and usage of T-cells and their replicative potential. The model equations are based on two main assumptions:

- the T-lymphocyte concentration in the peripheral lymphoid tissue must be maintained constant;
- the naive cells are superior to the memory cells in the competition for free space in the lymphoid tissue.

Based on these assumptions, we construct a model describing the age dynamics of the following variables:

N(t),* rate of naive T-cells influx in IPLT at the age t (cell/day);
V(t), volume of IPLT at the age t, (ml);
P(t)*, length of telomere repeats in naive T-cells produced at the age t, (bp/cell);
N(t), concentration of nai'ye T-cells in IPLT at the age t, (cell/ml);
M(t), concentration of memory T-cells in IPLT at the age of t (cell/ml);
PN(t), average length of telomere repeats in naive T-cell at the age t (bp/cell);
PM(t), average length of telomere repeats in memory T-cell at thew age t (bp/cell);
Function *L(t)* describes total antigenic load at the age t (g/day).

The mathematical model of age-related changes in peripheral T-cell population is represented by the system of the following seven ordinary differential equations:

$$
\begin{aligned}
&\frac{dN^*}{dt} = -k_T N^*,\\
&\frac{dN}{dt} = \frac{N^*}{V} - \alpha_1 \frac{L}{V} N - \mu_N N - \frac{dV}{dt}\frac{N}{V},\\
&\frac{dP_N}{dt} = \left(P^* - P_N\right)\frac{N^*}{NV},\\
&\frac{dM}{dt} = \rho_1\alpha_1 \frac{L}{V} N + \rho_2\alpha_2 \frac{L}{V} M + \mu_M \left(C^* - N - M\right) - \frac{dV}{dt}\frac{M}{V},\\
&\frac{dP_M}{dt} = \rho_1\alpha_1 \frac{L}{V}\left(P_N - \lambda_N - P_M\right)\frac{N}{M} - \left(\rho_2 + 1\right)\alpha_2\lambda_M \frac{L}{V}.\\
&\frac{dV}{dt} = -k_V V,\\
&\frac{dP^*}{dt} = -k_p P^*
\end{aligned}
\qquad (1)
$$

For simplicity, we assume that the antigenic load remains constant throughout life, but the production rate of naive T-lymphocytes and the volume of peripheral lymphoid tissues decrease with constant relative rate. However, developed model is flexible enough to investigate more complicated scenarios.

Numerical experiments with this model revealed some interesting dependencies: the lengthy production of naive T-lymphocytes strengthens the immune protection in advanced ages, but relatively weakens immunity in middle age because it reduces maintenance resources and duration of immune memory. The calculations also showed that an important factor in ensuring the immune protection in advanced ages is slowing of the stem cell aging.

These results allowed for addressing the question on how the body growth processes affect the aging of immunity.

3 Modeling Postnatal Changes in the Population of Peripheral T-cells

The most apparent changes in the population of peripheral T-cells in humans occur in childhood (Rufer et al. 1999; Zeichner et al. 1999), when the relative rate of body growth and the infection morbidity are maximal. These changes are accompanied by the early onset of thymus atrophy—a primary lymphoid organ, in which the development of bone marrow-derived progenitors into mature T-cells takes place (Steinmann et al. 1985) (Fig. 2). Such atrophy substantially restricts the ability of adults to produce naive T-cells, which, in turn, affects the strength and efficiency of adaptive immune response. An expansion of intact peripheral lymphoid tissue (IPLT) at early age by memory cells affects the immune system learning capacity at later ages. Therefore, when studying the immune system aging, it is important to take the conditions and regularities of the development of this system early in life into account.

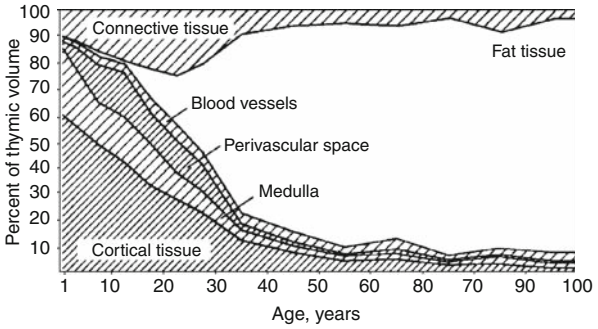

Fig. 2 Involution of thymus (Steinmann et al. 1985). After the age of 1, the volume of thymus remains relatively constant. The division of thymic precursor T-cells takes place primarily in cortical tissue

3.1 The Extended Model

We address these issues using the extended mathematical model of age-related changes in population of peripheral T-cells suggested by Romanyukha and Yashin (2003). The extended model adds one equation on age-related changes in body mass to the system of equations specified in (Romanyukha and Yashin 2003), and exploits the new fundamental assumption that the value of antigenic load is proportional to the intensity of basal metabolism. The resulting model allows for describing development of adaptive immunity during all postnatal life, including childhood. The dependence of basal metabolism on body mass is described using the Kleiber's 3/4 power scaling law (Kleiber 1932; West, Brown 2005).

Taking into account the above considerations, the mathematical model of age-related changes in population of peripheral T-cells can be written in the form:

$$
\begin{aligned}
&\frac{dN^*}{dt} = -k_T N^*,\\
&\frac{dN}{dt} = \frac{N^*}{V} - \alpha_1 \frac{L}{V} N - \mu_N N - \frac{dV}{dt}\frac{N}{V},\\
&\frac{dM}{dt} = \rho_1\alpha_1 \frac{L}{V} N + \rho_2\alpha_2 \frac{L}{V} M + \mu_M (C^* - N - M) - \frac{dV}{dt}\frac{M}{V},\\
&\frac{dP^*}{dt} = -\left(\frac{\bar{k}_P}{m}\frac{dm}{dt} + k_P\right) P^*,\\
&\frac{dP_N}{dt} = (P^* - P_N)\frac{N^*}{NV},\\
&\frac{dP_M}{dt} = \rho_1\alpha_1 (P_N - P_M - \lambda_N)\frac{L}{V}\frac{N}{M} - (\rho_2 + 1)\alpha_2\lambda_M \frac{L}{V},\\
&\frac{dV}{dt} = \alpha_3 \frac{L}{V}\frac{dm}{dt} - k_V V,\\
&\frac{dm}{dt} = \alpha_4 m^{3/4} - k_m m.
\end{aligned}
\tag{2}
$$

Here the variable t corresponds to individual's age; $N^*(t)$ is the rate of naive T-cells influx from thymus into IPLT; $N(t)$ is the concentration of naive T-cells in the IPLT; $M(t)$ is the concentration of the memory T-cells in the IPLT; $P^*(t)$ is the length of telomeres in naive T-cells leaving thymus at the age t; $P_N(t)$ is the length of telomeres in the naive T-cells; $P_M(t)$ is the length of telomeres in the memory T cells, $V(t)$ is the volume of the IPLT; $m(t)$ is the body mass. Rapid telomere shortening in the stem cells during the first years of life entails similar changes in telomeres' length of the newly produced naive T-cells in the thymus (Rufer et al. 1999). We assume that the corresponding rate is proportional to the relative increase in the body mass. So, the rate parameter in the equation for P^* can be written as a function of age: $k_P(t) = \bar{k}_P(dm/dt)/m + k_P$ where k_P is taken from the original model of Romanyukha and Yashin (2003). We assume also that the rate of the early IPLT expansion is proportional to specific anti-

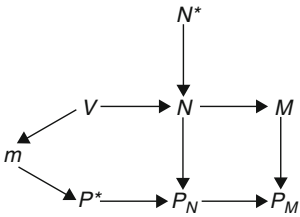

Fig. 3 The sequence of the model parameters adjustment

genic load (*L*/*V*) and the rate of body mass change. Initial conditions correspond to the age of birth:

$$N^*(0) = N_0^*, \quad N(0) = C^*, \quad M(0) = M_0^*, \quad P^*(0) = P_0^*,$$
$$P_N(0) = P_N^0, \quad P_M(0) = P_M^0, \quad V(0) = V_0, \quad m(0) = m_0. \tag{3}$$

The sequence of model parameters adjustment is shown in Fig. 3 Using this scheme, we constructed initial estimates of model parameters (Table 1).

Table 1 Initial parameters' estimates and initial conditions for simulation of age related changes in population of peripheral T-cells

Parameter	Physical meaning	Dimension	Value
α_1	Rate constant of naive T-cells stimulation	ml/g	1.5×10^{4}
α_2	Rate constant of memory T-cells stimulation	ml/g	1.5×10^{4}
α_3	Rate constant of the intact peripheral lymphoid tissue (IPLT) growth	$ml^2\times day/g$	3×10^{7}
α_4	Rate constant of body mass growth	$g^{1/4}/day$	2.5×10^{-2}
α_5	Parameter which relates antigen load and basal metabolic rate	$g^{1/4}/day$	2.8×10^{-10}
μ_N	Rate constant of natural death rate for naive T-cells	1/day	1.3×10^{-4}
μ_M	Rate constant of competitive death (or homeostatic proliferation) for memory T-cells	1/day	0.07
α_1	Number of memory T-cells produced by one naïve cell	—	100
α_2	Number of memory T-cells produced by one memory cell	—	1.1
λ_N	Length of telomere repeats lost during transformation of naïve T-cells to memory cell	base pairs (bp)	1400
λ_M	Length of telomere repeats lost during self-replication of memory cells	bp	500
C^*	Low limit for normal concentration of memory T-cells in intact lymphoid tissue	cell/ml	2.5×10^{9}
k_T	Rate of diminishing of naïve T-cells production with age	1/day	1.1×10^{-4}
k_V	Relative rate of reduction of the IPLT volume with age	1/day	2.7×10^{-5}
k_p	Relative rate of the telomere repeats reduction in the progenitor of naïve cells	bp/day	1×10^{-5}
k_P	Relative rate of accelerated telomere shortening in the progenitor of naïve T-cells in early childhood	bp/day	0.07
k_m	Rate parameter in the equation for body mass	1/day	1.5×10^{-3}
N^*_0	Rate of naive T-cells release from thymus at birth	cell/day	8×10^{8}
N^0	Concentration of naïve T-cells in the IPLT at birth	cell/ml	2.5×10^{9}
M^0	Concentration of memory T-cells in the IPLT at birth	cell/ml	2.5×10^{7}
P^*_0	Average length of telomeres in naive T-cells leaving thymus at birth	bp	10370
P^0_N	Average length of telomeres in naive T-cells in the IPLT at birth	bp	10370
P^0_M	Average length of telomeres in memory T-cells at birth	bp	8970
V_0	Volume of intact lymphoid tissue at birth	ml	150
m_0	Body mass at birth	g	3500

3.2 Parameters' Estimation

The level of agreement between the model and data was characterized by the value of the least-squares function for the log-transformed data and model solutions.

$$F(\alpha) = \sum_{i,j} \left(\lg \left(\frac{x^i(t_j, \alpha)}{X^i_j} \right) \right)^2$$

Here, α is the vector of model parameters, $x^i(t_j,\alpha)$ is the value of the i th component of model solution at age t_j, and X^i_j is the corresponding data. The solution of the constrained minimization problem of the function $F(\alpha)$ obtained on a subset of model parameters is shown as dotted lines on Fig. 4. It was obtained using differential evolution (DE) algorithm (Storn, Price 1997). The refined parameters are shown in Table 2. One can see from Fig. 4 that the model satisfactorily describes the data on age-related changes in T-cell populations at the entire interval of aging except for the initial age interval.

During the first 6 months of life, the immune defense is provided mainly by maternal antibodies though it was shown recently that the mature T-cell immune response against viral and macroparasitic infections may occur even in the prenatal conditions (King et al. 2002; Marchant et al. 2003; Hazenberg et al. 2004). Along with an increase in the volume of thymus, the total number of peripheral T-cells and the volume of the IPLT grow rapidly. Between ages of 0.5 and 6 years the number of lymphocytes in the body remains relatively stable and then increases, approaching a maximum at the age of 20 years (Valentin 2002). At the initial age interval a rapid decline in the length of telomeres of the newly produced T-cells in the thymus takes place (Rufer et al. 1999). These data were not fit well by the model (Fig. 4). In order to investigate the dynamics of relative antigen load and also of naïve T-cells division, we considered a refined model using explicit log-linear functions for N^*, P^* and V at the corresponding initial age intervals.

Table 2 The results of sequential parameters' estimation for modeling age related changes in population of peripheral T-cells. Permissible boundaries for the model parameters are shown as XVmin and XVmax. The values of the residual function F are shown in the last row

Parameter	XVmin	XVmax	Initial estimate	Refined estimate		
				1	2	3
N^*_0	4×10^8	10^9	8×10^8	8.34×10^8		
k_T	8×10^{-5}	2×10^{-4}	1.1×10^{-4}	1.06×10^{-4}		
α_4	0.01	0.04	0.025		0.023	
k_P	5×10^{-5}	2×10^{-5}	10^{-5}		1.3×10^{-5}	
k_P	0.01	0.1	0.07		0.06	
α_3	10^7	5×10^7	3×10^7		2.8×10^7	
α_1	5×10^3	5×10^4	1.5×10^4			10^5
μ_N	10^{-4}	10^{-2}	1.3×10^{-4}			5×10^{-5}
ρ_1	10	1000	100			2000
ρ_2	1	100	1.1			324
μ_M	0.001	0.1	0.07			8.7
F			0.32	0.28	0.26	0.25

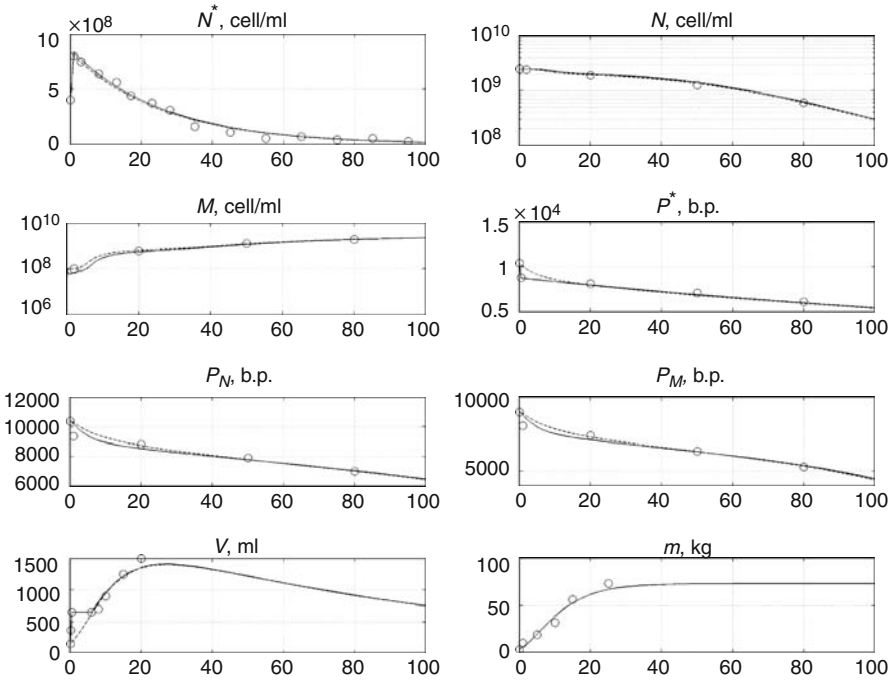

Fig. 4 Solution to the refined model system (solid lines). Dotted lines represent the solution to the initial model. Along the x-axis is age (years). The data are shown as open circles

The solution of the refined model is shown in Fig. 4 as solid lines. Because of the absence of parameters in the equation for P_N, it is interesting to see that the good agreement between P^* and the data turned out to be insufficient for the precise description of the telomeres' length in the naïve T-cells (P_N) early in life. One possible explanation involves the effect of the naive T-cells' *homeostatic proliferation* (Unutmaz et al. 1994). Such proliferation results in increased telomere shortening in the naive T-cells as compared with the rate induced by telomere shortage in the stem and/or precursor T-cells, and, hence, can be accounted for in the equation for P_N. One can see from the Fig. 4 that the rate of homeostatic proliferation of the naive T-cells is comparable with the rate of their production in thymus. Similar results were obtained in Hazenberg et al. (2000, 2004); Ye, Kirschner (2002); Dutilh, DeBoer (2003) when modeling data on the T-cell receptor excision circles (TREC) kinetics.

Figure 5 shows the dynamics of specific antigenic load L/V for the refined and initial models. The refined model is characterized by significantly smaller values of L/V at early ages. This can be interpreted as an initial "reserve" of the immune system owing to fast initial increase in the volume of the IPLT.

An important part of the antigenic load L is represented by the infection load, related to the impact of *multiplying* antigens. At present, it is difficult to obtain quantitative estimates of the relative contribution of the infection load to the total antigenic

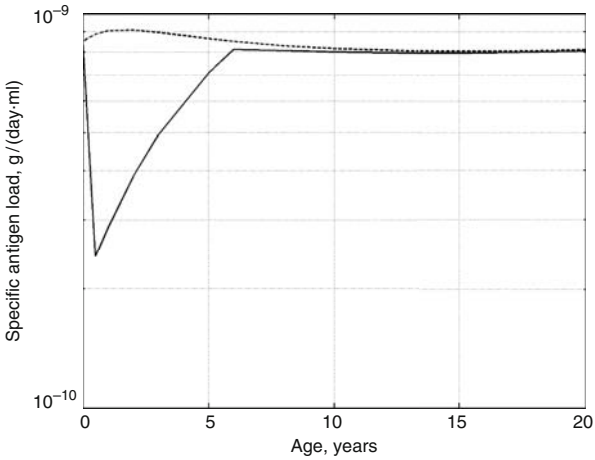

Fig. 5 Specific antigen load *L/V* as a function of age for refined (solid line) and initial models (dotted line)

load. However, the evidence is accumulating that this contribution can be significant. The results of simulation of the impact of the HIV infection on the rate of T-cell population aging suggest 2 to 8-fold increase in the fraction of divided naive T-cells, and, hence, of the total antigenic load (Hazenberg et al. 2000; Sannikova et al. 2004).

The magnitude of infectious pathogens growth in human body in case of acute infections vary from 10^5–10^6 for bacterial pneumonia (Romanyukha, Rudnev 2001) to 10^{10}–10^{11} for viral infections, such as influenza A, or hepatitis B (Marchuk et al. 1991; Bocharov, Romanyukha 1994).

We assume here that the total antigenic load L depends linearly from basal metabolic rate. The high rate of infection diseases in the childhood imply a significant excess of the value of L at this age compared to the value determined by the basal metabolic rate. One can assume that this "initial reserve" of the immune system is, in fact, "consumed" by the infection load. As a result, the specific antigenic load, L/V, can be significantly *higher* than the values suggested by the refined model (continuous line on Fig. 5). The comparison of graphs in Fig. 5 suggests that the initial reserve of the immune system early in life allows for 2–4-fold increase in the total antigenic load above the values permitted by the basal metabolic rate.

4 Immune System Development and Body Growth

The increasing body of evidence from animal and human studies supports the idea on the existence of trade-off between immune defense and organism's growth. For example, the data from gnotobiological studies show that the infection of germ-free chicken impairs body growth by 15–30% (Lochmiller, Deerenberg 2000). Primary immunodeficiencies in humans can also lead to growth impairment and even growth failure (Bjorkander et al. 1984). This holds true for the HIV infection, depending on

the extent of the viral load (Arpadi et al. 2000) which, presumably, reflects a rising energy deficit caused by the gradual increase in the antigenic load.

The suggested model allows for evaluation of possible consequences of such a trade-off. For this, we assumed a linear dependence of the body growth from the antigenic load: $\alpha_4 = a - b\alpha_5$, where α_4 is the rate constant of the body growth, and α_5 is the parameter, which relates antigenic load and basal metabolic rate. The parameter a in this formula characterizes a maximal rate of body growth attained in the absence of antigenic load, and b describes the detrimental effect of antigenic load on the body growth.

For illustrative purposes, based on the results of modeling the effects of HIV infection on the rate of immune system aging (Hazenberg et al. 2004; Sannikova et al. 2004), we assumed that the arrest of the body growth takes place when the value of antigenic load is 10-fold greater than normal. From this assumption, the values of a and b were determined. The results of calculations suggest the presence of stabilizing effect of the body growth on the immune system development: the antigenic load up to 1.5 times higher than normal insignificantly affects the dynamics of model variables except for the rate of body mass change and the stationary level of the body mass in the adulthood (changes from 73 kg to 60 kg). Further increase in the antigenic load results in a more pronounced effect on the immune system development with the remarkable effect on the volume of the IPLT at the adult age. Counter-intuitively, both an increase and decrease in the antigenic load result in the detrimental effect on the "adult" values of the volume of the IPLT with mild unidirectional effect on the dynamics of the naïve and memory cells and in the opposite effect on the telomeres' lengths. A decrease in the antigenic load results in the increased level of the adult body mass with a maximum of 115 kg in the absence of the antigenic load (Fig. 6).

The results presented in Fig. 7 show an increasing effect of antigenic load on body mass with age.

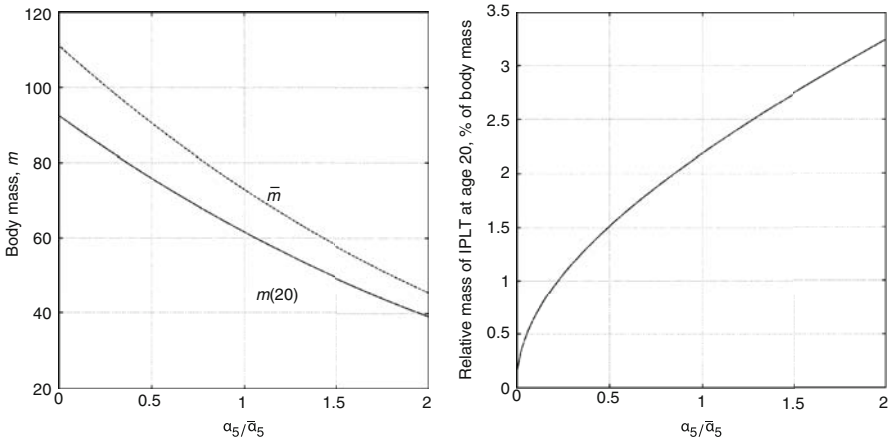

Fig. 6 The influence of antigenic load on body mass at age 20 (left panel), and on the relative mass of the IPLT (right panel)

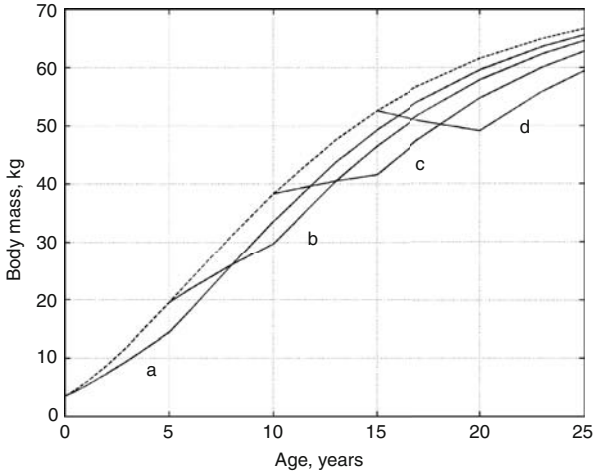

Fig. 7 The influence of 2-fold increase in antigen load at the age intervals (a) [0, 5 years], (b) [5, 10 years], (c) [10, 15 years] and (d) [15, 20 years] respectively, on the dynamics of body mass. The normal age-related changes of body mass are shown as dotted line

5 Model of Age-related Risk of Death from Respiratory Infections

Preliminary analysis revealed that mortality rates from pneumonia and other respiratory infections follow certain regularity pattern in different human populations (Sannikova 2007). The principal traits of the pattern are relatively high mortality level during infancy and early childhood, very low during the reproductive period, exponential (or faster) increase after age 50. Since such an increase takes place despite the presence of the modern health care systems we suppose that the aging of the T-cell immunity is responsible for the steep growth of pneumonia mortality curve at advanced ages.

We develop a mathematical model establishing the relationship between age-related changes in the peripheral T-cells population and mortality caused by respiratory infections (Fig. 8).

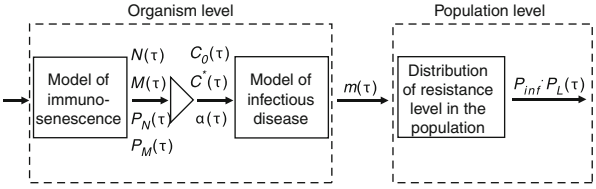

Fig. 8 The relationship between age-related changes in the peripheral T-cells population and increasing risk of death from infectious disease. The proliferative capacity of the T-cells decreases with age, which results in deceleration of lymphocyte proliferation during the immune response. So, the severity of the disease increases with increasing age. The higher the disease severity, the higher the risk of the lethal outcome

The model of age-related risk of death from respiratory infections consists of three component models: a model ofage-related changes in peripheral T-cells population (1), a model of infectious disease (Marchuk 1997) and a relationship between disease severity and risk of death. Numerical solution of the system (1) yields the sets of immune characteristics (such as the concentration of naive and memory T-cells and their replicative capacity) for each age. These characteristics are used in the second model, the model of infectious disease, to determine the value of the lymphocyte concentration at the beginning of disease and the rate of immune response. This model makes it possible to simulate the course of unified infectious disease for each set of immune characteristics or, in other words, for each age. Disease severity is defined as a maximum of target tissue damage in the course of the disease.

The third model is a function of the distribution of the resistance to infections in the population. Infection resistance is defined as a probability of recovery at a certain value of target tissue damage (disease severity). As an output of the model we have risk assessment of lethal outcome in the course of the disease. To estimate the probability of death from certain diseases during a time interval (e.g., during 1 year) we multiply the risk of lethal outcome in the course of the disease by the probability of becoming infected during the age interval under consideration.

5.1 Relationship Between Disease Severity and the Risk of Death

We define the infection resistance *Res* as a probability of recovery from the disease having the severity value *S*. Then, the probability of the lethal outcome is $p_L = 1 - Res$. Further, we assume that this characteristic is normally distributed in the population. Hence, the probability of the lethal outcome p_L at the severity value *S* could be represented as the corresponding distribution function

The values of the parameter were estimated based on the clinical observations. Thus, by means of the model of infectious disease and expression (3), a relationship between age-related changes in the T-cells population and the risk of death could be established.

$$p_L(S) = \Phi(S) = \int_0^S \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{(t-a)^2}{2\sigma^2}} dt \tag{3}$$

5.2 Results of Simulation

The WHO data on pneumonia mortality in Austria, Italy, Portugal, the United Kingdom, the USA, and Japan in 1999 are represented by symbols in Fig. 9. The prob-

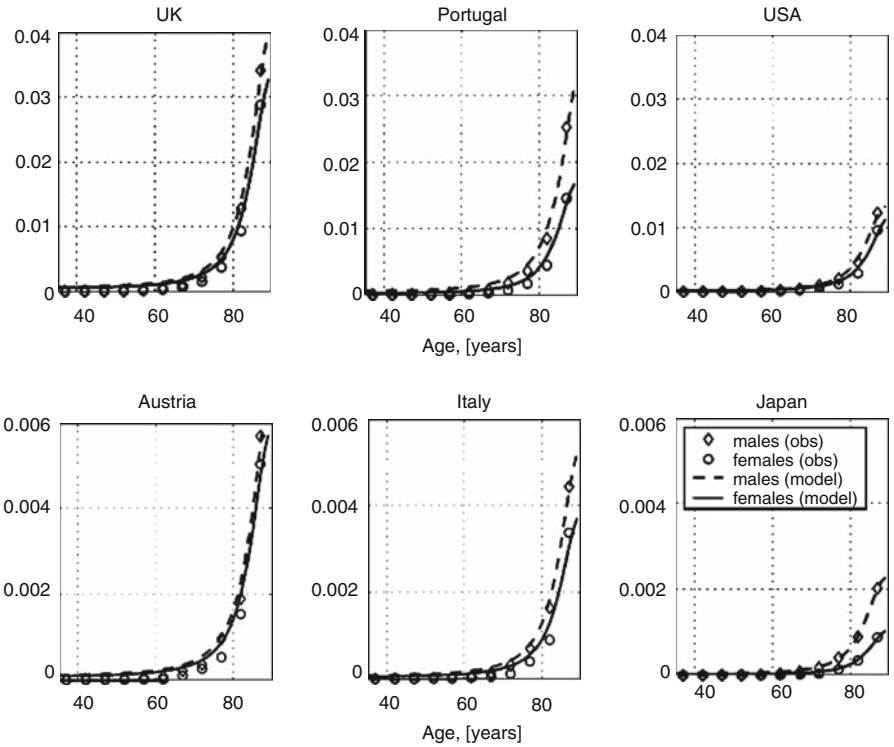

Fig. 9 Pneumonia mortality (probability of death from pneumonia per year) in Austria, Italy, Portugal, United Kingdom, USA, and Japan in 1999. WHO data are represented by symbols, results of simulation by lines

ability of death from pneumonia in the age group 80–84 in the UK is 27 times higher than in Japan and 10 times higher than in Italy.

We assume that these populations experience different antigenic load throughout adult life. This can be related to differences in climatic and ecological conditions, modes of living, and national cuisines. We fit the model of age-related risk of death from respiratory infections to the data. The results of the simulations are represented by the solid and dashed lines in Fig. 9. There is good agreement between the model and the data sets for medium and large values of the death rate. For small values (age group 35–39), the estimated risk of death is higher than observed.

To provide a good fit, two parameters of the model were estimated for every population: the value of the antigenic load and the frequency of pneumonia (Fig. 10). The differences in age-specific mortality between countries are mainly described by variations in the frequency of pneumonia. Males in Japan and in the US have higher estimate of the antigenic load than in other countries under consideration. The higher rate of immunosenescence in the male populations of these countries

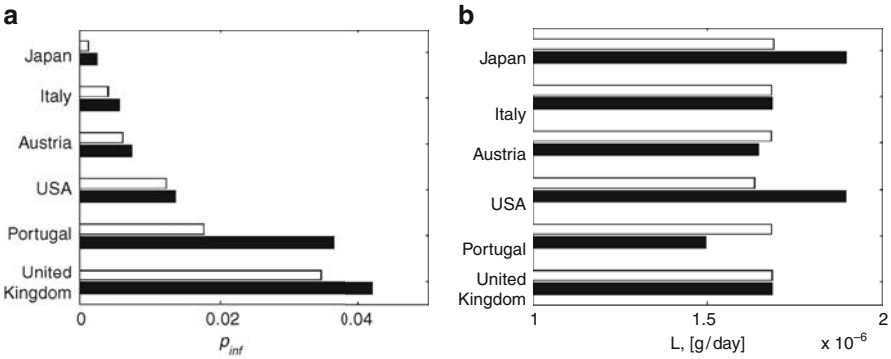

Fig. 10 Parameter estimates of environmental conditions which influenced immunosenescence in the populations under consideration. (a) frequency of pneumonia and (b) antigenic load. Black bars correspond to males; white bars to females

may also be related to the dynamic and stressful mode of living (Epel et al. 2004; Segerstrom, Miller 2004).

6 Conclusion

The proposed model describes the relation between immunosenescence and demographic aging. The initial values of variables in the model (1) correspond to the population average. In the case of availability of the clinical measurements, the proposed model can be transformed into the individualized risk model, which makes it possible to predict consequences of individual interventions. There is growing body of evidence that modification of the immune state by vaccination, antiviral and hormonal therapies, stem cell transplantation, and, possibly, by regulation of telomerase activity (Bodnar 1998), could slow down processes associated with immunosenescence. Mathematical modeling is a convenient tool for testing such intervention strategies.

Age, T-cell Homeostasis, and T-cell Diversity in Humans

David L. Lamar, Cornelia M. Weyand and Jörg J. Goronzy

Contents

1 Introduction

A fundamental feature of mammalian adaptive immunity is the highly diverse pool of antigen receptors found on lymphocytes. The T-cell receptor and the surface immunoglobulin on B cells facilitate the recognition of foreign structures found on tumors and pathogens that have overwhelmed the defenses of the innate immune system. Because pathogen encounters and neoplasic transformations are inherently unpredictable, an immense lymphocyte receptor repertoire is required to meet all of the possible challenges an organism will face. In young humans, the daily production of naïve B cells from the bone marrow and T cells from the thymus steadily

injects the lymphocyte pool with new antigen receptors. Unfortunately, as humans age functional thymic tissue gradually involutes and is replaced by fat. In parallel, the daily production of new naïve T cells declines such that no meaningful thymic T-cell production occurs after the age of fifty. Thus, the T-cell repertoire of an adult human must be maintained for decades in the absence of a replenishing source. Although homeostatic mechanisms are remarkably successful at maintaining the T-cell repertoire for many years, obvious changes begin to emerge with advanced age. Most strikingly, the naïve CD4 T cells that remain after the age of 65 undergo a sudden and dramatic collapse of T-cell receptor diversity. Naïve CD8 T cells may experience an earlier and more gradual diversity loss, although direct evidence for this is not yet available. A steadily expanding memory population maintains total T-cell numbers despite the decline in naïve T cells. Among these memory cells, an increasing percentage acquires a terminally differentiated phenotype characterized by abnormal expression of regulatory receptors and resistance to apoptosis. Oligoclonal populations accumulate after a lifetime of repeated challenges such as chronic infections, leading to a contracted memory repertoire. Although the consequences of repertoire contraction are not yet known, this phenomenon may have important implications for the health of the ever growing elderly population.

This review will first delineate the developmental steps that lead to a diverse naïve T-cell repertoire followed by a discussion of the homeostatic mechanisms required to maintain T cells in the periphery after thymic involution. Some of the techniques employed to monitor thymic decline, peripheral homeostasis, and repertoire integrity will be highlighted throughout. Finally, the impact of aging on maintaining a diverse repertoire with stable representation of functional T-cell subsets will be discussed.

2 T-cell Generation

2.1 T-cell Progenitors

Being highly dynamic and in constant turnover, the T-cell system is dependent on the generation of new T cells. T cells derive from self-renewing, pluripotent hematopoietic stem cells (HSC), the ancestors of all blood cells. Early lineage commitments occur in the bone marrow, but final T-cell differentiation and generation of T-cell diversity is entirely dependent on a functional thymus. HSC first develop into multipotent progenitors capable of becoming both myeloid and lymphoid cells. Additional differentiation leads to the common lymphoid progenitor cells which can become T cells, B cells, and NK cells. Little is known about the exact T-cell progenitor that exits the bone marrow and is destined to enter the thymus [1]. CD34, a marker of HSC in the bone marrow, is expressed on circulating cells with strong in vitro T-cell potential [2]. Intrathymic multipotent precursors also initially express CD34 suggesting that T-cell precursors come from the circulating $CD34^+$ population [3]. Within the thymus, committed T-cell precursors are thought to differentiate

from $CD34^+$ cells that have acquired CD1a expression [4]. Additionally, expression of the Notch1 receptor and signaling apparatus, which are required for T- versus B-cell lineage commitment, are likely characteristics of intrathymic T-cell precursors [5]. Whatever the true characteristics of circulating and intrathymic T-cell progenitors are, T-cell generation is dependent on a continual supply of potential thymocytes entering the thymus for further maturation.

2.2 Generation of T-cell Receptor Diversity

The effectiveness of the human adaptive immune system requires a diverse array of antigen receptors on lymphocytes. In both B and T cells, this diversity arises from the somatic rearrangement of gene segments encoding each subunit of the antigen receptor and the combination of these uniquely encoded subunits to make a complete receptor. For the T cell, this process occurs in the thymus and results in the expression of a single T-cell receptor (TCR) consisting of two rearranged receptor subunits. The vast majority of T-cells express receptor chains encoded by the TCRA and TCRB loci and are called αβ T-cells. The remaining T-cells (2–14% of peripheral T-cells [6]) are called γδ T cells and have TCR encoded by the TCRG and TCRD loci. This discussion will focus only on αβ T cells.

To appreciate what T-cell diversity generation entails, the remainder of this section will detail the intrathymic events that transform genetically homogeneous and undifferentiated thymocytes into mature naïve CD4 and CD8 T cells displaying genetically and structurally diverse TCR. The mature TCR is a heterodimer composed of two Type-I membrane-spanning subunits called the α- and β-chains [7]. Each chain has two Ig-like domains and a short transmembrane region. The membrane-proximal Ig-like domains are called constant domains because they are nearly identical on all αβ T cells. The membrane-distal Ig-like domains differ from T cell to T cell and are called variable domains. They are responsible for antigen recognition and are the basis for the immense diversity necessary to respond to the full array of potential pathogens encountered by naïve T cells.

A schematic representation of TCR genes is depicted in Fig. 1. Early thymocytes do not express any TCR, and both alleles of each TCR gene are fully intact. These $CD34^+CD1a^+$ thymocytes also lack the TCR coreceptors CD4 and CD8 and are thus known as double negative thymocytes. In humans, unlike in mice, before TCR rearrangement begins, thymocytes will express CD4 alone or both CD4 and CD8 in some cases [8]. The first step towards expression of a functional TCR is expression of RAG1 and RAG2 by thymocytes [9]. These proteins are essential for somatic recombination, and once they are expressed, the TCRB locus begins to rearrange. The diversity (D_β) and joining (J_β) gene segments are the first to be combined, followed by joining of a variable (V_β) segment to the D_β-J_β junction. The particular segments included are stochastically chosen and the order of segment joining is dictated by recombination signal sequences flanking the gene segments (reviewed in [10]). During recombination, the enzyme terminal deoxyribonucleotidyl trans-

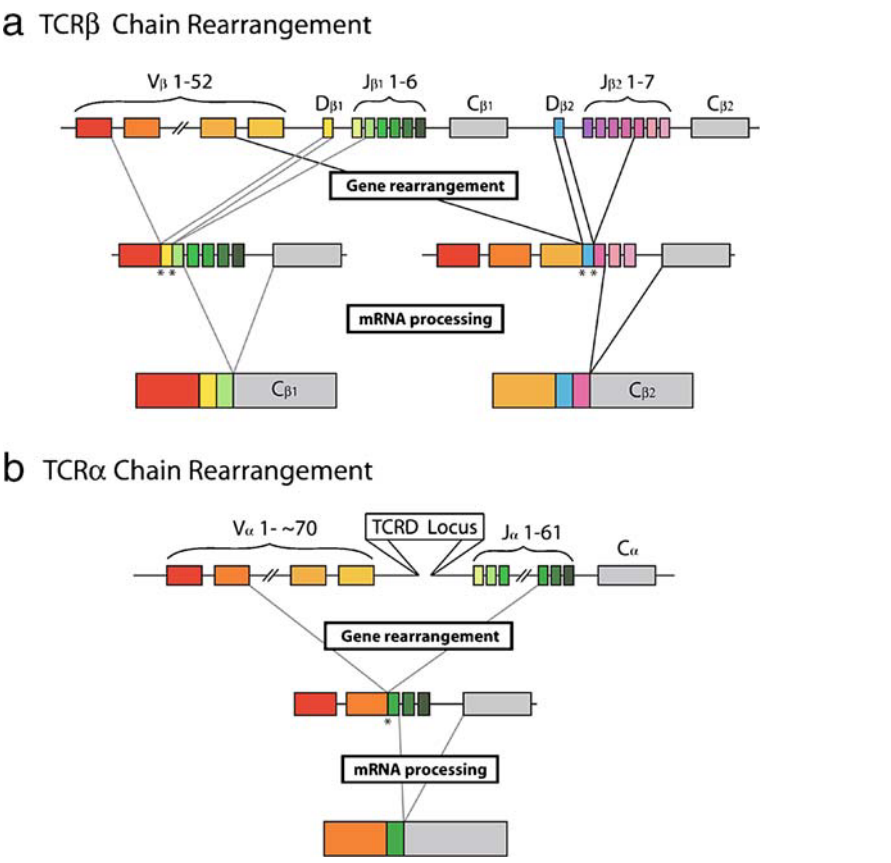

Fig. 1 Rearrangement of TCR Loci in αβ T cells Schematic representations of TCR gene rearrangement and mRNA processing to yield mature TCR chains (gene segments are not to scale). (a) The TCRB locus on chromosome 7 rearranges first. (b) The TCRA locus on chromosome 14 rearranges after successful β-chain rearrangement and expression. ferase (TdT) facilitates the random addition and subtraction of a variable number of nucleotides at segment junctions [11]. This imprecise joining, termed junctional diversity, is an important source of variable domain sequence diversity for both TCR chains. As depicted in Fig. 1, the TCRB locus has two C_{β} gene segments. A failed attempt to rearrange the locus using the $C_{\beta 1}$ gene segment can be followed by an attempt to use the $C_{\beta 2}$ locus on the same chromosome. When the TCRB locus is successfully rearranged, the resulting protein will be expressed at the surface in complex with the pre-Tα-chain, an invariant surrogate required for β-chain expression [12]. Expression of this pre-TCR signals completion of β-chain rearrangement. At this time, RAG1/2 expression ceases, preventing further rearrangement of the second TCRB allele and ensuring that all T cells express a single β-chain [4].

An additional consequence of successful TCRB rearrangement and pre-TCR expression is a massive proliferation of β-chain$^+$ thymocytes before TCRA rearrangement. By expanding at this stage, each unique successful β-chain rearrangement can be combined with many different α-chains, thereby dramatically enhancing the total TCR repertoire. It is estimated that roughly 10 divisions occur between β-chain expression and TCRA rearrangement, resulting in ~1000 thymocytes with the same β-chain [13]. This number is much higher than the number of distinct α-chains paired with a single β-chain in mature peripheral T cells because only 10% percent of β-chain$^+$ thymocytes will successfully rearrange the TCRA locus and survive positive and negative selection. After expansion, β-chain$^+$ thymocytes reexpress the RAG proteins and TCRA gene rearrangement begins [9]. TCRB and TCRA gene rearrangements proceed by the same mechanism with a few distinctions. Whereas the β-chain variable domains are comprised of V, D, and J segments, the TCRA locus only has V and J segments. Unlike β-chain rearrangement, a cell without a successful α-chain rearrangement can continue rearranging by joining upstream V_α segments to downstream J_α segments until a competent chain is formed [14]. Additionally, surface expression of a rearranged α-chain, in complex with the β-chain, does not silence RAG1/2 expression. Instead, RAG1/2 expression ceases after positive selection (discussed below), which signals completion of TCR gene rearrangement [15]. A consequence of prolonged RAG1/2 expression during TCRA rearrangement is the possible coexpression of more than one α-chain on each T-cell [14]. It is likely, however, that only TCR containing the positively selected α-chain allele will interact with MHC-peptide complexes in the periphery during an immune response.

2.3 Positive Selection and Negative Selection

Thymocytes with successfully rearranged TCR will only emerge from the thymus as CD4 or CD8 naïve T cells if they survive positive and negative selection. These selection processes require interactions between the TCR on thymocytes and the MHC class I and II molecules on bone marrow-derived cells and specialized epithelial cells within the thymus. Because a functional T-cell response requires recognition of pathogenic peptides presented in complex with MHC molecules, only TCR capable of making stable contacts with MHC are useful additions to the T-cell repertoire. Thymocytes must receive signals through the TCR to avoid death by neglect (positive selection), which is the fate of about 90% of all TCR$^+$ thymocytes [16]. The requirement for positive selection ensures the elimination of TCR least likely to contribute to an immune response. Additionally, an excessively high affinity interaction will lead to the death of the T cell and removal of that cell's TCR from the repertoire (negative selection). Because only self-peptides are presented on MHC molecules in the thymus, negative selection removes T cells with potentially autoreactive TCR. About half of the remaining 10% of TCR$^+$ thymocytes are removed by negative selection [16]. Survivors of both positive and negative selection exit

the thymus as mature T cells expressing a TCR that may recognize an epitope from potential pathogens.

In addition to ensuring that a T cell expresses a fully functional yet self-tolerant TCR, intrathymic TCR:MHC interactions dictate a key determinant of each thymocyte's future function: the choice of CD4 versus CD8 coreceptor expression [16]. A mature T cell whose TCR interacts with MHC class I molecules during positive selection will express CD8. Alternatively, if positive selection occurs against MHC class II molecules, the resulting mature T cell will express CD4.

2.4 How Diverse is the Human T-cell Repertoire?

As stated above, all receptor diversity in the T-cell pool is generated by somatic gene rearrangement during thymocyte maturation. By examining the key sources of this diversity, a theoretical upper limit of distinct αβ TCR has been estimated [7]. Three main factors contribute to the diversity of the TCR repertoire: the inclusion of a single V, D, and J gene segment (V and J only for the α-chain) in the variable domain of each TCR chain, the random addition and subtraction of nucleotides at the junction of combined gene segments (junctional diversity), and the pairing of one rearranged α-chain with one rearranged β-chain to yield a complete TCR. There are ~70 V_α and 61 J_α gene segments which when combined would yield 4,270 different α-chains if all combinations are productive. The 52 V_β, 2 D_β, and 13 J_β gene segments could potentially combine to form 1,352 different β-chains. Without accounting for junctional diversity, 5.8 million different TCR could be generated by combining one α-chain with one β-chain. Estimates suggest that junctional diversity may increase TCR diversity by a factor of 2×10^{11} to a total of 10^{18} potential unique TCR. This estimate is an overstatement of the true repertoire potential because many V_α-J_α and V_β-D_β-J_β combinations result in nonsense frame shifts and not all α-β-chain combinations can be expressed. Even with a more modest estimate, it is clear that the receptor repertoire of any individual, whose total T-cell compartment contains only ~3×10^{11} cells, represents only a minute fraction of the potential diversity.

A variety of techniques used to measure diversity (discussed below) estimate that the T-cell repertoire consists of about 10^8 different TCR in young humans. If TCR were all equally represented, the clonal size of T cells bearing the same receptor would be about 1,000. In reality, certain clones are more abundant than others, and the receptor repertoire differs among the different functional T-cell subsets. Naïve cells, which represent about 50% of total CD4 and CD8 T cells [17–19] in young humans, harbor the majority of total TCR diversity. An assessment of TCR repertoire within CD4 T cells in young donors revealed that memory cells have only 5–10% of the β-chain diversity of naïve cells [19]. As, each β-chain in the memory population is generally paired with a single α-chain, this translates to only 1% of the total naïve αβ TCR diversity.

Because an organism cannot predict which pathogens will be encountered by the immune system, it is beneficial that naïve lymphocyte antigen receptors are highly

diverse. Naturally, the receptor repertoire in the memory compartment can only be, and is only required to be, as diverse as the epitopes against which a primary response has already been raised. However, in addition to receptor diversity, memory T cells comprise several different functional populations. The paradigm of the memory T-cell life-cycle dictates that the cells remaining after the contraction phase of a primary immune response will be either central memory or effector memory cells [20]. Central memory cells, defined as $CD45RA^-$ and $CCR7^+$, reside in lymphoid tissues such as the spleen and lymph nodes. Effector memory cells, defined as $CD45RA^-$ and $CCR7^-$, are found in peripheral sites where antigen exposure is most likely, such as the skin, lungs, and GI tract.

In addition to distinct homing patterns, central and effector memory T cells respond differently upon antigen reexposure [21]. While both memory subsets are much more sensitive to TCR stimulation than naïve T cells, effector memory cells have an even lower activation threshold. Consistent with their localization at the frontlines of antigen exposure, effector memory cells are quickly and potently triggered to produce effector cytokines such as IFN-γ, a key molecule in a strong immune response. Conversely, central memory cells likely reencounter antigen only after it has been delivered to lymphoid tissue and presented on antigen-presenting cells. After stimulation, these cells produce high amounts of IL-2 which promote expansion of activated T cells. Several studies in mice suggest that central memory cells differentiate into effector memory cells, thereby enhancing the current immune response and seeding the periphery for future exposures [22, 23]. A third memory subset, the terminally differentiated effector cell (known as CD45RA effector cells), is defined by reversion of effector memory cells to CD45RA positivity while still lacking CCR7 [24]. These cells are much more common in the CD8 compartment and are characterized by potent cytotoxicity, resistance to apoptosis, and weak proliferative potential. As we will discuss later, CD45RA effector cells accumulate with age and may result in altered functionality of memory responses in the elderly.

2.5 Techniques for Assessing Diversity

Before discussing the mechanism of diversity maintenance and the TCR repertoire changes that occur with age, we will discuss the techniques used to estimate human TCR diversity. The staggering array of unique TCR gene rearrangements in peripheral T cells makes direct measurement of diversity a challenge. Only gross changes in repertoire, such as large clonal expansions or the loss of entire V_β families, can be detected using the following low sensitivity methods. Flow cytometry allows detection of differences in V_β family usage among various T-cell compartments or age ranges [25]. However, even a severe loss of repertoire diversity that affected the different V_β families similarly would be missed by this method. TCR clonotyping, which utilizes V_β-C_β or V_α-C_α specific PCR and denaturing gradient gel electrophoresis, relies on the existence of clonal expansions large enough to dominate the PCR products of entire V_β families [26]. Similarly, the "immunoscope" method (see

below) uses PCR to detect large expansions within V_β families [27]. While this technique is only slightly more sensitive than clonotyping, immunoscoping is a useful tool to estimate total T-cell diversity when combined with sequencing [28].

More direct assessments of TCR repertoire all use a common approach: isolate and characterize a small subset of sequences and extrapolate their frequencies, based on parameters such as V_β frequency and possible αβ combinations, to the whole T-cell pool. Wagner et al. examined repertoire diversity using TCR-specific probes and limiting dilution of CD4 T cells [29]. Using primers specific for two V_β-J_β combinations (V_β8-J_β1S4 and V_β18-J_β2S5), representative samples of β-chain gene sequences from CD4 T cells of several donors were obtained. Specific biotinylated probes complementary to the TCR N-D-N region (this region is highly variable and includes the junctional nucleotides that flank the D gene segment) were then generated. In a subsequent step, a second sample of CD4 T cells from the same donor was screened for the presence of these sequences in a limiting dilution system. cDNA was isolated from replicates of serially diluted T cells ranging from 10^5 to 5×10^6 cells, amplified by PCR with the appropriate V_β-J_β primer set and hybridized with the labeled probes specific for the isolated TCR sequences. This method determines the frequency of each specific β-chain sequence in the entire T-cell pool and allows for an estimate of the total diversity. Studies using this method [19, 29] have estimated that a given β-chain obtained from naïve CD4 T cells is present with a median frequency of <1 in 2×10^7 T cells in healthy young and middle-aged adult humans, i.e., the human naïve CD4 T-cell compartment encompasses around 20 million different TCR β-chains. Because the sensitivity of the limiting dilution system is less than 100%, this estimate represents the upper range.

The "immunoscope" technique, mentioned above as a method to detect T-cell clonal expansions [27], has been exploited to estimate human αβ TCR diversity. As with the limiting dilution assay of Wagner, et al. [29], this technique requires PCR amplification across the β-chain N-D-N region followed by sequencing. Previously, it was observed that the lengths of rearranged TCRB transcripts between constant sequences flanking the N-D-N region follow a Gaussian distribution. The span of sizes results from the stochastic addition and subtraction of nucleotides during the joining of gene segments [11]. Electrophoretic separation of PCR products amplified from a heterogeneous T-cell cDNA pool reveals a laddering of discrete bands separated by a gel distance corresponding to 3 nucleotides/1 codon. A graphical depiction of intensities of these bands reveals 6–8 peaks, with the most intense central peak corresponding to an N-D-N region length of 8–10 amino acids. A non-Gaussian spectrum results when one or a few TCR clones are overrepresented.

It has been shown that, when normally distributed, the intensity of each peak is proportional to the diversity of specific TCR sequences present in the peak. To estimate total human β-chain diversity, Arstila, et al. isolated a single band from the separation of V_β18-J_β1.4 PCR products and identified all TCR variants by sequencing [28]. The total number of V_β18–J_β1.4 sequences was extrapolated based on the intensity of the sequenced band and total β-chain diversity was extrapolated from the frequency of V_β18 and J_β1.4 positive T cells in the individuals used for the study. After repeating this procedure for several donors and other V_β-J_β segments, the authors arrived at a minimal estimate of 1.3×10^6 different TCR β-chains.

2.6 Thymic Decline with Age

The anatomy of the thymus is expressly suited to allow for the maturation of new T cells with a staggering array of unique TCR. The thymus is the sole organ where naïve T cells are produced and diversity can be generated or refreshed. Consequently, thymic integrity plays a key role in T-cell repertoire maintenance over the many decades of a human life. In the following section, we will discuss how aging affects the thymus and its ability to provide a steady supply of new naïve T cells and, therefore, new TCR clonotypes.

The thymic architecture consists of the thymic epithelial space and the perivascular space (reviewed in [30]). Thymopoiesis occurs entirely within the thymic epithelial space which includes the cortical and medullary epithelial cells and bone marrow-derived antigen-presenting cells required for positive and negative selection. The perivascular space is located within the thymic capsule and is separated from the thymic epithelial space by a basement membrane. The cellular component of the perivascular space consists of fibroblasts, lymphoid cells, and a few adipocytes and is notable for the absence of thymocytes. The classical description of thymic anatomy, consisting mostly of thymic epithelial space with only a small contribution from perivascular space, applies only to very young human thymi. As early as age 2, the thymic epithelial space begins to decline with a compensatory enlargement of the perivascular space by adipocytosis. Although total thymic mass remains constant, the loss of thymic epithelial space results in a steady decrease of new T-cell production after adolescence.

Numerous studies have observed decreased thymopoiesis with age. The most common techniques for evaluating thymic output involve quantifying the number of recent thymic emigrants in the peripheral blood. In the absence of a reliable surface marker for recent thymic emigrants, many groups have resorted to the detection of TCR excision circles (TREC) which are DNA remnants of TCR gene rearrangements. During thymocyte maturation, chromosomal DNA within the TCR loci is broken and religated to join V or D gene segments with J gene segments and V segments with D-J gene segments. In each case, the DNA sequence between the joined gene segments is excised from the chromosome and the cleaved ends of the deleted sequence are ligated together resulting in a TREC. The correlation of TREC with thymic output follows from the fact that, with each cell division, chromosomal DNA is replicated while TREC DNA is not [31]. After excision of a TREC during TCR gene rearrangement, subsequent mitotic events will dilute the TREC/cell ratio because only a single descendent of the original thymocyte, regardless of the number of future divisions, will retain the TREC. The stability of TREC in the absence of division has been debated, and the persisting TREC with aging may therefore derive from nondividing cells rather than from recent thymic emigrants.

Each TREC represents a single gene rearrangement event, and each step in the TCR rearrangement process can lead to the formation of a different TREC. TREC resulting from the V, D, and J segment-joining events are unique to the particular segments joined and are, therefore, rare in the total population and not useful for a global assessment of recent thymic emigrants. A fortuitous requirement for the

successful rearrangement of the TCRA locus is the deletion of the TCRD locus which is found between the TCRA V and J segments (see Fig. 1b). TCRD deletion requires the joining of two genetic elements flanking the delta locus, δRec and ψJα [32]. The resulting TREC (sjTREC) contains a δRec-ψJα signal joint that is identical for all TCRD deletion events. When the TCRA gene is subsequently rearranged, the δRec-ψJα coding joint will be included in the resulting TREC (cjTREC) regardless of which TCRA segments are joined (diagrammed in [33]). Although either of these TREC can be used for estimating αβ T-cell production, the sjTREC is the more common choice because the δRec-ψJα coding joint can still remain on the incompletely rearranged chromosome in 5% of αβ T cells [33]. An additional advantage of TCRD TREC, which are produced late in TCR rearrangement, is that only 3–4 divisions occur between TCRD deletion and full TCR rearrangement [34]. Thus, δRec-ψJα TREC are minimally diluted in newly matured αβ T cells.

Regardless of which TREC is used to assess recent thymic emigrants, thymic function comparisons can be made among donors of various ages. Multiple studies suggest that thymic production steadily declines with age [34–36]. This decline occurs at the rate of about 3% per year, which is the same rate estimated for the loss of thymic epithelial space with age [37, 38]. TCR rearrangement in thymocytes occurs normally regardless of age, generating a diverse Vβ repertoire [39]. Additionally, newly generated T cells in individuals up to at least age 50 perform as well as young T cells in in vitro assays. Therefore, it is thought that while total thymic epithelial space and consequently new naïve T-cell production declines with age, T-cell production in the remaining tissue is qualitatively intact [30]. Quantitatively, however, the thymus is unable to provide a meaningful supply of new naïve T cells after middle age as evidenced by the small numbers of peripheral TREC. Additionally, the ability to reconstitute the T-cell compartment following ablative bone marrow transplantation decreases steadily with age. In fact, patients in their fifties fail to return to pretreatment cell numbers even 2 years after transplant [40].

TREC levels in T cells are used as an indirect surrogate of thymic T-cell output and many papers treat $TREC^+$ naïve T cells as recent thymic emigrants. However, it has been noted that the interpretation of TREC measurements is more complicated [33]. Indeed, decreased thymic output results in dilution of the TREC/cell ratio over time; so does homeostatic proliferation or death of existing $TREC^+$ T cells. For this reason, TREC measurements tend to overestimate thymic output and interpretations should take into account the kinetics of T-cell turnover. Recently, one group has proposed a new marker for recent thymic emigrants that may help resolve the potential ambiguity of TREC dilution. Kimmig et al. reported that CD31 positivity on $CD45RA^+RO^-$ naïve T cells correlated strongly with the presence of sjTREC [41]. Conversely, $CD45RA^+RO^-CD31^-$ T cells, although functionally and phenotypically naïve, have almost no TREC. The authors suggest that recent thymic emigrants lose CD31 expression upon antigen-induced or homeostatic proliferation, an idea that is supported by the loss of CD31 by in vitro culture. An examination of the percentage of CD4 T cells with a $CD45RA^+CD45RO^-CD31^+$ phenotype with age revealed a steady decline similar to that seen when TREC are examined. It remains to be seen whether CD31 will become a widely used marker for recent thymic emigrants, but

the results of Kimmig and colleagues lend credence to the TREC-based findings that thymic production of new naïve T cells declines with age.

3 Maintenance of Diversity

In the absence of foreign antigen, all peripheral T-cell pools experience a steady-state turnover characterized by cell loss (to attrition, death, or phenotypic shift) and compensatory proliferation. In order to maintain the original diversity of recent thymic emigrants, death and replacement of naïve T cells must be completely random so as not to preferentially deplete or replace T cells of certain specificities. An additional requirement for maintaining diversity is that each clonal population expressing a given TCR is of an adequate size to ensure that normal cell death will not eliminate a TCR from the repertoire. The latter requirement is met by proliferation of thymocytes bearing a functionally rearranged TCR before and shortly after mature naïve T cells exit the thymus. Fully random steady-state turnover of peripheral T cells is much more difficult to achieve. In the context of thymic export of new naïve T cells, this problem is not likely to result in a compromised repertoire. However, the severe and early decline of thymic production of T cells seen in humans suggests that peripheral homeostatic mechanisms are crucial for life-long TCR diversity.

Maintenance of the TCR repertoire is a balance between factors that introduce or preserve diversity and those that pose a threat (see Fig. 5). Naïve and memory T cells share some of these factors. For both cell types, the thymus is the ultimate source of new diversity; however, the proximal source of diversity in the memory compartment is activation and differentiation of naïve cells in response to antigen. Therefore, establishment of the memory repertoire depends both on the initial naïve repertoire and the history of antigen exposure. T-cell activation against a novel antigen, while seeding the memory compartment after contraction of the primary response, represents an important threat to naïve T-cell diversity. Normal daily turnover leads to loss of T cells, and potentially TCR, from all compartments. Assuming an adequate initial clonal size, homeostatic proliferation of remaining T cells will replace lost cells and maintain normal compartment sizes. While total T-cell numbers can easily be maintained by replacement proliferation, it is unlikely that all TCR clones are lost and replaced with equal kinetics. Consequently, over many years of homeostatic maintenance, the TCR representation, for both memory and naïve cells, is at risk of skewing and contraction.

3.1 Assessment of T-cell Turnover

A crucial component to T-cell homeostasis, and therefore maintenance of T-cell heterogeneity, is cell turnover. The persistence of a T-cell clone with a given TCR

depends on proliferation of existing cells in the face decreased thymic output and daily cell loss. It is important to understand the power and the limitations of the techniques used to examine T-cell kinetics and turnover in humans before reviewing the available data.

3.1.1 Ki67 Staining

One easy method for assessing the fraction of proliferating cells within a lymphocyte population is by intracellular staining for Ki67. Ki67 is a nuclear antigen expressed in the G_1, S, G_2, and M phases of proliferating cells. Its absence in resting G_0 cells makes it a good marker of cycling cells [42]. Using standard flow cytometric identification of intracellular antigens [43], a panel of antibodies can be designed to assess the proportion of proliferating cells within T-cell subsets at a given time. This method has been used to estimate the T-cell turnover rates in several contexts, including HIV and aging [19, 44, 45]. The accuracy of Ki67 staining has been confirmed by more advanced metabolic labeling techniques (see below) that simultaneously assess proliferation and loss from a population. While these newer techniques provide a more complete picture of T-cell kinetics, Ki67 staining remains a useful method for immediate ex vivo assessment of proliferation within peripheral blood subsets.

3.1.2 Deuterated Glucose or Water Incorporation

To obtain direct in vivo measures of human T-cell kinetics, several studies have utilized deuterated glucose or water [46–49]. Each of these methods allows for the labeling and monitoring of dividing cells because glucose and water contribute molecules to the biosynthesis of DNA. Consequently, in the presence of these deuterated substances, a certain percentage of molecules in newly synthesized DNA will be labeled with deuterium, ^2H [47, 48]. After a defined administration period, the ^2H source is discontinued and blood samples are taken at several time points to determine the ^2H content in the DNA of cell types of interest. Measurements made before and soon after delivery of labeled glucose or water are used to determine the percentage of cells that proliferate during the administration period. Further measurements made at multiple later time points allow for calculation of the loss rates and half-lives of the isolated cell subsets.

Because deuterated glucose and water are neither radioactive nor a mutagenic threat, they are useful tools for in vivo studies of human T-cell kinetics. The use of ^2H_2O is the more recent of the two labeling methods and, as described by Neese, et al. [48], has financial, feasibility, and experimental advantages over deuterated glucose. For example, deuterated water can simply be added to normal drinking water whereas glucose must be administered intravenously. Without the need for expensive supervised infusion, deuterated water can be delivered over a longer period of time which is beneficial for examining low turnover cell types such as naïve T cells.

3.2 T-cell Homeostatic Mechanisms

In light of the well-documented steady decline in thymic production of new naïve T cells with age, the kinetics and mechanisms of T-cell survival and turnover are vital for maintenance of a diverse and functional adaptive immune system. Using techniques described above, direct estimates of replacement rates and half-lives of human T-cell subsets have been made in vivo. Examination of T-cell kinetics in young adult humans by deuterated glucose [46] revealed that about 0.59 and 0.45% of naïve ($CD45RA^+$) CD4 and CD8 T cells, respectively, proliferate each day. These figures translate to a replacement time of 118 and 145 days, respectively. $CD45RO^+$ memory T cells divide much more frequently than naïve cells. 2.65% of CD4 and 5.09% of CD8 memory T cells proliferate each day, which corresponds to replacement times of 26 and 14 days, respectively. Additional studies by the same group [49, 50] and Ki67 staining of CD4 T-cell subsets by our group [19, 29] confirmed these estimates. Extrapolations from these data suggest that a total of 4×10^9 T cells are produced by peripheral expansion each day [46]. As total T-cell numbers remain stable over time, a comparable loss of T cells also must occur each day. Without a constant supply of new naïve T cells from the thymus, and keeping in mind the requirement of fully random replacement of T cells to maintain a complete TCR repertoire, this extensive daily turnover poses a potential threat to TCR diversity in adults.

3.2.1 Naïve T-cell Homeostasis

In a young, healthy human, the normal daily turnover of naïve T cells is replaced with new T-cell production by the thymus and by proliferation of existing naïve T cells. Our examination of neonatal T-cell kinetics showed that about 10% of daily naïve T-cell production in infants comes from the thymus [45]. Other estimates based on modeling suggest that, at the age of twenty-five, about 20% of the peripheral naïve T-cell pool is populated directly from the thymus [51]. Therefore, even in individuals with an intact thymus, peripheral expansion is the major source of circulating naïve cells. As long as the thymus continues injecting new TCR into the naïve pool, extensive homeostatic proliferation does not threaten receptor diversity. However, as thymic involution proceeds, the burden of maintaining the naïve pool increasingly lies with homeostatic mechanisms. In fact, by age 55, the thymus contributes, at maximum, 5% of the peripheral naïve T cells [51] and probably much less.

Mounting evidence suggests that survival and proliferative maintenance of human T cells in the periphery depend on both TCR- and cytokine-delivered signals. In the absence of exogenous antigen, TCR:MHC interactions in the periphery are analogous to those that mediate positive selection in the thymus; namely, a self-peptide conjugated with the appropriate MHC allele acts as a ligand to provide a survival signal to T cells with a TCR that binds with sufficient affinity. Studies in mice do indeed suggest that peripheral naïve T cells are lost in mice lacking MHC molecules. CD4

T cells are vastly reduced in animals lacking MHC class II [52, 53] and similarly, adoptively transferred CD8 T cells will only persist in mice that express MHC class I [54, 55]. For CD8 T cells, it has been shown that the peripheral MHC requirement extends to the exact class I allele against which the T cell was positively selected in the thymus [54]. Additional studies show that peripheral T cells rely on TCR-generated signals not only for survival but for homeostatic expansion [56, 57].

The role and requirement for a TCR-generated signal to maintain T-cell homeostasis has implications regarding the long-term integrity of the TCR repertoire in the context of dwindling thymic output. If homeostatic responses depend on the strength of the TCR:MHC interaction, it is necessarily the case that some TCR will more readily receive survival or expansion signals. An obvious consequence of this scenario is nonrandom TCR maintenance and/or proliferation and, therefore, repertoire skewing. Because a given TCR's affinity for a self-peptide:MHC complex is unlikely to predict a strong response to a pathogen peptide:MHC complex, the skewed repertoire generated by self-antigen-driven homeostatic proliferation would not only deplete T-cell clonal diversity but would do so without promoting enhanced protection.

Fortunately, antigen-independent stimuli delivered by cytokines also play an important role in peripheral T-cell maintenance. Extensive work in the mouse, and more recently in the human, has established that cytokines signaling via the common γ-chain (which include IL-2, IL-4, IL-7, IL-15, and IL-21) play a key role in peripheral T-cell maintenance and expansion [58]. While the cytokine requirements for homeostasis differ among the various T-cell subsets and with regard to the particular function examined, IL-7 and IL-15 seem to be the most important. In mice, naïve T cells, in addition to TCR:MHC interactions, require IL-7 for steady-state survival in vivo. Although other molecules are likely involved, studies in mice [59] and humans point to upregulation of the antiapoptotic protein Bcl-2 as a mechanism for cytokine-mediated T-cell survival [60].

Homeostatic expansion of peripheral T cells is controlled by the same general mechanisms that mediate survival. Steady-state naïve T-cell turnover, as discussed above, is quite low compared to memory T cells. This implies that memory cells have a stronger proliferative response to the required signals. While this may be true, naïve T cells are capable of a robust expansion in lymphopenic situations [61]. From these studies it can be argued that, while naïve T-cell survival and proliferation require the same TCR- and cytokine-mediated signals, space in the compartment is also necessary for homeostatic expansion. In the steady state, the characteristic naïve and memory T-cell replacement rates [46] may be a direct response to fill compartmental space made available by attrition or cell death.

4 Aging and the Loss of T-cell Heterogeneity

Given that thymic production is the only source of new naïve T cells, and that very little meaningful thymic output remains after early adulthood, one may expect dramatic changes in the peripheral T-cell pool with age. In fact, some obvious changes occur while other features remain intact. Total T-cell numbers decrease only slightly

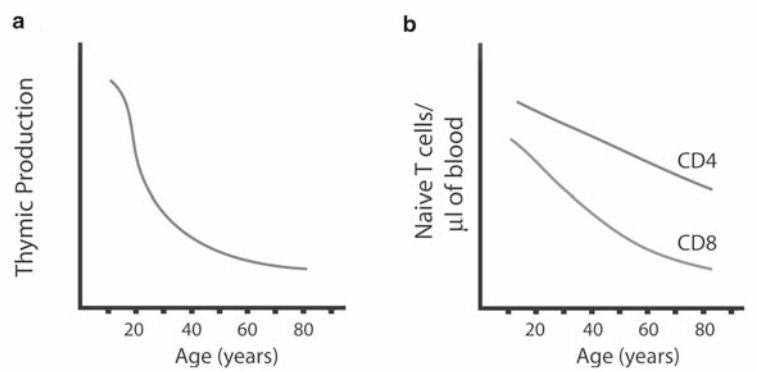

Fig. 2 Naive T-cell Production and Maintenance with Age (a) Schematic representation of loss of thymic production of naive T cells with age. (b) Schematic representation of loss of peripheral naive T cells with age

with age, exhibiting a steady but shallow decline throughout adulthood [17]. Although the maintenance of T-cell numbers is remarkable considering negligible thymic output, the composition of peripheral T cells in the elderly becomes increasingly distinct from young individuals. A consistent and striking finding is the significant loss of naïve cells with age (depicted in Fig. 2). About 50% of young adult T cells are naïve compared to about 35% in 70-year-olds [17]. Remarkably, this naïve loss is much more pronounced for CD8 T cells than for CD4 T cells. In fact, by the age of 70, the percentage of naïve CD8 T cells is consistently around 10%. In contrast, naïve CD4 T cells still make up about 40% of total CD4 T cells [17, 19, 62]. At ages beyond 70, naïve CD4 T cells continue to decline at a steady rate

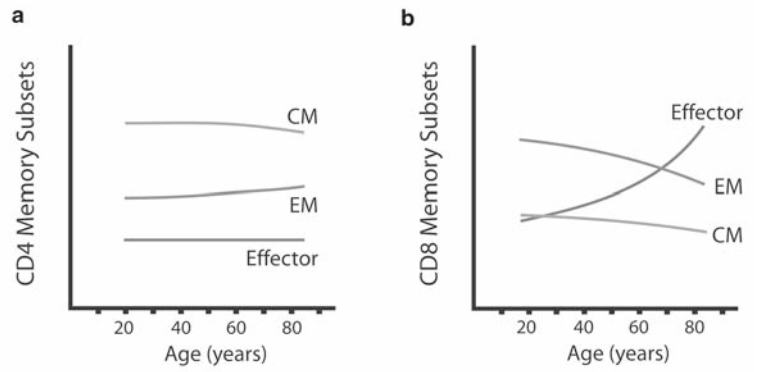

Fig. 3 Changes in Memory T-cell Subsets with Age (a) Schematic representation of changes within CD4 memory T-cell subsets with age. (b) Schematic representation of changes within CD8 memory T-cell subsets with age. CM, central memory; EM, effector memory; Effector, $CD45RA^{+}$ effector memory

whereas naïve CD8 T cells drop to single digit percentages and are virtually gone in individuals who reach 100 [17].

Naturally, with declining naïve T-cell numbers in the context of only slightly reduced total T-cell numbers, the percentage of memory T cells increases with age. In addition, it is clear that memory populations are also qualitatively different in the elderly (depicted in Fig. 3). As appears to be the case for most features of T-cell aging, the CD8 memory T-cell pool experiences a more striking transformation than does the CD4 memory T-cell pool. In young adults, about half of the CD8 memory T-cells have an effector memory phenotype [18, 63]. The remaining half is split equally between central memory and CD45RA effector cells. Throughout adulthood, these proportions shift in favor of CD45RA effector cells which, by the mid-seventies, represent over 50% of all memory CD8 T cells [63]. Because the memory pool as a whole is increased, this translates into more than a 4-fold increase in the absolute numbers of circulating $CD8^+$ CD45RA effector cells. Even central and effector CD8 memory T-cell subsets in the elderly, while comprising a decreased percentage of total CD8 memory T cells, are increased in absolute numbers relative to young adults. Within the CD4 memory T-cell population, aging does not have a significant effect on subset distribution [63]. However, as total memory cells are increased, the absolute numbers of each subset within the CD4 memory T-cell population does increase with age.

A well-established feature of memory T-cell aging is the loss of the costimulatory molecule CD28 [64]. Additional molecules have been identified whose patterns of expression changes with age. Interestingly, many of these molecules, like CD28, are immunoregulatory receptors that might alter the ability of T cells to respond to antigen. Similar to the effects of age on memory T-cell subset distribution, CD8 T cells more readily exhibit these changes than do CD4 T cells. For example, up to 70% of CD8 T cells have lost CD28 by age 80, compared to a maximum of 25% of CD4 cells [63]. Similarly, CD85j, an inhibitory receptor for most classical and nonclassical MHC class I molecules [65], is dramatically increased on memory CD8 T cells in the elderly [63]. This acquisition, which in CD8 T cells is as robust as the loss of CD28, occurs on only a very small subset of CD4 T cells. The distinct behaviors of aging CD4 and CD8 T cells, which are also seen in nonhuman primates [66], extends to more artificial human settings as well; long-term in vitro culture of T cells, which mimics aging in many molecular respects, induces characteristic changes much more readily in CD8 T cells [63].

4.1 TCR Repertoire Loss with Age

In light of thymic decline and the steady decrease in naïve T cells with age, it is important to know whether the naïve TCR repertoire undergoes a similar contraction. Our lab developed a technique (described above) to estimate TCR β-chain frequency in an individual. Two studies of naïve CD4 T cells [19, 29] using this method revealed that, in young individuals, the median frequency of T cells bearing

a given β-chain is <1 in 20 million. This predicts a total β-chain repertoire of 20 million in naïve CD4 T cells. This value is an upper estimate due to the suboptimal sensitivity of the limiting dilution system used. Arstila, et al. used the immunoscope technique, which should underestimate true diversity, to arrive at a figure of 1–2 million different β-chains in naïve CD4 T cells in the young [28]. The actual value is probably in between this and our estimate.

How does the naïve CD4 TCR repertoire change with age? Remarkably, in spite of little to no thymic output, β-chain sequences from individuals up to the age of 65 are present in frequencies similar to those of 20-year-olds. Not only do the most infrequent β-chains represent over 60% of the tested sequences, resulting in the same median frequency of <1 in 20 million, the 60- to 65-year-old donors do not have an increase in overrepresented β-chain sequences; only 20% of tested sequences in both age groups are more frequent than 1 in 1 million. These findings indicate that homeostatic mechanisms effectively maintain the naïve repertoire through age 65 even without significant input of new T cells from the thymus.

When individuals in their late seventies are examined, a dramatic change in naïve CD4 T-cell repertoire maintenance is revealed. Whereas in younger individuals, about 60–70% of β-chain sequences examined are less frequent than 1 in 5 million, nearly 100% of β-chain sequences from 75- to 80-year-old individuals are more frequent than 1 in 1 million. In fact, the majority of sequences are present at a frequency greater than 1 in 200,000. Thus, in a single decade, 99% of the β-chain repertoire is lost. A similarly dramatic repertoire collapse is seen in the memory compartment of CD4 T cells in the elderly (depicted in Fig. 4). This may reflect a generalized break down in T-cell homeostatic mechanisms at advanced age.

While a similar examination of the naïve CD8 T-cell repertoire in the elderly has not been done, indirect evidence suggests that diversity loss occurs earlier and more steadily in CD8 T cells. As discussed above, the loss of naïve CD8 T cells is more severe than for CD4 T cells (see Fig. 2). The corresponding homeostatic pressure to counteract this loss may proceed without preservation of the TCR repertoire. Indeed, CD8 T-cell clonal expansions emerge early in life and continue to accumulate with age [67]. As depicted in Fig. 4b, clonal expansions are much less common and occur later in life with the CD4 T-cell compartment [68]. While many

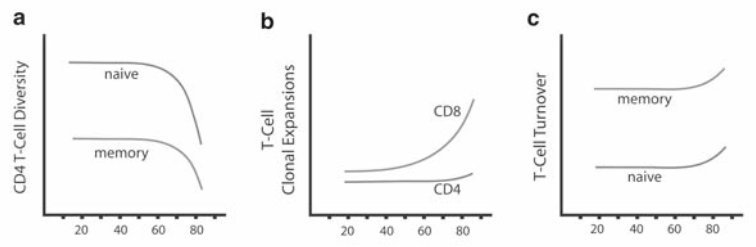

Fig. 4 Changes in T-cell Heterogeneity and Turnover with Age (a) Schematic representation of CD4 TCR repertoire collapse after age 65. (b) Schematic representation of accumulation of CD4 and CD8 T-cell clonal expansions with age. (c) Schematic representation of increased peripheral T-cell turnover late in life

expanded clones come from the memory compartment, naïve TCR clones may each respond differently to increased homeostatic stimuli, and unbalanced proliferation may compromise the diversity of the dwindling naïve compartment. Future studies that directly assess naïve CD8 T-cell diversity are needed to more fully appreciate the consequences of age on the naïve T-cell pool.

In the absence of new thymic T-cell production, naïve CD4 TCR diversity is maintained until the seventh decade of life. Similarly, the naïve CD8 T-cell population, while experiencing a steadier decline in numbers and probably diversity, is remarkably stable for many years after thymic involution. Why, after years of successful repertoire preservation, does this maintenance begin to fail? One possibility is that, with a minimal influx of new T cells from the thymus, peripheral homeostatic mechanisms are capable of maintaining a diverse repertoire [69]. In this case, the collapse of naïve diversity after age [65] may follow the *absolute* end of thymic production, thereby overwhelming homeostatic mechanisms.

Alternatively, evidence from humans and nonhuman primates points to a failure of homeostasis late in life. For both human naïve CD4 T cells [19] and rhesus macaque naïve CD4 and CD8 T cells [70], T-cell turnover significantly increased in old individuals (depicted for humans in Fig. 4c). In macaques, the increases proliferation seems to be a reaction to increased cell loss. In fact, animals with the smallest naïve compartments experience the most dramatic cell turnover. As the authors suggest [70], declining naïve T-cell numbers trigger a compensatory, yet inadequate, proliferation to refill the compartment. This stimulus exacerbates the problem by shifting naïve cells to a memory phenotype, thereby further depleting naïve numbers. Thus, the very mechanism for preserving the naïve population may contribute to its ultimate demise by creating a feedback loop that overwhelms the homeostatic capacity of elderly individuals. The factors leading to declining T-cell diversity in the elderly are depicted in Fig. 5.

5 Implications of Diversity Loss

A wide array of unique TCR within the naïve T-cell compartment is necessary to protect against an unpredictable and diverse antigen pool. Without a naïve response, many ubiquitous and benign infections would be deadly. Emerging neoplastic cells, whose presence would normally be detected by naïve T cells, could survive for the time required to accumulate the additional mutations needed for malignancy. Effective vaccinations require the long-lived memory cells that remain following activation and expansion of naïve T cells specific for the target antigen. Additionally, existing T-cell memory, from past infections or vaccines, must persist to prevent reactivation of chronic infections or reinfection by a familiar pathogen. It seems clear that the elderly, who face a steady decline in naïve T-cells and a dramatic collapse of naïve and memory T-cell repertoire diversity late in life, should respond poorly to challenges requiring full T-cell function. Although infections, cancer, and poor vaccine responses disproportionately affect the very old, it is difficult to assess

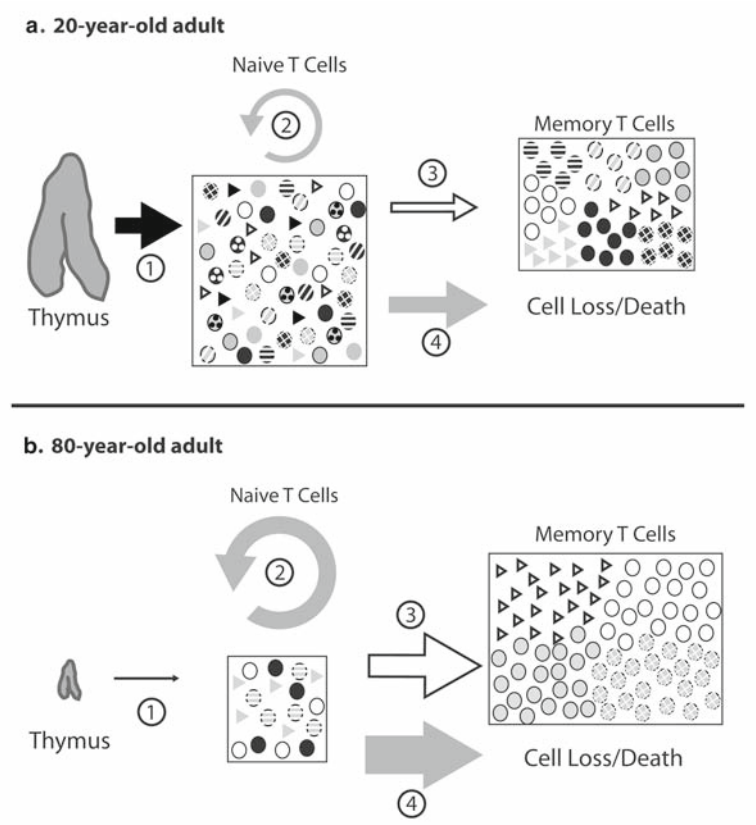

Fig. 5 Determinants of Naive T-cell Diversity (a) Young adult human. 1- A steady supply of new naive T cells continually adds to TCR repertoire. 2- Existing naive T cells proliferate in response to daily cell loss. 3- Exposure to antigen shifts naive clones to the memory compartment. 4- Naive T cells are lost to cell death or attrition. (b) Elderly adult human. 1- Thymus no longer contributes new naive T cells. 2- Declining naive T-cell numbers result in severe homeostatic pressure to proliferate. 3- In addition to antigen exposure, naive T cells shift to memory phenotype because of excessive homeostatic expansion. 4- Naive T-cell death is accelerated due to exhaustion from strong proliferative pressures. Black arrows—promotes diversity of naive TCR repertoire; Black-outlined arrows—depletes naive TCR repertoire; gray arrows—can have neutral and/or detrimental effects on naive TCR repertoire

how much of this is due to a loss of TCR diversity. Several examples of decreased T-cell repertoire in mice and humans hint at the importance of a diverse response.

Many natural and experimentally manipulated genetic backgrounds in mice result in contracted T-cell repertoires. These settings have been used to assess how reduced TCR availability affects immune responses. NZW mice and strains with the *tcr*$^{\alpha}$ haplotype (e.g. C57L) lack certain elements of the TCRB locus [NZW: deletion of $C_{\beta 1}$, $D_{\beta 2}$, and all $J_{\beta 2}$ segments (71); *tcr*$^{\alpha}$: deletion of five V_{β} segments and altered $V_{\beta}10$ sequence (72)] resulting in a 50–60% reduction in potential TCR. T cells

from these mice exhibit reduced ex vivo responsiveness after immunization against some, but not all, tested antigens. TdT-deficient mice are unable to diversify D-J, V-J, and V-DJ junctions during TCR gene rearrangement resulting in a ~90% repertoire contraction. Interestingly, these mice are fully protected from lymphocytic choriomeningitis virus and Sendai virus infections [73]. Although other challenges have not been examined, it is clear that a limited repertoire is capable of enough cross-reactivity to control certain pathogens.

Gene targeting of TCR loci reduces TCR diversity even more dramatically than deletion of the TdT enzyme. For example, all T cells from the TCR OT-1β transgenic mouse express the same TCR β-chain (specific for an OVA peptide when expressed with the OT-1α-chain) and, therefore, all TCR diversity results from TCRA gene rearrangement. In the context of this dramatic repertoire contraction (>98%), these mice are unable to reject allogeneic bone marrow [74]. Other experiments using a different TCR β-chain transgenic strain have shown that some antigen-specific responses are not absent, merely different [75]. After immunization with the bacteriophage protein cl, splenic T cells from both TCR β chain transgenic mice and wild-type littermates responded ex vivo to the cl protein. When challenged with peptides derived from cl, wild-type splenocytes responded most strongly to the peptide known to be immunodominant. In contrast, transgenic mice responded more strongly to a different peptide that yielded no response in wild-type splenocytes. Interestingly, both strains of mice were equally capable of a strong response to both peptides when the peptide, rather than whole cl protein, was the immunizing antigen. Therefore, it seems the severe repertoire contraction in these TCR β-chain transgenic mice created a shift of immunodominance without creating a "hole" in the repertoire. That is to say, T cells from these mice *can* respond well to the classical immunodominant peptide but, when faced with the full protein antigen, expand more readily against a different peptide.

From the above examples, it is clear that the requirement for TCR diversity in the mouse is context dependent. This is most likely true for humans too, although direct examination of repertoire contraction in humans is more difficult. A single patient with a partial X-linked severe combined immunodeficiency (Xid) reversion has provided a rare glimpse at the in vivo consequences of TCR contraction in humans. Although family and clinical history and gene sequencing suggested the patient had Xid, a disease caused by the genetic lack of a functional cytokine common γ-chain [76], he had a nearly full-sized T-cell compartment [77]. The Xid mutation usually blocks T-cell development by preventing IL-2 signaling. In this patient, a compensating somatic mutation in the common γ-chain gene occurred in a single T-cell precursor allowing descendants of this cell to undergo normal thymic development. Immunoscope analysis at age 3 revealed that extensive post-thymic expansion of an estimated 25,000 distinct TCR clones managed to fill the T-cell compartment [78]. In vitro challenge of T cells with a variety of antigens revealed blunted responsiveness. While some in vivo T-cell functions, such as a skin test for the BCG vaccine, were intact, it is unclear if these responses would be protective in the face of a pathogen challenge [78]. Subsequent follow-up has not been reported,

and it remains to be seen if this patient will be at increased risk of immune deficiency in the future.

An in vivo Hepatitis C virus study in chimpanzees revealed a setting where the antigen-specific CD8 T-cell repertoire predicted the outcome of infection [79]. A cohort of animals were all inoculated with an identical strain of virus and followed. Some animals exhibited a diverse array of TCR antigen-binding domains within virus-specific T cells while other responses were more homogeneous. Those animals with a narrow repertoire among responding T cells were more likely to carry viral escape mutants and to never clear the infection. This homogeneity preceded viral escape and persisted after a response was mounted to the new mutants. Presumably, animals with more diverse responses were able to respond to viral mutations as they arose, thus preventing expansion of novel epitopes. These findings highlight the contribution of TCR diversity to a flexible immune response capable of adapting to pathogens that evolve during an infection.

Indirect evidence from studies of human aging suggests that age-related repertoire collapse may indeed have detrimental effects on survival. A longitudinal examination of octogenarians in Sweden revealed an "immune risk phenotype" (IRP) that predicted 2-year mortality. Individuals with the IRP, which was originally defined as inversion of the CD4:CD8 ratio (normal is >1; IRP is <1) and decreased in vitro T-cell proliferation, were more likely to die within the 2-year follow-up period compared to non-IRP individuals [80]. Additionally, the prevalence of the IRP doubled from 16 to 32% over the 2 years. A subsequent study showed that a decreased CD4:CD8 ratio alone is an adequate marker of the IRP and its accompanying increased mortality risk [81]. Importantly, as the proportion of CD8 cells increases, the contribution to total CD8 T cells comes from fewer and fewer clonotypes [26]. Thus, in this elderly population, the individuals with the least diverse CD8 populations were more likely to die during the 2-year study period. While the direct cause of increased mortality is unknown, this correlation is consistent with other studies linking CD8 clonal expansions to decreased EBV [82] and influenza responses [83, 84].

Interestingly, a more recent report following the nonagenarians found that those individuals who reach the age of 100 are free from the IRP and have T cells more similar to middle-aged individuals than even the younger-elderly [85]). For example, the CD4:CD8 ratios of centenarians are not only >1 but are consistently more CD4-heavy than even individuals in their early nineties. Additionally, centenarians had fewer $CD8^{+}CD28^{-}$ T cells, by absolute numbers and as percent of total CD8 T cells, than younger-elderly. As the authors suggest, the collective characteristics of the centenarian population obviously excludes those individuals who have died and, therefore, may represent features of "successful aging." For this reason, a longitudinal examination of T-cell repertoires in the very old may contribute to our understanding of the requirement of TCR diversity for longevity. Can TCR diversity within various T-cell compartments predict mortality as successfully as the IRP? Do the successfully-aged exhibit the dramatic collapse of the naïve CD4 repertoire that we have found in individuals after age 75? Answers to questions like these will help clarify the true in vivo importance of declining TCR diversity with age.

The Role of T-regulatory Cells in Immune Senescence

Paul Moss

Contents

1 Introduction

T-regulatory cells have come to dominate immunology over the last decade [1]. The ability of cellular components of the immune system to suppress immune function was noticed more than 20 years ago and was recognized by a number of highly cited publications [2]. However, the lack of a specific phenotype for these cells, and an inability to document precise physiological mechanisms for their action, limited their investigation by detailed experimental study. The pioneering work of Sakaguchi and colleagues reestablished regulatory cells and has generated a field of research that extends into all areas of clinical immunology, including immune senescence [3].

At first sight, the concept that the immune system must require some form of cellular control of immune activation is surely no surprise. There are very few physiological systems that can proceed without any form of feedback mechanism and it is now appreciated that there are many different subsets of regulatory cells involved in immune haemostasis. By far the most widely recognized is a CD4+ T-cell population that expresses high levels of CD25. The CD4+CD25+ subset has become the prototypic "T-regulatory" cell in both murine and human studies and has provided the basis for many thousands of publications. However, the fact that CD25 is also expressed on all activated effector T-cells has lead to the quest for a "third marker" that will provide a more definitive and unique phenotype for the regulatory population. Several of these molecules have been suggested over recent years, including

GITR and low expression of CD127. However, it is the transcription factor FOXP3 that has emerged as the most reliable marker for this functional subset [4, 5] (Fig. 1). FOXP3 is a member of an important family of transcription factors that are involved in processes such as language development and which seem to have a central role in development of developmental functions. This is supported by observations in mice deficient in FOXP3 gene function, which develop an autoimmune condition secondary to unregulated immune responses. Even more compelling are the findings in rare human individuals that were born without FOXP3 function and suffer from an unusual syndrome of autoimmune disease dominated by inflammation of endocrine organs. Although there is some evidence that FOXP3 may be up-regulated on activation of effector T-cells in humans, most authors now agree that this marker is a valid and reliable marker of functional regulatory phenotype across both species. Unfortunately, one concern with the use of FOXP3 is that its detection requires the permeabilisation of cells and therefore renders cells unviable for further downstream analysis. For this reason, a surface membrane phenotype which would allow for the cloning and isolation of regulatory cells would provide a significant boost to this area of research. In 2006 low level expression of CD127 emerged as a good marker of FoxP3 expression in regulatory CD4+ T-cells [6, 7]. CD39 is the most recently evaluated phenotypic marker and is positively associated with FoxP3 expression [8].

The mechanism of action of T-regulatory cells remains the subject of active investigation and it is perhaps fair to say that no consensus has emerged on this topic. Some regulatory populations appear to secrete immunosuppressive cytokines such as IL10 or TGFβ but these properties are not documented in all subsets. Cytotoxic activity has also being observed in some experiments. The target cells for T-regulatory function are also uncertain, as it appears that regulatory cells can act both at the level of antigen presenting cells, and therefore modulate induction of immune responses, as well as act directly on effector cells.

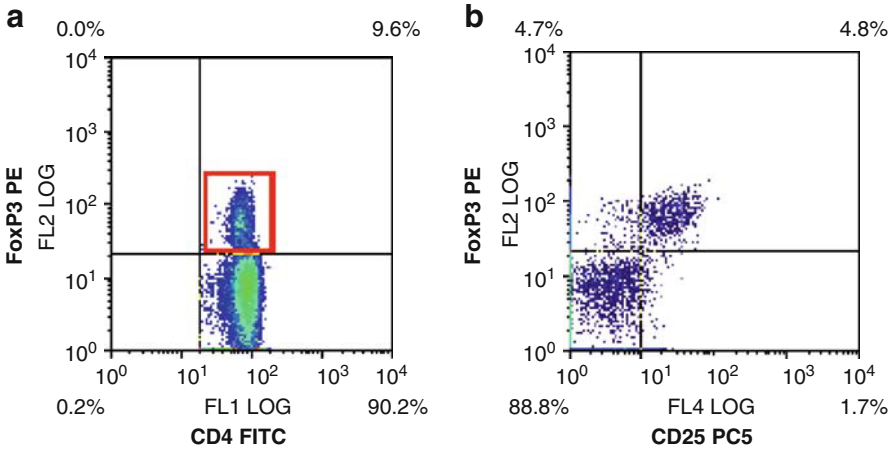

Fig. 1 Phenotypic analysis of regulatory T cells
a. The characteristic phenotype is of CD4+FoxP3+ cells. b. FoxP3 expression correlates with high expression of CD25.

2 The Origin of T-regulatory Cells: Thymically-derived or Generated in the Periphery?

Much has been made of the concept that most regulatory cells are derived by a discrete developmental pathway within the thymus which leads to a committed population of "natural" regulatory cells which never have the capacity to act as typical effector populations. Whilst much of this work has, necessarily, been performed in murine models, it has been much more difficult to determine that this is the case within human individuals. Interestingly, studies from both young and aged mice have shown that CD4+ FoxP3+ T-cells are found in both cohorts with some evidence of increased production during ageing. This raises the question as to whether CD4+ FoxP3+ T-cells continue to be produced by the human thymus throughout life. At first sight this might be considered unlikely given the well documented process of thymic involution that occurs during healthy human ageing, although it should be appreciated that the deterioration in naïve T-cell output is much more marked for the CD8+ population in comparison to CD4+ subsets. The reason for this last observation has never been entirely explained and could conceivably be partly explained by some contribution of ongoing CD4+ regulatory production.

However, it is also now clear that T-regulatory cells can be induced within the peripheral immune system by derivation from naïve or effector CD25- T-cell populations [9] (Fig. 2). The conditions that give rise to the generation of regulatory

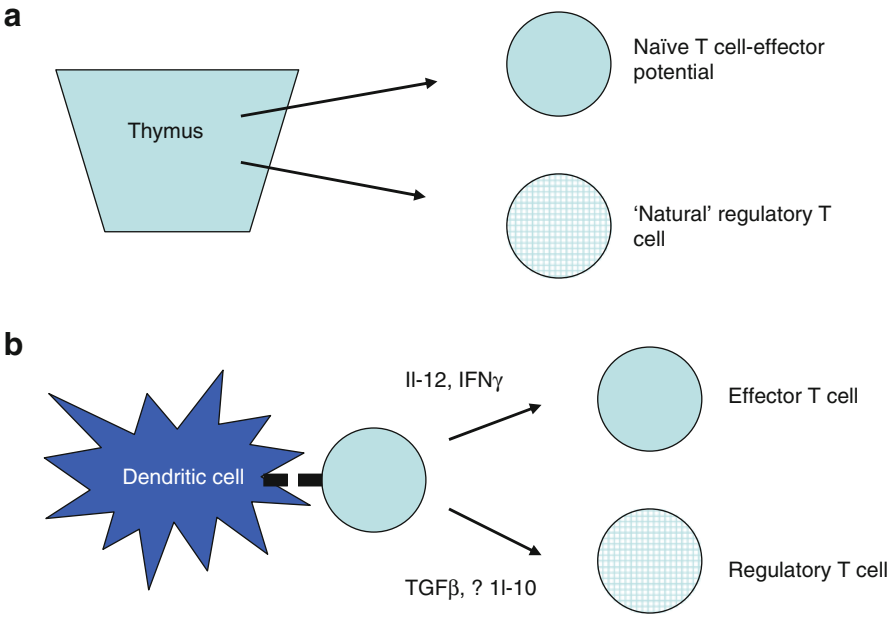

Fig. 2 Model for generation of T regulatory cells
Regulatory cells might arise from (a) a discrete pathway of differentiation through the thymus or (b) be induced from naïve T cell populations during T cell priming.

cells have not been entirely resolved, but are likely to involve microenvironmental signals including the presence of immunosuppressive molecules such as TGFβ and Il-10 at the time of dendritic cell priming of T-cell effector molecules [10]. When present during the first 3 days of T-cell priming the presence of TGFβ can induce FoxP3 expression in up to 90% of responding T-cells and this expression can be sustained for long periods of time in at least a subset of this population [11]. This mechanism of T-regulatory cell production is likely to become increasingly important during ageing of human populations. Given the longevity of humans and the well characterized involution of thymic function that occurs, it would appear highly unlikely that a discrete pathway of thymic maturation could provide the only source of T-regulatory cell production in adult life. Moreover, recent evidence has emerged to suggest that the turnover of T-regulatory cells is actually surprisingly short and that these cells are a highly proliferative population with short telomeres and great susceptibility to apoptosis [12]. Taken together, this evidence does strongly suggest that the peripheral production of T-regulatory cells within the immune system is a powerful factor in their generation. The site of origin of regulatory cell induction is also likely to be important in the functional properties of the mature cell as evidence is accumulating that extrathymic maturation is associated with impaired proliferative potential [13].

The number of CD4+ regulatory cells within the human immune system is variable depending both on the precise definition of such cells, the age of the individual and any underlying disease processes. Typically, between 2 and 5% CD4+ T-cells will express a CD25+ or FoxP3+ phenotype and further studies are required to show whether these numbers are influenced by any genetic or environmental factors.

3 T-regulatory Cell Populations During Healthy Ageing

An important question in relation to immune senescence is how the number and function of T-regulatory cells is influenced by physiological ageing, both in humans and in murine models. T-regulatory function certainly appears to be required throughout life and depletion of FoxP3+ T-cells in mice leads to a breakdown of self-tolerance at all ages [14]. Within murine systems, a number of investigators have shown an apparent increase in the number of CD4+ FoxP3+ T-cells in aged mice. CD4+FoxP3+ T-cell numbers can increase early in murine development with the BDC2.5NOD mouse showing an increase between the age of 6 and 18 weeks. However a 4 month old mouse is not aged in terms of the natural murine lifespan so this observation has limited relevance to studies of immune senescence. Zhao et al. studied Balb/c mice that were over 20 months of age and therefore represented a physiologically aged cohort [15]. In a comprehensive study they showed that the number of CD4+CD25+FoxP3+ T-cells increased with age in virtually all lymphoid compartments. However, the regulatory function of these cells did show some deficiencies in comparison to cells from young mice. In particular there was reduced inhibition of cytokine production by effector cells despite comparable sup-

pression of proliferation. It is interesting that the proportion of natural T-regulatory cells within the thymus can also increase during ageing suggesting that this mechanism may continue to make a contribution to peripheral accumulation [16]. Thymic-regulatory cells from elderly mice were able to suppress effector T-cells from young animals with similar efficiency to regulatory cells from younger mice. However, their ability to suppress effector cells from elderly mice was impaired indicating some functional differences between cells from young and older animals.

Sakaguchi's group has also addressed accumulation of T-regulatory cells during murine ageing and identified only a marginal increase in natural CD4+CD25+FoxP3+ T-cells. In contrast, increased levels of FoxP3 expression were seen in the CD4+CD25- population and identified a population with hyporesponsive function [17]. Their interpretation was that decreased immune function during ageing was primarily a reflection of a decrease in effector cell function rather than regulatory cell accumulation [18]. Comparable findings have been demonstrated in human subjects.

A number of studies are now addressing the number and function of T-regulatory cells in adult human populations. Our own data published in 2005 used CD4+CD25^{high}+CD45RO+ membrane phenotype as a marker of regulatory cell function [19]. Somewhat to our surprise at that time, we observed a significant increase in the regulatory T-cell population during ageing. In addition, we showed that the functional activity of these populations was also maintained during the ageing process with equivalent suppressor activity to that seen in young patients on a cell for cell basis. There are a number of methods by which T-regulatory function may be assessed, but suppression of interferon-γ cytokine production by effector T-cells in coculture experiments is one of the most reliable and sensitive methods. Suppression of proliferation of effector cells in antigenic stimulation or allogenic mixed lymphocyte cultures can also be a valuable test.

Other investigators have also addressed the question of T-regulatory cell numbers in human ageing [20, 21] and have demonstrated that CD4+ FoxP3+ T-cells are seen to increase during ageing [22]. This is reassuring as it indicates that the more contemporary phenotype of regulatory cells, namely FoxP3 expression, can also be used to corroborate the increase in regulatory cells with ageing. Despite this, some evidence continues to suggest that functional activity is not equivalent in older subjects [23].

An important question that needs to be addressed in T-regulatory cell biology is the degree of coexpression of FoxP3 and CD25 on CD4 regulatory populations. In particular, CD25- T-cells expressing FoxP3 are observed in a number of clinical settings and may be related to the use of immune-suppression, ongoing chronic activation, or potentially immune senescence. There have been few studies to address this within humans although within murine systems an increase in CD25- FoxP3+ regulatory cells with ageing has been observed. In general, the evidence seems to suggest that FoxP3 is the more reliable marker of functional regulatory activity and the expression of CD25 therefore becomes less significant. CD25 is the high affinity receptor for interleukin 2 and its physiological role in T-regulatory functions has never been completely explained. Some authors have suggested that CD4+ CD25+

T-cells act as a "sink" for cytokine production and thereby act to limit cellular proliferation within the microenvironment but this proposal has not yet received substantial and confirmatory support.

The accumulation of regulatory cells with ageing does suggest that there may be increased generation of regulatory cells within the peripheral immune system in association with ageing. The mechanisms that may underlie this are unknown but differences have been reported between signalling processes in dendritic cells from young and old donors [24]. Reduced phosphorylation of AKT within DC in response to cell stimulation may be one reflection of differential signalling responses in these cells from elderly donors.

As with effector populations, T-regulatory cells can be divided into naïve and memory subsets based on their expression of CD45 isoforms. Naive regulatory populations characterized by CD45RA expression are predominant in infants but are still detectable in adult subjects [25]. The extent to which these remain in elderly donors with immune senescence has yet to be studied.

4 Regulatory T-cell Populations within the CD8+ T-cell Repertoire

In contrast to the extensive investigation of CD4+ regulatory T-cells there has been much less study of regulatory populations on cells within the CD8+ population. Suppressor T-cells have been described for many years and their phenotype appears to be dominated by lack of expression of the CD28 costimulatory molecule whereas expression of FoxP3 on CD8 has been poorly characterized. Naive CD8+ T-cell numbers decline dramatically with age to be replaced by accumulation of effector populations and this homeostatic instability may contribute to the differential structure of CD4 and CD8 T-cell pools [26].

A complexity is that FoxP3 may be expressed transiently after T-cell activation of effector T-cells although this induction does not lead to acquisition of complete regulatory function [27]. CD8+ populations that do express FoxP3 have been reported in a number of clinical scenarios [28, 29] but their functional role, and relevance to ageing, has not yet been addressed.

5 The Potential Contribution of T-regulatory Cells to Immune Senescence

One area in which there has been disappointing progress in T-regulatory biology has been confirmation of the antigenic specificity of these populations. Great debate continues to address the issue as to whether effector CD4+ T-cells and CD4+ regulatory cells recognize the same population of antigenic determinants or display specificity against discrete epitopes which may themselves play a role in determining

the physiological direction of T-cell differentiation [30]. T-regulatory cells do appear to have specificity for self-epitopes and in this regard overlap at least partially with a population of potentially self reactive effector cells [31]. The former hypothesis gains considerable import from use of T-cell receptor transgenic models in which alteration of environmental conditions can lead to the generation of T-regulatory or T-effector cells with the same T-cell receptor expression. It had been believed that T-regulatory cells may represent a population with uniquely high affinity for self-antigen but such experiments suggest that critical determinants during T-cell priming maybe more important in determining the nature of T-cell differentiation after antigen priming.

Despite this, it has been widely reported that, although T-regulatory cells may require antigenic stimulation for activity, their activity, once triggered, is non-specific in nature and therefore can act to suppress bystander populations. In this regard, it is entirely possible that individuals who accumulate large populations of T-regulatory cells can be subject to some form of generalized immune suppression which may impact on their ability to mount effective immune responses against infectious agents or, potentially, tumour cells. There is great interest in studying the number and function of T-regulatory cells in patients with active malignant disease and a number of trials and animal models, either targeting CD25 or CTLA4, are now addressing how suppressional manipulation of T-regulatory cell function may serve to increase antigen-specific T-cell immune responses against transformed tissue [32, 33]. Some of these studies are already providing encouraging clinical responses but, perhaps not surprisingly, such treatments can often unleash powerful autoimmune phenomena with unusual antigenic specificities, including hypophysitis or hepatitis [34].

The question therefore needs to be addressed as to whether the increase in T-regulatory cells that is observed during healthy ageing contributes directly to immune senescence in this population [35]. In contrast, despite an increase in absolute numbers the suggestion that regulatory cell function may be impaired in ageing might also be relevant to the increase in autoimmune disease with age. To date there has been little experimentation which has allowed any detailed interpretation of this concept. However, Trzonkowski et al. have shown that the accumulation of regulatory cells that is observed with ageing is directly associated with impaired activity of CD8+ and NK-cells [21]. When effector cells were purified away from regulatory populations they regained their natural level of activity whereas add-back of regulatory populations led to reestablishment of impaired function. Within the murine system it should be possible to deplete these populations and assess T-cell immunity in mice of different ages and these experiments are eagerly awaited. Sharma et al. have shown that the accumulation of regulatory T-cells in aged Balb/c mice is directly responsible for the inability of older animals to reject tumour tissue [36]. Encouragingly, depletion of regulatory T-cells with an anti-CD25 antibody was able to reverse this deficiency.

Within the human system, such experiments are clearly much more difficult to devise but there is surely enough evidence now to make this an important clinical aim. Useful information is likely to be gleaned from the increasing number of early

phase trials of T-regulatory modulation in both malignant and infectious disease which will reveal something regarding contribution of T-regulatory cells to immune senescence. Therapeutic manipulation of T-reg numbers will prove a difficult challenge but the use of agents such as interleukin-7 may modulate the nature of thymic output [37]. Granulocyte colony stimulating factor (G-CSF) administration leads to increased recruitment of regulatory cells through activation of tolerogenic plasmacytoid dendritic cells [38] and this cytokine axis might therefore offer scope for intervention. Adrenergic innervation of the thymus has been postulated to play a role in thymic involution and pharmacological blockade leads to increased T-regulatory cell production [39]. One interesting question will be the relative serum level and tissue availability of TGFβ during ageing as this may play an important role in the peripheral accumulation of regulatory cells.

6 Conclusion

In conclusion, T-regulatory cells are emerging as the most intensively studied population of cells within the human immune system at the current time. As such, it is not surprising that they are now being addressed in relation to immune senescence, itself one of the most important areas of clinical immunology. Initial data suggests that regulatory cell numbers are indeed increased in healthy elderly individuals, and that the functional properties of these cells are also maintained. Although more needs to be discovered regarding the antigenic specificity and functional activity of these cells, it is likely that manipulation of T-regulatory cell function could represent a novel form of immunotherapeutic intervention in elderly individuals. Whether or not it will be possible to limit regulatory cell function without an associated increase in autoimmunity is currently unknown. Such clinical intervention is likely only to be possible when much greater understanding is made of the natural physiological role of these cells in immune responses.

Age-related Changes in Subpopulations of Peripheral Blood Lymphocytes in Healthy Japanese Population

Masanori Utsuyama, Yuko Kikuchi, Masanobu Kitagawa and Katsuiku Hirokawa

Contents

Abstract: Peripheral blood mononuclear cells were obtained from healthy Japanese individuals ranging in age from 20 to 90 years old and analyzed by using three color flow cytometer with regards to the number and percentage of various lymphocytes. In addition, we assessed the proliferative capacity of T-cells in the presence of an anti-CD3 monoclonal antibody and the amount of cytokines produced in the supernatant.

The results showed that an age-related decline was observed in the numbers of $CD3^+$ T-cells, $CD8^+$ T-cells, naive T-cells, $CD8^+CD28^+$ T-cells, and B-cells and in the proliferative capacity of T-cells. The rate of decline in these immunological parameters except for the number of $CD8^+$ T-cells was steeper in males than in females ($p<0.05$). An age-related increase was observed in the number of $CD4^+$ T-cells, memory T-cells, and NK-cells and in the CD4/CD8 ratio The rate of increase of these immunological parameters was steeper in females than in males ($p<0.05$). The T-cell proliferation index (TCPI), which was calculated based on T-cell proliferative activity and the number of T-cells, showed an age-related decline. The rate of decline in the TCPI was again steeper in males than in females ($p<0.05$). The score of immunological vigor calculated using 5 T-cells parameters also declined with age, and the rate of decline was steeper in males than in females ($p<0.05$). The

DOI 10.1007/ 978-1-4020-9062-2_11,

present study has confirmed the age-related changes in immunological parameters reported in literature. In addition, we found that a statistically significant difference was observed between males and females in some immunological parameters such as the number of T-cells and TCPI. The slower rate of decline in the immunological parameters studied in females than in males may be consistent with the fact that women survive for longer period of time than men.

1 Introduction

Immunological functions are known to decline with age in many animal models and humans (Linton and Dorshkind 2004; Utsuyama et al. 1992; Hirokawa et al. 2006). Understanding the level of immunological functions at an individual level is clinically important, since the immunological decline is accompanied by various diseases such as infections, cancer and vascular diseases.

Accumulating evidences mainly obtained from animal models have shown that age-related immunological decline mainly occurs in T-cell dependent immune functions, and is mainly caused by thymic involution that begins in the early phase of life (Hirokawa et al. 2006).

In humans, data regarding immunological functions are mainly obtained from blood serum and blood cells. Serum contains immunoglobulins, complements and cytokines. The levels of IgG and IgA in serum show a trend of increase with age (Suzuki et al. 1984). The level of complements does not change remarkably with age. The level of cytokines in healthy people is generally low. In contrast, the level of white blood cells (WBC) changes remarkably during disease and also with aging. WBC comprises granulocytes, lymphocytes and monocytes. There are various subpopulations of lymphocytes with different functions. Data regarding the age-related changes in lymphocytes and their functions are not sufficiently available as yet.

The purpose of this study is to provide immunological data on peripheral blood lymphocytes obtained from 162 male and 194 female healthy volunteers, ranging in age from 20 to 90 years. Our study discusses the age-related changes in subpopulations of peripheral blood lymphocytes from both immunological and gerontological viewpoints.

2 Materials and Methods

Blood specimens: Two milliliters of blood was taken in a tube containing ethylenediaminetetraacetic acid (EDTA-2K) for hematological analysis performed using a PENTRA80 analyzer (Horiba, Kyoto, Japan). Eight milliliters of blood was taken in a cell preparation tube (vacutainer, 362761, Becton Dickinson (BD), NJ) for collecting mononuclear cells and was used for immunological analyses.

Subjects: Healthy volunteers were selected based on clinical records and laboratory examinations. None of the blood donors were suffering from neoplastic or autoimmune disease; further, none were receiving any medications that could

Table 1 Number of male and female subjects

Age	20 – 29	30 – 39	40 – 49	50 – 59	60 – 69	70 – 79	80 –	Total
Male	13	23	35	37	29	22	3	162
Female	44	32	36	34	18	26	4	194

influence immune functions. Routine laboratory examinations of the serum were performed to examine the liver and kidney functions. A total of 162 males and 194 females were examined in the present study. Table 1 shows the number of male and female subjects and their ages.

Flow cytometry: Mononuclear cells that were obtained from the peripheral blood, as described above, were stained with a combination of 2 or 3 monoclonal antibodies (mAbs) conjugated with 2 or 3 chromophores. A fluorescence-activated cell sorting flow cytometer (FACScan BD) was employed in the present study.

Monoclonal antibodies: The antibodies used were fluorescein isothiocyanate (FITC) conjugated anti-CD4, FITC-conjugated anti-CD20 and FITC-conjugated anti-CD16; phycoerythrin (RD1) conjugated anti-CD3, RD1-conjugated anti-CD8 and RD1-conjugated anti-CD25; phycoerythrin-Texas Red (ECD) conjugated anti-CD45RA and ECD-conjugated anti-CD3; phycoerythrin-cyanin 5.1 (PC5) conjugated anti-CD28: phycoerythrin (PE) conjugated anti-CD56. Those mAbs were purchased from Beckman Coulter. The following combinations of mAbs were used: CD3-RD1/CD20-FITC, CD4-FITC/CD8-RD1/CD45RA-ECD, CD4-FITC/CD8-RD1/CD28-PC5, CD56-PE/CD16-FITC, CD3-ECD/CD4-FITC/CD25-RD1.

Proliferative response of T-cells: The proliferative response of T-cells to anti-CD3 mAb (ORTHOCLONE OKT3, ORTHO BIOTEC, NJ) was assessed according to MTS method (Cell Titer 96 Aqueous One Solution Cell Proliferation Assay (Promega Co., WI)).

Assays were performed in microplates (3860-096, Asahi Glass Co. Japan). The cells (1×10^5) in 0.2 ml of RPMI 1640 medium supplemented with 5% fetal bovine serum (FBS) were stimulated with immobilized anti-CD3 mAb (Orthoclone OKT3, Ortho Biotec, NJ). The plates were then placed in a 5% CO_2 incubator for 72 hrs. After incubation for 68 hrs, 40 µl of MTS solution (Cell Titer 96 Aqueous One Solution Cell Proliferation Assay (Promega Co., WI)) was added into each well and absorbance at 490nm was recorded with a spectrophotometric plate reader; this value was used for determining the relative magnitude of T-cell proliferation.

T-cells proliferation index (TCPI) and immunological age (IA): TCPI was calculated by the following equation.

TCPI = T-cell proliferative activity × (T-cell number/1000)

In this equation, T-cell proliferative activity was obtained as optical density (OD_{490}) ranging between 0.95 and 2.0 by the abovementioned MTS method. The TCPI and age showed a statistically significant correlation: TCPI = −0.0174 x (Age)+ 2.5348 (Fig. 5c and 5d). Using this equation, it is possible to calculate age by assigning a value to TCPI. The age calculated by this equation was referred to as immunological age (IA).

Scoring and grading of immunological functions: The values of immune parameters were standardized by assigning scores of 3 (high level), 2 (moderate level) and 1

Table 2 Scoring and grading of immunological vigor

Scoring		
SIV-7 7 parameters	SIV-5 5 parameters	Grading
21	15	Grade V Sufficiently high
20 ~ 18	14 ~ 13	Grade IV Safety zone
17 ~ 14	12 ~ 10	Grade III Observation zone
13 ~ 10	9 ~ 7	Grade II Warning zone
9 ~ 7	6 ~ 5	Grade I Critical zone

(low level) according to the data base obtained from 300 healthy people. After standardization, the scores of different types of immune parameters were summed and the numerical value obtained for each individual was termed the score of immunological vigor (SIV). These scores were then classified into 5 grades, as shown in Table 2.

SIV-7 comprises 7 parameters that are number of T cells, TCPI, CD4/CD8 ratio, number of naïve T cells, naïve/memory ratio, number of B cells and number of NK cells. SIV-5 comprise 5 T cell-related parameters that T cells, TCPI, CD4/CD8 ratio, number of naïve T cells and naïve/memory T cells ratio.

Assessment of cytokine production: Assays were performed in microplates (3860-024, Asahi Glass Co. Japan). Cells (1×10^6) in 1.5 ml of RPMI 1640 supplemented with 10% FBS were stimulated with immobilized anti-CD3 mAb (Orthoclone OKT3, Ortho Biotec, NJ). Culture supernatant were collected at 48 hrs and stored at -80°C until use. A flow cytomix kit (BMS810FF, Bender MedSystems, Austria) was employed for the evaluation of cytokines (Interleukin (IL)-1β, IL2, IL-4, IL5, IL-6, IL-8, IL-10, IL-12/p70, interferon (IFN) γ, tumor necrosis factor (TNF) α, TNFβ and the assessment was performed using a FACScan analyzer.

Statistical Analysis: All statistical analyses were performed using StatView software. Statistical significance was defined as $p < 0.05$. Gender difference was examined by SMA analysis.

3 Results

3.1 Number of Whole WBCs, Red Blood Cells and Lymphocytes in the Blood

The number of red blood cells (RBC) showed a significant age-related decrease ($p < 0.001$) in males and a declining trend with age in females (p=0.9535) (Fig. 1a and 1b) (Table 3). The difference between males and females with regard to the age-related decline in the number of RBC was statistically significant ($p < 0.001$). Although an age-related decline was observed in males, but not in females, the absolute level of RBC was higher in males than in females regardless of age.

The number of WBCs including granulocytes, lymphocytes and monocytes showed a declining trend with age in both males (p=0.0824) and females (p=0.2588); no statistically significant difference was observed between males and females in this regard (Fig. 1c and 1d) (Table 3).

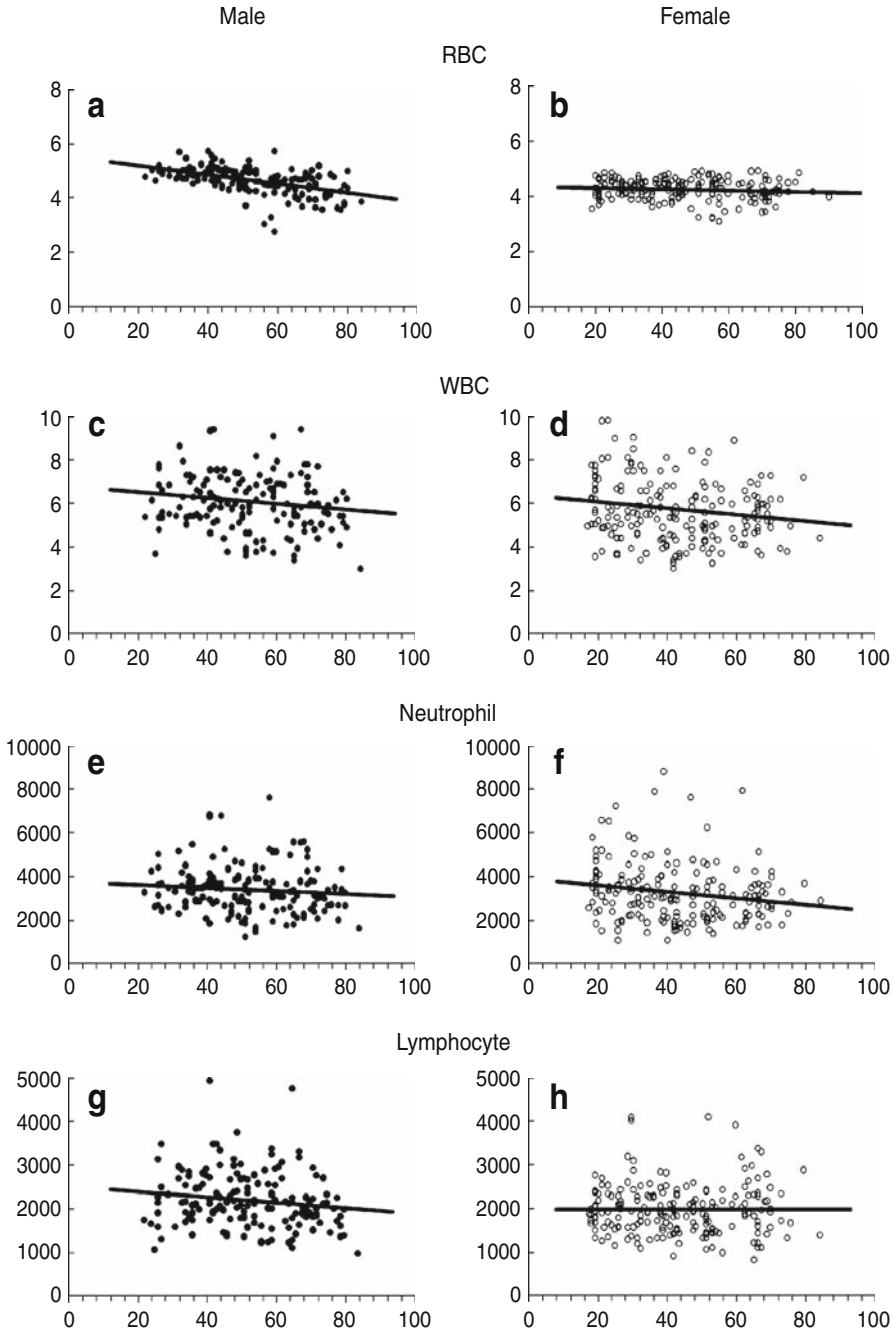

Fig. 1 Age related changes in the number of red blood cells (RBC) in males (a) and females (b), white blood cells (WBCs) in males (c) and females (d), neutrophils in males (e) and females (f), and lymphocytes in males (g) and females (h)

$: Number of $CD8^+$ $CD28^+$ cells was obtained from 107 males and 103 females.

$$: Number of regulatory T-cells ($CD4^+$ $CD25^+$) was obtained from 154 males and 181 females.

The number of neutrophils showed a decreasing trend with age in both males (p=0.2178) and females (p=0.1063); no significant difference was observed between males and females (Fig. 1e and 1f) (Table 3).

The number of lymphocytes showed a decreasing trend with age in males (p=0.0593) and an increasing trend with age in females (p=0.1249); statistically significant difference was observed in the age-related change between males and females (p=0.015) (Fig. 1g and 1h) (Table 3).

3.2 Flow Cytometric Analysis

(a) $CD3^+$ T-cells.

The number of $CD3^+$ T-cells showed a statistically significant decrease with age in males (p =0.0186), and a decreasing trend with age in females (p =0.1249). The difference in the age-related change in the number of $CD3^+$T-cells between males and females was statistically significant (p=0.049) (Fig. 2a and 2b) (Table 3).

(b) $CD4^+$ T-cells.

The number of $CD4^+$ T-cells showed an increasing trend with age in both males (p=0.9897) and females (p=0.1075). This trend was greater in females than in males, and the difference between males and females with regard to this trend was statistically significant (p=0.005) (Fig. 2c and 2d) (Table 3).

(c) $CD8^+$T-cells.

The number of $CD8^+$T-cells showed an age-related decrease in both males ($p < 0.0002$) and females ($p < 0.0001$), but no difference was observed between males and females with regard to this decrease (Fig. 2e and 2f) (Table 3).

(d) The ratio of $CD4^+$ T-cells to $CD8^+$ T-cells (CD4/CD8 ratio).

The CD4/CD8 ratio increased with age in both males (p <0.0001) and females ($p < 0.0001$), and this increase was significantly greater in females than in males ($p < 0.003$) (Fig.2g and 2h) (Table 3).

(e) $CD8^+CD28^+$ T-cells.

The number of $CD8^+CD28^+$ T-cells showed an age-related decrease in both males (p <0.0001) and females (p <0.0001) (Fig. 3a and 3b), and the rate of this decline was more pronounced in males (-6.089) and in females (-4.136) ($p < 0.003$) (Table 3).

(f) $CD4^+CD45RA^+$ naïve T-cells.

The number of $CD4^+CD45RA^+$ naïve T-cells showed a decreasing trend with age in both males (p=0.2615) and females (p=0.4470) (Fig.3c and 3d). This decreasing trend was greater in males than in females, and the difference between males and females was statistically significant (p=0.004).

(g) $CD4^+CD45RO^+$ memory T-cells.

The number of $CD4^+CD45RO^+$ memory T-cells showed an increasing trend with age in males (p=0.1531), and an age-related increase in females (p=0.0001) ($p < 0.0001$) (Fig. 3e and 3f). In this case, there is no significant gender difference (Table 3).

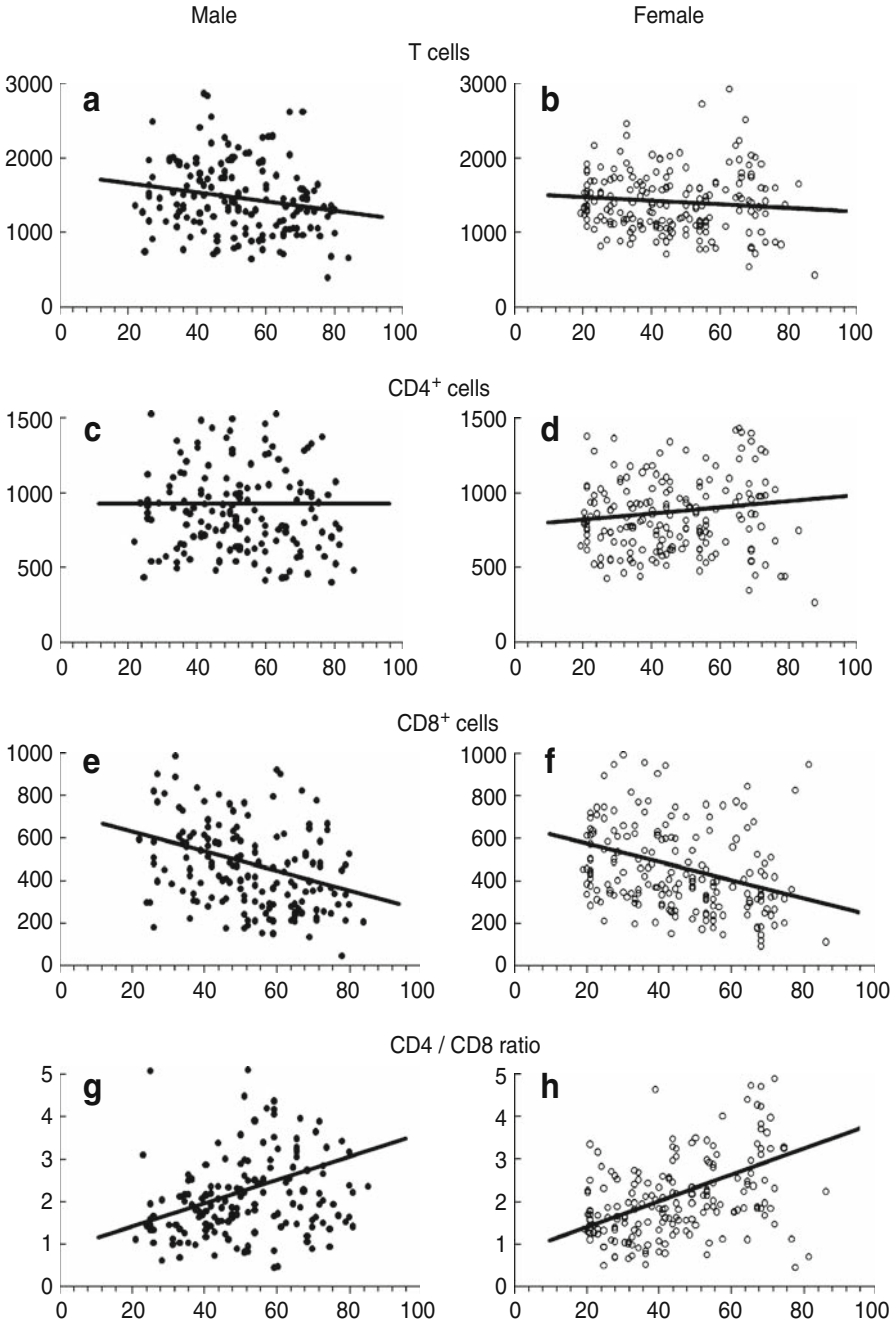

Fig. 2 Age related changes in the number of T-cells in males (a) and females (b), $CD4^+$ T-cells in males (c) and females (d), $CD8^+$ T-cells in males (e) and females (f), and the CD4/CD8 ratio in males (g) and females (h)

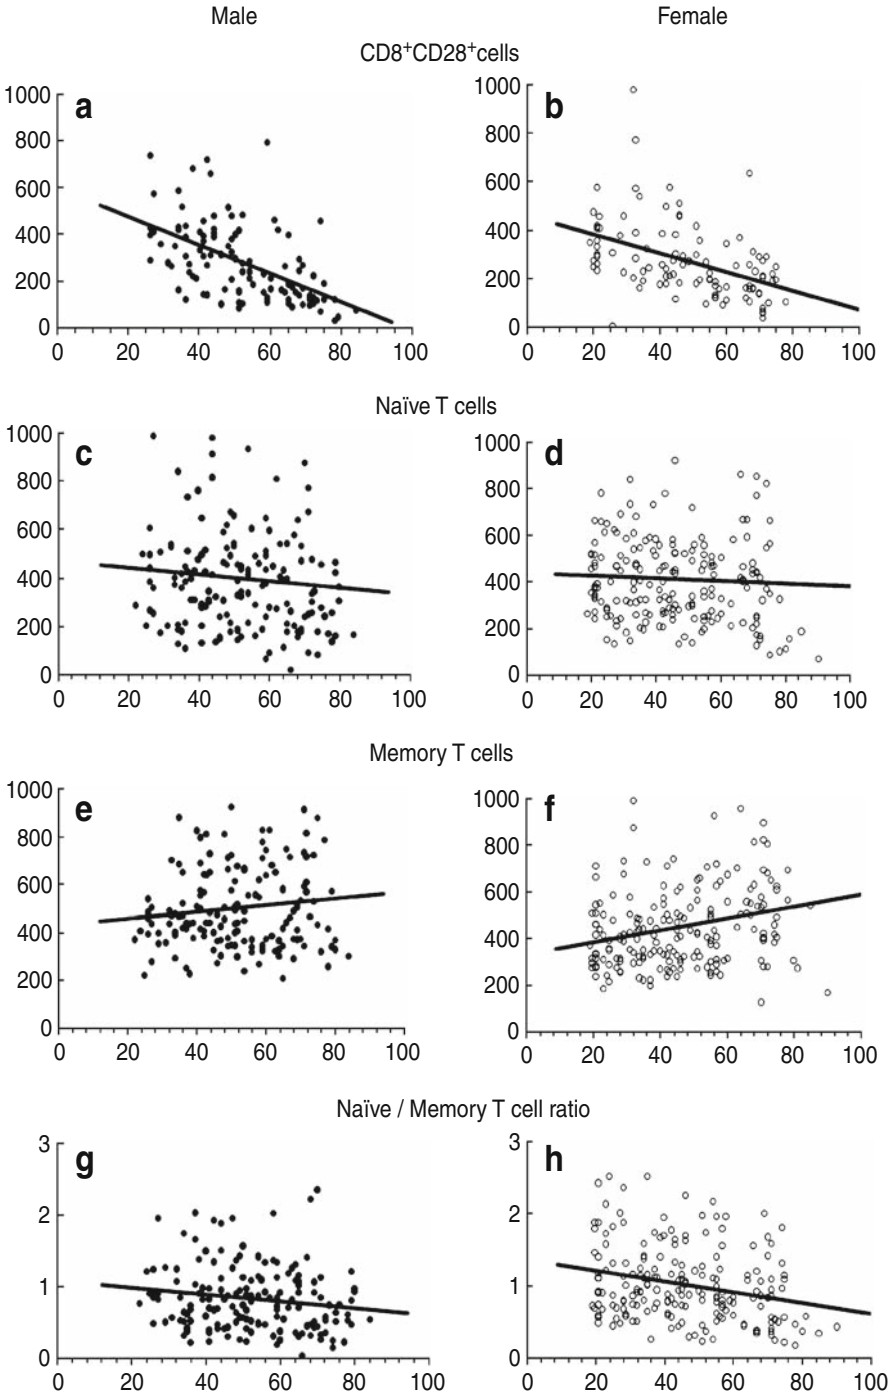

Fig. 3 Age related changes in the number of $CD8^+CD28^+$ T-cells in males (a) and females (b), naive T-cells in males (c) and females (d), memory T-cells in males (e) and females (f), and native to memory T-cells (N/M) ratio in males (g) and females (h)

(h) Ratio of naïve to memory T-cells.

The naïve to memory T-cells (N/M) ratio showed an age-related decrease in both males (p <0.0001) and females (p <0.0003), and this decrease was statistically significant (Fig. 3g and 3h). However, no significant gender difference was observed (Table 3).

(i) $CD4^+CD25^+$ T-cells.

The number of $CD4^+CD25^+$ T-cells showed an increasing trend with age in both males (0.7502) and females (0.1818) (Fig. 4a and 4b), but this increase was statistically not significant. Further, no gender difference was observed (Table 3).

(j) $CD20^+$ B-cells.

The number of $CD20^+$ B-cells showed a decrease with age in males ($p < 0.05$) and showed a decreasing trend with age in females (p =0.15) (Fig. 4c and 4d); no statistically significant difference was observed between males and females with regard to this decrease ($p < 0.001$) (Table 3).

(k) $CD56^+CD16^+$ NK-cells.

The number of $CD56^+CD16^+$ NK-cells showed an age-related increase in females (p <0.0002) and an increasing trend with age in males (p=0.19) (Fig. 4e and 4f). A statistically significant gender difference was observed (p <0.001) (Table 3).

3.3 Proliferative Response of T-cells

(a) Proliferative response of T-cells by anti-CD3 monoclonal antibody ($MTS\text{-}OD_{490}$).

The proliferative response of T-cells was measured by MTS method and was expressed as OD_{490}. It showed an age-related decrease in both males (p<0.0001) and females (p<0.002) (Fig. 5a and 5b), but no gender difference was observed.

(b) T-cell proliferation index (TCPI).

The TCPI showed an age-related decrease in both males ($p < 0.0002$) and females (p <0.008) (Fig. 5c and 5d). The decrease was more pronounced in males than in females ($p < 0.01$) (Table 3).

(c) Correlation between $CD8^+CD28^+$ T-cells and T-cell proliferative response ($MTS\text{-}OD_{490}$).

The number of $CD8^+CD28^+$ T-cells and $MTS\text{-}OD_{490}$ showed an age-related decease in both males and females; this decrease was statistically significant. It is interesting to note that a good correlation was observed between the number of $CD8^+CD28^+$ T-cells and $MTS\text{-}OD_{490}$ (Fig. 4g and 4h).

3.4 Scoring of Immunological Vigor (SIV)

(a) SIV-7.

SIV-7 was calculated based on 7 parameters: T-cells number, TCPI, CD4/CD8 ratio, naïve T-cell number, naive/memory T-cells ratio, B-cell number and NK-cell number.

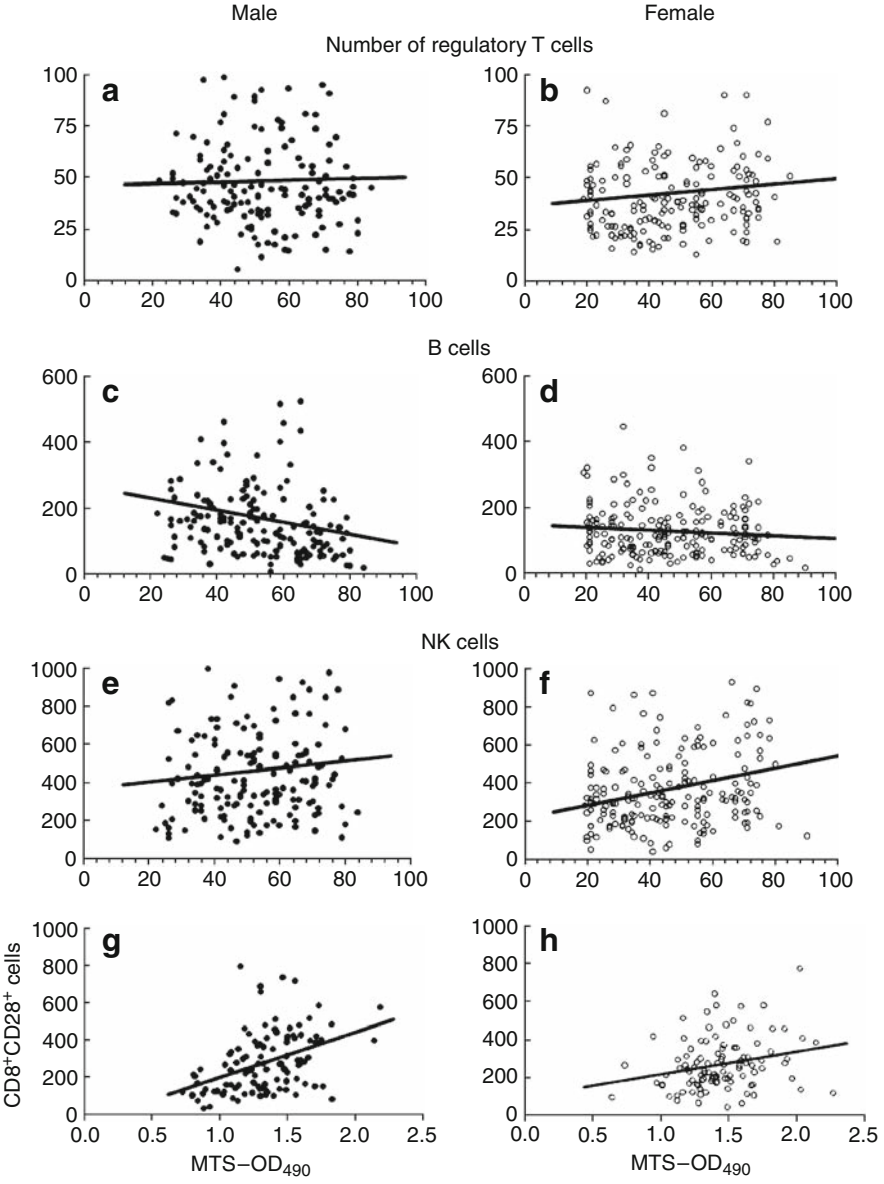

Fig. 4 Age related changes in the number of regulatory T-cells in males (a) and females (b), B-cells (WBC) in males (c) and females (d), NK-cells in males (e) and females (f), and the correlation between the number of $CD8^+CD28^+$ T-cells and the T-cell proliferative response (MTS-OD490) in males (g) and females (h)

SIV-7 showed an age-related decrease in both males ($p < 0.0005$) and females ($p < 0.0002$) (Fig. 5e and 5f). No gender difference was observed (Table 3).

(b) SIV-5.

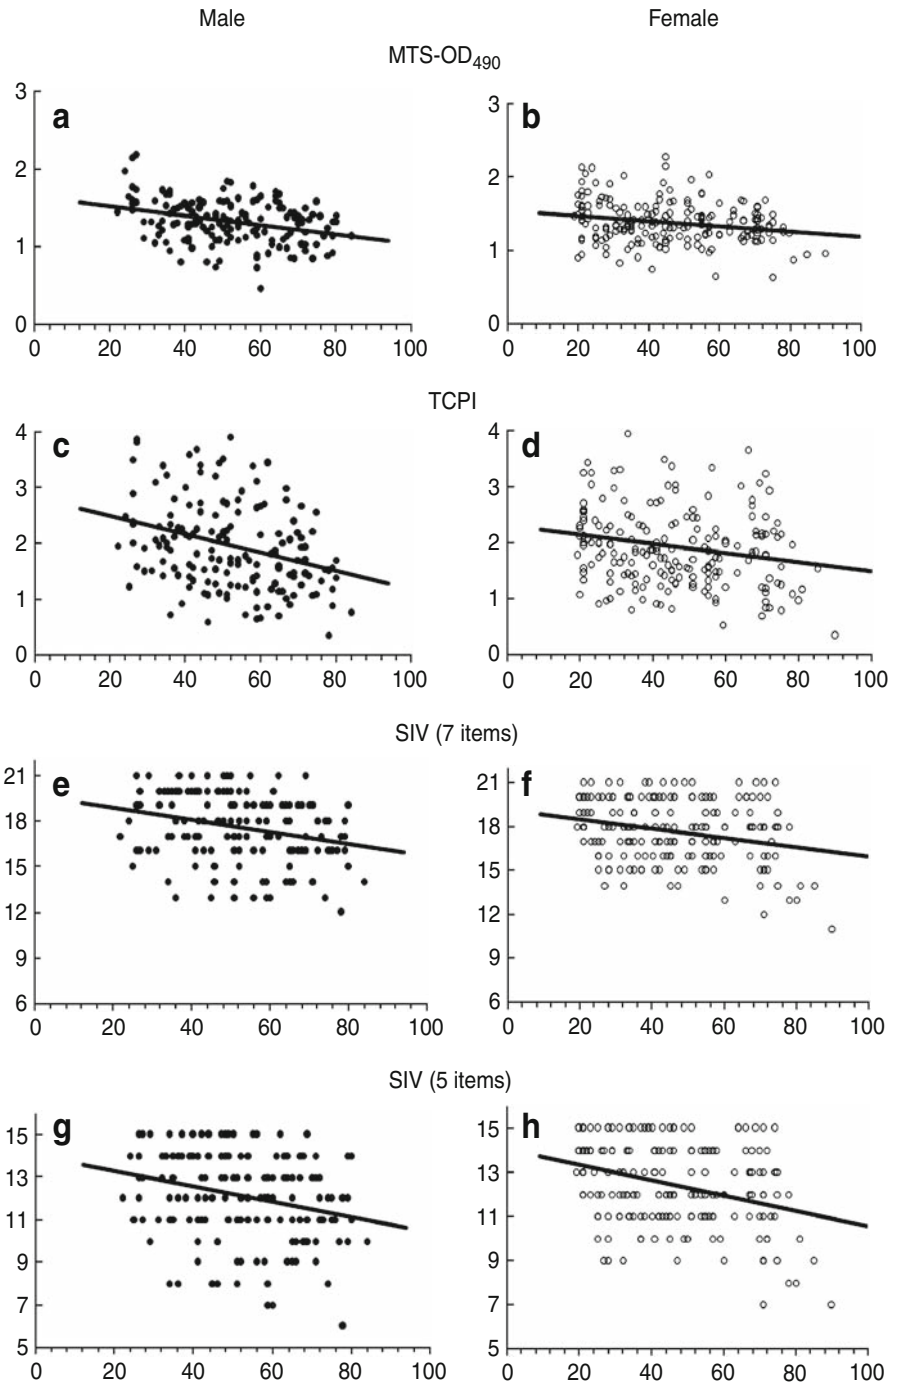

Fig. 5 Age-related change in the T-cells proliferative response (MTS-OD490) in males (a) and females (b), T-cell proliferation index (TCPI) in males (c) and females (d), score of immunological vigor (SIV)-7 in males (e) and females (f), and SIV-5 (T-cell immune score) in males (g) and females (h)

Table 4 Regression analysis on cytokine productions and age in males and females

*R: Correlation coefficient. [#] SMA: Standardized Major Axis Test. NS: Not significant.

SIV-5 was calculated by using 5 parameters: T-cells number, TCPI, CD4/CD8 ratio, naïve T-cell number, and naive/memory T-cells ratio; SIV-5 is sometimes termed as T-cell immune score.

The T-cell immune score showed an age-related decrease in both males ($p < 0.001$) and females ($p < 0.0001$) (Fig. 5g and 5h). A more pronounced decrease was observed in males than in female ($p < 0.02$) (Table 3).

3.5 Cytokine Production

In the present study, lymphocytes were cultured in vitro in the presence of immobilized anti-CD3 mAb and the cytokines produced in the supernatant were assessed as described previously. The subjects for cytokine production comprised 64 males and 49 females; this sample size was not adequate for statistical analysis. This preliminary examination has revealed that an age related decrease in the levels of IFNγ, IL-1β, IL-2, IL-4, IL-5, IL-6, IL-10, TNFα and TNFβ in both male and female subjects. In contrast, an age-related increase was observed in IL-8 (Table 4).

3.6 Difference in Gender

Table 3 lists the regression curves calculated for the data described above, and the significance of gender difference was examined by standardized major axis test (SMA) analysis.

The rate of decrease in the number of T-cells, naïve T-cells, and $CD8^+CD28^+$ cells; T-cell proliferation index (TCPI), SIV-5 parameters was slower in females than in males. Further, this difference was statistically significant ($p < 0.05 – 0.003$). The

Table 5 Gender difference in people over 60 years old

	Male over 60 years N=54	Female over 60 years N=48
T-cells (number/mm^3)	1365 ± 53	1395 ± 73
CD4$^+$ T cells (number/mm^3)	910 ± 59	961 ± 55
T-cell proliferation index	1.72 ± 0.11	1.87 ± 0.12
SIV-5 (T-cell immune score)	11.6 ± 0.3	11.7 ± 0.3
CD8$^+$CD28$^+$ (number/mm^3)	181 ± 19	200 ± 20

rate of increase in the number of CD4$^+$ T-cells was greater in females than in males and a statistically significant difference was observed between males and females ($p < 0.005$). In other words, the slower rate of decline or the greater rate of increase in these parameters may indicate that the immunological functions are relatively well preserved in elderly females than in elderly males; this finding may be consistent with the fact that women survive for longer periods than men. Table 5 shows the values of these immunological parameters in elderly males and females over 60 years of age. All parameters show higher values in elderly females than in males; however, the difference is statistically not significant because of the small sample size.

4 Discussion

In 1992, we reported age-related change in subpopulations of lymphocytes in healthy subjects ranging in age from 6 to 102 years (Utsuyama et al. 1992). In the present study, we confirmed most of the results presented in our previous report; i.e., an age-related decrease in CD3$^+$ T-cells, more pronounced decrease in CD8$^+$ T-cells than in CD4$^+$ T-cells, an age-related increase in CD4/CD8 ratio, a decrease in the number of naïve T-cells with a concomitant increase in memory T-cells, a decrease in B-cells and an increase in NK-cells.

In the present study, we examined the proliferative activity of T-cells and confirmed that it gradually declines with advancing age. In addition, we developed a new parameter, T-cell proliferation index (TCPI), which is calculated by using the proliferative activity and the number of T-cells. TCPI was also observed to significantly decrease with age.

It is interesting to note that the rate of decline in the studied parameters differed with gender. The rate of decline in the number of T-cells calculated by the regression curve was -6.150 in males and -2.390 in females. The rate of decline in TCPI was -0.016 in males and -0.008 in females. This gender difference in the T-cells and TCPI vales was statistically significant (Table 3). A relatively gradual decrease in the studied parameters in females than in males may be consistent with the fact that women survive for longer period than men in Japan.

A low number of CD8$^+$CD28- T-cells and high CD4/CD8 ratio are associated with populations that survive until the age of 100 years (Strindhall et al. 2007). Susceptibility to influenza infection in older adults is associated with an increased population of CD8$^+$CD28- T-cells (Xie, McElhaney 2007). In this respect, we confirmed that the number of CD8$^+$CD28$^+$ cells decreased with age and this decrease

was associated with a decrease in the T-cell proliferative response (MTS-OD_{490}); i.e., the rate of decline was significantly slower in females than in males.

The absolute number of total B-lymphocytes increases about 3-fold from the base line in the first year of life and progressively decreases until adult age (Veneri et al. 2007). We further confirmed that the number of B-cells continued to gradually decrease throughout the life and decline was significantly steeper in males than in females.

It is still not clear whether the age-related increase in the prevalence of $CD4^+CD25$(high) regulatory T-cells (TREGs) is responsible for immune dysfunction in the elderly (Dejaco et al. 2006). In this respect, we found that the number of TREGs showed an increasing trend with age.

An age-related increase was observed in the number of NK-cells and this rate of increase was significantly steeper in females than in males. In this respect, Lee et al. (1996) reported that higher percentage of NK-cells in the Asian population than in Caucasian subjects.

Olsson et al. (2000) reported that a decrease in the CD4/CD8 ratio was an important indicator of the immune risk phenotype (IRP). In the present survey, a contrasting feature was observed between $CD4^+$T-cells and $CD8^+$T-cells. The number of $CD4^+$ T-cells was relatively steady level or showed an increasing trend with age, while the number of $CD8^+$ T-cells significantly decreased with age; therefore, the CD4/CD8 ratio showed a distinct age-related increase. Higher percentage and number of $CD8^+$ T-cells and a decreased CD4/CD8 ratio was observed in the Saudi male population compared with Caucasian controls (Shababuddin 1995). Hence, racial difference should be considered in this case.

Anti-CD3 stimulation of T-lymphocytes significantly increased IL-8 production and this increase was more evident in the nonagenarian subjects (Mariani E et al. 2001). Centenarians showed high level of IL-8, indicating that an increased level of IL-8 is related to longevity (Wieczorowska-Tobis et al. 2006). These reports were consistent with the result of the present study indicating an age-related increase in IL-8.

Individuals who are genetically predisposed to produce high level of IL-6 have a reduced capacity to reach the extreme limits of the human lifespan. On the other hand, a high IL-10 producing genotype is observed among centenarians (Caruso C et al. 2004). These results were partly consistent with those of the present study, which showed that both IL-6 and IL-10 decreased with age. In future studies, an adequate sample size should be selected for analysis of cytokine production.

TCE	T-cell clonal expansions

Abstract: Age-related T-cell clonal expansions (TCE) are an incompletely understood disturbance in T-cell homeostasis found frequently in old humans and experimental animals. These accumulations of CD8 T-cells have the potential to distort T-cell population balance and reduce T-cell repertoire diversity above and beyond the changes seen in the aging of T-cell pool in the absence of TCE. This chapter discusses our current knowledge of the role of these expansions in health and disease, with a special focus on their influence upon immune defense against infectious diseases.

T. Fulop et al. (eds.), *Handbook on Immunosenescence*,
DOI 10.1007/ 978-1-4020-9062-2_12,

1 Introduction

As was extensively discussed in other chapters of this handbook, immunosenescence encompasses a number of diverse age-related cellular and extracellular milieu changes that affect cells and molecules of the immune and inflammatory system. The very definition of immunosenescence, however, operationally includes not only the decline of immunity with age by itself, but also its most important clinical manifestation, the increased susceptibility to infection and decreased immunosurveillance of cancer. Other factors can contribute to the increased exposure to infectious diseases and increased colonization with infectious pathogens (e.g., reduced barrier function of skin and mucosal membranes) with age, and multiple factors certainly strongly contribute to the age-related increase in incidence of cancer. However, it is clear that the inability to mount rapid and vigorous immune defense once an infectious invasion (and, likely, detectable malignant transformation) had occurred lies at the heart of many of the clinical manifestations of immunosenescence. Due to the involvement of numerous other nonimmunological factors in the age-related increase of cancer-related morbidity and mortality, this review will solely deal with infectious diseases.

It has long been known that aging is accompanied by an increase in mortality and morbidity from a number of common respiratory infections such as influenza (20,000–40,000 annual deaths in the USA alone) (Bender 2003; Betts and Treanor 2000; Couch et al. 1986; Glezen and Couch 2003; High 2004; Yoshikawa 2000), pneumococcal pneumonia (Bender 2003; High et al. 2005; Yoshikawa 2000) and RSV (Glezen and Couch 2003; High et al. 2005; Yoshikawa 2000), and urinary infections (Bender 2003; Hazelett et al. 2006). Moreover, this vulnerability extends to dangerous established pathogens such as variola (Hanna 1913) as well as the newly emerging pathogens that disproportionally affect the elderly such as the West Nile virus (Murray et al. 2006) the Severe Acute Respiratory Syndrome-causing Coronavirus (SARS-CoV) (Chan et al. 2007; Leung et al. 2004) and others.

Several types of age-related defects in the immune function can contribute to this increased susceptibility to infection, including defects in innate immunity, antigen uptake, processing and presentation, provision of second and third signals to the adaptive immune system and impaired humoral immunity, all of which are competently covered in other chapters of this handbook. However, T-cells have been known to exhibit some of the most pronounced age-related defects (Miller 1996), and intervention to correct these defects resulted in successful correction of the immune function in a number of cases (Effros et al. 1991; Haynes et al. 2004; Haynes et al. 1999; Messaoudi et al. 2006a). These defects can be grossly divided into cell-autonomous defects, which affect T-cells regardless of age-related or compensatory alterations that affect other components of the immune system and which can be detected in assays where T-cells are the only component of the immune system affected by aging; and age-related changes in the T-cell population balance, which mostly involve the initial loss of naïve T-cells and the compensatory, reactive changes aimed to maintain T-cell homeostasis in the face of this loss.

This chapter will focus upon the latter changes, given that other aspects of T-cell dysfunction will be covered in other chapters of this volume. Moreover, we will discuss the impact of a specific type of age-related T-cell disturbances, T-cell clonal expansions (TCE) (Callahan et al. 1993; Hingorani et al. 1993a; Posnett et al. 1994), upon immune defense and pathogen resistance, highlighting the extent and the limits of our current knowledge, and the tasks and problems that need to be solved before we can fully understand and treat these disturbances.

2 T-cell Homeostasis and Development of T-cell Clonal Expansions (TCE)

The current evidence strongly suggests that the involution of the thymus and the decline in production of new naïve T-cells are the initiating factors behind the generation of at least some TCE (Messaoudi et al. 2006b), whereas latent persistent viral infections may be the perpetrators driving other types of TCE (Pawelec et al. 2004). Moreover, homeostatic mechanisms that are activated as a consequence of naïve T-cell loss may themselves participate in the onset and/or maintenance of TCE (Messaoudi et al. 2006b, 2006c). Therefore, at the risk of being redundant, we will very briefly review thymic T-cell production, involution, latent persistent infections and T-cell homeostasis. For a more detailed review of these topics, the reader is encouraged to read sections of this handbook devoted to thymic involution, as well as the recent volume of Seminars in Immunology devoted to T-cell rejuvenation (Nikolich-Žugich 2007; Zuniga-Pflucker and van den Brink 2007).

2.1 Homeostatic Maintenance of T–cell Subsets

T-cell homeostasis is defined here as maintenance of naïve and memory T-cell pool numbers and diversity and the ability to restore these numbers and diversity following antigenic (Ag) challenge. T-cell homeostasis is regulated by the response of T-cells to environmental trophic and survival signals and by the presence and availability of such signals. The most important and best understood of these signals are the common γ-chain cytokines (most notably IL-7, IL-15 and IL-2) and self-peptide: MHC (pMHC) complexes. The contribution of each of these signals to homeostatic maintenance varies depending on the T-cell subset.

Following maturation and selection in the thymus, new T-cells are released into the periphery as recent thymic emigrants (RTEs) (Scollay et al. 1980). Release of RTEs bearing a variety of randomly rearranged TCRs ensures the diversity of the peripheral T-cell pool. Once released from the thymus, the RTE join the naïve T-cell pool. Naïve T-cells have no preset life spans and are maintained by IL-7 and trophic signals from interaction of their TCR with self-p:MHC complexes (rev. in (Lee and Surh 2005). When these two signals are present, naïve T-cells are believed to be

able to survive indefinitely, based upon the results of serial transfer experiments (Sprent et al. 1991). Murine RTE proliferate faster than naïve peripheral T-cells in the first three weeks after export, perhaps in order to maximize naïve T-cell diversity, before they equilibrate with other naïve T-cells (Berzins et al. 1998). Naïve T-cells display very low levels of spontaneous (or homeostatic) cycling in vivo. Homeostatic cycling is greatly increased in lymphopenia, where T-cells sense a signal, most likely provided by an excess of unused IL-7 and IL-15 (Surh and Sprent 2002). Under lymphopenic conditions T-cells undergo Ag-independent homeostatic proliferative expansion (HPE), in a seeming attempt to fill the empty compartment (Fry and Mackall 2005; Surh et al. 2006). Unlike naïve T-cells, memory T-cells do not require specific p: MHC contact for survival. Instead, their survival is dependent on continued homeostatic proliferation, driven mainly by IL-15, or by IL-7 in the absence of IL-15. Memory cells cycle and self-renew in vivo significantly (up to four times) faster than naïve T-cells and also exhibit faster proliferation during lymphopenia (Surh et al. 2006). It is likely that there may be other, presently unknown pathways regulating T-cell homeostasis, some of which could include energy metabolism regulation (Frauwirth and Thompson 2004).

The above described homeostatic mechanisms function to maintain a balanced and diverse T-cell pool. Over lifetime this means regulating the process of Ag-driven expansion of naïve T-cells, their contraction, and selection and maintenance of memory T-cells. The role of the homeostatic mechanisms is to balance the composition of the T-cell pool so that it contains both naïve precursors with diverse TCRs, as well as Ag-experienced memory T-cells, as both of these subsets are crucial for the health of the host. The homeostatic forces work very efficiently in adult mice housed under specific pathogen free (SPF) conditions, as evidenced by remarkably similar size and diversity of the T-cell pool among individual mice of the same strain. However, maintenance of homeostasis becomes more complicated in the face of constant encounters with new acute pathogens, long-term interactions with persistent pathogens and the aging-associated defects, all of which are discussed below.

2.2 Disruption of T-cell Homeostasis in Ageing

Thymic involution begins soon after birth in humans and quickly after puberty in mice, which results in decreased RTE output (Haynes et al. 2000; Hirokawa and Utsuyama 1984). Thus, 22-mo-old mice receive less than 10% of RTE compared to young adult mice (Hale et al. 2006; Heng et al. 2005). Even in old age the thymus continues to produce RTE proportionally to its overall cellularity, but as the cellularity itself decreases, so does the output (Gruver et al. 2007; Hale et al. 2006). The cause of thymic involution is discussed in more detail elsewhere in this volume. From the standpoint of this chapter, thymic involution presents a challenge for the homeostatic mechanisms, which strive to maintain the size and diversity of the peripheral T-cell pool in the face of decreased influx of diverse new T-cells.

Despite the fact that thymus involution begins early in life, it is only in old age that homeostatic mechanisms falter and allow dysbalance amongst T-cell subsets.

A marked difference between the adult and old lymphocyte T-cell compartment is an age-related decrease in representation of naïve phenotype T-cells and concomitant increase in frequency and numbers of memory phenotype T-cells. The exact mechanisms leading to this population shift were not formally dissected, but are believed to likely involve a combination of 1) decrease in naïve T-cell production, 2) their conversion into effector or memory cells as a result of encounters with pathogens, and 3) changes in the environment, including the availability of homeostatic cytokines (IL-7, IL-15, IL-2). For example, IL-2 production by CD4 T-cells is decreased in old mice(Gillis et al. 1981; Miller and Stutman 1981; Thoman and Weigle 1981). Less is known about age-related changes in IL-7 or IL-15 levels or the expression and function of their receptors on different T-cell subsets. In addition, the naïve T-cell pool could be indirectly affected by a growing pool of memory T-cells that may compete with naïve T-cells. Considering that there is some overlap in the use of survival and maintenance cytokines by these two pools, particularly in case of IL-7(Fry, Mackall 2005; Tan et al. 2002), it is possible that the two are not always independently regulated, particularly in aging where there is many fewer naïve T-cells. Thus, if naïve T-cells continue to decrease in number, this may lead to an excess of survival and maintenance cytokines which normally would have been consumed by naïve T-cells. This could trigger homeostatic proliferative expansion (HPE) of the remaining naïve T-cells and drive their conversion to memory-phenotype. This was demonstrated in mice under lymphopenic conditions (Cho et al. 2000; Goldrath et al. 2000), and strongly suggestive results were also obtained in aging monkeys (Cicin-Sain et al. 2007) and humans (Naylor et al. 2005).

2.3 T-cell Clonal Expansions (TCE)

One of the hallmarks of immune aging is loss of TCR repertoire diversity (rev. in (Nikolich-Žugich 2005)), due in large part to the dominance of memory T-cells over the naïve ones. However, on top of that reduction, the CD8 T-cell compartment often shows additional loss of diversity, in the form of large, often clonal expansions of T-cells bearing the same TCR, named T-cell clonal expansions (TCE) (Callahan et al. 1993; Hingorani et al. 1993b; Posnett et al. 1994). Development of TCEs has been documented across mammalian species, including rodents, nonhuman primates, and humans, with fractions between 30 and 60% of individuals surveyed exhibiting one or more age-associated TCE (rev. in (Nikolich-Žugich, Messaoudi 2005). More on the biology of TCE can be found in the excellent review by Clambey and Marrack elsewhere in this book. However, for the purpose of this chapter, it is most pertinent to classify TCE into at least two types with respect to the mechanism of their generation and/or maintenance. Large Ag-independent TCE (AI-TCE) are thought to arise and/or be maintained independently of antigenic stimulation, due to age-

related changes in perceiving homeostatic signals. This is based upon: (i) activation marker expression on these cells, which dominantly exhibit central memory phenotype, with no evidence of recent or repeated antigen-driven activation (Callahan et al. 1993; Ku et al. 2001; Messaoudi et al. 2006c); (ii) cytokine receptor, specifically IL-7R and IL-15R, expression, which is higher on these cells compared to other memory or naïve T-cells (Messaoudi et al. 2006c); (iii) the ability of these cells to proliferate upon adoptive transfer (Ku et al. 2001), with a constant rate regardless of whether the recipient is lymphopenic or not (Messaoudi et al. 2006c); and (iv) the ability of manipulations that induce lymphopenia to increase the incidence and accelerate the onset of development of AI-TCE (Messaoudi et al. 2006b). While these results have been obtained in mice, there is evidence that similar fundamental principles are at work in primates, including humans (Cicin-Sain et al. 2007; Naylor et al. 2005). In contrast, TCE that have general characteristics consistent with the response to antigen, also called Ag-reactive TCE (AR-TCE), were linked to latent persistent herpesviral infections in mice (Holtappels et al. 2000; Karrer et al. 2003; Podlech et al. 2000) and humans (Almanzar et al. 2005; Fletcher et al. 2005; Ouyang et al. 2003c; Pawelec et al. 2004). Broad discussion of these virus-related abnormalities is also presented in other chapters of this handbook.

TCE can occupy up to 90% of the total murine and up to 50% of the human memory CD8 T-cell pool. TCE themselves are not malignant and do not affect the overall size of the CD8 T-cell pool (there is no increase in total T-cell numbers in individuals carrying TCE). However, TCE do disturb T-cell homeostasis and diversity (Callahan et al. 1993; LeMaoult et al. 2000; Posnett et al. 1994) and a drastic disturbance of this type can be expected to impair the ability to mount T-cell responses. While T-cell responses are plastic, with a significant reserve that allows T-cells to respond to pathogens despite loss of much of the repertoire, this plasticity is not unlimited (rev. in (Nikolich-Žugich et al. 2004). However, we still do not have precise quantitative understanding of limits of T-cell diversity necessary to mount protective responses against pathogenic challenge, an issue highly relevant from the standpoint of evaluating the impact of TCE upon immune defense.

3 Impact of TCE on Pathogen Resistance—the Mouse Model

The most important question related to the presence of TCE is related to their impact upon the health of the organism. One could envision several possibilities in that regard. First, TCE could be neutral and not impact the overall health or the immune defense of the old organism. While this possibility is intellectually unexciting, it is likely that many TCE coexist with the state of health based on their high incidence in asymptomatic individuals (Hingorani et al. 1993b; Posnett et al. 1994). Indeed, it is likely that a TCE needs to grow to a certain size before it becomes a problem for its bearer. Second, TCE could affect other components of the organism, without impacting immune defense. While this is possible, this scenario had not been

documented so far and will not be further discussed here. Third, TCE could have an active effect, whereby they would secrete cytokines and other short-acting mediators that could alter the function of other components of the immune (and other) systems in the body. This would be akin to the functional shift seen in replicatively senescent fibroblasts, which upon cessation of replication drastically change their secretory properties and have the potential to alter extracellular matrix, neovascularization and other microenvironmental properties (rev. in (Campisi 2002). At the present, there is some evidence in support of this possibility (Ortiz-Suarez and Miller 2002; Ortiz-Suarez and Miller 2003), but more precise studies at the level of isolated, highly purified TCE are needed. Moreover, the impact of the observed changes upon pathogen resistance remains untested.

Finally, the role of TCE could be passive, but nevertheless negative. Under that scenario, which was invoked by immunologists before (Callahan et al. 1993; Hingorani et al. 1993a; Posnett 1994 #1976), and which will be discussed in more detail as it currently appears the most likely, these accumulating T-cell clones would constrict the repertoire and reduce the useful T-cell repertoire that defends us against new infection. Mechanistically, this would most likely occur by these cells gaining a survival/maintenance advantage over other T-cells in the body. The fact that TCE which occur spontaneously in SPF mice express high levels of IL-7Rα and IL-2/15Rβ (Messaoudi et al. 2006c) is consistent with the possibility that TCE operate as IL-7 and/or IL-15 "cytokine sinks", taking them slowly away from other T-cells. Consistent with that, we (Lang et al. submitted) and others (Ely et al., 2007) have recently found that often TCE can arise from the pool of cells that respond(ed) to prior acute or latent infection. Of interest, once these cells begin to significantly expand in old age, they tend to acquire high levels of IL-7 and IL-15 receptors (Lang et al. submitted), raising the possibility that the "cytokine sink" may be the unifying mechanism by which both "spontaneous" and antigen-specific large TCE constrict the remainder of useful T-cell repertoire. In fact, it is likely that the "spontaneous" TCE designation simply covers up the fact that we don't know the original antigen that was recognized by these cells, and that may be irrelevant if indeed these cells primarily respond to cytokines once they become TCE.

In order for a TCE to have a demonstrably negative effect upon immune defense via TCR repertoire constriction, such a TCE needs to sufficiently erode the numbers and diversity of other T cells needed to respond to a new pathogen. Numerous studies have shown that manipulations which take away up to half or more of TCR diversity are reasonably compatible with T-cell responsiveness (rev. in (Nikolich-Žugich et al. 2004). However, in other models losses of this or greater magnitude have been shown to impair responsiveness to certain antigens (rev in. (Nikolich-Žugich et al. 2004) and references therein). In terms of the impact of TCE upon the residual diversity of aged naïve T- cells in relationship to immune defense against infectious diseases, it is important to consider the overall diversity and overall numbers of T-cells involved in a typical response to a pathogen. Exciting new studies with direct measuring of precursor T-cell frequencies concur that on the average a hundred, and in some cases as few as 15-20 CD4 or CD8 T-cells may

be responding to a single epitope (Badovinac et al. 2007; Moon et al. 2007). Even if this is an underestimation, reducing that number by 90%, or even by half, due to the presence of a TCE, certainly has the potential to diminish and cripple the response to epitopes where few T-cell precursors exist. This low responsiveness would be further compounded by an already diminished overall reserve of naïve T-cells in aging, as well as by the blunted T-cell signaling (Tamir et al. 2000). On the other hand, most pathogens present multiple epitopes to the immune system, and even if one accounts for immunodominance, usually a handful of epitopes are available for T-cell stimulation. Moreover, in many cases other arms of the immune system will synergize to provide protection even if T-cell responses are diminished. Thus, for a TCE to impact pathogen resistance, T-cells have to provide primary and nonredundant protection against that pathogen, the pathogen should have few, rather than many, immunodominant and protective epitopes and frequency of T-cells specific for these epitopes should be low. In the one case where the impact of TCE upon immune defense was tested (Messaoudi et al. 2004), most, if not all, of the above conditions were met. In that study, resistance to herpes simplex virus (HSV-1) was studied in B6 mice, where an octamer derived from the glycoprotein B accounts for > 90% of the total CD8 T-cell response (Dyall et al. 2000; Messaoudi 2001 #1644; Wallace et al. 1999). Moreover, the response itself is highly restricted with regard to TCRV region utilization (with Vβ10 and 8 contributing >80% of the response (Cose et al. 1995)). Old animals with and without TCE were challenged with HSV and magnitude and functional characteristics of the response measured. It was found that TCE could impair the generation of productive responses in a selective manner. So, when an animal contained a large TCE which expressed Vβ10 and 8, it was unable to mount a response to HSV gB, whereas TCE expressing other TCR Vβ segments did not impair responsiveness beyond the reduction seen due to age in a littermate control group (Messaoudi et al. 2004). These results were somewhat puzzling and suggested that TCE preferentially competed out against the T-cells bearing the same TCRVβ segment. This could be explained, for example, if TCRVβ residues conserved within the Vβ family but differing between Vβ families (e.g. CDR1 & 2 and "framework" parts of CDR3) were important in contacting self-pMHC complexes in the course of trophic interactions needed for T-cell maintenance, so that a TCE would compete out naïve T-cells of the same TCRVβ family. Such a mechanism remains to be substantiated. Nevertheless, the above study (Messaoudi et al. 2004) does show that TCE can potentially impair protective immunity.

While the above experiments were performed with spontaneously arising TCE, which were most likely AI-TCE, there is no reason to believe that a similar situation may not exist with AR-TCE as well. Our group is in the process of testing this possibility. Another unaddressed question relates to the impact of TCE upon memory responses. Memory T-cells are more difficult to compete out than naïve T-cells, possibly due to their ability for self-renewal and relative resistance to apoptosis. Perhaps the most pertinent question is whether TCE can affect the response to latent and/or chronic persistent pathogens, where a large fraction of the immune system is periodically or continuously stimulated by these pathogens. At the present, this issue remains unresolved.

4 Impact of TCE on Pathogen Resistance—Evidence from Humans

In reviewing the known impact of TCEs on pathogen resistance, one needs to distinguish between two parameters: 1) correlation of presence of TCE with presence of other immunological factors known to impair immune responses, and 2) direct evidence for impact of TCE on pathogen resistance. The occurrence of TCEs has been well documented in patients and in a variety of animal models, so we shall first review that scenario. One should bear in mind, however, that it is often difficult to distinguish the specific effect of TCE from the effects of old age-associated defects in antipathogen immunity, since in most cases TCEs are detected only in advanced age. It is therefore most appropriate to evaluate TCE as a superimposing, possibly aggravating factor that may, or may not, further impair protective immunity in an already suboptimal setting of an old organism.

Some TCEs have known antigenic specificity. Two types of conclusions on the effects of these TCEs on pathogen resistance can be drawn: 1) effect upon resistance to the pathogen the TCE is specific for, and 2) effect upon resistance to unrelated pathogens. In humans, the most commonly documented cases of TCEs of known specificity involve memory CD8 T-cells specific for CMV (rev. in (Pawelec et al. 2004)) and, to a lesser extent, EBV (Ouyang et al. 2003b). Original studies documented the presence of $CD28^{-}$ $CD8^{+}$ TCEs in elderly patients (Hingorani et al. 1993b; Posnett et al. 1994). With the advent of tetramers and intracellular cytokine staining techniques that allowed enumeration of Ag-specific T-cells, it was shown that the CD28- CD8 T-cell expansions were frequently specific for CMV and were clonal or oligoclonal in nature (Ouyang et al. 2002). Moreover, longitudinal studies in the Swedish elderly cohorts concluded that CMV seropositivity, together with an array of additional immune characteristics such as the inverted CD4:CD8 ratio and poor proliferative responses of T-cells to mitogens, constitute an immune risk phenotype (IRP, discussed in detail elsewhere in this book) (Wikby et al. 2005), which predicted mortality within 2 years in octogenerians of the Swedish cohort (Hadrup et al. 2006). It will be important to reproduce these results in genetically diverse populations of the elderly, particularly in light of early reports that the elderly from West Sicily may not show the same effect (Colonna-Romano et al. 2007). Moreover, it is not clear exactly how the presence of CMV-specific TCE might affect pathogen resistance, in isolation from the other IRP-associated defects, highlighting one of the problems inherent to the otherwise highly informative human longitudinal studies.

At the present, there is some evidence that CMV-specific T-cells may themselves be compromised as a direct result of development of TCE. Several studies demonstrated accumulation of dysfunctional CMV-specific memory CD8 T-cells in the elderly (Ouyang et al. 2003a; Ouyang et al. 2003c; Ouyang et al. 2004). In addition, the large CMV-specific memory cell population expressed a marker of replicative senescence, KLRG-1, and its expression correlated with decreased production of IFNγ upon antigenic stimulation (Ouyang et al. 2004). The key question is whether this leads to inability to mount an adequate functional response to viral reactivation, permitting viral replication above the subclinical level normally associated with

CMV seropositivity. In that regard, one study (Stowe et al. 2007) demonstrated the presence of CMV and EBV DNA in urine (CMV) and blood (EBV) of elderly patients, as opposed to the seropositive adults, implying some loss of control of viral reactivation in the elderly. Consistent with that explanation, these authors also found elevated expression of lytic and latent EBV genes in blood of elderly but not adult seropositive patients (Stowe et al. 2007). It is possible that accumulation of dysfunctional CMV- or EBV-specific TCE, which were unable to control the virus, may be the reason for increase in viral reactivation in aging. However, in that study, the elderly actually had an elevated frequency of IFNγ-producing CMV- and EBV-specific memory CD8 T-cells, making the hypothesis unlikely. Moreover, CMV-mediated disease does not seem to be associated with aging in the absence of iatrogenic or acquired immune suppression, suggesting that a manifest loss of CMV control does not occur in the elderly. Further studies are needed to decisively address the role of accumulation of dysfunctional CMV-specific TCEs on the persistent latent Herpes virus control in old age.

A separate issue is whether CMV-specific TCE affect immunity to other infections in humans, and how. There is some evidence that presence of CMV-specific TCE is associated with lower frequency of memory CD8 T-cells specific for coresident EBV infection (Khan et al. 2004). This study did not examine whether control of latent EBV in patients with large CMV-specific TCE is impaired. While one could speculate that the T-cell response, and therefore immunity to EBV will be compromised in patients with large CMV-specific TCE similar to the results seen in mice with the effect of spontaneous TCE upon HSV immunity (Messaoudi et al. 2004), the mechanism by which these TCE affect the size of the EBV memory CD8 T-cell pool is currently unknown.

Since many of the TCEs identified in humans are specific for CMV, it was proposed that CMV is the main driver behind generation of TCEs (Pawelec et al. 2004). While this may be the case, evidence from murine studies suggests that virus-specific TCE can also develop independently from ongoing antigenic stimulation. Ely et al. (Ely et al. 2007) detected presence of TCE specific for Sendai virus and flu in old mice that had been infected as adults. Similarly, we have found that old mice infected with WNV at a young age developed expansions of virus-specific memory CD8 T-cells in old age (A Lang et al. submitted). In a different infection model, we found that following localized (ocular) HSV-1 infection, mice develop expansions of HSV-specific memory CD8 T-cells once they reach old age. This process was unlikely to be caused by viral reactivation, as mice treated continuously with antiviral drugs also developed these age-associated T-cell expansions. At present, only a small number of these antigen-independent age-associated expansions were confirmed to be clonal, with oligoclonality being seen more often (A Lang et al. submitted). Unlike is the case with CMV-specific TCEs, the T-cell expansions that developed independently from ongoing antigenic stimulation were fully functional, showing excellent correlation of percentage of tetramer$^+$ and IFNγ$^+$ cells (A Lang et al. submitted). Therefore, it is not likely that development of TCEs by this mechanism will affect immunity to the cognate pathogen. Additional studies will be required to determine whether TCEs can develop from

preexisting memory CD8 T-cells specific for nonpersisting pathogens in elderly humans, as they do in old mice.

Are these TCE impairing productive immunity in humans? Of interest, the number of influenza-specific memory CD8 T-cells was shown to decline with age in humans (Goronzy et al. 2001). This phenomenon was independent of the patients' CMV status. In another study of success of flu vaccination in CMV-seropositive patients, CMV seropositivity correlated with impaired response to vaccination (Saurwein-Teissl et al. 2002). However, the authors did not delineate whether this correlates best to the presence of TCE, to the overall decrease in number of naïve cells or to proliferative/replicative senescence, and, as with most clinical studies, the mechanism responsible for this outcome has not been resolved. Therefore, the presence of TCE could be one of the useful biomarkers predicting poor outcome of flu vaccination (Goronzy et al. 2001; Saurwein-Teissl et al. 2002), or perhaps even general immunological vulnerability, but that requires further and rigorous verification in larger and heterogeneous populations of human subjects.

5 Concluding Remarks, Challenges and Questions

It follows from the above discussion that much remains to be learned about the biology of TCE and their precise impact upon resistance to infectious diseases. Drawing generalized conclusions about the impact of TCEs on pathogen resistance from the available data is often difficult, since they come from a number of different experimental models. At present we do not know how closely the mechanisms of generation of TCEs and their subsequent effects on pathogen resistance compare between them. However, the models and the reagents that are currently available provide good tools to systematically address the questions that still remain regarding the impact of TCEs on immunity. In particular, new quantitative tools are becoming available allowing us to precisely dissect the breadth and the reserve of T-cell receptor repertoire and the size of precursor populations specific for immunodominant epitopes of various pathogens, and that should allow us to quantitatively evaluate to what extent is TCR repertoire constricted by different types of TCE, and to determine what type of intervention (many of which are now in clinical trials (Zuniga-Pflucker, van den Brink 2007)) could be applied in individual situations.

Overall, the most important practical issues related to TCE and the infectious diseases of the elderly are:

1. Which groups of elderly are at an increased risk of infection and which are not? Are TCE a risk factor in that regard?
2. For those groups that are at risk, can they be helped with the existing vaccines or do they need alternate ways of immunostimulation? Can TCE be removed or shrunken?
3. If immunostimulation is to be attempted in a targeted manner, which modes of immunostimulation are the most efficacious? Different vaccination regimens, additional costimulation or cytokine treatments?

4. For those where immunostimulation may be insufficient, is T-cell rejuvenation the best option?

Answering these questions will undoubtedly be rewarding for scientists and physicians,as well as to the growing populations of elderly around the world.

T-cell Cycle and Immunosenescence: Role of Aging in the T-cell Proliferative Behaviour and Status Quo Maintenance

Jacek M. Witkowski

Contents

Organismal aging is affecting the performance of the immune system of mammals (including human one, being the topic of this chapter), and usually is associated with decreased ability to built adequate immune response to new and even cognate antigenic challenges on one side, and with reported increased frequency of autoimmune reactivity against own antigens [34, 61, 64] (but see the chapter by Ewa Bryl and JMW in this volume). Common manifestations of this immunological impairment are thus increased susceptibility (and more difficult curability) of infectious diseases (which in the old age become one of the most important killers despite the achievements of modern "western" medicine), as well as increased frequencies of at least certain malignancies.

The pool of T-lymphocytes, getting their name from its intrathymic period of maturation and selection after exiting the bone marrow and prior to settling in the peripheral lymphatic organs, is a variable, multifunctional and multi-phenotype group of not-so-similar cells. There is—of course—the basic subdivision into the "T-helper" or $CD4^+$ and "T cytotoxic/suppressor" $CD8^+$ lymphocytes, but this is by far a simplification. Thus, within each of the abovementioned, one would encounter first the subpopulations differing in their "life history" prior to the moment of analysis. Among them, the cells that are still "fresh" from the thymus, or had never yet encountered the antigenic epitope for which their T-cell receptors or TCRs were selected, are rightly called the naïve or virgin T-lymphocytes, while those that are a result of such an encounter would be further subdivided into the—relatively short-lived—effector lymphocytes and the supposedly long-lived memory cells (but see below on the lifespan of naïve and memory T-cells). Within the latter, a further subdivision exists that allows the distinction of so called central and effector memory cells. These subpopulations can be relatively easily detected and quantified with the use of monoclonal antibodies recognizing their specific antigens (e.g. CD45RA, CD45R0, CD62L, CCR7 and many others, as described in all current immunology

textbooks) and flow cytometry, in the samples of peripheral blood, and—when an animal (usually mouse) model is studied, also in other lymphatic organs and bone marrow.

All these cell types function with one major goal: to survey the organism in search of alien moieties that are or may become damaging to the integrity of the organism, and to develop specific ways of their neutralization and elimination (called adoptive immunity), regardless from their origin, which may obviously be extra- and intra-organismal. To achieve this goal, the T-lymphocytes must properly **interact with each other** within the general, and, as sketched above, already complex "family", by means of either direct contact or secreted mediators (cytokines). The scheme of these interactions is depicted in Fig. 1. Their function towards this goal is not standing alone; contrarily, in order to perform adequately (i.e., to eliminate or otherwise neutralize the alien antigen or cell) T-lymphocytes must interact with, influence and be influenced by other cell types, including the broad family of antigen-presenting cells (professional APCs, requiring the MHC (or HLA) Class II to interact with the $CD4^+$ cells) on one side, and the two remaining groups of lymphocytes—the NK- and B-cells—on the other. One has to remember however, that the above does NOT constitute all contacts and interactions of the T-cells. Thus, practically every cell may influence the behavior of $CD8^+$ lymphocytes via its HLA Class I molecules and epitopes anchored onto them; cells belonging to the players in the inflammatory process (especially, but not exclusively, all forms of macrophages) would affect the T-cells by secreting the "pro-inflammatory" cytokines (e.g., IL-1, IL-6 or TNF) that are known to trigger specific receptors on these cells. Finally, T-lymphocytes contain receptors (and relevant intracellular signalling pathways) able to react to the plethora of other biologically important mediators that may appear in the organism under stress, exercise, injury and on many other instances; these would include first of all neuromediators generated by the central nervous system and hormones (Fig. 1). Through these integrative systems of the organism the lymphocytes get knowledge about its status and about external factors that might require their activity. Any and all of these interactions might be (and, according to the current knowledge mostly are) affected by the aging process.

Now, the effectiveness of an immune response, understood as the quickness and completeness of the neutralization/removal of potentially dangerous antigen is therefore **dependent on the two major, related factors. The first** is the availability of adequate numbers of the cells that can react to the antigenic challenge. They would have appropriate, broad repertoire of the TCR/CD3 complexes and accessory molecules (including first of all the CD4 or CD8 and CD28 in right numbers on their surface, and the intracellular machinery of signal transduction, protein synthesis, DNA replication, cell division etc. in good working order. **The second** stems from the first and is the ability of a T-cell population to temporarily increase numbers of effector T-cells, whose role is to neutralize the invading antigen directly or with the help of cytokine-driven NK killer cells or antibody-producing B-lymphocytes, and which should then quickly get stopped by regulatory/suppressive T-cells and ultimately disappear by the Activation-Induced Cell Death (AICD) being a form of apoptosis (see the chapter by Ewa Sikora in this volume). This second

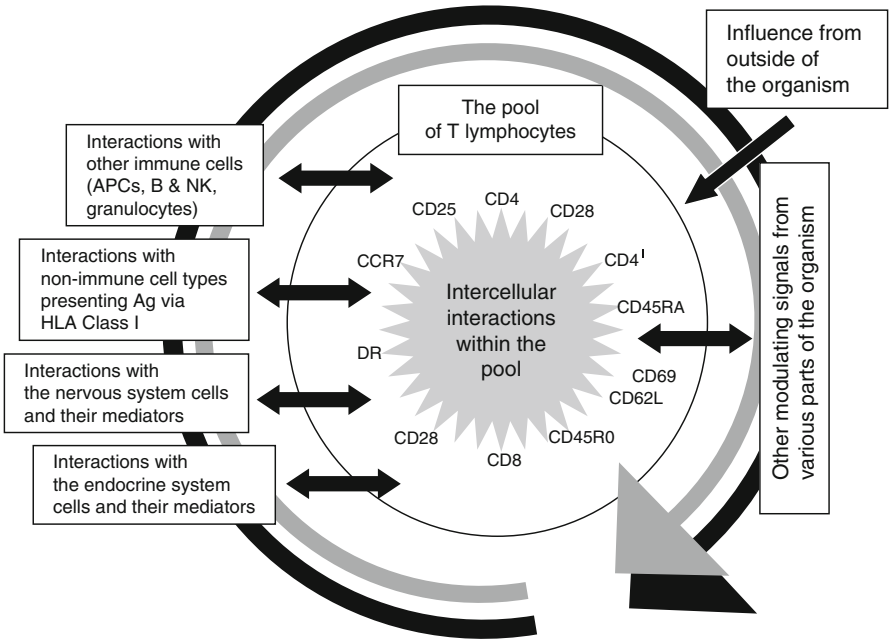

Fig. 1 The idea of T-cells' pool interactions within the broader organismal network, requiring proper numbers and functionalities of all members

utmost important factor ascertaining the optimal immune response is therefore the process, called **T-cell proliferation**.

The above is of course the basic tenet of current immunology. However, what perspires as important for our consideration of aging-related changes in the performance of the immune system, is the need to maintain the right **proportions and numbers** of all of the abovementioned cellular (sub)populations in order to keep the whole system optimally effective (please mark "optimally", which does not mean "maximally" and might mean the difference between the immunity and the autoimmunity). As mentioned above, direct intercellular contacts and humoral signals form the two ways various cells of the immune system communicate with each other and with other cell types. For these "means of communication" to be optimally effective and lead to the goal being the antigen neutralization, the communicating cells have to be in proximity to each other and in adequate numbers, which is maintained by effective proliferation (multiplication) of various T-cell subpopulations responding to an antigenic challenge. It is commonly accepted that both the proportions as well as absolute numbers of various subpopulations of the human T-cell pool change with advancing age which may be at least one of the reasons for decreased overall performance of the system in the elderly.

Thus, T-lymphocyte pool appears as a component of a very complex, dynamic, (and by far not fully understood) web or network of interactions, where the signals conveying information may be either direct intercellular contacts or cellular

(secreted) molecules. Each and every component of this network may undergo aging- and/or pathology-associated changes, affecting its functions and—among other—its interactions with the immune system and with the T-cells in particular. It is a very hard task to understand, how in fact aging *"as such"* is affecting the (T) cells of the immune system (example: a whatever subpopulation of T-cells drawn from an old organism might be absolutely normal and do not functionally differ from the same population drawn from a young organism; however, at the moment of sampling, the nervous (or say, hormonal) system in the old organism could have failed to secrete some mediator or hormone and this lack would affect the T-cell under study leading to an observed different reactivity, when compared with these from a young individual). Therefore in practically all current studies such broad analysis of multivariable status of organisms, from which the immune cells are drawn, is not performed and it is assumed that whatever "extra-T-cell" influences may affect the T-cells of an old individual they would integrate and be relatively similar through the healthy elderly cohort (yet different from the healthy young cohort, as a matter of course). Thus, the result of any test comparing the immune cells' function in the healthy young and elderly bear the burden (and thus—doubts) of our lack of general knowledge about the individual's status preceding the experiment.

While trying to understand the complexity of the T-cell system as a part of the (more general) immune system, its interactions and interrelations (both within the system and with the other ones (Fig. 1)) and, especially, any changes in its function related to advancing age and the process of aging, one has to be very aware of a basic difference between the immune systems of human beings and of model laboratory animals. The latter, usually germ-free or at least "specific pathogen-free" mice, have their immune systems all but dormant until the experimenter challenges them in vivo or in vitro (with possible exception of newly transformed neoplasm cells, that may form an unpredicted source of antigens even under such conditions). On the other hand, our own immune cells are not only on constant alert, but, in fact, constantly in-fight (although not all of them at the same time, of course!); our environment (the air we breathe, the foods and drinks, other members of our species, our pets and farm animals etc.) is full of antigens, both those already known to the immune (memory) cells and the new ones, challenging the naïve T-cell pool.

Within the abovementioned network pervading the organism, the T-cells will dwell only in certain locations or microenvironments, providing for them the relevant survival and sometimes mitogenic signals; these locations can be collectively called the "T-cell niche" (Fig. 2), even if it is already known that different T-cell subpopulations would require different sets of these survival-and-proliferative signals and thus will rather live in a few partially overlapping "niches". A very good example here is the memory T-cell niche, which had recently been shown to be defined by the ligands belonging to the TNF family and in fact differentiating between the $CD8^+$ memory and $CD4^+$ memory "subniches" [74].

Thus, the T-cell niche (being, in fact, a sum of all "T-cell subpopulations' niches") in a human organism is never static. Both the proportions and the absolute numbers of various T-cell (sub)populations are homeostatically maintained throughout most of our adult life, in order to keep this niche (consisting of the T-cell compartments in

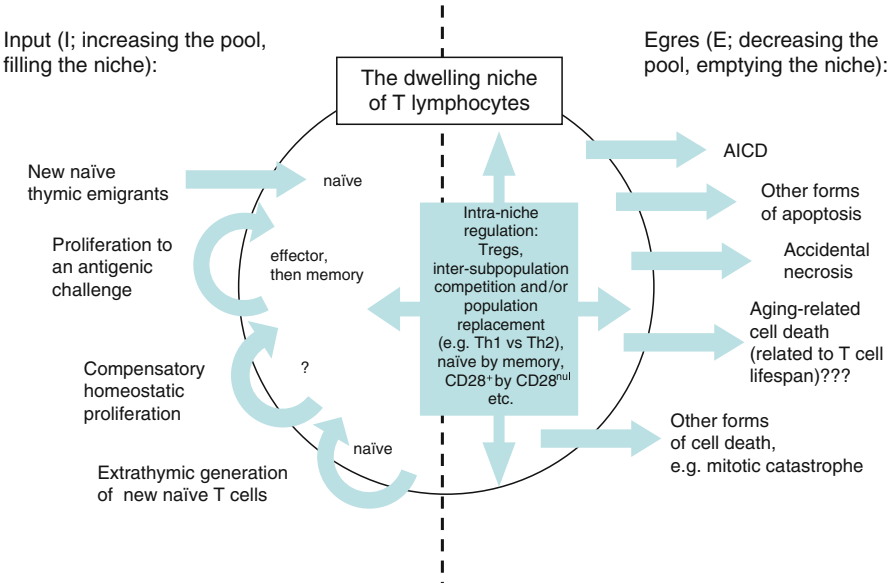

Fig. 2 The idea of T-cell niche homeostasis; I = E

the lymphatic organs, bone marrow and circulating lymphocytes, although the latter can also be considered a "common sink" or corridor for all of the relevant "niches", where members of different ones may meet and interact) relatively constant in volume, yet ready to respond to any antigenic challenge with enough effectiveness to keep the organism healthy (or, at least, to ascertain its survival when confronted by a pathogen). These **homeostatic regulators (homeostats)** consist of the mechanisms leading on one hand to fast and concerted accumulation of all the required effector cells (the "input" side in the Figs. 2 and 3), but containing various ways the T-cell may die (apoptosis, necrosis etc., the "egres" side in the Figs. 2 and 3), including the production of regulatory T-cells with one or another type of suppressive activity against their activated sisters on the other (see below and the chapters by K Hirokawa and by P Moss in this volume for more detail on T-cell homeostasis and regulatory T-cells respectively).

One of the most important questions for our understanding what happens with our T-cells when we age was interesting gerontologists for many years and it is still not answered yet. Why—knowing that our immune system is impaired and generally loosing its functionality when we age—we do not observe major decrease in its volume—in the peripheral blood lymphocytosis for example, or in the palpable volume of the lymph nodes in the old individuals? In other words: what keeps the T-cell niche in an active equilibrium over our young and middle age, i.e., what homeostats play the major role(s) in the process, and how they change when we get old? Let us consider the general situation in the T-cell niche (Fig. 2.). The mechanisms increasing the volume of the niche(s) (the "input" side in the Fig. 2.) can be divided into intrinsic and extrinsic to the niche-dwelling cells itself. Those

intrinsic to the in-niche T-cells themselves will mostly depend on the antigenic (or, in vitro—also mitogenic) challenge. They will consist of: **ability to recognize the stimulatory signal** (an antigen, in vitro also mitogens) from environmental noise, which requires proper diversity and numbers of the TCR/CD3 complexes, **ability to distinguish the signal as "requiring response"** which requires proper MHC/HLA context, availability of other (costimulator) molecules (especially CD28) interacting with the antigen-presenting cells, adequate numbers (surface densities) of these, and the **ability to properly respond to incoming signals** which requires functional signal transduction mechanisms (starting from the proper numbers of relevant T-cell surface receptors), functional gene activation and transcription machinery, functional protein synthesis apparatus. Within this proper response lays, of course, the a**bility to divide** (proliferate, i.e., undergo productive mitosis, leading to the generation of viable daughter (effector) cells), which requires adequately functional cellular machinery directly involved in the processes of error-free DNA replication, and in its separation into newly formed nuclei of the daughter cells.

The mechanisms **extrinsic to the in-niche T-lymphocytes** would contain **influx of new, naïve T**-cells generated in the thymus or extra-thymically, **T-cell survival signals,** which may be generated in the niche or outside (these include IL-2 and other growth factors) and, possibly, also the hypothetical and currently mostly unknown **factors that govern the development and size of the microenvironment** creating the niche stroma. One has also to bear in mind the postulated homeostatic proliferation of the T-cells—one that supposedly provides new naïve T-cells even after the cessation of thymic lymphopoiesis; it can probably also increase or at least sustain the numbers of the memory cells (possibly *ex definitione* also without antigenic stimulation) and thus would get more and more importance with advancing age (see below).

Considering the mechanisms decreasing the volume of the niche(s) or the eliminators of "surplus" (or temporary surplus) T-cells (the "egres" side in the Fig. 2), one would have to list first those intrinsic to the activation process, i.e., any form of Activation Induced Cell Death (AICD). This is a major safety valve against uncontrolled overproduction or protracted dwelling of activated T-lymphocytes in the niche, which could—and sometimes does—result in either autoimmunity or transformation into leukaemic growth, that eliminates practically all no-more-necessary effectors. Apparently, the AICD occurs only or mostly at the early G1A phase of the cell cycle [43]. Other forms of apoptosis will constitute another negative homeostat—like the one related to lack of growth- or survival-promoting factors, or that induced by irreparable (or not repaired soon enough) DNA damage. These would not be limited to any specific phase of the cell cycle.

Another somewhat similar way of elimination of the T-cells will be the **mitotic catastrophe**—when all the signals and processes are in order until the moment of mitosis, where "something" goes wrong and proper separation of genetic material does not occur; however, in case of normal human lymphocytes, this way of cellular dying is not yet well understood or even proven [82].

The T-cell (similarly to other 300+ cell types of our of organism) my also die by other means, not directly related to their physiological function. First of all, they

may die by **accidental necrosis**—when the intracellular compensatory (homeostatic) mechanisms fail when confronted with—for example—a metabolic toxin, lack of oxygen, or (admittedly very unlike for lymphocytes) mechanical damage.

And finally, what should be of an utmost interest considering the topic of this chapter and the entire book, it is possible that **T-cells die "of old age"** i.e., because they had aged so much that their intracellular homeostats cannot support life anymore. This last possibility bears with it another question, that about the actual lifespan of human lymphocytes. Are they short-lived (on the scale of days) and rapidly replaced? Are they long-lived and—when not confronted with an antigenic challenge—is their lifespan comparable to that of the organisms (i.e., measured in many years for human beings)? This question, obviously of an utmost importance for understanding the balance within the T-cell niche, is not so easy to answer. In order to know the actual (or maximal) lifespan of any T-cells' subpopulation, one would have to mark it somehow at the beginning of the individuals' life and then observe how long these marked cells would stay present in the organism under study. In fact, such analysis has been performed both for mice and for humans. In the former, it is possible to draw and isolate the lymphocytes, mark them with a stable fluorescent tag (for example the carboxyfluorescein diacetate succinimidyl ester (CFSE)), reinject in the animal and then seek the fluorescent cells in the blood or lymphatic organ of the animal after at least many months, which correspond to a substantial portion of the animals' life [46]. The fluorochrome is found not only to be a stable marker of the tagged cell, but also to be proportionally, arithmetically diluted into its daughter cells; i.e., if the CFSE-tagged cell divided once, their daughters would contain ½ of the fluorescent signal, their daughters $1/4^{th}$ etc. Thus, if after some time we would still see the cells with the fluorescent signal exceeding ½ of the original, we must assume they did not divide since the tagging operation, so their lifespan has to be at least equal to the period between the tagging and the observation. For murine T-cells it was shown to exceed on average half a year, which for most mice strains is about $1/4^{th}$ of their typical lifespan. This constitutes a proof that at least some murine T-cells may live for a major portion of the animal's life and, possibly, their lifespan would be similar to the lifespan of the mouse.

The same is much more difficult in humans—for obvious reasons we cannot tag and observe our own cells that way. Also, one has to be careful to distinguish between the proliferative lifespan of a T cell—i.e., how long it and its progeny of the same clone would stay in the organism—and the lifespan of a T-cell "as such"—i.e., how long a nondividing T-cell can stay alive and "clog the niche". A dreadful event in recent history actually did the human cell tagging for us. In 1945, citizens of two Japanese cities were exposed to extremely high radiation of atom bombs. Many of those, who survived the holocaust, exhibited various mutations and changes in their genetic material, frequently leading to the development of malignancy (including the leukemias). However, in some of them a special type of chromosomal mutation can be demonstrated; this one leads to the appearance of circular chromosomes and other chromosomal mutation, precluding the symmetrical division of such T-cells [40, 41]. Thus, putting the two together: if the cell with this mutation was generated in 1945 and it can still be detected today, it must be more than 60 years old; in fact,

these are the maximal estimates of the human lymphocyte lifespan based on this singular phenomenon [53–55].

Newer data, utilizing other approaches for establishing the maximal (or average) lifespan of human T-cells are more confounding and yield much smaller values, from a few days or weeks in the case of naïve, to at most a couple of years for the memory T-cells [5, 47, 48] (albeit some papers state that the memory T-cells do not differ or have a shorter lifespan [87]. However, these tests, marking the cells for example with deuterated (^{2}H)-glucose, do NOT actually "see" the marked cells throughout their life, but estimate average lifespans based on incorporation of the ^{2}H-glucose deuterium in the DNA; thus it is rather an average than a maximal lifespan that they estimate. Another popular way of assessing the T-cell clone lifespan is by the estimation of number of population doubling in vitro and then multiplying it by the time required for a single population doubling. This is of course the T-cell proliferative lifespan, not the maximal (or even average) time any single T-lymphocyte may live when undisturbed in an organism. This type of study yields the average lifespan for human memory cells about 15 years and their maximal lifespan of about 35 years [1]. More recent data from the in vitro cultivated T-cell clones show that hey can perform close to 100 population doublings, which would extend their maximal lifespan to that close to observed for T-cells of the A-bomb victims [62, 63]. Concluding, at least some T-cells may stay alive for a long time even if not dividing and thus "clog the niche";—i.e., limit the available space for the progeny of the still-reactive lymphocytes.

As long as the two processes (i.e., production and/or influx of new T-cells and the removal of the T-lymphocytes that are no more needed) are in relative balance, the niche "volume" or total numbers of included T-cells will stay more or less stable (even if the properties (phenotype) of the cells filling it will change, the quantity will be homeostatically maintained). This seems to be true for the fate of T-cell niche in the healthy young individuals (Fig. 3a). Still, all the time one has to be aware that the above description is general (using the keyword "T-cells" rather than alluding to separate subpopulations of these) and that so far there are not much data regarding the behaviour of any single T-cell subpopulation as a niche-filler. One consideration that must be made here and that would impact on the overall reactivity of the T-cell system in the aged (but would not in fact change much the total numbers of T-cells in the niche) would be the slow replacement of many very diversified variants of the T-cell receptor TCR (deciding on the ability of T-cells to react to multitude of previously unknown antigens) by much fewer numbers of these, leading to the phenomenon described as TCR repertoire contraction and resulting in vastly reduced ability of T-cells of even healthy elderly to recognize and react to new antigenic challenges [60].

However, as the organism/individual ages, these homeostats seem to become more and more impaired, as we know from the observational and experimental evidence accumulated so far.

Based on the early studies of the ability of T-cells of old mice and elderly people to proliferate in vitro to mitogenic challenge, it was long ago established that their overall proliferative capacity is significantly dwindling with advancing age. It

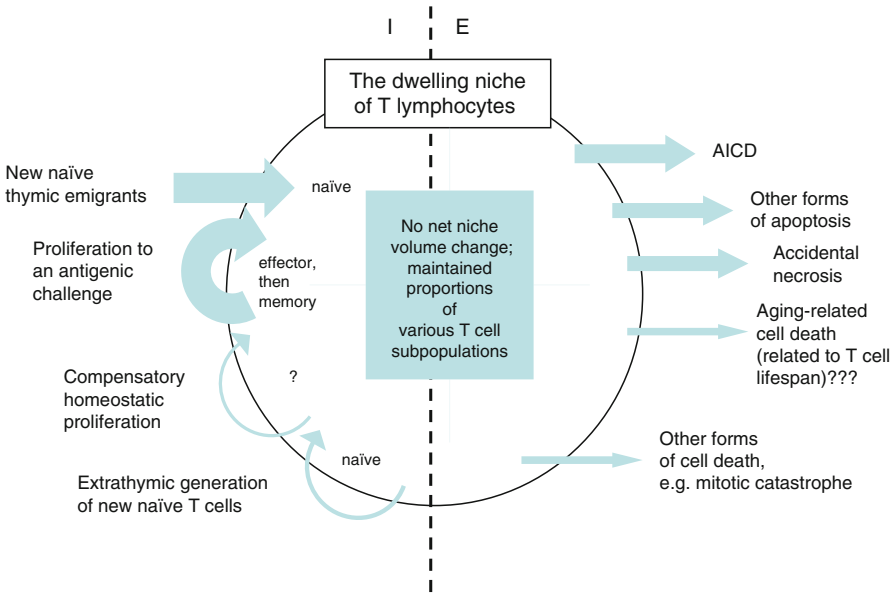

Fig. 3a The T-cell niche homeostasis in young adults: I ≈ E

has been shown many times both for the T-cells of old mice as well as for human peripheral blood lymphocytes (for the review see for example [33, 61]). T-cells of old organisms incorporate less ^{3}H-thymidine when stimulated in vitro with either immobilized anti-CD3/anti-CD28 or with plant mitogens (like phytohaemagglutinin or concanavalin A) or with the "membrane-bypassing" cocktail of calcium ionophore ionomycin and phorbol ester. Also, when their ability to double their numbers in vitro is calculated, it is significantly, much lower than that of young cells. Both these parameters tell us that the general, T-cell population-wide ability to respond to relevant stimuli is decreased in the T-cells of old individuals (reviewed in [20 33]). The net result should be the reduction of the T-cell niche volume/cellularity (Fig. 3b).

One of the problem a researcher of T-cell aging encounters when studying the field is the T-cell phenotypic shift occurring in the elderly. The best known forms of this remodeling are the naïve-to-memory shift and the accumulation of T-cells deprived of CD28 costimulatory molecule [9, 24, 28]. The first, naïve-to-memory shift (or accumulation of phenotypically memory T-cells at the expense of naïve ones) is intuitively obvious: given relatively constant T-cell niche volume and many years of exposure to environmental antigens and pathogens, our adaptive immune system must produce many variants of memory cells left behind after each antigenic challenge, that will take the niche space [16]. In addition, we know for many decades that the main if not sole provider of new naïve T-cells in our youth, the thymus, is grossly reducing its output after the puberty (even if we know now, that it does NOT stop working then; in fact, naïve T-cells and the thymic hormones are

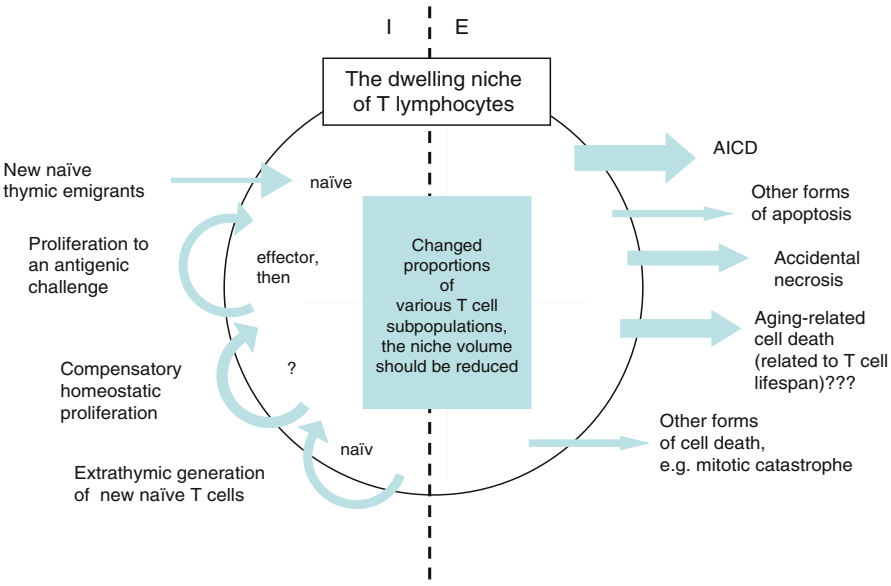

Fig. 3b The T-cell niche homeostasis in elderly: I << E (old paradigm)

produced still when we are approaching old age) [15, 59]. At the very old age the thymus is apparently no more the source of new, naïve T-lymphocytes, yet even in the very old people we can still detect some of them [59, 65]. This leads to the conclusion that either they are the survivors from our youth or middle age (but see the discussion on the T-cell lifespan in this chapter!) or they are maturing from the bone marrow precursors without the need of the thymic microenvironment (extrathymically). The data showing decreased numbers of new thymic emigrants containing the TCR gene rearrangement excision circles or TRECS suggest that in the very old (centenarians) such cells are practically absent [59] which would rather support the first possibility. The question how it in fact is and another—whether these naïve T-cells that appear in the elderly are still fully functional (for instance, can they still divide as dynamically as the naïve T-cells of young individuals when challenged)—remains unanswered so far.

A related factor is that the proportion of T-cells that do not enter division cycle upon stimulation (nonzero even in the young individuals) is vastly increasing among T-cells of old people. These lymphocytes are presumably proliferatively senescent, i.e. post-mitotic and unable to divide anymore. However, it is not known as yet, whether they in fact only "stay there" and "clog the niche", or are they still able to perform some other, nonproliferative functions, like the cytotoxic or regulatory (cytokine- or contact-related) activities. One of the possibilities is that they could be devoid of certain essential molecule (or signalling pathway) necessary for initiation of proliferation; an important candidate here could be the major costimulator molecule of the T-cells, the CD28.

Accumulation of the $CD28^{nul}$ subpopulation in both the $CD4^+$ and $CD8^+$ lymphocyte populations was found to accompany even healthy aging [9, 21, 24, 88, 92]. Certain studies demonstrated that these $CD28^{nul}$ cells have many features ascribed to the aging T-cell population, including the decreased proliferative capability measured by ^{3}H-TdR incorporation [9, 13, 18, 19, 22, 23, 92], contracted T-cell repertoire [78, 89] (see also the chapter by J. Goronzy in this volume) and modified cytokine production [2, 26, 76]. Thus it was assumed that their accumulation might be responsible for the impaired functioning of the T-cell pool in the elderly. However, while $CD28^{nul}$ cells may form even more than 50% of all circulating $CD8^+$ lymphocytes they rarely exceed 10% of the $CD4^+$ cells in a healthy elderly individual [9, 11, 21, 24, 88, 92]. Thus, their accumulation cannot be considered the culprit for grossly decreased proliferation rate of either $CD4^+$ or even $CD8^+$ lymphocytes (even in the latter population, the decrease in 3H-thymidine incorporation is by far more than 50% when we compare cells from young and elderly individuals). Interestingly, even the relatively high accumulation of $CD8^+CD28^{nul}$ lymphocytes in the elderly cannot be responsible for decreased proliferative capacity of the $CD8^+$ population in old people; it was recently found (using the flow cytometric DCT technique utilizing the supravital staining of proliferating cells with the fluorescein derivative, CFSE) that in fact, these $CD8^+CD28^{nul}$ cells do proliferate more and more with advancing age and, when drawn from the blood of oldest old, they can make in vitro many divisions [14]. This was also shown for t he $CD4^+CD28^{nul}$ cells, albeit the latter seem to be less proliferatively active in the elderly than their $CD8^+$ counterparts [12]. Thus, overall effect of accumulation of $CD28^{nul}$ cells on the status of the T-cell pool in the aged (at least for its $CD4^+$ compartment) cannot be that much, unless they would be functional regulators/suppressors. This latter possibility is tempting, however until now (mid-2007) it had not been sufficiently documented, despite showing at least some cytotoxic abilities in them [52, 56, 58].

On the other hand, the existence and potential importance of the $CD28^{nul}$ cells (at least within the $CD4^+$ population of human lymphocytes) may be just the tip of an iceberg, with the most of it metaphorically containing the $CD4^+$ cells with lowered numbers of CD28 molecules on their surfaces, but not lacking them altogether. In fact, we were able to show some transcriptive activity of the CD28 gene by RT-PCR even in the notorious $CD4^+CD28^{nul}$ clones, which suggests that the actual range of CD28 expression level on the human $CD4^+$ lymphocytes might be from near-zero to whatever maximum (Witkowski, unpublished). We have shown before that this is the case: $CD4^+$ lymphocytes of healthy elderly people express on average fewer CD28 molecules per cell than those from healthy young people [12, 93]. This observation is similar to that obtained for the $CD4^+$ lymphocytes of rheumatoid arthritis (RA) patients, considered to show the phenotype of accelerated aging [11]. Decreased numbers of CD28 on elderly $CD4^+$ cells expectedly have their consequence, the CD28 being known as a major costimulatory molecule for these cells. Using advanced DCT technique we were able to show that the CD28 molecules' number inversely correlates with the time, required by the T-cell to exit the resting G_0 phase and to enter their first division upon stimulation [12, 93].

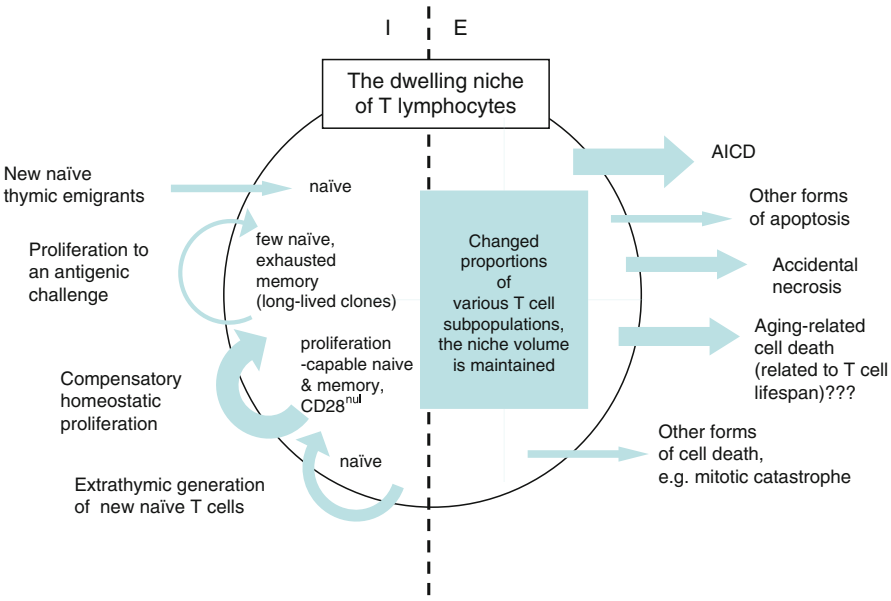

Fig. 3c The T-cell niche homeostasis in elderly: I ≈ E (proposed model)

Summarizing current knowledge, with aging the production of new cells [both naïve (first of all) and effector as well as memory] seems to be reduced, and the accumulation of post-mitotic, senescent T-cells is increased. On the other hand the AICD and, possibly, other forms of apoptosis and—hypothetically—T-cell death related to the more and more of them attaining cellular old age (senescence) and dying of it, as well as possibly the mitotic catastrophe related to accumulating DNA damage are increased. This would result in the net emptying of the T-cell niche, observed as lower numbers of T-lymphocytes in the circulating blood, reduced volume of the T-cell compartments in the lymphatic tissues etc (Fig. 3b). However, these symptoms do not occur, so some mechanism must maintain the filling of the niche (Fig. 3c).

Why do the T-cells proliferate differently in the aged individuals remains not fully understood. It is well established that various facets of the signal transduction mechanisms leading to the turning on of the DNA replication and cell division are impaired in the T-cells of the elderly [31–33] (see also Tamas Fulop's chapter in this book). The major mechanism governing the progression of the cell cycle when it was already initiated consists of the interplay between the cyclin-dependent kinases (the cdks, in the lymphocytes mostly cdk 2, 4 and 6) that are supposed to phosphorylate specific proteins at specific times during the process, the cyclins (A through G, forming regulatory parts of the active phosphorylating complexes, but must be tightly controlled and timely eliminated or the cell may become neoplastic) and the cyclin-kinase complex inhibitors including the p21cip/waf, p16ink4 etc. The latter are already known to accumulate in many cell types of old individuals including

the lymphocytes [36]; ultimately their amount is supposedly that high that the cell cannot perform any cdk-dependent phosphorylation and stops dividing completely, reaching proliferative senescence. On the other hand, the levels of cyclins and the cdks are posing more difficulties for interpretation. It was shown that the levels of cyclins A, G and D (2 and 3) are lowered in the T-cells of old individuals. These observations are related to their increased destruction by the ubiquitin-dependent proteolytic machinery [68–70] and possibly also due to decreased activity of relevant genes [4, 25, 36, 73]. Similarly T-cells of the elderly are containing less cdk kinases, which disrupts the phosphorylation processes needed for cell cycle progression [4, 25, 36, 73]. However, the data available so far do not consider the remodelling of the T-cell pool, including the increase in the proportion of senescent cells. Thus, it is theoretically possible that those T-cells that are still capable to proliferate in the elderly may have these mechanisms even more active than the young ones! In fact this is precisely what we see: using the DCT cytometric technique we had demonstrated more divisions made in vitro by fewer $CD4^+$ cells of the elderly people, associated with increased levels of D1 cyclin (governing the length of the G1 phase of the cycle), both total and cdk-bound in an active complex [93].

This brings us to the whole huge question of possible changes in the cell cycle length and productivity related to aging.

When we consider the actual cell cycle length (or the time between the two consecutive mitoses) we have to bear in mind the serious consequences of shortening or elongation of the cycle by relatively minor span of time per cycle. Using simple enough arithmetic one can show that the cells, for which the cell cycle is shorter, will make more divisions at the same time compared to other with longer cycle. As the average length of the human T-cell cycle is somewhere between 12 and 20 hours [93] and stimulated T-cells are able to perform up to 15 or more division in vitro without artificial support (like feeder cells or IL-2 and other growth factor supplementation), one can easily calculate that after the time the cells with longer cycle spent on x division, those with shorter cycle would make x + 1/cell cycle length * number of cycles until time of observation; eventually, after a precisely calculable time faster cells would make one division more than the slower ones, i.e, at the end of that time, there should be up to twice as many faster cells than slower ones! This may be of physiological importance, for example as a reason for elimination of less active clones by more active ones and changed TCR diversity in the elderly. Thus, it seems important to know if the cell cycle length changes with advancing age.

In fact such studies were performed already a few times for murine and human T-cells from donors of different ages. The methodology applied was mostly staining the cellular DNA after a designed time of stimulation and detecting the proportions of the cells in G0/G1, S, and G2/M stages of the mitotic cycle which, with appropriate analytical tools, allows for approximate estimation of the length of each stage. This technique yielded some intuitively expected results—namely, T-cells from old individuals tended (on average) to have their cell cycle longer than cells from young individuals [4, 25, 73]. While looking at the various stages of the T-cell cycle, various authors reported: no change or elongation of G1 (the latter related to the accumulation of the inhibitor of cyclin D/cdk4/6 kinase complex, the p21 cip/waf (by

BrdUrd/Hoechst staining; [6]) and an elongated S phase (here the example is the Werner's syndrome S phase length [71], but one can easily, intuitively understand that the T-cells (and other cycling cells) of the elderly individuals may have more DNA damage accumulated, and less effective mechanisms of its detection (including the p53 [51]) and repair [3, 39, 77], thus may be prone to slowing down the cycle to allow more time for repairs). Also, and for the same reasons, elongated G2 phase was reported [66, 67]. According to these reports, age-related G2 elongation can be reversed by caffeine which, in turn, is reversed by adenosine (which provokes the—currently unanswered yet—question on the role of changed availability of energy and/or cAMP in the observed process).

Thus, in a model of the T-cell cycle changes related to aging, that arises from the abovementioned observations (Fig. 4a), with aging all or at least some of the cycle phases are elongated, leading to the elongation of the whole cycle. Accordingly, compared to the young, the T-cells of elderly would make fewer divisions in the same time from stimulation and, assuming other factors influencing the progeny number would not change (which is not entirely true, as the level of AICD changes with aging, as do probably other means a T-cell might die) we would see fewer daughter cells at the end of any observation period. This is in agreement with old data on ^{3}H-TdR incorporation in the DNA of mitogen-stimulated T-cells of young and elderly. However, assuming the above as the whole truth we would expect not only the immune response involving the T-cell proliferation to be much less effective (due to not enough effector cells produced on time), but also the numbers of T-cells in the elderly to dwindle quite rapidly, both during activation (AICD and the mitotic catastrophe on the rise) and during the rest period, where the homeostatic mechanisms to fill the niche would also fail. Yet, we do not see a significant change in the volume of lymph nodes, spleen and the MALT when we age, even if their internal histology may change with age [84, 85, 90, 91].

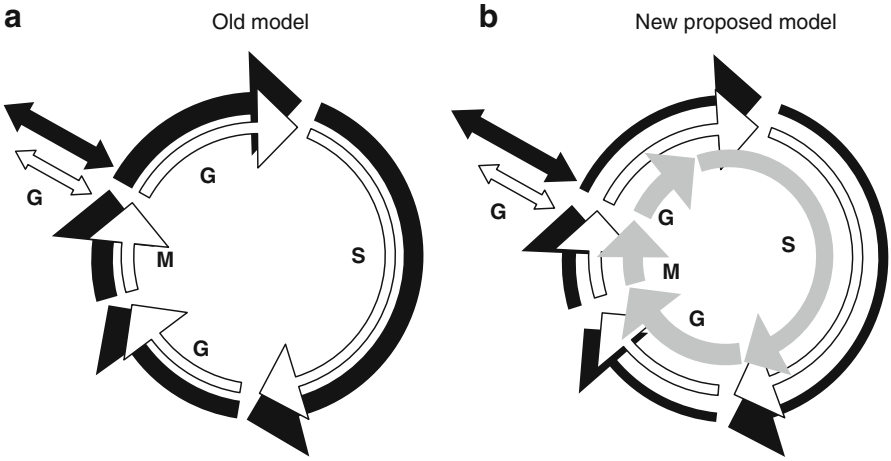

Fig. 4 Changes of the length of cell cycle phases (G0 through M) in the T-cells of healthy elderly. Relative lengths of cell cycle phases of T-cells of young (□), and elderlyindividuals(■—presenescent, ■—homeostatically proliferating). Smaller radius indicates shorter cell cycle

One common mistake in such studies is that the researchers assume some special value for the length of any specific cell cycle stage. For instance, according to Kypreou et al, at 72 hours stimulation (in vitro) the lymphocytes are in the S phase [42]. In fact even if we assume the initial synchronization of these cells' entry in the activation process (by the token of almost immediate contact of all tested cells with the stimulus upon its admixture), we do not know the actual timing of stages preceding the S phase, including first of all the G0→G1 transition as well as the G1 phase itself, which is the most variable and prone to change in length. Thus, any *a priori* assumption of the length of any phase of the cell cycle skews our understanding of possible changes, by not allowing the researcher to assume that any of them might actually be changing with age! As we had demonstrated confirming earlier suggestions, the G0→G1 phase is significantly elongated (in some cases to more than 50 hours!) for the $CD4^+$ cells of healthy elderly and this elongation depends on the availability of CD28 as a source of costimulatory signal [93].

On the other hand, when we applied the abovementioned DCT flow cytometric technique to tag and enumerate dividing human T-cells obtained from people of various age, and the not-so-complicated mathematics for calculations, we have found that, in fact, on average the cell cycle of the $CD4^+$ lymphocytes of the healthy elderly is shorter than that of the same cell type from young people [93]. In detail, the $CD4^+$ population that we studied that way was more diversified: apart from the cells that divided fast (making more divisions per a dividing cell) there were many (more that among the lymphocytes of the young people) those that did not divide at all (senescent?). Also, the shortening of the cell cycle was true for those $CD4^+$ cells that were still expressing some (but FACS-detectable) CD28 on their surface, while the $CD4^+CD28^{nul}$ cells of the elderly divided with the speed not different from the same population dwelling in the young. This observation—in our opinion—is indicating that the cell cycle behavior does NOT undergo any COMMON type of changes in aging, even within such a seemingly uniform class of cells like the T-cells; rather, different subpopulations of the T-cells, including those differing in the expression of CD28, but possibly also the broadly different $CD4^+$ and $CD8^+$, naïve and memory cells etc. would follow their separate patterns of cell cycle change, requiring separate studies. In our opinion this once again describes the $CD28^{nul}$ population as an end product of the process of aging. At the end, of course, all of them would fit into the common pattern of remodeled T-cell niche observed in the healthy elderly.

Thus, we propose another model (which according to our experiments is true at least for the $CD4^+$ lymphocytes) where those T-cells of the healthy elderly that still had not reached proliferative senescence would actually divide faster (their cell cycle would be significantly shorter), while these approaching it, but not yet senescent—slower (Fig. 4b). That way in the same time fewer cells than in the young would make more divisions than the dividing lymphocytes of young individuals and the number of their progeny would remain reasonably similar to that seen in the healthy young people. In our opinion, this model fits well in the aged immune system remodeling theory [27, 30], adding a changing functional component to its—already known—changing phenotypic characteristics. The mixed cell population that fills the T-cell niche in the aged organism would

therefore consist of increased numbers of the progeny of those clones that can still divide relatively vigorously, steadily reduced numbers of those which still divide slowly (presenescent), and relatively constant or slowly rising numbers of senescent (postproliferative) T-cells clogging the niche (resulting *inter alia* in the observed TCR repertoire contraction)—Fig. 3c. Interestingly, homeostatic proliferation—one that plays a role if filling supposedly empty space in the T-cell niche after the demise of exhausted clones—is reported for both the naïve and memory T-cells of the elderly [60].

The model we propose might gain another aspect, related to the concept of inflamm-aging (readiness of the immune system of elderly to initiate the inflammatory reaction or even permanent state of such mild, subclinical inflammation [17, 29, 75]). It was shown earlier that dexamethasone (a synthetic antiinflammatory glucocorticoid) extends the G1 phase of stimulated human lymphocytes and it is suggested that natural glucocorticoids do the same [7, 8]. The levels of glucocorticoids in the sera of elderly people are variably reported as lowered, unchanged or (quite frequently) increased as compared with these observed in young people; the latter are associated with inter alia worsening of the hypothalamic functions (including memory) [49, 50, 81]. However, these data concern mostly the total levels of the hormone and not the levels of its free, active form. Yet, in our opinion, the inflamm-aging state should be associated with lowered levels of **free** glucocorticoids observed in the elderly. Thus, shorter G1 that we suggest as the reason for overall cell cycle shortening of elderly $CD4^+$ cells might be related not only to high D1 cyclin in these cells that we have reported [93], but also to less free glucocorticoids. Our recent work shows very much decreased amount and activity of cellular β-glucuronidase being the product of Klotho gene in the $CD4^+$ lymphocytes of healthy elderly people [94]. Klotho, recently dubbed the aging hormone, is deeply related to the process of aging, mostly due its involvement in the regulation of calcium and phosphate balances [38, 83, 86]. However, the enzymatic activity of Klotho β-glucuronidase is directed *inter alia* towards the steroid glucuronides (a major water soluble conjugate of steroids manufactured in the liver as means of eliminating the hormones with urine and thus regulating their concentration and activity) and thus, when active, it is keeping the free steroid levels up [35]. In the elderly, decreased Klotho expression and activity would not prevent glucuronidation and elimination of glucocorticoids which then exert less antiinflammatory activity (hence inflamm-aging) and less G1 phase elongating activity (hence shorter G1 phase in the 'Klotho-depleted' T-cells of old people). Accordingly, T-cells of old people seem to be less sensitive to antiproliferative activity of cortisol [45]. Interestingly, very recently Klotho has been described as a direct antagonist of the Wnt gene product, at least in certain stem cells [10, 44]. The role of Wnt—related pathways in the development, differentiation and function of human B- and T-lymphocytes is recognized (for the review, see [72, 80]), and its relation to cellular aging on one hand and to the pathogenesis of rheumatoid arthritis on the other at least strongly suggested [37, 57, 79]. Negative association between Klotho and Wnt opens a new, interesting avenue for aging research.

Concluding, despite already broad and constantly increasing knowledge on the aging-related changes in the dynamics of human T-cell proliferation, this knowledge is so far (end 2007) by no means complete and requires much further study.

Abstract: Age-related accumulation of DNA damage in human T-cells has been well documented and could be associated with T-cell malfunctions. Therefore, an age-related reduction in DNA repair capacity of human lymphocytes may contribute to this phenomenon and play a key role in the modification of the immune response observed in the elderly. Because the Mismatch Repair system is the main post-replicative pathway for the correction of replication errors and few data suggest a possible alteration with age of this repair pathway, it is conceivable that, also in the immune system, age-related alterations of mismatch repair could contribute to the accumulation of genetic damage. This is particularly true for adaptive immune response, whose function depends on the ability of T-cells to undergo repetitive replications after antigenic challenge. The present chapter will focus on the role of the Mismatch Repair System that is recently emerging as a possible additional mechanism contributing to the accumulation of genetic instability during aging in peripheral blood cells. In vivo data at present available in the literature and results from studies on cloned human T lymphocytes cultured for different periods in vitro, as a model of immunosenescence, will be reviewed.

Keywords: Aging • Microsatellite instability • Mismatch repair system • T-cell clones

1 Introduction

The understanding and prevention of age-related diseases rely on the study of the molecular mechanisms underlying the physiological aging process and different theories have been proposed. According to the "soma theory", the aging process is caused by a life-long accumulation of random damages in somatic cells and tissues (Kirkwood, Kowald 1997) compromising the functional activity of cells and ulti-

mately leading to cell death. This indicates a central role for the different mechanisms of cell care and stress response cooperating in the regulation of life span, allowing a definition of the so-called "network theory of aging" that includes the effects of defective mitochondria, aberrant proteins, free radicals and DNA mutations (Kirkwood, Kowald 1997) as contributors to the overall process of senescence.

2 Aging and DNA Damage

DNA damage might contribute to the aging process by interfering with DNA replication and transcription impairing the functional ability of cells and thus leading to a senescent phenotype, loss of cellular function, cell death or tumours (Walter et al. 1997).

A wide range of damages to the native structure of DNA (single and double strand breaks, apurinic and apyrimidinic sites, base alterations, methylation, inter and intra-chromosomal cross links, bulky and smaller adducts and distortion of helix by intercalation) can occur through spontaneous damages arising from byproducts of the cellular metabolism or by exogenous chemical, radioactive, viral and mutagenic agents (Reddy, Vasquez 2005). However, the steady state level of spontaneous DNA lesions is very low and therefore difficult to evaluate, under normal conditions. Experimental results do not show directly that decreased genomic integrity causes senescence of somatic cells, but many studies have demonstrated direct correlations: base adduct levels in nuclear and mitochondrial genomes shorten life span and are related to decreased functions of aging. In addition, chromosome aberrations in human peripheral blood lymphocytes do increase with age (Prieur et al. 1988), as well as mutation frequencies at the level of specific genes (as HPRT locus) (Vijg 2000). In any case, the critical load of cellular mutation able to induce physiological consequences is still undetermined.

3 Aging and DNA Repair

Genetic stability is controlled by a number of cellular functions including DNA replication, repair and recombination complexes. Mutations in DNA repair genes frequently lead to genome destabilization and consequent increases in the frequency of mutations. Since systems regulating genome stability are considered to be major safety systems for longevity, it is likely that the inactivation of one or more of such pathways accelerates both age-related deterioration/death and mutation accumulation, at the same time. Indeed, several studies have addressed relationships between DNA damage, its repair and aging, and have suggested an age-dependent accumulation of DNA damage as partially responsible for the impairment of cellular functions and an increased rate of diseases, such as cancer, in the elderly. The accumulation of DNA damage with age (Walter et al. 1997; Barnett, Barnett 1998; Vijg 2000; Doria, Frasca 2001) seems to affect various tissues at different rates, as observed in trans-

genic mice harbouring the LacZ gene (Ono et al. 2000). In addition, a positive correlation between DNA repair capacity and life-span has been demonstrated (Hart, Setlow 1974). The impact of a malfunctioning DNA repair system on genomic integrity is also evidenced by progeroid syndromes in which mutations in DNA repair genes induce a premature aging phenotype characterised by immune defects and increased susceptibility to cancer development (Bohr 2002).

3.1 DNA Repair Pathways

Mammalian DNA repair processes depend on a number of complex pathways to cope with lesions in DNA structure. At least four main pathways have been described so far:

a) the Direct Reversal Repair pathway catalyses a direct reversal only involving single enzymes (e.g., alkyltransferase, removing the methyl group from O6-methylguanine) and DNA ligase (rejoining single-strand breaks) (Harris et al. 1983);
b) the Excision Repair pathway is the predominant mechanism for the maintenance of genomic integrity. This pathway repairs different DNA lesions, ranging from simple base methylations to interstrand adduct formation resulting in major distortion of the DNA structure. Two distinct systems belong to it:

– Nucleotide Excision Repair, which corrects a broad spectrum of structurally unrelated lesions such as UV-induced photoproducts, chemical adducts, intra strand crosslinks and some form of oxidative damage. It can repair any part of the genome, however, damage recognition and repair of trascriptionally active genes (Wood et al. 2001) is performed preferentially by an alternative pathway, termed transcription-coupled repair (Hanawalt 1994);
– Base Excision Repair, which is, perhaps, the most fundamental and ubiquitous DNA repair mechanism in all higher organisms that depend on oxygen for living (Wilson, Bohr 2007). It has evolved to handle the numerous minor alterations (such as spontaneous modification, oxidation, deamination and loss of bases) that can occur in the structure of DNA as a result of cell metabolic activity. This kind of repair is important in post-mitotic tissues, where simple base modifications are likely more prone to occur than major damages;

c) the Recombination Repair pathway that corrects DNA double strand breaks frequently arising from the stalling of the replication fork and from the attack of exogenous agents (such as ionising radiation or chemicals), inducing interstrand or intra-strand cross links and preventing the use of one of the strands as a template for the repair process (Thompson, Schild 2002). Two types of Recombination Repair are described:

– Homologous Recombination, a complex and poorly understood process that entails an intact homologous DNA strand as a template to repair DSB (Sonoda et al. 2006);

– Nonhomologous End Joining that, by contrast, entails relegation of the broken ends without respecting homology and is consequently relatively error prone. Nevertheless, it is a major pathway for double strand break repair in mammalian cells and is thought to be of vital importance in post mitotic tissues (Sonoda et al. 2006).

d) the Mismatch Repair pathway that corrects mispaired bases occurring most frequently during replication (Kolodner, Marsischky 1999).

Finally, the discovery of a number of novel DNA polymerases with the ability to carry out DNA synthesis across a damaged or altered base added new possibilities for understanding DNA repair mechanisms in mammalian cells. These polymerases have different substrate specificities, enabling them to deal with many different types of damaged bases, a process known as translesional synthesis (Rattray, Strathern 2003; Lehmann 2006).

3.2 The Mismatch Repair Pathway (MMR)

The Mismatch Repair system is the main post-replicative pathway for the repair of mismatched DNA (base-base mismatches and insertion/deletion loops occurring during replication, homologous recombination and DNA damage) (Kolodner, Marsischky 1999) and it is essential for maintaining the stability of the genome during repeated duplications. Essential components of the MMR system were identified in *Escherichia coli* and their main activities are reported in the Table 1.

All eukaryotic organisms have MutS (MSH2, MSH3 and MSH6 genes) and MutL (MLH1, PMS1 and PMS2—PostMeiotic Segregation 1 and 2 genes) homologues (Wood et al. 2001; Modrich, Lahue 1996), acting in form of heterodimers, in contrast to bacteria in which MutS and MutL function as homodimers.

In humans, DNA mismatch repair confers to the genome a 100–1,000 fold protection against replication-induced mutations (Loeb 1994). The initial recognition of mismatches is carried out by MutSα and MutSβ, functional heterodimers of Msh2 bound to either Msh6 or Msh3, respectively. They display some functional overlap, with MutSα playing the major role in mismatch correction and being prevalently expressed in the cell. In the following step, MutLα or MutLβ (heterodimers of Mlh1

Table 1 Principal components and functions of the bacterial Mismatch repair system

MutS	Detects mismatches in DNA duplex and initiate the MMR machinery
MutL	Makes a connection between the recognition of a mismatch and its excision from the strand within which it is contained
MutH	Cleaves hemimethylated GATC sites for excision of mismatch-containing strand and formation of nick
Uvr/Helicase	Enters into the nick generated by MutH together with single-stranded DNA-binding proteins

bound to either Pms2 or Pms1, respectively) mediate the recruitment of additional proteins for the completion of the repair process, giving rise to the excision of the mutated strand in either direction to the mismatch and to the resynthesis of the correct sequence (Kolodner, Marsischky 1999). Efficient DNA mismatch repair requires the combined functions of MutS and MutL. The other proteins involved in the repair are: PCNA (Proliferating Cell Nuclear Antigen), whose activity increases the binding of MutSα to mismatched DNA suggesting a role of this protein in the recognition stage (Flores-Rozas et al. 2000; Lau, Kolodner 2003); ExoI (exonuclease I); RPA (replication protein A) and RFC (replication factor C). Once the mutated strand is excised beyond the mismatch, polymerase δ resinthesizes DNA and the nick is sealed by DNA ligases not yet identified (Jun et al. 2006) (Fig. 1).

In addition to a role during replication, MMR proteins have been reported to have other important functions, such as: antirecombination activity between divergent

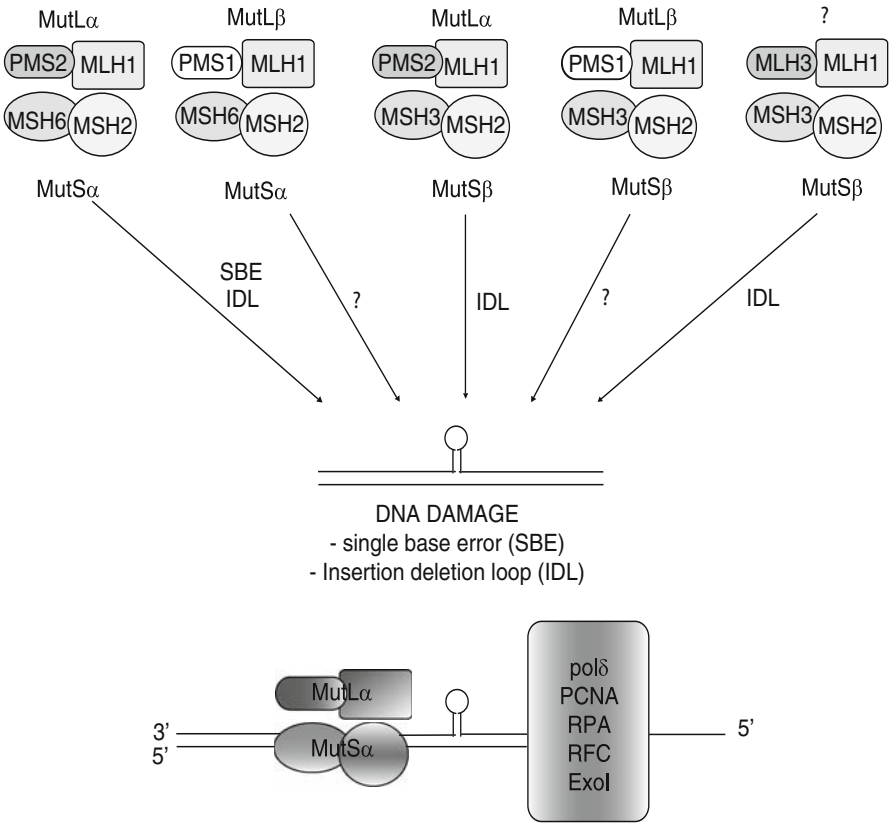

Fig. 1 Schematic representation of the Human DNA Mismatch Repair System. MutS heterodimers (MSH2-MSH6 or MSH2-MSH3) combined with heterodimers of MLH1 with PMS2, PMS1 or MLH3 have different specificities for DNA mismatches or loops (upper panel). Correction is targeted to the primer strand possibly through the interaction with PCNA and additional factors are required to complete the process (lower panel). polδ = polymerase δ; PCNA = proliferating cell nuclear antigen; RPA = replication protein A; RFC = replication factor C; Exo I = exonuclease I

sequences, promotion of meiotic crossover, DNA damage surveillance and diversification of imunoglobulins (Jun et al. 2006). The involvement of MMR in DNA damage response is evidenced by the fact that MMR-defective cells are resistant to alkylating and other DNA damaging agents (Fink et al. 1998). In fact, DNA damage triggers MMR-dependent G2/M arrest, followed by the induction of MMR-dependent apoptosis p53- or p73-mediated. The hypothesis for how MMR is involved in somatic hypermutation and class switch recombination is that, after generation of mutations by AID (activation-induced cytidine deaminase), MMR proteins are recruited to the mismatched DNA and resynthesise the DNA strand with the help of an error-prone polymerase such as polymerase η (Wilson et al. 2005).

Defects in MMR correction pathways are associated with a substantial destabilization of microsatellites, highly polymorphic, tandemly repeated sequences (from one to six bp) interspersed in the genome and particularly prone to slippage during replication. Slippages determine changes of allele length either for insertion or deletion of repeated units. The experimental evidence of this phenomenon is called microsatellite instability (MSI), that is the appearance of additional bands of different lengths or modification of the expected ones. Mutations are observed in repeated sequences, but can also occur randomly in all the genome; therefore, MSI indicates a higher susceptibility to mutations.

Mutator phenotypes due to inactivation of MMR were initially described in HNPCC (hereditary nonpolyposis colorectal cancer) caused by germ line mutations in several members of MMR genes (MLH1 and MSH2 in about 90% of cases), inducing accelerated mutations in microsatellite sequences compared to normal DNA, the so-called replication error (RER) phenotype (Aaltonen et al. 1993; De la Chapelle 1995). Subsequently, it was also described in cancer cell lines and in sporadic cancers of the colon, cervix, endometrium, pancreas, lung, prostate and stomach (Eshleman et al. 1995; Modrich 1996; Kane et al. 1997), due to somatic mutations in MMR genes or, more frequently, to epigenetic mutations, in particular hypermethylation-mediated gene inactivation (Liu et al. 1995; Liu et al. 1996; Moslein et al. 1996; Kane et al. 1997; Herman et al. 1998; Kolodner, Marsischky 1999; Suzuki et al. 1999).

4 Genetic Damage and Immune System

The immune system develops an enormous number of genetically different cells generated by breaking and rejoining DNA sequences coding for antigen receptors, by adapting the DNA repair mechanisms normally used to maintain genome stability. Small populations of naïve and memory T-cells, in order to ensure a correct immune response, have to expand clonally upon antigen stimulation. The ability to expand may depend on the amount of accumulated genetic damage and processes limiting T-cell proliferative capacity might impair the overall immune response. The overlap between DNA repair and immune system efficiency is evidenced by the fact that individuals with defective DNA repair pathways frequently show immunodeficiency.

In addition, immune system efficiency is affected by aging, particularly the T-cell compartment. The impact of age-related immune alterations on lifespan and diseases is in accordance with results from studies in centenarians showing that healthy individuals who have reached the extreme limit of human life in good clinical conditions are equipped with well preserved and efficient immune defence mechanisms (Franceschi et al. 1995).

An age-related accumulation of DNA damage and mutations in human T-cells has been well documented and could be associated with T-cell dysfunctions; it follows that a reduction in DNA repair capacity of human lymphocytes may contribute to this accumulation of DNA damage with age and may play a prominent role in the deterioration of the immune response observed in the elderly and to the development of age-associated immune malfunctions possibly affecting lifespan.

5 MMR System and Aging

MMR deficiency inducing high levels of mutations may only increase the rate of cancer, but not aging. Since cancer is one of the most important causes of mortality in the elderly, it is possible that alterations of the MMR system occurring with age predispose to cancer. Indeed, some emerging evidence indicates that MMR efficiency might be impaired in normal somatic cells with progressive aging.

Msh-2 deficient mice die within one year of cancer with lymphomas (also a common cause of death in aged mice) (Reitmar et al. 1996), while in the first year of life no difference was observed between wild type and Msh2 heterozygotes. MSH2- and PMS2-deficient mice crossbred with transgenic mutation reporter mice generate animals with elevated spontaneous point mutation frequencies in several organs and tissues (Andrew et al. 1997; Narayanan et al. 1997). However, at present nothing is known about mutations accumulated at later ages, since complete lifespan studies on these mice have not yet been performed.

Toyota et al. (1999) found an age-related methylation of CpG islands in normal colon cells affecting different DNA promoter regions, including MLH1 promoter. A large number of CpG in the human genome are progressively methylated during the aging process and, for many genes, this methylation process correlates with reduced expression. The phenomenon appears to be physiologically induced because it is very frequent, it affects large numbers of cells, and it is present in colon tissue from healthy donors and in residual normal colon tissue from cancer patients. The age-related methylation of MLH1 promoter in cancer cells suggests therefore a decreased activity of the MMR system predisposing the elderly to malignant transformation in the colon. In agreement, a spread of methylation in the MLH1 promoter in the normal colonic mucosa closely associated with age and with the development of sporadic MSI in colorectal cancers was found (Nakagawa et al. 2001). The hypermethylation of the MLH1 gene promoter occurring with age correlates with inhibition of its expression and the appearance of MSI.

The frequency of MSI in the pathologic tissue of patients suffering from gastric lymphoma showed a tendency to increase with age, as did microsatellite variability (Starostik et al. 2000).

5.1 Analysis on Peripheral Blood Cells

The immune system, whose impairment is documented with age, is also a possible target of the MMR deficiency, in particular the adaptive immune response that depends on the ability of T-cells to undergo consecutive replications after antigenic challenge. This prominent proliferative stress presumably renders T-cells more prone to possible inefficiencies of DNA repair systems and replicative senescence. In recent years, some data are emerging on age-dependent alterations of the MMR pathway in peripheral blood cells.

A preliminary study demonstrated an age-associated MSI by analysing eight different microsatellite loci on DNA from peripheral blood cell samples from young and old healthy subjects obtained at a ten-year interval (Ben Yehuda et al. 2000). A significantly higher rate of MSI after ten years (in 40% of the loci tested and in 45% of the subjects) was found in older individuals, whereas no difference between paired samples of any of the young subjects was observed. An overall genomic instability in the elderly was subsequently confirmed with an additional panel of microsatellites, together with the lack of an association between MSI and methylation of MLH1 or MSH2 promoters (Krichevsky et al. 2004).

The possible involvement of the MMR system in the accumulation of genetic damage with age was also studied in peripheral blood cell DNA from a wide survey of differently aged subjects (Neri et al. 2005). Five polymorphic microsatellite loci (CD4, p53, VWA31, TPOX and FES), in accordance with the international criteria for the study of MSI in cancer (Boland et al. 1998), were analyzed to find possible age-related instabilities or modifications in allele frequencies. Indications of instability were supplied by both altered allele frequencies in different groups of age and the appearance of trizygosis (three alleles at one locus instead of one or two). Excluding the appearance of plurizygosity, that represents a direct indication of instability, but whose frequency is expected to be low in healthy subjects without germline mutations in MMR genes, in this study it was not possible to compare the allelic pattern with a control (as between normal and tumour DNA from the same patient). For this reason, shifts in allele length, evaluated in terms of age-related modifications of allele frequencies, gave only an indirect indication of genetic instability, possibly due to defective mechanisms of genomic conservation, such as MMR pathway, with progressive aging.

The VWA31 microsatellite showed a significant shortening with increasing age. VWA31 and FES microsatellite alleles presented peculiar distributions in differently aged groups, further suggesting modifications in microsatellite stability as shown by shifts in patterns of allelic frequencies from young (considered as basal condition) to old populations. Only the FES locus, (the most unstable among the

five analyzed), resulted trizygotic in five samples among the more than two hundred analyzed. All samples that were trizygotic belonged to the old and the centenarian groups, while no young subjects ever showed this pattern (Fig. 2). In addition, the majority of trizygotic centenarians displayed, among the three, a rare allele, never observed in homo- or heterozygosis (Neri et al. 2005).

These data show both an increased instability in very advanced age and an age-dependent genetic damage affecting repeated sequences (whose stability is predominantly guaranteed by the MMR system), or a weaker ability to balance the increased rate of genetic damage due to advancing age. Cells repeatedly undergoing proliferation were more exposed to the repair activity of the MMR pathway and possibly, due to its inefficiency, accumulated a greater genetic damage than naive cells. A basic characteristic of immunosenescence is the decline of naive T-cells as well as the accumulation of specific T-lymphocyte clones, mostly of memory and effector T-cells, due to persistent exposure to different antigenic challenges (Franceschi et al. 2000; Globerson, Effros 2000) (Epstein-Barr virus and cytomegalovirus, being the most frequent) (Wedderbrun et al. 2001; Ouyang et al. 2004). It is conceivable that these clonal cells, repeatedly expanded in vivo, may have progressively incorporated a genetic damage not evident in young subjects that, conversely, present a prevalent naïve phenotype. The presence of such populations, frequently dramatically expanded, (Ouyang et al. 2004) could justify the finding of additional allele bands (trizygosis) in DNA from heterogeneous populations of circulating peripheral blood cells. In fact, to be detectable, mutated alleles should be present in an adequate amount of cells, since the appearance of new alleles might be undetectable in poorly represented cells (less than 5–10%) among a mixed population, because of the overloading amount of normal alleles, therefore inducing an underestimation of MSI.

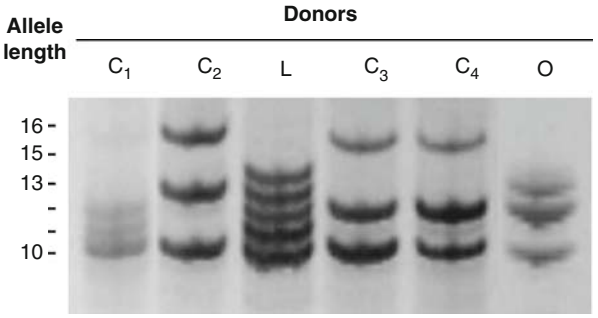

Fig. 2 Trizygosity observed at the FES locus in DNA from peripheral blood lymphocytes of four centenarian (C1-C4) and one old (O) donors. The presence of three alleles at one locus indicates heterogeneity among the analyzed cells, presumably acquired during in vitro replication and giving a different genotype to a portion of cells. Total DNA was amplified by PCR with primers specific for FES microsatellite sequence, then products were electrophoresed on polyacrylamide gel and silver stained. Allele length is indicated on the left and refers to the number of repeats. L= allelic ladder. (from Neri et al. 2005)

As far as the higher instability at the FES locus is concerned, a different sensitivity of this region to the assumed inefficiency of the MMR system is suggested by the evidence that not all sequences are susceptible to, or show the same rate, of MSI. In agreement, a specific FES somatic instability was described in sporadic gastric cancer (Silva et al. 1997) and in lymphocyte clones after in vitro aging (Neri et al. 2004). It is also possible that some alleles undergoing an age-related selection, tend to disappear in the most advanced ages due to a relationship with the FES microsatellite sequence, or with other sequences in linkage disequilibrium with the FES one. The analyzed FES microsatellite lies at intron five of the coding region of FES proto-oncogene that encodes for a nonreceptor protein-tyrosine-kinase whose activation can mediate cellular transformation. Several growth factors, cytokines, immunoglobulin/receptor pairs trigger the activation of cellular FES, shown to play important roles in the regulation of inflammation and immune response (Greer 2002; Yates, Gasson 1996), particularly for survival and terminal differentiation of hematopoietic myeloid lineage (Manfredini et al. 1997). Taking into account the involvement of this factor in the homeostasis of the immune system and modifications of FES-associated microsatellite allele distributions with age, a possible relationship between allelic variants and aging cannot be excluded. Since FES microsatellite alleles are nonexpressed, modifications in allele frequencies might depend on coding sequences in linkage disequilibrium with the analyzed ones, but also on the correlation between the number of repeats and the aging process, thus influencing for example the expression of the gene they are located on, as proposed for VNTR sequences (Bennet et al. 1995). Accordingly, polymorphic alleles of inflammatory cytokines play an important role in age-related chronic inflammatory response diseases, by determining changes in cytokine production (Lio et al. 2002). In addition, it cannot be excluded that polymorphic variations at multiple loci might have produced genotype characteristics contributing to longevity; indeed, a strong familial component of longevity was observed in centenarians (Perls et al. 1998). Different frequencies of variant alleles would indicate a potential functional advantage of those alleles that are more frequent in the disease-free long-lived individuals, as suggested by associations between longevity and allelic variants for polymorphic markers at specific loci such as HLA (Takata et al. 1987), ACE (Schachter et al. 1994), APOB (Kervinen et al. 1994), APOC (Louhija et al. 1994), APOE (Kervinen et al. 1994; Louhija et al. 1994; Schachter et al. 1994), TH and APOB-VNTR (De Benedictis et al. 1998), HRAS1-3'VNTR (Bonafé et al. 2002), as well as mtDNA haplogroups (De Benedictis et al. 1999). Recently, an association between MLH1 gene and longevity was found in centenarians (Kim et al. 2006). In particular, polymorphisms of MLH1 seemed to influence genomic stability and thereby lifespan. By analyzing three SNPs (single nucleotide polymorphisms) leading to amino acid substitutions, a significantly more represented haplotype was found in centenarians than in controls. On the contrary, CD4 (Neri et al. 2005) and p53 (Bonafè et al. 2002; Neri et al. 2005) microsatellites appeared to be stable in different studies, allowing the exclusion of a role of variants of these genes in age-related mortality to such an extent as to alter gene frequency in old people and centenarians.

5.2 The T-cell Clonal Model

To overcome the possible bias of underestimating instability in poorly represented cells, because of the overloading amount of normal alleles, Parsons et al. (1995) performed the analysis on highly diluted peripheral blood lymphocytes in order to amplify the DNA corresponding to maximum three genome equivalents. By analogy, Coolbaugh-Murphy et al. (2005) developed "small pool" PCR for sensitive and quantitative analysis of MSI in somatic tissues by diluting DNA and subsequently amplifying by PCR so that each small pool contained less than a single genome equivalent. Rare mutant fragments contained in one or more small pools would not be overwhelmed by progenitor fragments and could be readily amplified and identified. By using this technique, significant differences in MSI frequencies in DNA from differently aged groups and a positive correlation between age and MSI phenotype were found (Coolbaugh-Murphy et al. 2005). In addition, the frequency of mutant fragments linearly increased with age in peripheral blood lymphocytes from normal individuals, indicating an age-dependent alteration of MMR efficiency.

Long-term CD8+ cell cultures from aged donors undergoing repeated duplications develop MSI as in vitro cell senescence progress, while no MSI develops in young-derived CD8+ T-cells (Krichevsky et al. 2004).

Other studies overcame the problem of heterogeneous cell population analysis by using CD4+ T-cell clones (TCC) (Krickevsky et al. 2004; Neri et al. 2004; Neri et al. 2007). This model allows the longitudinal follow-up of a homogeneous cell population and the functional analysis of a single cell type that, spending its finite lifespan in vitro, provides both important knowledge related to T-cell immunosenescence in vivo and a system to study ways of modulating the aging process (Pawelec et al. 1998; Pawelec et al. 2002). The advantage offered by the analysis of a homogeneous cell population, allowing to join microsatellite instability to increasing duplications in culture, increases the likelihood of detecting new alleles in usually underrepresented cell populations. Indeed, consecutive antigenic stimulation in vitro imposes a marked replicational stress on T-cells, mirroring the antigenic challenge in vivo, as well as, the culture over the entire clonal replicative lifespan mimics the chronic stress thought to really contribute to the possible clonal exhaustion (Hadrup et al. 2006).

Available data indicate that MSI develop with increasing in vitro culture senescence in CD4+ T-cell clones (Krickevsky et al. 2004; Neri et al. 2004), involving different microsatellite sequences, suggesting that a progressive impairment of the MMR system may contribute to the acquisition of genetic damage during chronic antigenic stress in vitro, a phenomenon thought to be of great importance for immune response physiology (Pawelec et al. 2005; Hadrup et al. 2006).

In addition, by a modification of the alkaline comet assay, a reduced ability to repair acridine ICR-191-induced DNA mismatches was observed with aging in culture, indicating that MMR capacity may become deficient in clonal T-cells when they are challenged with supra-physiological levels of DNA damage (Annet et al. 2005).

Moreover, no MSI was observed at increasing population doublings in TCC from young donors, even almost at the end of their finite lifespan in culture (Neri et al. 2004), suggesting an additional relationship between MSI and donor age, in agreement with in vivo data (Ben Yehuda et al. 2000; Krickevsky et al. 2004; Coolbaugh-Murphy et al. 2005; Neri et al. 2005).

Furthermore, microsatellite instability was particularly evident in clones obtained by CD34+ progenitor cells, after undergoing repeated duplication in culture, indicating also the influence of the cell type in addition to in vitro proliferation and aging (Fig. 3).

This may suggest that the efficiency of the MMR system is already optimal in mature T-cells, but that it is less efficient in CD34+ progenitors due to their maturation stage and requirement for differentiation to T-cells in vitro and not in the normal in vivo environment (Pawelec et al. 1998); indeed, early progenitors are

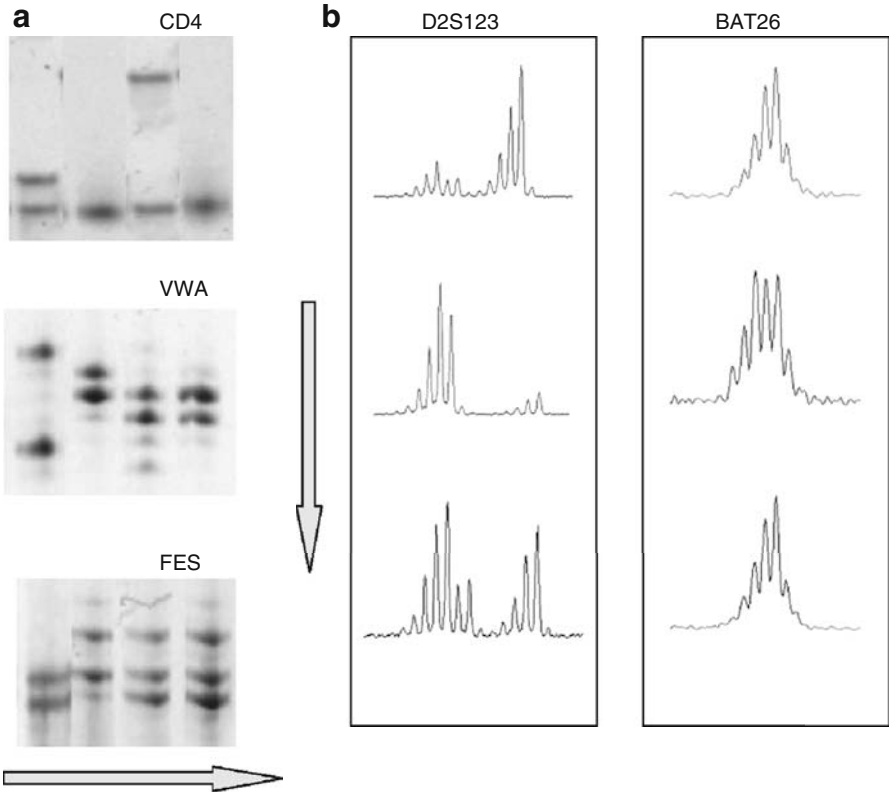

Fig. 3 Example of MSI evidenced during in vitro culture of one clone obtained from CD34+ precursors. CD4, VWA, FES, D2S123 and BAT26 allelic patterns, determined after different population doublings (PD) in culture, are shown. Genotyping was done: a: by PCR followed by analysis on standard acrilamyde gels for CD4, VWA and FES microsatellites; b: by analysis on an automated DNA sequencer for D2S123 and BAT26 microsatellites. Modifications of band length or peak position appear at increasing PD (grey arrows) (Neri et al. 2007)

highly proliferative and, during this period, most susceptible to DNA damage (Park, Gerson 2005). Maturation-dependent alterations in DNA repair function have been demonstrated for the lymphohematopoietic system in association with shifts in DNA repair gene expression profiles (Bracker et al. 2006). In addition, CD34+ cells might have lower levels of genetic integrity control, because they perform T-cell receptor rearrangement in culture. On the other hand, a role of the MMR system in general recombinational processes, VDJ hypermutation and class-switch recombination is well documented (Cascalho et al. 1998; Bellacosa 2001; Larson et al. 2005). Finally, it cannot be excluded that the in vitro system is unable to remove cells that acquired genetic alterations as in vivo occurs by apoptosis. The high instability found during in vitro culture of CD34+ cell-derived clones may suggest the need for particular care for the clinical use of these cells, such as in stem cell transplantation.

The observed MSI did not depend on modifications in the methylation status of MLH1 and MSH2 promoters, as assessed by methylation-specific PCR following bisulfite treatment of clone DNA and no association among methylation status, MMR gene expression, advanced population doublings or presence of MSI was found (Krichevski et al. 2004; Neri et al. 2007).

Semi-quantitative real time RT-PCR showed that transcript levels of the six MMR genes were similar to those observed in total RNA from normal PBMC. MSH6 RNA showed a progressive increase until about 50–60 PD, followed by a slow decrease, while MSH3 mRNA exponentially increased until the more advanced PD, thus suggesting a possible shift from MutSα to MutSβ heterodimer at advanced culture passages. MLH1 RNA did not change significantly during PD, while PMS2 and PMS1 RNA levels increased exponentially (Neri et al. 2007). During aging in culture, unstable clones often presented unstable or decreasing levels of expression, while stable ones constantly increased their expression levels, consistent with a relationship between MMR gene expression, PD and MSI (Neri et al. 2007). In agreement, multivariate regression analysis identified advanced PD as one of the predicting variables for FES MSI, trizygosis and intra-donor changes among clones. MSI and MMR gene expression at the mRNA level were found to correlate, mostly due to a reduced expression of the components of MutL heterodimers, pointing to a role of MMR in the acquisition of DNA damage with in vitro aging: the MutS components MSH6 and MSH3 appeared to be slightly increased in unstable clones; in contrast, the MutL components PMS2 and PMS1 showed decreased transcript levels in unstable compared to stable clones (Neri et al. 2007). This might suggest that unstable TCC maintain the ability to interact with mismatched DNA via MutS, but have a reduced capacity to recruit the enzymes necessary to complete the repair via MutL complexes. Therefore, the upregulation of MutS components in unstable clones, possibly in order to correct DNA mismatches occurring during in vitro proliferation, seems to be not accompanied by an upregulation of MutL components leading to MSI for a reduced expression of PMS2 and PMS1. However, additional posttranscriptional regulation of these genes cannot be definitely excluded. Only limited information is available thus far on the genetic regulation of the MMR system. In MMR proficient cell lines, the regulation seems primarily at the transcriptional level, but mutational inactivation of the components of the system leads

to posttranslational down-regulation of heterodimerizing partners. MMR activity appears to be strictly regulated and modulated by changes in gene expression as demonstrated by MSI induction for loss of MLH1 expression secondary to promoter-hypermethylation (Herman et al. 1998) or by overexpression of MLH1 and MSH3 genes (Marra et al. 1998; Shcherbakova, Kunkel 1999). Therefore, it cannot be excluded that the upregulation of RNA for the MutS components is induced by a defect in the corresponding proteins.

Concerning a possible effect of donor age on MSI, clones from centenarians (an example of successful aging and of preserved immune function) presented a level of instability very similar to young-derived clones, despite the presence of significantly higher levels of MMR transcripts. In contrast, clones from old subjects presented a higher instability compared to young ones, but similar levels of MMR gene expression (Fig. 4). This might reflect the importance of up regulating MMR genes in order to maintain genomic stability and to correct DNA errors accumulating with age, thus suggesting a protective effect of higher MMR transcript levels on genomic integrity.

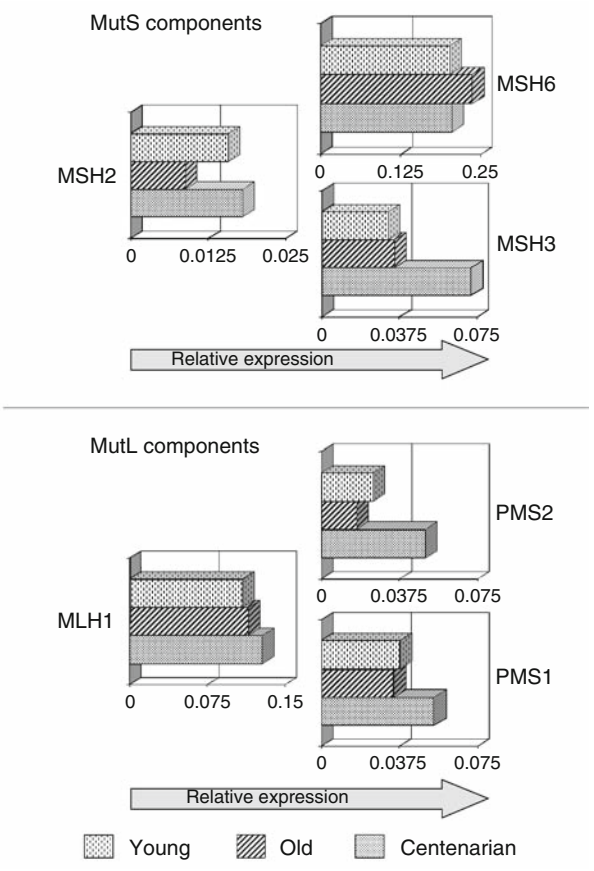

Fig. 4 MMR gene expression at mRNA level (medians) during culture aging of TCC from young, old and centenarian donors (from Neri et al. 2007)

The evidence of differences in allelic patterns among different clones from the same donor suggests the acquisition of new alleles in previous not analyzed culture passages or even before cloning, further supporting the accumulation of MSI even in vivo, as suggested by studies on peripheral blood cells (Ben-Yehuda et al. 2000; Coolbaugh-Murphy et al. 2005; Neri et al. 2005).

In conclusion, it appears that in vitro aging leads to an accumulation of genetic instability manifesting as MSI, possibly to a different extent, depending on cell type, and/or that repeated replication could lead to an accumulation of genetic alterations not counteracted by the MMR system. The correlation between MMR gene expression levels and MSI appeared mostly due to a reduced expression of the components of MutL heterodimers. However, the involvement of other repair pathways (Guo, Loeb 2003) or a possible alteration in polymerase functional activity (Srivastava, Busbee 2003) cannot be excluded. Senescence-associated MMR alterations might also be induced by defects of nuclear localization, assembly and activity of the proteins of this pathway, therefore studies on MMR gene protein levels and functional activity of the MMR system could help in the understanding of these alterations associated to senescence, likely critical for appropriate adaptive immune response.

Acknowledgments This work was partially supported by grants from Bologna University RFO (60% fund), Ricerca Corrente IOR, Italian Health Ministry fund and was performed under the aegis of EU ZINCAGE project (FOOD-CT-2003-506850) and T-CIA (QLK6-CT-2002-02283). Activation-Induced Cell Death of T-cells in Elderly

Ewa Sikora and Agnieszka Brzezińska

Contents

Abstract: The elimination of expanded T-cells at the end of immune response is crucial to maintain homeostasis and avoid any uncontrolled inflammation. Resting mature T-lymphocytes when activated *via* their antigen-specific receptor (TCR) and CD28 coreceptor start to proliferate and acquire resistance to apoptosis. Reactivation of T-cells induces expression of CD95L which after binding to CD95 surface-expressed death receptor triggers signaling pathway to apoptosis. The process is named Activation-Induced Cell Death-AICD. However, in executing AICD death receptor-dependent apoptotic pathway (extrinsic) can overlap with mitochondrial (intrinsic) signaling to apoptosis. Immunosenescence leads to the shrinkage of T-cell repertoire due to the reduction of naïve cells and accumulation of oligoclonal CD8+ and to a lower extent CD4+ cells, which are mainly CD95-positive and CD28-negative. Also, propensity to undergo apoptosis changes with age. However, data so far collected are inconclusive as they show an increased, unchanged or decreased propensity to AICD in the elderly in comparison with young individuals.

1 Introduction

Precursor T-cells from the bone marrow enter the thymus, where they undergo negative or positive selection to produce CD4+ and CD8+ mature cells with diverse functions in the peripheral immune system [34]. In the periphery, T-cells are resting until they encounter foreign antigens and gain the ability to proliferate, differentiate into effector cells, produce cytokines and eliminate target cells. T-cell activation is induced by signal receive through the TCR (T-Cell Receptor) activated by the antigen

presented by APC (Antigen Presenting Cells) in MHC context, and costimulatory molecules, including CD28, adhesion molecules and cytokines (IL-2, IL-13, IL-15). This clonal expansion phase is followed by the contraction phase in which T-cell numbers decline to maintain homeostasis and avoid any uncontrolled inflammation. The majority of activated T-cells die by apoptosis and only a few T-cells that have been exposed to the antigen remain. These cells develop into apoptosis-resistant memory T-cells. The mechanism of memory T-cells' survival is not fully recognized, but it can be controlled by cytokines [27, 46]. Thus, T-cell activation is highly regulated and requires a switch from an apoptosis-resistant (clonal expansion phase) towards an apoptosis-sensitive state (elimination phase). The process in which expanded cells are eventually eliminated is named Activation-Induced Cell Death (AICD).

The term AICD was proposed by Green's group, when they showed that T-cell hybridomas or thymocytes died by apoptosis following activation through their CD3 molecules [44]. It is now know that AICD of hybridomas and of activated T-cells is driven by so called death receptors, such as CD95 (another name is Fas receptor) or the tumor-necrosis factor receptor (TNFR) which, once engaged, activate downstream pathways that lead to cell death by apoptosis [26].

An alternative pathway to that driven by death receptors is activated T-cell autonomous death (ACAD), which is determined by the ratio of anti and proapoptotic BCL-2 family members with the major role of a proapoptotic BIM protein. This type of cell death is known also as death by cytokine deprivation or by neglect [18]. Namely, the absence of appropriate survival signals induces BIM, which on the mitochondrial membrane can bind and neutralize the antiapoptotic BCL-2 or BCL-X_L (see below).

T-cells, similarly to other cells, can undergo Damage-Induced Cell Death (DICD), which is a cell response to DNA damage induced by both extracellular and intracellular insults, such as reactive oxygen species [13].

All three processes, although differentially regulated culminate in apoptotic cell death named also programmed cell death.

2 Apoptotic Pathways in T-cells

Apoptosis, or programmed cell death, is a fundamental process essential for both development and tissue homeostasis (reviewed in [21]). In the immune system, apoptosis plays a crucial role in selection of T-cell repertoire in the thymus, deletion of self-reactive T- and B-lymphocytes both in the central and peripheral lymphoid compartments, and in the killing of target cells by cytotoxic T-lymphocytes and natural killer cells [33]. Defects in apoptosis have been associated with a number of disease states, including autoimmunity and AIDS [48].

Cells undergoing apoptosis exhibit specific morphological changes, including membrane blebbing, cytoplasmic and chromatin condensation, DNA fragmentation, nuclear breakdown and assembly of membrane-enclosed vesicles termed apoptotic bodies, eventually subjected to phagocytosis [55]. The dying cells express "eat-me" signals, such as phosphatidyl serine, which allow the cells to be removed by phagocytosis.

Two major signaling pathways of apoptosis have been described: the extrinsic pathway induced by ligation of death receptors, and the intrinsic pathway comprised of the mitochondrial and endoplasmic reticulum pathways and induced by DNA damage, cytokine deprivation, gluccocorticoids or stress (Fig. 1). There is some crosstalk between these apoptotic pathways, but they lead to activation of different initiator caspases, which in turn activate common effector caspases 3, 6 and 7 [16, 26]. One of the terminal events of the apoptotic signaling pathways is activation of specific endonucleases cleaving DNA into oligunucleosomal fragments: Endo G and DFF/CAD. The latter is activated by effector caspases which cleave the DFF/CAD inhibitory protein [53]. The effector caspases cleave also a number of other important cellular proteins including actin, lamins, gasoline, plectin and others; their degradation in turn leads to the blebbing and formation of apoptotic bodies and final cell destruction.

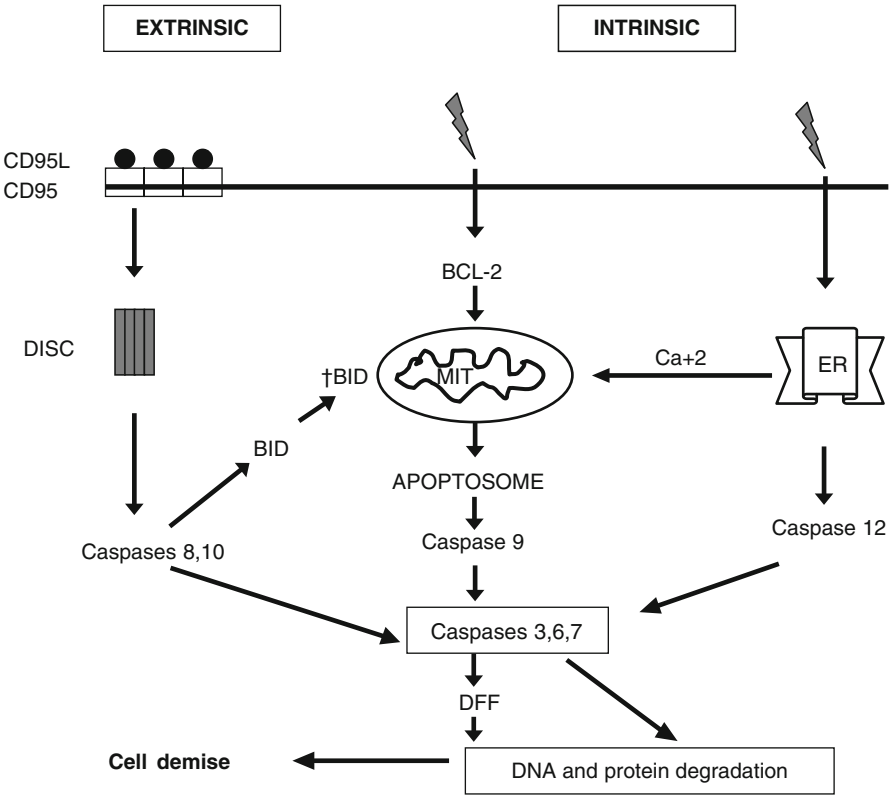

Fig. 1 The cross-talk of apoptotic pathways
The extrinsic pathway is mediated by interaction between death receptor and its ligand and leads to activation of initiator caspases 8, 10. The intrinsic pathway is comprised of the mitochondrial pathway (MIT) and the endoplasmic reticulum (ER) pathway. The mitochondrial pathway leads to activation of initiator caspase 9 and endoplasmic reticulum pathway to activation of initiator caspase 12. All initiator caspases activate effector caspases 3, 6 and 7 which in turn activates specific endonuclease (DFF) and depredate cellular proteins.

The intrinsic apoptotic pathway crucially depends on permeabilization of the outer mitochondrial membrane and mitochondria seem to be integrators of the many apoptotic signals coming from the outside and inside the cell. After receiving an apoptotic signal, mitochondria release a variety of molecules of which cytochrome c seems to be the most important one, which together with cytoplasmic apoptotic-protease-activating factor 1 (APAF1) forms the apoptosome. At the apoptosome initiator caspase 9 is activated. Crucial roles in determining the mitochondrial membrane permeability is controlled primarily by a balance between the antagonistic actions of the proapoptotic and antiapoptotic members of the BCL-2 family. Antiapoptotic members, such as BCL-2 and BCL-X_L possess so named BH1-4 domains. Proapoptotic BCL-2 family proteins comprise two subfamilies: the first including BAX, BAK and BOK, which have BH1-3 domains and the second including BH3-only members, such as BAD, BID, BIM and others. BH3- only proteins, like BIM can bind and neutralize the antiapoptotic BCL-2 or BCL-X_L. This in turn activates proapoptotic BAX or BAK which release cytochrome c from mitochondria.

The extrinsic apoptotic pathway is triggered by signals originating with cell-surface death receptors belonging to the TNF receptor (TNFR) superfamily that are activated by several ligands such as CD95L (also known as FasL), tumor necrosis factor (TNF) or TNF-related apoptosis-inducing ligand (TRAIL). Transduction of the apoptotic signal from the death receptors starts with the formation of a large protein complex at the cell membrane, known as the death inducing signaling complex—DISC. The CD95 DISC consists of trimerized CD95, the adaptor molecule FADD containing so called DD domain, procaspase 8a (also named FLICE), procaspase 8b, procaspase 10 and the cellular FLIP (cFLIP) protein. FLIP protein contains inactive caspase-like domain. Three isoforms of cFLIP are known, but only cFLIPs seem to exert an inhibitory effect on caspase 8 activation. Procaspases 8 and 10 as well as FADD and cFLIP contain DED domain which is required for DISC formation. Thus, formation of the DISC results in the assembly of procaspase 8 and procaspase 10 leading to their autoproteolytic activation. In some cells this signaling pathway suffices to induce executor caspases and eventual cell death (Type I cells). However, the level of CD95 DISC and of active caspase 8 may be too low (Type II cells) and the signal requires on additional amplification loop involving the cleavage of a BH-only BCL-2 family protein, BID, by caspase 8 to form truncated BID (tBID). tBID in turn aggregates BAX or BAK, which leads to mitochondria membrane permebilization and cytochrome c release [26].

3 Mechanism of Activation-Induced Cell Death

AICD is believed to be the major mechanism of elimination of T-cells during the termination phase of immune response. Following pathogen entry, T-cell activation *via* TCR and coreceptors induces their proliferation and clonal expansion. Pathogen killing by effector cells is followed by a severe decrease of T-cell proliferation and the beginning of T-cell elimination by death receptor-dependent apoptosis (Fig. 2)

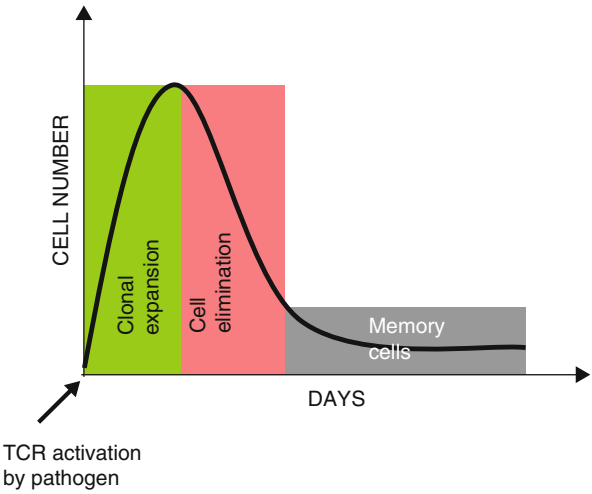

Fig. 2 Immune response Following patogen entry, TCR activation induces T-cell proliferation and clonal expansion. Pathogen killing by effector cells is followed by cell elimination by death receptor-driven apoptosis.

[22]. Upon stimulation of activated T-cells CD95L mRNA and protein expression on the surface of cell are rapidly induced. CD95L binds to the CD95 receptor on the same cell that express CD95L or on neighboring cells and triggers CD95-dependent apoptosis. The first type of CD95/CD95L interaction results in autocrine (suicide) and the second type in paracrine (fratricide) type of death [26].

Studies performed on murine and human T-cells suggested several transcription factors to be involved in activation of CD95L expression, such as Ap-1, NFAT, NFκB, c-Myc, Erg 1 & 3, and others. Cooperation between some of them is necessary for CD95 gene activation. Also, several tyrosine kinases known to be involved, such as PKC, Lck, ZAP-70 and MAPK, among others [14, 19].

An in vitro system of T-cell immune response believed to mimic the shutdown of immune response occurring in vivo has been developed by Krammer's group [24] and now this model is used, with some modifications by many investigators. Originally, freshly isolated primary human T-cells were activated with the non-specific mitogen-PHA for several hours (short–term activated), which respond to CD95 driven apoptosis resistance. However, after in vitro culture lasting for several days (long-term activated), the activated T-cells acquired sensitivity to death receptor-driven cell death, and IL-2 was found to be necessary for this sensitization [27, 43].

CD95 is not expressed on T-cells derived from cord blood or on naïve resting T-cells, but is rapidly up-regulated upon T-cell activation [23]. Although it was shown that long-term activated cells prone to AICD and short-term activated cells resistant to AICD express similar high amounts of CD95 [24]. This observation suggests that the signaling cascade downstream of CD95 must be modulated. Indeed, the cFLIP protein, and particularly its cFLIPs isoform, a potent inhibitor of CD95-mediated apoptosis, was found to be expressed at a high level in short- but not in long-term activated T-cells [2, 20]. Moreover, it was shown that inhibition of IL-2 production or signaling prevented down-regulation of FLIP protein levels and conferred resistance to CD95-mediated apoptosis on TCR-activated cells [2]. It cannot be

excluded that expression of antiapoptotic BCL-2 family members, such as BCL-2 and BCL-X_L, might provide additional protection against cell death at the level of mitochondria [3].

Overall, AICD regulation is rather complex and involves both extrinsic and intrinsic mechanisms of apoptosis; it is also tightly connected with survival signaling pathways triggered by TCR and cytokines [26] (Fig. 3).

TCR–mediated NFkB signaling is critical for cell survival (death resistance) by inducing prosurvival and antiapoptotic genes [3]. It has been postulated that the hematopoetic progenitor kinase HPK1-C mediates sensitivity towards AICD by suppression of NFκB activity [4].

4 Age-Related Alterations of Activation-Induced Cell Death of Human T-cells

The aging of the immune system, termed immunosenescence involves several components which lead to its decreased functionality contributing to the morbidity and mortality of elderly people. The main aspects of immunosenescence are: (i) the

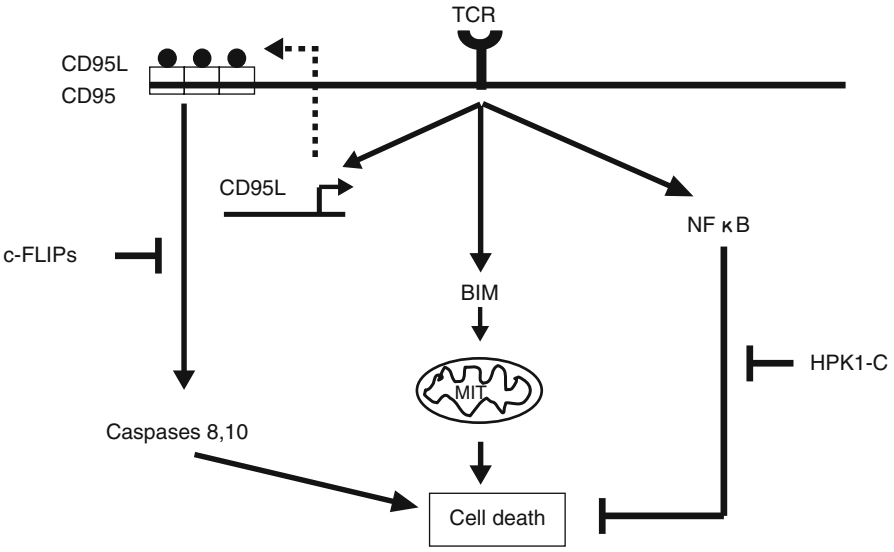

Fig. 3 TCR-mediated signals to cell death and survival
Stimulation of the TCR receptor can lead to CD95L transcription and engagement of CD95, thus activation of the extrinsic apoptotic pathway. TCR stimulation can also cause activation of the intrinsic apoptotic pathway via BH3-only BCL-2 family BIM. The extrinsic death pathway can be connected to the intrinsic pathway by caspase 8-mediated cleavage of the BH3-only BCL-2 family member BID towards truncated BID (tBID). TCR-mediated NFκB signaling is critical for cell survival and can be blocked by HPK1-C. On the other hand, apoptosis can be blocked by c-FLIPs.

involution of the thymus and exhaustion of naïve T-cells; (ii) the diminution of the T-cell repertoire and accumulation of oligoclonal expansions (megaclones) of memory/effector cells; and (iii) a chronic inflammatory state called inflamm-aging [8].

T-cell senescence in humans involves alterations similar to those observed in other cell types, such as changes in functions, cessation of cell proliferation due to shortening of telomeres and a changed propensity to undergo apoptosis. The senescence is seen primarily in the CD8+ T-cell population but it also occurs in CD4+ T-cells [11, 50].

Alterations of apoptosis in T-cells from aged individuals have been reported by many investigators, however, a consensus is still lacking in this matter especially since many studies were only correlative. Some authors show that aging is associated with increased apoptosis of T-cells, whereas others report the opposite (reviewed in [15, 19, 29]). These apparent discrepancies might be due to differences in the stimuli investigated, the phenotype of the cells as well as the general experimental approach. Also, some experiments were performed on lymphocytes undergoing in vitro replicative senescence [45] while others on cells derived from donors of different ages [36]. According to our results, replicative senescence in vitro only partially reflects the in vivo process [5-7].

Moreover, there is profound confusion in the literature concerning the term AICD, partially due to some overlapping of dead receptor-driven and mitochondria-mediated apoptosis in this process. Second, the question is whether the propensity of activated T-cells to undergo apoptosis upon death receptors activation (treatment with CD95L or anti CD95 mAb) can be considered as AICD? Taking into account that AICD is undergoing *via* engagement of death receptors this can help in understanding this process. (Death receptor-driven apoptosis is the subject of another chapter).

However, we must keep in mind that according to classical definition, AICD is induced by religation of TCR on activated cells [25]. Finally, it should be also remembered that AICD is not the only mechanism of T-cell death during shutdown of the immune response [47].

Generally, the literature guides us to three possibilities concerning AICD in the aging process. The first is that **T-cell susceptibility to AICD is increased**.

Despite the induction of CD95L, the main indictor of the cell ability to undergo AICD is the expression of CD95 receptor. While T-cells from cord blood are CD95-negative, the proportion of CD95-positive cells are growing with age [12, 41]. Moreover, Aggarwal and Gupta [1] reported on increased expression of CD95 mRNA in the elderly in comparison with young subjects. Fagnoni et al. [12] postulated the CD95-negative cells disappearing with age are unprimed, naïve cells. We also found a dramatic decrease in percentage of CD95-negative cells with age, from virtually 100% (not shown) in the cord blood to almost undetectable in peripheral blood of centenarians (Fig. 4). However, PBMC cultures from young and old individuals alike show an increase in CD95 expression upon activation, the cells from old individuals reaching even higher CD95 levels than those from young individuals [31, 37, 40]. Therefore, T-cells from the elderly are able to respond to activation with CD95 engagement. Moreover, some studies of T-cells from elderly subjects do appear to show a correlation between the increased CD95 expression and increased activation-induced

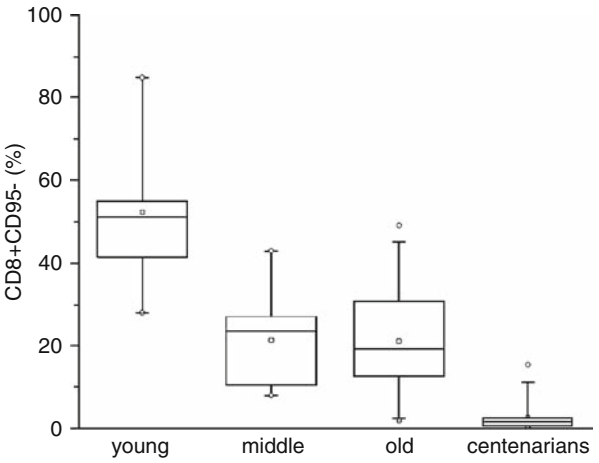

Fig. 4 Fraction of CD95- cells in peripheral blood of donors at different ages Young (aged 25–35, N=16), middle (aged 45–55, N=11), old (aged 65, N=37), centenarians (N=32).

cell death [30, 37, 40]. Lechner et al. [30] observed no differences in the incidence of apoptosis in response to activation between PBMC from young and old subjects. However, under long-term cultivation, namely at replicative senescence in vitro, an increase of AICD was observed and it was more pronounced in T-cell populations from old than from young individuals. Phelouzat et al. [36] reported a greater depletion of T-cells upon stimulation in old than in young PBMC which was shown to be due to apoptosis. Similar results were obtained by Potestio et al. [40]. Schindowski et al. [42] described a slight but statistically significant increase of AICD in elderly in comparison to young individuals. Pawelec et al. [35] reported on increased susceptibility to AICD in a late-passage in comparison to an early-passage CD4+ cultured T-cell clone. Greater CD95-induced apoptosis was found in anti-CD3 stimulated CD4+ than in CD8+ cells derived from healthy donors, and both CD4+ and CD8+ T-cells from the elderly were more sensitive than those from young individuals [1].

The presented so far data indicate that activated T-cells from the elderly are more susceptible to undergoing AICD than cells from younger subjects, moreover, the population of CD4+ cells is more sensitive to cell death then the CD8+ cells.

Based on those studies as well as the results emerging from studies on mice, Ginaldi proposed recently an increased propensity to AICD as a hallmark of aging [13]. However, the literature also shows evidence in favor of other possibilities, namely that **T-cell susceptibility to AICD is unchanged or even decreased with age.** Pinti et al. [38], similarly to others reported on increasing number of CD95-positive cells and an increased level of Fas mRNA with age. Although the reverse trend was observed in the case of FasL in resting cells, the amount of FasL produced by lymphocytes upon activation with anti-CD3 was the same irrespective of the age of donors (young, middle-aged, centenarians). Also AICD level was the same in T-cells from all three groups. This is in agreement with our results showing no differences in AICD levels in T-lymphocytes derived from young in comparison to old donors. Following a slightly modified classical protocol described by Krammer's group [24], PBMC cells were stimulated with PHA for 72 h and then cultured in the presence of IL-2

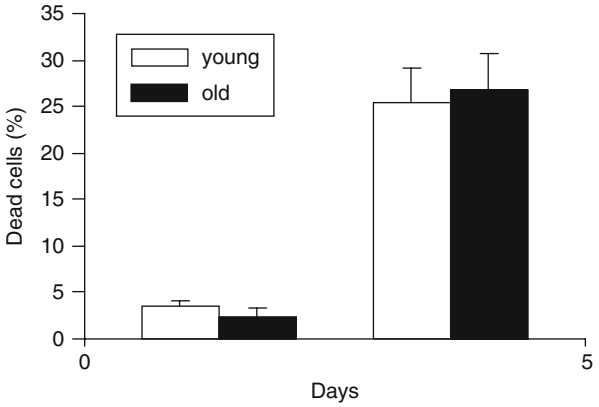

Fig. 5 AICD of T-cells derived from young (aged 25-31, N = 4) and old (aged 65, N = 4) donors. PBMC cells were stimulated with PHA for 72 h and then cultured in the presence of IL-2.

(Fig. 5). However, this protocol does not correctly reflect the situation in vivo, as the production of IL-2 is severely diminished with age. Similar results, namely the same level of AICD in young and old subjects, were obtained by Herndon et al. [17]. However, more recent results from this laboratory indicated for decreased AICD in donors aged 70–85 years in comparison with younger ones (25–65-year old), but also in comparison with nonagenarians. Thus from this results it is difficult to conclude whether AICD is really diminished with the age [19]. Whereas, Donnini et al. clearly showed that the AICD level analyzed in CD4+ cell subsets, namely naïve (CD62L+CD95-) and memory (CD62L-CD95+), did not correlate with the age [10].

Indirect, but convincing arguments of reduced AICD in elderly come from experiments on the role of lipid rafts in immunosenescence. Lipid rafts are involved in many processes, but mainly in signal transduction in T-cells, which is obviously impaired in the elderly [28, 29]. It was shown that disruption of lipid rafts reduced the sensitivity to Fas-mediated apoptosis after TCR restimulation of CD4+ cells. Thus, the redistribution of Fas and other tumor necrosis factor family receptors into and out of lipid rafts may dynamically regulate the efficiency and outcomes of signaling by these receptors [32]. Larbi et al. [29] reported a decreased expression of Fas and FasL in old in comparison with young donors. Expression of Fas was diminished and expression of FasL was completely abolished in stimulated lymphocytes after disruption of lipid rafts. It was shown that activation of lipid rafts was possible only upon ligation of both TCR and CD28, implying that CD28 might be critical in the signal transduction leading to AICD.

5 The Role of CD28 Coreceptor in Age-Dependent AICD of T-cells

Senescence effects numerous changes in the phenotype and the functioning of T-cells. Lifelong and chronic antigenic load may represent the major driving force of immunosenescence due to reducing the number of naïve antigen-nonexperienced

cells and their replacement by expanded clones of antigen-experienced effector and memory T-cells with late differentiated phenotype. The thymus releases fewer naïve cells with age and those T-cells remaining, especially the CD8+subset, show increased oligoclonality with age [51].

The recognition of MHC-bound antigen by TCR is a low-affinity interaction unable to sustain activation of T-cells; productive activation requires costimulation with CD28 which serves as an amplifier of the TCR signal [50]. By activating Akt, CD28 acts as a typical transducer of the prosurvival pathway [19].

It is known that T-cell activation leads to CD28 down-regulation. Indeed, various models of T-cell replicative senescence show that subsequent rounds of cell divisions eventually lead to accumulation of CD28-negative cells, which are the progeny of CD28-positive ones [7, 11, 39]. We showed a gradual replacement of CD8+CD28+ cells by CD28- cells in long-term cultures both in the cord blood and in the peripheral blood of donors of different age, including centenarians [7]. It was also shown that purified human CD28+ T-cells progressively lose CD28 during each successive stimulation, with CD8+ T-cells losing CD28 more rapidly than CD4+ cells [50]. Also in vivo the accumulation with age of CD8+CD28- and to lesser extent CD4+CD28- is observed [7, 11, 12, 19, 50, 54]. CD28-negative cells are highly oligoclonal and have very short telomeres [50]. It is believed that they are unable to proliferate, however, we found that this is only true in the case of cells undergoing replicative senescence in vitro, but not for those aging in vivo [7].

As they accumulate progressively through life and large clones persist for years, CD28-negative cells are considered to be resistant to AICD. Indeed, Posnett et al. [39] demonstrated that CD8+CD28- cells activated with a superantigen were less susceptible to apoptosis than their CD8+CD28+ counterparts. Spaulding et al. [45] showed that T-cells reactivated after achieving in vitro the state of replicative senescence acquired resistance do apoptosis induced with different stimuli, including antiCD3 and antiFas.

Many of the CD8+ and CD28- expanded clones seem to result from previous infections by persistent viruses, especially CMV and to lesser extent, EBV and other herpesviruses. These are considered dysfunctional, “anergic” cells possibly at least partly due to apoptosis resistance, however a direct proof of their AICD resistance is lacking [51]. Thus it seems that accumulation with age of long-living CD8+CD28- cells can actually be explained by their relative resistance to AICD. Also CD4+CD28- cells, unlike their CD28+ counterparts, were shown to be protected from AICD due to high expression of cFLIP [49].

On the other hand, the data showing quite opposite correlation between CD28 and AICD can not be neglected. We showed no differences between CD28+ and CD28- in susceptibility to undergo AICD [6], but there are results providing evidences that maintenance of CD28 expression on T-cells may be even crucial for prevention of Fas-mediated apoptosis during the course of antigen engagement. Indeed, it was documented that within a superantigen-activated T-cell population, cells which were sensitive to Fas ligation were characterized by low CD28 expression prior to treatment with Fas [52]. It was also shown that CD28-mediated signaling increases expression of antiapoptotic BCL-X_L and thereby promotes survival

implying antiapoptotic activity of CD28. Indeed, Krammer's group reported that activated and cultured in the presence of IL-2 T-cells (undergoing AICD) when co-stimulated by CD28 showed, besides strong up-regulation of BCL-X_L, down-regulation of CD95L mRNA and strong up-regulation of cFLIPs [23]. In agreement with these results are data presented by others showing that low CD28 expression predispose to CD95L mediated apoptosis in activated T-cells and CD28 ligation protects from apoptosis [9].

6 Concluding Remarks

Immunosenscence is believed to be driven by thymus involution, continuous pathogen load and common damaging insults. This leads to the shrinkage of T-cell repertoire due to the reduction of naïve cells and accumulation of oligoclonal CD8+ and, to a lesser extent, CD4+ cells, displaying a highly differentiated and senescent phenotype with diminished functioning. Activation-Induced Cell Death plays a crucial role in the proper function of the immune system by elimination of expanded cells at the end of immune response. This logically implies a crucial role of AICD in immunosenescence. Indeed, some data published so far indicates AICD changes in the elderly. Nonetheless, this observations are inconclusive, some showing an increased some a decreased propensity of T-cells to AICD in the elderly. There are also reports of unchanged AICD with age. This apparent controversy probably stems from different experimental approaches and highly fragmentary data, especially concerning human studies. Systematic and comprehensive studies are still needed for a conclusive elucidation of the role of AICD in human aging.

TRAF	Tumor necrosis factor receptor associated factor
TRAIL	Tumor necrosis factor-related apoptosis-inducing ligand

Abstract: Aging is associated with a variety of perturbations in the immune system. One frequent alteration is a significant skewing of the CD8 T-cell repertoire. This alteration manifests as a clonal expansion of CD8 memory T cells, which in some cases can occupy the majority of the CD8 T-cell pool. CD8 clonal expansions are associated with impaired immunity in the elderly. Although CD8 clonal expansions are commonly found in aging humans and mice, the etiology of this phenomenon is unknown. Here, we describe our current understanding of CD8 clonal expansions as it relates to the current state of knowledge about CD8 T-cell memory. In addition, we discuss the heterogeneity observed between different types of clonal expansions in mice, and how distinct factors may influence both the development and properties of clonal expansions in the aging individual.

Keywords: Ageing • CD8 clonal expansion • CD8 memory T-cell • Homeostasis • TCE

1 T-cells, TCR Diversity and the Phenomenon of CD8 Clonal Expansions

A hallmark of the adaptive immune system is its capacity to respond to a myriad of different challenges. One way that individuals are able to respond to diverse pathogens is through the generation of a highly diverse T-cell repertoire, in which each T-cell expresses a slightly different T-cell receptor (TCR). Each TCR is created through a process of gene rearrangement of TCR gene segments, followed by further diversification methods. Notably, each distinct TCR recognizes a slightly different

combination of a short peptide (referred to as antigen) presented in the context of a major histocompatibility complex (MHC) molecule. Once a T-cell (and TCR) encounters its correct antigen and the appropriate stimulatory conditions, the T-cell can undergo a series of steps, including activation, proliferation, and the acquisition of effector functions through which the T-cell mediates its protective effects. CD8+ T-cells recognize antigen in the context of MHC Class I molecules and respond to, and control, a variety of intracellular infections (such as bacteria and viruses).

While young, healthy individuals possess a diverse CD8 T-cell pool, many aged individuals develop significant perturbations in the repertoire of TCR specificities. In these individuals, a single CD8 T-cell achieves a competitive advantage relative to its neighbors and comes to dominate the entire CD8 T-cell pool, a phenomenon referred to as CD8 T-cell clonal expansions (or TCEs). This phenomenon is of significant interest for many reasons. First, it is a common age-associated alteration to the immune system. Second, it results in a significant perturbation to the normally diverse CD8 T-cell repertoire. Third, it has been associated with impaired immunity in the aged. Fourth, it represents a significant breakdown in the normal homeostatic mechanisms that regulate CD8 T-cell survival and proliferation.

This chapter will focus on the biology of CD8 clonal expansions in mice, with only brief discussion of clonal expansions in humans. It should be noted that while there are some differences between clonal expansions in mice and in humans (for further discussion see [24]), CD8 clonal expansions in both species are characterized by the selective outgrowth of a specific subtype of CD8 T-cell, the CD8 memory T-cell. In order to understand the properties of clonal expansions, it is essential to have basic information about CD8 memory T-cells, their development, regulation, and biological properties.

2 CD8 Memory T-cell Differentiation

2.1 Memory T-cell Differentiation Following an Acute Exposure to Antigen

Following TCR stimulation by antigen, a naïve CD8 T-cell initiates a program of activation, proliferation and differentiation (Fig. 1a) [56]. The resulting CD8 T-cell response is characterized by multiple phases: i) proliferation and expansion of antigen-specific CD8 T-cells, during which these cells acquire a variety of effector functions (such as cytokine secretion and the capacity to kill target cells expressing the appropriate antigen), ii) a period of contraction during which 90–95% of the total number of antigen-specific CD8 T-cells undergo apoptosis, and iii) a period of further differentiation during which the remaining 5–10% of antigen-specific CD8 T-cells acquire additional phenotypic changes, to ultimately become a CD8 memory T-cell (Fig. 1a). During the expansion phase, antigen-specific CD8 T-cells can occupy a massive fraction of the CD8 T-cell pool (e.g., during acute lymphocytic choriomeningitis virus (LCMV) infection, at least 80% of the CD8 T-cells in the spleen are specific for LCMV [84]).

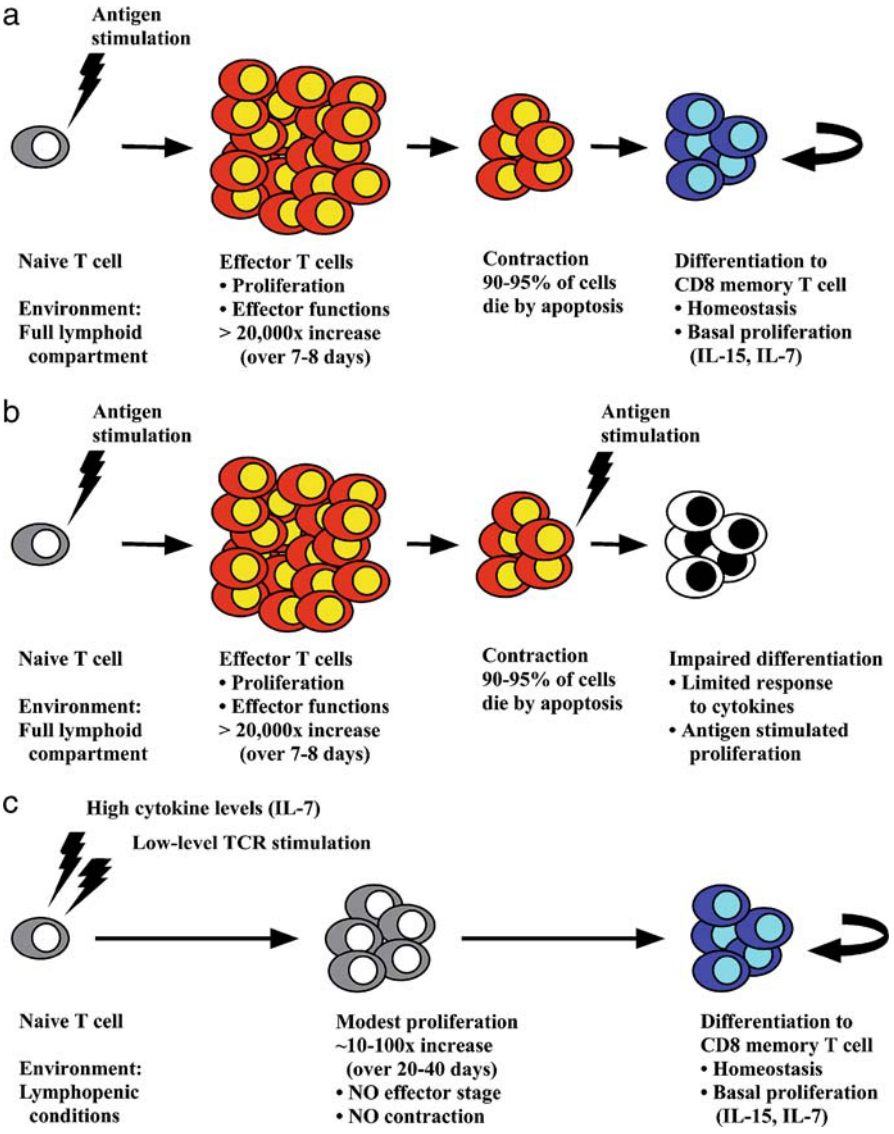

Fig. 1 CD8 memory T-cell differentiation in various contexts
The dynamics of an antigen-specific CD8 T-cell response in individuals possessing a full lymphocyte compartment following either transient, acute antigen exposure (panel a) or prolonged, persistent antigen exposure (panel b). CD8 memory T-cells can also develop when naïve T-cells are placed in a lymphopenic environment, devoid of other lymphocytes (panel c). The different stages of CD8 T-cell differentiation are indicated as follows: naïve (gray cytoplasm, white nucleus), effector cell (red cytoplasm, yellow nucleus), memory cell (deep blue cytoplasm, light blue nucleus). In the case of persistent antigen, there is impaired memory cell differentiation, as indicated by white cytoplasm, black nucleus. Stages of differentiation and factors that influence CD8 T-cell response are discussed further in text. Diagram indicates relative, not absolute abundance of CD8 T-cells at each stage.

CD8 memory T-cells differ from naïve CD8 T-cells in many ways. In contrast to naïve CD8 T-cells, CD8 memory T-cells have an accelerated response to antigen stimulation, are found at many sites in the body and are maintained at very constant levels for months to years following initial antigen exposure (a process facilitated by cytokines). The self-renewing capacity of CD8 memory T-cells can occur in the absence of continued antigen exposure, providing an antigen-independent mechanism of CD8 memory T-cell maintenance. The combination of these characteristics, as well as the increased frequency of antigen-specific CD8 T-cells in antigen-exposed individuals, means that individuals who develop a CD8 memory T-cell response against an antigen will have a rapid, robust response upon antigen reexposure. In many contexts, CD8 memory T-cells provide an important mechanism of immunological protection, or immunity to reinfection [56, 140].

In the context of CD8 clonal expansions, one particularly important property of CD8 memory T-cells is their steady, slow rate of proliferation in the uninfected animal. The long-term proliferation and survival of CD8 memory T-cells is heavily dependent on the cytokines interleukin (IL)-7 and IL-15 [7, 37, 72, 116, 118, 125]. CD8 memory T-cells receive these cytokine cues through expression of the IL-7 receptor alpha chain (IL-7Rα, CD127), the IL-2 receptor beta chain (IL-2Rβ, CD122), and the common gamma chain cytokine receptor. As discussed below, CD8 clonal expansions have alterations in their capacity to respond to these cytokines.

2.2 Memory T-cell Subsets

Though CD8 memory T-cells arise following antigen stimulation, not all CD8 memory T-cells have the same properties. CD8 memory T-cells are most frequently categorized as either central memory (T_{CM}) or effector memory (T_{EM}) cells [113]. While both these subsets of memory cells express cell surface receptors thought to be typical of CD8 memory T-cells (e.g. in the mouse, $CD44^{high}CD127^{high}CD122^{high}$), these two subsets differ in their expression of L-selectin (CD62L) and the chemokine receptor, CCR7, two proteins that promote trafficking to peripheral lymph nodes. Central memory T-cells are CD62L+ CCR7+, and are found in blood, spleen, and lymph nodes. In contrast, effector memory T-cells do not express CD62L or CCR7, and are found in blood, spleen, and nonlymphoid tissues. T_{EM} cells are generally absent from lymph nodes, except in situations of ongoing inflammation [38, 85].

The precise factors that influence whether a CD8 memory T-cell becomes a central or an effector memory cell remain contentious. One factor that might influence this balance is the magnitude of the initial antigenic stimulus [132]. It should be noted, however, that at this time it is debatable whether the T_{CM} and T_{EM} subdivisions of CD8 memory T-cells represent true independent cell fates, are capable of interconversion, or whether their differences reflect in part the impact of local environments on the phenotype and function of a CD8 memory T-cell (for further discussion see [76]). Regardless of the precise development details of T_{CM} and T_{EM} cells, local tissue environments can significantly influence the phenotype and properties of a CD8 memory T-cell [67, 83, 86].

Following the identification of T_{CM} and T_{EM} subsets of CD8 memory T-cells, further subsets of memory cells have been identified. For example, the IL-7Rα (CD127) was identified as a marker to identify activated CD8 T-cells that gave rise to long-lived memory cells [46, 55]. Subsequent work has shown that the usefulness of this marker varies depending on the experimental system [73], and that IL-7 plays an important but perhaps not instructive role in the development of CD8 memory T-cells [15, 40, 66, 123]. A recent study also identified expression of CD8αα homodimers as a potential marker for CD8 memory T-cell precursors [80], although the significance of this observation remains contentious [21, 135, 143]. Additional subtypes of CD8 memory T-cells, differing by various criteria (e.g., ability to divide in the absence of antigen, tissue distribution, and capacity to respond upon antigen rechallenge) have also been identified [12, 44, 109]. Despite the identification of these various subsets, a major unanswered question is the interrelationship between different types of memory T-cells and the factors that drive these distinct phenotypes and properties.

It is worth noting that in some studies of CD8 memory T-cells, cells have the phenotype of a memory T-cell (in the mouse, typically defined as $CD44^{high}$), but the precise antigen reactivity and origin of this memory cell is poorly defined. These cells are often referred to as CD8 memory phenotype (MP) T-cells. Some CD8 MP T-cells probably result from conditions of lymphopenia (discussed below).

2.3 CD8 Memory T-cell Differentiation in the Context of Chronic Infection

The above discussion of CD8 memory T-cell differentiation focused on this process following an acute, transient infection. It is important to note, however, that CD8 T-cells are highly attuned to external cues, and that the process of CD8 memory T-cell differentiation can be significantly influenced by the nature of the eliciting infection (e.g., [2]). In addition, the phenotypes and properties of a CD8 T-cell can vary between CD8 T-cells responding to different epitopes within the same pathogen [45, 121]. These different outcomes likely reflect differences in the patterns of antigen expression at various stages of infection.

The most dramatic perturbations to CD8 memory T-cell differentiation occur in situations of chronic infection (e.g., certain strains of LCMV) that are characterized by a prolonged, high pathogen burden. In these situations, CD8 T-cells develop an altered state of "memory" in which the resulting CD8 T-cells remain actively dependent on persistent antigen and TCR engagement for their survival (Fig. 1b). These cells express reduced levels of cytokine receptors for IL-7 and IL-15 (IL-7Rα and IL-2Rβ, respectively), and do not achieve antigen-independent survival and proliferation [120, 131]. In addition, these cells can express sustained levels of inhibitory receptors such as programmed death-1 (PD-1), which can actively impair the capacities of a CD8 T-cell [6]. Situations of chronic infection can also result in the continual recruitment of naïve CD8 T-cells into the CD8 memory pool [130].

Based on the above differences, it is worth considering whether the CD8 "memory" T-cells that result during a chronic infection are true CD8 memory T-cells or if they instead exist in an altered state of "quasi-memory". For the purpose of this chapter, we will refer to CD8 memory T-cells that develop in the context of chronic infection as antigen-dependent CD8 memory T-cells (referring to their continued requirement for antigen to survive). This is in contrast to CD8 memory T-cells that arise following an acute infection, which we will refer to as antigen-independent CD8 memory T-cells (referring to their capacity to survive in the absence of antigen).

2.4 An Alternate Way to become a CD8 Memory T-cell: Lymphopenia-induced Proliferation

While CD8 memory T-cells have been traditionally studied in individuals following exposure to a variety of antigens, there is an alternate way for a naïve CD8 T-cell to become a CD8 memory T-cell. This phenomenon occurs in individuals characterized by a state of severely reduced lymphocyte numbers, a condition known as lymphopenia. Lymphopenia is observed in various conditions, including individuals exposed to high dose irradiation or chemotherapy, as well as in neonates [75, 92]. In mice, genetic models of lymphopenia are also available (such as mice completely devoid of T-cells).

The observation that lymphopenia could promote the generation of CD8 memory T-cells was made by multiple groups who transferred naïve, antigen-specific CD8 T-cells into lymphopenic mice (whether irradiated or genetically deficient) (reviewed in [51]). In these studies, naïve CD8 T-cells began to proliferate once placed in the lymphopenic environment, a process referred to as either homeostatic proliferation or lymphopenia-induced proliferation (LIP). In addition to proliferating, however, these CD8 T-cells also acquired many of the characteristics associated with a CD8 memory T-cell [22, 35, 64, 93, 96]. For clarity, these cells will subsequently be referred to lymphopenia-induced proliferation (LIP) CD8 memory T-cells.

At this time, it is unknown whether LIP CD8 memory T-cells and antigen-elicited CD8 memory T-cells are identical. There are clear differences in the generation of these two cell types (compare Fig. 1a and 1c). First, LIP CD8 memory T-cells do not go through a stage of acute activation (e.g., LIP CD8 memory T-cells do not express various early activation markers), in contrast to antigen-elicited CD8 T-cells [22, 93]. In addition, LIP memory cells undergo a much more modest proliferation than antigen-elicited memory T-cells, and have no significant contraction phase [22, 93]. Despite these differences, LIP memory cells do have a transcriptional profile that is similar to that of antigen-elicited CD8 memory T-cells [36], and these cells are capable of mediating a protective response against secondary infection [39].

The observation that a naïve CD8 T-cell can become a memory cell in the absence of strong antigenic stimulation indicates that there is at least one alternate way for a naïve cell to become a memory T-cell (Fig. 1c). While lymphopenia-induced proliferation

can be promoted by TCR stimulation by low affinity ligands [30, 34, 64], this phenomenon is also driven by the high levels of unconsumed cytokines (particularly IL-7) present in an environment that is almost devoid of neighboring lymphocytes (reviewed by [51, 124]). At this time, the precise contribution of LIP memory T-cells to the complete CD8 memory T-cell repertoire is unclear. Nonetheless, given some of the factors that influence the development of CD8 clonal expansions (described below), lymphopenia-induced proliferation and memory differentiation may contribute to at least part of this age-associated phenomenon.

3 The Regulation of CD8 Memory T-cell Homeostasis

3.1 The Role of IL-7 and IL-15

As previously alluded to, the regulation of CD8 memory T-cell proliferation and survival is heavily influenced by extracellular factors. The cytokines IL-7 and IL-15 are the best-characterized extracellular proteins that promote the survival and proliferation of CD8 memory T-cells [7, 37, 72, 116, 118, 125, 142]. Both of these cytokines belong to the common gamma chain (γ_c) family of cytokines.

In general, the functions of IL-7 and IL-15 are thought to be compartmentalized, such that IL-7 primarily provides survival signals whereas IL-15 provides proliferative signals (reviewed in [124]). Although excess IL-7 can overcome a deficiency in IL-15 [65], the mechanism by which these two cytokines are perceived differs significantly. IL-7 is present in a secreted, soluble form. In contrast, IL-15 appears to be retained on the cell surface of certain cells, requiring direct cell contact of the CD8 T-cell with an IL-15 presenting cell in order to receive an IL-15 signal [17, 27, 114, 117]. While IL-7 and IL-15 can function alone, their effects can also be influenced by other cytokines. For example, IL-21 can synergize with IL-15 to promote proliferation of CD8 memory T-cells in vitro [141].

Given the central role of IL-7 and IL-15 in promoting CD8 memory T-cell homeostasis, the levels of these cytokines are tightly controlled and for good reasons. Limited cytokine expression appears to be important in limiting excessive proliferation; transgenic mice that express excessive amounts of IL-15 can develop a fatal leukemia [32]. Cytokine signals are also subject to additional regulation. For example, IL-7 can downregulate expression of its own receptor, IL-7Rα [101].

3.2 The Role of Other Cytokines, Cell Surface Receptors and Cells

In addition to IL-7 and IL-15, other cytokines also influence the homeostasis of CD8 memory T-cells. For example, IL-2 appears to be critical for CD8 memory

T-cells to robustly proliferate upon antigen reexposure [136]. In contrast, transforming growth factor beta (TGF-β) appears to limit the rate of proliferation of CD8 memory T-cells, possibly through antagonism of IL-15 signals [79]. High levels of IL-10 can also impair the appropriate formation of CD8 memory T-cells, as revealed by studies of chronic LCMV infection [14, 28].

Various cell surface proteins of the immunoglobulin and tumor necrosis family (TNF) families can also influence the magnitude and homeostasis of CD8 memory T-cells. Mice deficient in the B- and T-lymphocyte attenuator (BTLA), an immunoglobulin superfamily member, have an increased number of CD8 MP T-cells and a higher rate of homeostatic proliferation, indicating that BTLA limits the magnitude of CD8 memory T-cells [69]. In contrast, mice deficient in the TNF receptor ligand 4-1BBL have impaired CD8 memory, suggesting a positive role for 4-1BB signaling in the formation of a robust CD8 memory T-cell response (reviewed in [111]). Similar data indicate a positive role for CD27 and OX40 in promoting CD8 memory T-cell responses [42, 43]. Notably, some of the effects of these proteins may be directly regulated by cytokine cues elicited by IL-15 [107].

While many of the above cues influence the long-term maintenance of CD8 memory T-cells, initial signals received during T-cell activation can also heavily influence the differentiation of a naïve CD8 T-cell to a CD8 memory T-cell. One example of this regulation is the observation that inflammation can prolong the time required for CD8 memory T-cell differentiation [41]. As such, CD8 T-cells activated in a context of minimal inflammation become memory T-cells more rapidly (e.g., following immunization with antigen-pulsed dendritic cells) [5]. At least part of this effect is mediated by the effect of inflammatory cytokines, such as interferon gamma (IFN-γ), on the responding CD8 T-cell [5]. It is worth noting, however, that the effects of IFN-γ on the immune system are pleiotropic, and in some contexts, IFN-γ can promote an optimal CD8 memory T-cell response [133, 134]. IL-12 and type I interferons can also promote optimal CD8 T-cell activation and CD8 memory responses [68, 88].

The properties of CD8 memory T-cells are also heavily influenced by the presence or absence of CD4+ T-cells. Over the past few years, there has been an increasing appreciation that CD8 memory T-cells generated in the absence of CD4 T-cell help can be compromised in various ways (reviewed in [8]). At least part of the defect observed in CD8 memory T-cells that do not receive CD4 T-cell help may be due to tumor-necrosis factor (TNF)-related apoptosis-inducing ligand (TRAIL) induced apoptosis of CD8 memory T-cells upon antigen re-exposure [39, 52]. However, additional mechanisms are also likely involved in CD4 T-cell optimization of CD8 memory T-cell responses [4, 95].

Finally, the properties of CD8 T-cells can be influenced by the frequency of antigen-specific T-cells that participate in a response, as well as subsequent antigenic exposure. Studies analyzing the response of TCR transgenic CD8 T-cells, in which each CD8 T-cell expresses the identical TCR as its neighbors, have revealed that an artificially elevated number of identical antigen-specific T-cells (achieved by adoptive transfer of a high number of TCR transgenic CD8 T-cells) results in CD8 T-cells with distinct properties not observed during an endogenous CD8 T-cell response

[3, 59, 82]. At this time, it is unclear whether this observation reflects an experimental artifact, or whether it reflects some basic physiological regulation observed in certain conditions of CD8 T-cell responses. Although CD8 memory T-cells can be maintained in an antigen-independent manner, subsequent antigen exposures can influence the TCR specificities of CD8 memory T-cells that are maintained [119].

3.3 The Influence of Intracellular Factors

While the properties of CD8 memory T-cells are well defined, the intracellular factors that coordinate these changes remain poorly characterized. CD8 memory T-cells are clearly characterized by a wide variety of transcriptional changes [54], as well as changes in chromatin modifications relative to naïve CD8 T-cells [31, 61, 95]. While there is no identified master regulator for the development of CD8 memory T-cells, there have been an increasing number of transcription factors that either facilitate differentiation to, or the properties of, CD8 memory T-cells. These include Bcl-6 [47], STAT5 [16, 58], eomesodermin and T-bet [49, 103], Bcl-6b/BAZF [81], c-myc [9], MeCP2 [60], and Id2 [19]. At this time, the precise molecular targets of these transcription factors and their contribution to CD8 memory T-cell development remain largely undefined.

Intracellular proteins that influence the proliferation and survival of CD8 T-cells can also impact the development of CD8 memory. The suppressor of cytokine signaling (SOCS) family of proteins is known to inhibit various cytokine signals [1]. In particular, SOCS1 is an important regulator of CD8 T-cell responses to cytokine signals by IL-7 and IL-15, and deficiency of this molecule results in an increased number of CD8 MP T-cells [23, 26, 48].

Regarding proteins that regulate cell survival, the proapoptotic Bcl2-family member, Bim, appears to limit the number of cells entering the CD8 memory T-cell pool [138]. Signal transduction through tumor necrosis factor receptor associated factor (TRAF) 1 is one mechanism that may regulate levels of Bim protein during a CD8 T-cell response [112]. The optimal development of CD8 memory also depends on appropriate protection of CD8 T-cells against internal damage from cytotoxic proteins expressed by CD8 T-cells (e.g. granzymes, cathepsins), something which can be mediated by various serine protease inhibitors expressed in CD8 T-cells [78, 104].

4 The Discovery of CD8 Clonal Expansions

Following the discovery of the T-cell receptor, there was an explosion of reagents to analyze the properties and diversities of the T-cell pool. One technical advance that allowed the discovery of CD8 clonal expansions was the development of monoclonal antibodies that recognized different TCR V alpha (Vα) and V beta (Vβ)

gene products. By using these reagents, investigators identified that young, healthy individuals had a relatively consistent number of T-cells expressing each Vα and Vβ gene product [18, 105]. In contrast, aging individuals frequently had significant perturbations in the abundance of T-cells expressing various Vα and Vβ gene products [18, 105]. Significantly, these aged individuals frequently had a massive overrepresentation of a single Vα or Vβ that was at least three standard deviations above the mean Vα and Vβ usage observed in young individuals. The selective outgrowth or accumulation of a single Vα or Vβ gene product within the CD8 T-cell pool suggested that these CD8 T-cells might be clonal expansions. Molecular analysis of the T-cell receptors used by these expanded populations of CD8 T-cells revealed that these overrepresented populations of CD8 T-cells were truly clonal [77, 105]. Notably, these clonal expansions were predominantly found within the CD8 T-cell lineage, and were rarely identified in CD4 T-cells.

Today, CD8 clonal expansions are frequently identified using antibodies against various Vβ gene products (Fig. 2). Based on this method, individuals with CD8 clonal expansions are identified as those with an overabundance of a single Vβ within the CD8 T-cell pool that is increased at least three standard deviations above the mean Vβ usage found for that Vβ in young individuals. The strength of this approach is that it identifies an overabundance of one Vβ within the entire CD8 T-cell pool. CD8 clonal expansions can also be identified by molecular analysis of TCR diversity (e.g. the spectratyping method [97]). When using such molecular methods, however, it is worth noting that these methods can detect reduced diversity within a specific Vβ gene family, despite the fact that that Vβ is not over-represented within the entire CD8 T-cell pool (a phenomenon we have referred to as clonal restriction [24]). Because of this caveat, we consider it preferable to identify the presence of clonal expansions by monoclonal antibodies against the TCR, followed by molecular analysis of TCR diversity. Age-associated clonal expansions are routinely clonal by such analyses.

One important observation about CD8 clonal expansions is that clonal expansions in different individuals express a diverse range of T-cell receptors. Even in genetically identical inbred mice that are housed together, CD8 clonal expansions express a wide variety of TCR Vαs and Vβs. The same is true for humans. Based on these observations, CD8 clonal expansions appear to arise from a diverse set of CD8 T-cells.

5 Properties of Clonal Expansions

5.1 Incidence and Abundance of Clonal Expansions in Humans and Mice

CD8 clonal expansions are a common age-associated alteration within the immune system. In specific-pathogen free (SPF) mice, almost 60% of mice develop clonal

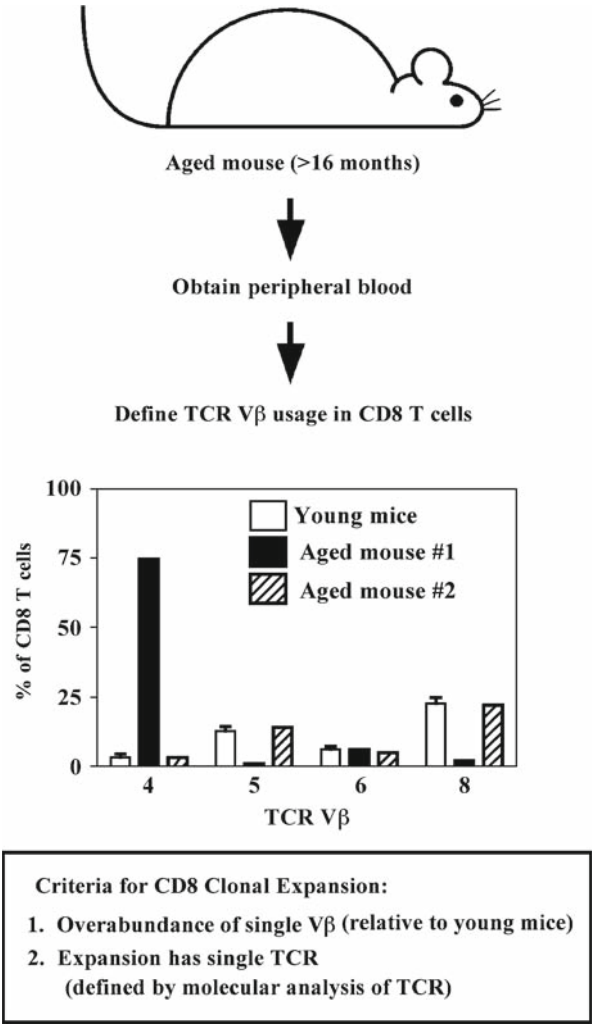

Fig. 2 Methodology to identify CD8 clonal expansions in aged mice
CD8 clonal expansions can be identified based on the percentage of CD8 T-cells expressing various TCR Vβ receptors. While young mice have a highly consistent percentage of CD8 T-cells that express each Vβ (open bars), certain aged mice (e.g., hypothetical aged mouse #1 in black bars) have an overabundance of CD8 T-cells expressing one Vβ (in this situation, a Vβ4+ clonal expansion). CD8 clonal expansions are identified in those mice that have an overabundance of one TCR Vβ, that is increased at least three standard deviations above the mean Vβ usage observed in a cohort of young mice. Data for young mice indicate mean Vβ usage +/- three standard deviations of the mean. Young mice are typically between 3–6 months of age. Aged mice develop detectable clonal expansions by 16 months of age. In this example, aged mouse #2 (hatched bar) does not have any detectable CD8 clonal expansions.

expansions by 2 years of age [71]. In humans, 33% of adults over the age of 65 have a detectable clonal expansion [108]. CD8 clonal expansions vary widely in their size within the CD8 T-cell pool. In the most dramatic situations, CD8 clonal

expansions can occupy 50% of the CD8 T-cell pool in humans [33] and 90% of the CD8 T-cell pool in mice (Clambey et al. unpublished data).

Since clonal expansions are found in many, but not all, mice, it is worth noting that studies of T-cell responses in aging mice may be profoundly influenced by whether an individual mouse contains a clonal expansion or does not. Given the idiosyncratic nature of clonal expansions, we strongly recommend that studies of T-cell function in aging mice be carefully controlled to minimize the impact of clonal expansions on the interpretation of the experiment.

5.2 Factors Associated with the Development of Clonal Expansions

While the precise origin of clonal expansions remains unclear, ongoing research has provided clues about potential cues that may facilitate the development of clonal expansions. One of the strongest factors associated with the development of clonal expansions is age. This age-association with clonal expansions is particularly pronounced in the mouse, where CD8 clonal expansions are virtually undetectable until 16 months of age [18]. In humans, increasing age is associated with an increasing prevalence of clonal expansions [108]. In contrast to mice, however, clonal expansions in humans can be found in younger individuals [108]. It is possible that these latter clonal expansions may reflect immune responses to childhood infections, something that would not be observed in SPF mice [50].

Although clonal expansions are particularly observed in aging individuals, it is unknown what factors within the aging environment, if any, contribute to the development of clones. It is worth noting that clonal expansions can be transferred to young individuals and still retain their competitive advantage [70, 91]. This observation indicates that while aging may contribute to the development of clonal expansions, the aging environment is not essential for the maintenance of clonal expansions.

Beyond the correlation of age and the development of clonal expansions, there are two other factors positively associated with the development of clonal expansions.

i) *Humans infected with human cytomegalovirus (HCMV)*. Over the past few years, the use of MHC Class I tetramers has allowed investigators to investigate the TCR specificity of human clonal expansions. Based on these studies, at least some human clonal expansions specifically recognize human cytomegalovirus, a common chronic herpesvirus infection [63, 98]. In the most dramatic case, 27% of CD8 T-cells in one individual were specific against a single HCMV epitope [98]. Although HCMV infection can be controlled in healthy individuals, there is increasing evidence that HCMV infection in the elderly is associated with a variety of negative outcomes [62, 102, 106, 122]. Importantly, while some humans develop clonal expansions against Epstein-Barr virus (EBV), another common chronic Herpes virus infection, these clonal expansions are

much smaller in size [62, 97, 129]. Thus, there appear to be certain factors associated with HCMV infection that are capable of eliciting pronounced CD8 clonal expansions in humans. This association may be related in part to the observation that chronic CMV infection can elicit large, and in some cases, highly focused T-cell responses that often increase in size with age, even in individuals without clonal expansions [57, 63, 127].

ii) *Lymphopenia and inflammation in mice*. Additional insights into cues that promote CD8 clonal expansions came from the analysis of CD8 clonal expansions in various mouse models. Significantly, mice characterized by lymphopenia (e.g., mice lacking the IL-7 receptor or mice subjected to adult thymectomy) develop clonal expansions at an earlier age and with a higher prevalence than intact, unmanipulated mice [90]. Although the precise mechanisms behind this outcome remain to be elucidated, one likely explanation for this effect is the increased rate of proliferation of CD8 memory T-cells in lymphopenic conditions [90]. In the same study, it was noted that repeated treatment of mice with adjuvants (compounds known to induce inflammation and to facilitate antigen-specific T- and B-cell responses to coinjected antigen) also modestly increased the incidence of CD8 clonal expansions [90]. It is interesting to note that states of inflammation, such as those of viral infections, have been associated with transient states of lymphopenia (e.g., [87]). Thus, it is possible that adjuvants promote the development of clonal expansions through the temporary generation of lymphopenic conditions. For further discussion of lymphopenia and its effects on the generation of clonal expansions please see chapter by Nikolich-Zugich.

5.3 CD8 Clonal Expansions may Impair Immune Function in the Aged

Given the dominance of CD8 clonal expansions within the aged individual, it is likely that clonal expansions have some impact on the immune function of aged individuals. To date, there are two studies to support this contention. First, in humans, there is a correlation between the presence of clonal expansions and an impaired response to influenza vaccination, a common defect in aged individuals [115]. Second, in mice, there are data that clonal expansions may result in highly focused holes in the T-cell repertoire (particularly in the Vβ subfamily used by the clonal expansion) [89]. These narrow holes may be particularly problematic in individuals responding to infections in which the T-cell response is heavily restricted to use of a single Vβ subfamily. Please see chapter by Nikolich-Zugich for more extensive discussion of the negative impact of clonal expansions on immune function in the aged.

While CD8 clonal expansions can have deleterious effects on immune function, we postulate that perhaps not all clonal expansions are deleterious to health

in the elderly. This may be particularly true in the case of clonal expansions specific for HCMV, a chronic virus infection that can cause disease, especially in the immune-suppressed. Although inflated responses to HCMV have often been viewed as a negative indication for health in the elderly (e.g., [102]), this is not to say that these HCMV-specific expansions are not playing some role in containing HCMV infection. Based on this concept, it will be important to test what consequence depletion of CD8 clonal expansions has in animal models of chronic infection (e.g., individuals which develop comparable clonal expansions in response to either mouse or primate cytomegalovirus infection) before further considering the possibility of therapeutic intervention to remove CD8 clonal expansions in the elderly.

One other important consideration when contemplating therapeutic interventions to remove CD8 clonal expansions in the aged is the effect that this depletion might have on subsequent T-cell homeostasis. For example, depletion of a clonal expansion that occupies 50% of the CD8 T-cell pool would likely create a transient state of lymphopenia, which may, in turn, provoke the subsequent development of another clonal expansion.

5.4 CD8 Clonal Expansions are Nonmalignant

Given the growth advantage of CD8 clonal expansions relative to other CD8 T-cells, one curious feature of clonal expansions is that they are nonmalignant. This conclusion is based on the following observations: i) individuals with CD8 clonal expansions do not have an increase in the total number of CD8 T-cells [89] and ii) clonal expansions can exist for an extended period of time without progressing to malignancy (up to 4 years in mice, up to 9 years in humans) (Ku, personal communication) [20]. Given the common occurrence of CD8 clonal expansions, the incidence of human tumors with a CD8 memory phenotype is extremely low [99]. It is important to note that individuals diagnosed with CD8 T-cell lymphomas not only have a clonal expansion of T-cells, but are also characterized by additional abnormalities (including elevated lymphocyte counts and frequent neutropenia) [110, 137]. At this time, there is no known relationship between those individuals with CD8 clonal expansions and those individuals who are diagnosed with T-cell lymphomas.

Despite the similarities of clonal expansions to tumors in terms of their clonality and competitive advantage relative to their neighbors, CD8 clonal expansions are clearly still subject to certain constraints. For example, CD8 clonal expansions do not increase in number above the normal number of CD8 T-cells contained within an individual [89]. Although the precise mechanisms that limit the growth of clonal expansions remain to be elucidated, we propose that a major factor constraining the growth of CD8 clonal expansions is availability for cytokines and other extracellular growth factors.

6 CD8 Clonal Expansions Have an Increased Rate of Proliferation

Many CD8 clonal expansions occupy a sizable fraction of the CD8 T-cell pool. The ability of expansions to out-compete other CD8 T-cells could result from either an increased rate of proliferation or from a decreased rate of attrition (e.g., apoptosis). Currently, there are no published reports rigorously examining the survival properties of CD8 clonal expansions relative to normal CD8 memory T-cells. In contrast, there are clear data regarding the rate of proliferation of CD8 clonal expansions. Initial evidence regarding the rate of proliferation of CD8 clonal expansions came from analysis of the rate of dilution of carboxyfluorescein diacetate succinimidyl ester (CFSE), a fluorescent dye that can be used to track the number of cell divisions of CD8 T-cells. Based on transfer of CD8 clonal expansions into syngeneic, nonirradiated recipients, CD8 clonal expansions had a modest increase in their rate of proliferation (dividing once every 15 days, compared with polyclonal aged CD8 memory T-cells which divided once every 22 days) [70]. Significantly, many CD8 clonal expansions were also capable of growing upon adoptive transfer into mice lacking beta-2 microglobulin and therefore having little to no MHC Class I ligands for the T-cell receptor [70]. This property is consistent with the previous observation that CD8 memory T-cells can achieve long-term antigen-independent proliferation [94]. In sum, these data indicate that clonal expansions have an increased rate of proliferation and that this proliferation is not dependent on active engagement between TCR and MHC.

In this initial study, manipulating cytokine signals also influenced the proliferation of CD8 clonal expansions. Clonal expansions had diminished proliferation when the beta-chain of the IL-2 and IL-15 receptors was blocked by antibody treatment, suggesting that clones were likely growing in response to IL-15 (a common proliferative cue for CD8 memory T-cells) [70]. In contrast, CD8 clonal expansions had accelerated proliferation when mice were treated with IL-2 antibodies [70], a condition now known to create a strong mitogenic signal for CD8 memory T-cells [13].

Since this initial analysis, an additional study examined how CD8 clonal expansions respond to conditions of lymphopenia, a condition known to increase the proliferative rate of CD8 T-cells and to promote the generation of LIP CD8 memory T-cells (discussed above). While these studies showed that CD8 clonal expansions have an increased rate of proliferation in a nonirradiated recipient relative to other CD8 T-cells, they also revealed a surprising finding: CD8 clonal expansions have a relatively constant rate of proliferation that is not accelerated in conditions of lymphopenia [91]. In this study, CD8 clonal expansions were also identified to have a modest increase in the expression of both the IL-7Rα and IL-2Rβ cytokine receptors [91]. Based on these studies, Nikolich-Zugich and colleagues proposed that CD8 clonal expansions have an altered capacity to respond to the homeostatic cues normally perceived by a CD8 T-cell [91]. On one hand, clones do not stop dividing in a full lymphoid compartment. On the other hand, clones do not accelerate their

division in a lymphopenic setting. At this time, it is unclear why clonal expansions are capable of accelerating their proliferation in response to strong mitogenic IL-2 signals [70], but do not accelerate their proliferation in lymphopenic settings [91]. One potential explanation for this apparent discrepancy may be that the proliferative cues perceived in a lymphopenic environment are less potent than that received by hyperstimulation with IL-2, IL-2 antibody complexes.

Based on the above data, clonal expansions do not simply have a higher rate of proliferation than other CD8 T-cells, but instead are capable of prolonged, continuous proliferation with little apparent regulation by the normal cues perceived by neighboring CD8 T-cells. One perplexing issue about these observations is that the state of lymphopenia is associated with an increased rate of development of clonal expansions, yet clonal expansions do not seem to have a proliferative advantage in the context of lymphopenia. One possible resolution for this paradox might be that lymphopenia promotes the initiation but not the maintenance of CD8 clonal expansions. For further discussion of this topic, please see chapter by Nikolich-Zugich.

7 The Spectrum of CD8 Clonal Expansions

7.1 Heterogeneous Characteristics of CD8 Clonal Expansions

One of the challenges in understanding CD8 clonal expansions in both mice and humans is the observation that distinct clonal expansions have variable properties. While heterogeneity between clonal expansions might be expected in humans, a genetically diverse population with significant differences in infection history, heterogeneity has also been observed between clonal expansions in genetically identical, inbred mice housed together [18]. To date, heterogeneity between clonal expansions has been best characterized in CD8 clonal expansions in mice [18], as described below.

i) *Stability of clones in vivo:* CD8 clonal expansions have widely discrepant stabilities in vivo. Some CD8 clonal expansions appear to be extremely stable and can continue to grow over a 4-year period, as revealed by serial adoptive transfer studies in mice (Ku, personal communication). In contrast, other CD8 clonal expansions are very unstable and disappear within 2 months of their initial identification [18, 77].
ii) *Response to stimulation in vitro:* CD8 clonal expansions in mice are also variable in their response to stimulation in vitro [18]. For example, some CD8 clonal expansions have a normal proliferative response to polyclonal stimulation in vitro (e.g., following culture with the concanavalin A or phorbol 12-myristate 13-acetate (PMA) and ionomycin). In contrast, other CD8 clonal expansions have an impaired capacity to proliferate and/or survive following similar stimulation conditions, becoming less abundant in bulk cultures following stimulation.

Despite these differences between CD8 clonal expansions, CD8 clonal expansions are uniformly considered to be CD8 memory T-cells, as defined by cell surface markers (in the mouse, $CD44^{high}$ as well as IL-7Rα^{high}IL-2Rβ^{high}) [70, 91]. Many CD8 clonal expansions belong to the T_{CM} subset of CD8 memory T-cells [91]. While our recent data (discussed below) have revealed additional heterogeneity in cell surface phenotypes, to date all clonal expansions are $CD44^{high}$, consistent with a CD8 memory phenotype in the mouse.

7.2 A New Method to Subclassify CD8 Clonal Expansions in Mice

Given the above heterogeneity between CD8 clonal expansions, we have been interested in identifying methods to subclassify clonal expansions in mice. To do this, we initially focused our efforts on microarray analysis in which we analyzed the transcriptional profile of multiple, independent clonal expansions in mice.

Through this analysis, we identified integrin α4 (also known as very late antigen-4 (VLA-4) or CD49d) as a candidate marker that was differentially expressed in distinct types of clonal expansions. [25] Next, we analyzed the expression of integrin α4 on a large number of age-associated CD8 clonal expansions. This analysis identified that there were two major types of clonal expansions: those expressing high levels of integrin α4 and those expressing low levels of integrin α4.

Based on the differential expression of integrin α4 between different types of clones, we analyzed the properties of integrin $\alpha4^{high}$ and integrin $\alpha4^{low}$ clones. There were clear differences between these two types of clonal expansions [25]. First, these clonal expansions were identified in mice of different ages, with integrin $\alpha4^{high}$ clones identified predominantly in mice 16–20 months of age, while integrin $\alpha4^{low}$ clones were found predominantly in mice 20–36 months of age. Notably, a longitudinal analysis of these two types of clonal expansions revealed that there was no interconversion between these integrin α4 phenotypes. Second, these clones differed in their in vivo growth dynamics, with integrin $\alpha4^{high}$ clones frequently decreasing in size over a 2-month interval, in contrast to integrin $\alpha4^{low}$ clones that rarely decreased in size. Third, integrin $\alpha4^{high}$ clones had an impaired response to in vitro stimulation with PMA and ionomycin, becoming less abundant following stimulation. Integrin $\alpha4^{low}$ clones had no advantage or disadvantage following this same stimulation. Fourth, integrin $\alpha4^{high}$ and integrin $\alpha4^{low}$ clones had differential localization in vivo. Integrin $\alpha4^{high}$ clones were absent from peripheral lymph nodes, while integrin $\alpha4^{low}$ clones were absent from Peyer's patches. Fifth, integrin $\alpha4^{high}$ clones had evidence of chronic TCR stimulation, as revealed by decreased expression of cytokine receptors (both IL-7Rα and IL-2Rβ) and expression of various inhibitory receptors (PD-1 and killer cell lectin-like receptor G1, KLRG1). In sum, integrin $\alpha4^{high}$ clonal expansions had many characteristics of chronic antigen stimulation, whereas integrin $\alpha4^{low}$ clonal expansions appeared similar to an antigen-independent CD8 memory T-cell [25].

The identification of integrin α4-defined clonal expansions in mice is significant for multiple reasons. First, it provides a molecular marker to distinguish between two types of clonal expansions with highly divergent properties. Second, it provides an explanation for the previous dichotomy observed in the properties of clonal expansions [18, 77]. Third, it indicates that these types of clonal expansions may have arisen from very different origins. In particular, we hypothesize that integrin $\alpha4^{high}$ clones may arise due to an inappropriate response against self-antigens, which would result in chronic antigenic stimulation. It is worth noting that while both types of clonal expansions meet the current definition of CD8 clonal expansions, integrin $\alpha4^{low}$ clones appear to be the subtype of expansion that is most capable of long-term growth.

8 Models Regarding the Development and Properties of CD8 Clonal Expansions

8.1 Models to Understand the Development and Properties of Clonal Expansions

Given the heterogeneity between distinct clonal expansions and the apparent differences in clonal expansions between mice and humans (discussed in further detail in [24]), it is challenging to determine whether there are common mechanisms underlying divergent types of CD8 clonal expansions. Here we discuss three conceptual models for the development of CD8 clonal expansions and discuss basic tenants of each model.

Model 1: Clonal expansions arise from natural variation in the rate of proliferation of memory T-cells. Clonal expansions are simply those memory T-cells with the fastest rate of proliferation.

Basic details of this model: This model is based on the principle that there is a range of proliferative rates of memory T-cells present in a normal individual. While the vast majority of cells will proliferate at a very similar rate, there inevitably will be some cells that proliferate slightly faster or slower. At first inspection, this idea is particularly appealing: CD8 clonal expansions only have a modest increase in their rate of proliferation (dividing about once every 15 days compared to CD8 MP T-cells which divide about once every 22 days) [70].

Predictions of this model: CD8 clonal expansions will be identical to CD8 memory T-cells in all parameters, with only a modest acceleration in their rate of proliferation.

Evidence against this model: The major observation that is inconsistent with this model is that CD8 clonal expansions have an altered capacity to respond to proliferative cues typically perceived by lymphocytes in a lymphopenic environment [88]. This property of clones is clearly different than a normal CD8 memory T-cell, and these data indicate that clones are not simply derived from the fastest cell in the

CD8 memory T-cell pool. Despite this, it is worth noting that subtle variations in the expression level of cytokines receptors or inhibitory proteins may still play some role in the basic biology of CD8 clonal expansions.

Model 2: Clonal expansions arise from common alterations to growth regulatory pathways. The variable properties of clonal expansions reflect differences in TCR reactivity and antigen persistence.

Basic details of this model: This model proposes that clonal expansions arise from a discrete set of changes in the expression of growth regulatory proteins (e.g. cell cycle inhibitory proteins or cytokine receptors) (Fig. 3a). These alterations in mRNA or protein expression and/or function may arise to due genetic mutations (i.e., creating mutant gene products) or due to perturbations in epigenetic regulation (e.g., DNA methylation or chromatin alterations that alter transcriptional expression of growth regulatory genes).

Predictions of this model: A basic prediction of this model is that clonal expansions will arise from a common fate, and possess common changes in growth regulatory pathways (e.g., cytokine signaling). Moreover, clonal expansions with divergent biological properties should have similar mRNA and protein expression profiles (discussed further below).

Evidence against this model: Currently, there are two pieces of evidence against this model. The first is that the two major types of clonal expansions in mice (integrin $\alpha4^{high}$ and integrin $\alpha4^{low}$) have widely divergent properties, suggesting that they may arise from different age-associated alterations. Integrin $\alpha4^{high}$ clones have many characteristics consistent with T-cells actively responding against chronic (potentially self) antigen. If these cells are self-reactive, integrin $\alpha4^{high}$ clones may arise from age-associated alterations in central or peripheral T-cell tolerance. In contrast, integrin $\alpha4^{low}$ clones do not possess such characteristics, suggesting that they may arise from a distinct mechanism (such as epigenetic inactivation of a growth regulatory gene). The second piece of evidence against this model is microarray analysis, in which integrin $\alpha4^{high}$ and integrin $\alpha4^{low}$ clonal expansions appear to have different gene expression profiles (Clambey et al. manuscript in submission). The interpretation of this latter point, however, has caveats (discussed below), and will require analysis of a larger number of integrin α4-defined clonal expansions.

Model 3 : Clonal expansions arise from multiple, distinct age-associated alterations.

Basic details of this model: In contrast to model 2 (above), this model proposes that clonal expansions reflect a common physiological outcome (i.e. selective outgrowth of a single CD8 T-cell), but that these clones arise due to different age-associated alterations (Fig. 3b). As such, different types of clonal expansions have little in common other than their overabundance in the CD8 T-cell pool.

Predictions of this model: In contrast to model 2, a prediction of this model is that different types of CD8 clonal expansions (with different biological properties) will have different gene and protein expression profiles. While different types of clones will have some common expression profiles since they are both CD8 memory T-cells, the underlying molecular changes and growth requirements for these clones will differ. Based on the properties of integrin $\alpha4^{high}$ and integrin $\alpha4^{low}$ clones detailed above, integrin $\alpha4^{high}$ clones would depend on ongoing antigen/

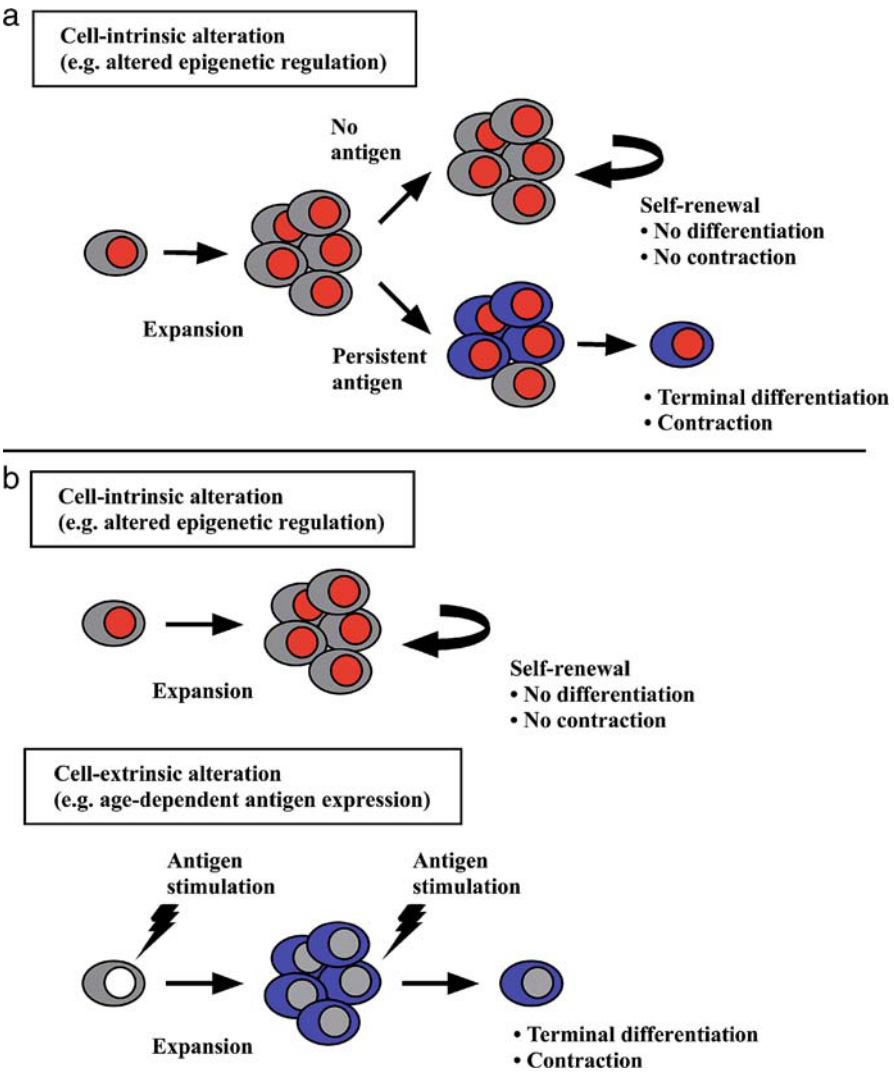

Fig. 3 Models for the development and phenotype of CD8 clonal expansions
In panel a, model 2 (see text for details) proposes that CD8 clonal expansions result from a common set of changes in growth regulatory genes (indicated here by a red nucleus, denoting a common transcriptional alteration). Following their initial expansion, the presence or absence of antigen then significantly influences the properties and dynamics of the clonal expansion. Clones that recognize persistent antigen undergo further differentiation (indicated by a blue cytoplasm). In panel b, model 3 (see text for details) proposes that CD8 clonal expansions result from distinct age-associated changes. While these distinct changes both result in a CD8 clonal expansion, the underlying factors that promote these expansions are completely distinct (indicated by either a red nucleus representing a transcriptional alteration or a blue cytoplasm representing antigen driven stimulation). See text for further discussion of each model.

TCR engagement for their proliferative advantage, whereas integrin $\alpha 4^{low}$ clones would not.

Evidence against this model: Currently there is no direct evidence that contradicts this model.

One important limitation to the above models and predictions is our current inability to distinguish between changes in gene expression profiles that promote the growth of CD8 clonal expansions, compared to changes in gene expression profiles that reflect TCR specificity and the presence or absence of antigen. For example, a clonal expansion responding to a persistent antigen will have major alterations in gene expression (e.g., in the expression of inhibitory receptors such as PD-1). As such, it may be very difficult to discriminate between the influence of TCR and antigen versus the underlying mechanism that creates a clonal expansion. The ability to resolve these issues will only become possible when CD8 clonal expansions can be reliably generated with defined antigen specificities, and such clones can be analyzed in the context of varying conditions of antigen persistence. Future insights into the molecular bases of clonal expansions will be significantly advanced through gain- and loss-of-function studies in both CD8 clonal expansions and CD8 memory T-cells.

8.2 The Probability of Becoming a Clonal Expansion

With regard to models 2 and 3, both models predict that certain stochastic events would change the growth properties of a CD8 memory T-cell. We postulate that this growth-promoting event is a relatively rare event. This statement is based on the observation that not all mice appear to develop CD8 clonal expansions, and mice that do develop clonal expansions frequently only have one clone (Clambey et al.unpublished data). Given that each mouse has more than 1 x 10^7 CD8 T-cells, the frequency of this growth-promoting event in an aging immune-competent mouse (e.g., C57BL/6J mouse) is probably not more frequent than 1 in 10^7 cells. We predict that the likelihood that a particular CD8 T-cell specificity becomes a clonal expansion would be influenced by the overall abundance of that antigen specificity within the CD8 T-cell pool (further discussed in [24]).

It is interesting to note that lymphopenic mice, which have fewer CD8 T-cells, have an accelerated rate of clonal expansion development, as well as a higher overall incidence of clones [90]. Based on these data, the frequency of the growth-promoting event is increased in conditions of lymphopenia. Since lymphopenic mice are characterized by a higher number of proliferating CD8 T-cells [90], we hypothesize that the probability that a growth-promoting event occurs is directly related to the number of cell divisions that the CD8 T-cell has undergone. Mechanistically, this hypothesis is based on the fact that with each cell division, appropriate epigenetic programming must be perpetuated from the mother to the daughter cells. If there is a certain rate of failure for this event to occur, the more rounds of cell division, the more likely it is that any cell would undergo this growth-promoting event.

8.3 When Do Clonal Expansions Initially Emerge?

In mice, CD8 clonal expansions are not detected until mice are approximately 16 months of age [18]. Although clonal expansions become apparent at this age, it is likely that there is a period during which an emerging clonal expansion remains below the limit of detection within the T-cell repertoire. The events within the early phase of clonal expansions are completely unknown, and at this point, strictly hypothetical. Nonetheless, it is worth considering how long it might take for a clonal expansion to emerge and dominate the CD8 T-cell pool.

CD8 clonal expansions divide once every 15 days, in contrast to polyclonal CD8 MP T-cells that divide once every 22 days [70]. If this was the only advantage that a CD8 clonal expansion had relative to other CD8 T-cells, how long would it take for a clonal expansion to outcompete its neighbors?

In an attempt to approximate the growth history of a clonal expansion, we have used a very simple model to compare the growth dynamics of a clonal expansion relative to a pool of CD8 MP T-cells. In this model, we made the following assumptions:

i) a clonal expansion results from a single CD8 memory T-cell achieving a growth advantage relative to its neighbor
ii) the only advantage that a clonal expansion has relative to other CD8 memory T-cells is its slightly higher rate of proliferation (dividing once every 15 days, instead of once every 22 days)
iii) the relative size of the proliferating, polyclonal CD8 MP T-cell pool contains approximately 10 x 10^6 cells (Clambey et al. unpublished data) [11, 47, 89] and
iv) both the clonal expansion and the CD8 MP pool have an infinite growth capacity.

While this model is clearly too simplistic (e.g. it does not take into consideration rate of death nor the changing abundance of naïve T-cells with age), it does provide a very useful piece of information (Fig. 4). If a clone only has this subtle growth advantage relative to a large CD8 MP T-cell pool, it would take 855 days (approximately 28.5 months) for the clone to reach just 5% (a small clonal expansion) of the size of the CD8 MP T-cell pool (Fig. 4). However, in mice, larger CD8 clonal expansions are already detectable by 16 months of age (~480 days). Based on this, clonal expansions are likely to have additional factors which promote their dominance within the CD8 T-cell pool.

One condition that could expedite the dominance of a clonal expansion within the CD8 T-cell pool is if there were a higher starting number of cells with a growth advantage. Since clonal expansions are clonal, however, cells with a growth advantage would need to come from a common precursor. One way in which this could happen is if a naïve T-cell achieves a growth-promoting event, and then encounters its antigen. Notably, this growth-promoting event does not need to change the antigen driven proliferation phase or the extent of death following the

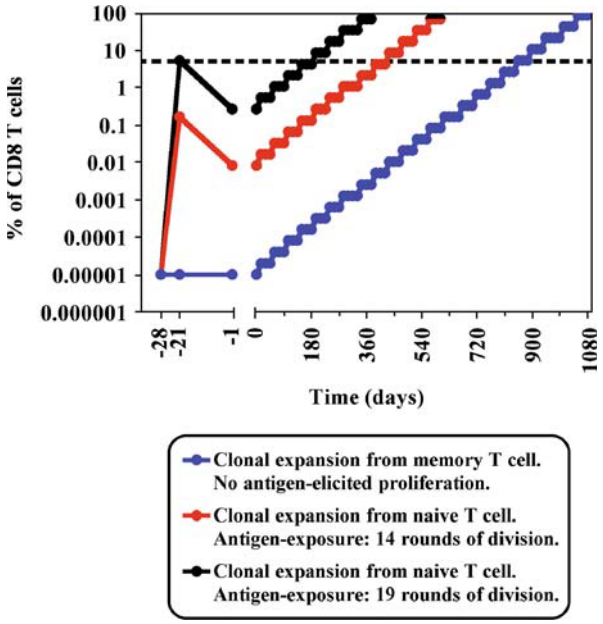

Fig. 4 A simple model to predict how long it takes for a clonal expansion to achieve dominance within the CD8 T-cell pool

Graph indicates the relative abundance of a clonal expansion (dividing once every 15 days) relative to the size of a pool of ten million proliferating CD8 MP T-cells (dividing once every 22 days). This model compares three different growth projections for an emerging clonal expansion: i) in blue, a single CD8 memory T-cell achieves a growth-promoting event that results in an increased rate of proliferation (expansion divides once every 15 days, compared to CD8 MP T-cells that divide once every 22 days) or ii) in black and in red, a single naïve T-cell achieves a growth-promoting event, followed by antigen stimulation. After antigen stimulation, the naïve T-cell goes through a normal phase of expansion and contraction. In contrast to the normal CD8 memory T-cell pool, however, the resulting CD8 memory T-cells all contain a common growth–promoting event that confers an increased rate of proliferation (clonal expansion divides once every 15 days, compared to CD8 MP T-cells that divide once every 22 days). For this latter model, growth projections include two different estimates for the extent of naïve T-cell proliferation following antigen stimulation (either 14 rounds of division indicated in red, or 19 rounds of division indicated in black). Antigen driven proliferation and contraction (95% of cells dying by apoptosis) are indicated from day—28 to day—1. Dashed line indicates 5% of the CD8 T-cell pool, which is a conservative estimate for the detection of a CD8 clonal expansion. Each data point indicates the relative abundance of the clonal expansion relative to the CD8 MP T-cell pool with each round of division (occurring every 15 days). This model presumes that both the clonal expansion and the CD8 MP T-cell pool have an infinite growth capacity, and does not take into consideration rate of death for either population (this parameter is undefined for clonal expansions at this time). See text for further details of model.

peak of the response. Instead, this growth-promoting event simply needs to increase the basal rate of proliferation of the resulting CD8 memory T-cells (so that the resulting cells divide once every 15 days). The end-result of this outcome would be that there would be a higher number of memory cells with a growth advantage. This, in turn, dramatically alters the time required for the clonal expansion to domi-

nate the CD8 T-cell pool. By using a conservative estimate for how many times a naïve T-cell proliferates following an acute antigen exposure (14 rounds of division [3, 10, 84]), a clonal expansion can achieve 5% of the CD8 T-cell pool within 435 days (14.5 months), and occupy more than 30% of the repertoire within 535 days (17.5 months) (Fig. 4, red line). If a naïve T-cell undergoes 19 rounds of division (a recent estimate for naïve T-cell proliferation during acute infection [3]), it would only take 195 days (6.5 months) to achieve 5% of the CD8 T-cell pool, coming to occupy >30% of the repertoire within 285 days (9.5 months).

The bottom line from this overly simplistic model is that although a subtle increase in proliferation may contribute to the development of clonal expansions, there are likely to be other contributing factors. For example, changes in the rate of death could significantly influence the ability of clones to compete with other CD8 T-cells; in addition, if a clone ever goes through a proliferative burst (e.g., following antigen engagement) this could also accelerate the development of clonal expansions. Future reductionist studies will allow a more careful dissection of the time required for a CD8 T-cell to become a clonal expansion.

9 Factors that Influence the Properties of CD8 Clonal Expansions

Regardless of the precise mechanisms that are behind the development of clonal expansions, the phenotype and properties of individual clones are certain to be influenced by multiple factors, most importantly the interaction between the TCR and antigen.

9.1 The Role of Antigen Persistence

It is increasingly clear that the persistence of antigen significantly impacts the phenotype and dynamics of the CD8 T-cell. While CD8 T-cells only require a very brief period of antigen engagement of the T-cell receptor to become activated [53, 128, 139], the duration and context of antigen presentation can significantly influence the capabilities of the resulting CD8 T-cell. The crippling effects of chronic antigen exposure can be best observed in certain models of chronic infection, where CD8 T-cells never differentiate to a state in which they can survive in the absence of antigen [120, 131].

With regard to CD8 clonal expansions, clonal expansions encountering chronic antigen would be predicted to have significantly different cell surface phenotypes (Fig. 3). These changes in cell surface phenotype would likely influence the expression of cytokine receptors for IL-7 and IL-15 (possibly influencing IL-7Rα and IL-2Rβ), as well as result in the upregulation of various inhibitory receptors (such as PD-1 and KLRG1, which are both receptors whose expression is associated

with chronically stimulated T-cells [6, 126]). In addition, these clonal expansions would be predicted to disappear if antigen ultimately disappears.

Although chronic antigen exposure would most significantly impact the phenotype and properties of clonal expansions, initial encounter of antigen could also play a more modest effect on the resulting phenotype, for example influencing the fate of the resulting CD8 memory T-cell to become a T_{CM} or a T_{EM} cell.

9.2 The Impact of Initial Conditions of Stimulation

As discussed above, a naïve CD8 T-cell can differentiate into a CD8 memory T-cell by at least two distinct paths: i) engagement of the TCR by its appropriate antigen, resulting in the full activation of the T-cell, followed by subsequent proliferation, contraction and differentiation (referred to as antigen-elicited memory) or ii) lymphopenic conditions in which a naïve CD8 T-cell is capable of undergoing proliferation in the absence of full activation (referred to as LIP memory). While the precise characteristics of these two types of memory cells is a subject of ongoing investigation, it is worth noting that there are surprisingly few differences in the properties of these two types of memory cells. Careful microarray analysis of these two types of memory cells has revealed very similar transcriptional profiles [36], and LIP memory cells can mediate immunological protection, a hallmark of memory T-cells [39]. Although no obvious differences between these two types of memory cells have been identified to date, the very different conditions from which they originate make it highly unlikely that they are absolutely identical.

With regard to CD8 clonal expansions, it appears that CD8 clonal expansions may become CD8 memory T-cells through either an antigen-elicited or LIP mechanism. This conclusion is based on the following data:

i) in mice, conditions of lymphopenia are associated with the accelerated development of clonal expansions indicating that LIP memory cells can become CD8 clonal expansions [90]
ii) mice infected with certain infections such as Sendaivirus, influenza, Herpes simplex virus or LCMV can occasionally develop very large antigen-specific clonal expansions in aged mice ([29, 74], Zajac, personal communication), indicating that antigen-elicited memory cells can become CD8 clonal expansions (see chapters by Woodland and Nikolich-Zugich for further discussion),
iii) humans infected with HCMV can develop HCMV-specific clonal expansions [63, 98].

Given that both LIP and antigen-elicited memory CD8 T-cells can become CD8 clonal expansions, it is worth noting that the relative contribution of these two types of memory cells differs between SPF mice and humans. For example, in SPF mice that are typically used to study clonal expansions in mice, the majority of clonal expansions almost certainly represent LIP memory T-cells given the relative paucity of antigen exposure these animals experience. In contrast, humans have an extremely high rate of

antigen exposure, with relatively few memory CD8 T-cells likely to arise from lymphopenia-induced proliferation. Based on this difference, we postulate that the majority of human clonal expansions will recognize a variety of antigens primarily from infectious agents, whereas the majority of clonal expansions in mice will recognize a wide variety of antigens without a bias for infectious agent antigens. Despite this difference, exposure of mice to a variety of infections should be capable of recapitulating the diversity of antigen-elicited clonal expansions that we postulate to occur in humans.

10 Major Questions about CD8 Clonal Expansions

CD8 clonal expansions are a common age-associated perturbation in the immune system. The goal in studying this phenomenon is that it will reveal previously unappreciated effects of the aging environment on CD8 memory T-cell homeostasis, and identify basic cellular and molecular factors that also regulate CD8 memory T-cells in healthy, young individuals. While there is increasing information about this phenomenon, there are still many unanswered questions:

1. How does the aging environment influence the development of CD8 clonal expansions?
2. What are the molecular alterations that contribute to increased growth of CD8 clonal expansions?
3. What factors constrain the growth of CD8 clonal expansions?
4. What is the underlying cause for the heterogeneous phenotype of CD8 clonal expansions?
5. Can every subset of CD8 memory T-cell become a clonal expansion?

We anticipate that research in the upcoming years will shed light on many of these questions, providing new insights into how the aging immune system influences the dynamics of CD8 memory T-cell homeostasis.

Acknowledgments We thank Drs. Linda van Dyk and David Woodland for insightful discussion on the underlying forces that drive development of clonal expansions, Dr. Fred Peyerl for discussion on theoretical growth dynamics of clonal expansions, Drs. Megan MacLeod and Linda van Dyk for helpful comments on the manuscript, and Drs. Chia-Chi Ku, David Woodland and Allan Zajac for personal communication of unpublished data. This work was supported by USPHS grants AI-22295 and AI-52225.

Generation and Gene Expression of CD28$^-$ CD8 T-cell in Human

Nan-ping Weng

Contents

Abstract: Increase of CD28$^-$CD8 T-cells is one of the hallmarks of aging in the human immune system. Recent studies reveal the mechanism of generation and gene expression features of CD28$^-$CD8 T-cells. Here, I summarize the recent progress focusing on the role of interleukin-15 (IL-15) in generation of CD28$^-$CD8 T-cells and the identification of unique gene expression in CD28$^-$CD8 T-cells by microarray gene expression analysis. These new findings enhance our understanding of the origin and function of the CD28$^-$CD8 T-cells and may provide new means for clinical intervention.

1 Overview

CD8 T-cells play an essential role in the control of intracellular pathogens and cancerous growths for the host. The capability of the immune system, particularly CD8 T-cells, to protect the host declines with age [1, 2]. Accumulating evidence suggest that increase of CD28$^-$CD8 T-cells in peripheral blood, a consistent age-associated change, account for the decline of CD8 T-cell mediated protection in the elderly [3–6]. However, the mechanisms underlying the age-associated changes in the immune system are complex and have just begun to be understood.

CD28, a membrane glycoprotein serving as a major co-stimulatory receptor for TCR mediated activation, plays multiple roles during T-cell activation from amplification of the TCR signal to induction of key cytokine production such as IL-2 to

ensure a complete activation of T-cells after stimulation with antigen [7, 8]. Loss of CD28 expression has profound impact on the function of T-cells [9]. For example: (1) decreased production of IL-2 and IFN-γ in response to stimulation [10]; (2) resistance to apoptosis [11]; (3) reduced antigen repertoire diversity [5], and (4) associated with the lack of antibody production after immunization [12]. In addition, $CD28^-$CD8 T-cells gain expression of some NK cell markers such as KIRs, CD16, CD56, KLRK1 (NKG2D), and retain or increase cytotoxicity with high expression of granzyme B and perforin [3].

Despite recent findings, the key issues related to $CD28^-$CD8 T-cells remain to be elucidated. What are the causes of $CD28^-$CD8 memory T-cells? How $CD28^-$CD8 memory T-cells are maintained in vivo? What are the molecular features of $CD28^-$CD8 memory T-cells compared to $CD28^+$CD8 memory T-cells? In this chapter, I review the ontogeny of $CD28^-$CD8 memory T-cells and summarize the genome-wide analysis of gene expression profiles of $CD28^-$CD8 memory T-cells from peripheral blood. I will discuss the features of gene expression of $CD28^-$CD8 memory T-cells as compared to their $CD28^+$ counterparts.

2 Ontogeny of $CD28^-$CD8 T-cells

In newborn human, all T-cells in the peripheral blood express CD28 on the cell surface [3, 13]. As $CD28^-$ T-cells appear after birth and gradually increase with age [14], it has been suggested that $CD28^-$CD8 T-cells are derived from $CD28^+$CD8 T-cells. In the past decades, accumulating evidence support such a notion and the causes of $CD28^-$CD8 T-cells are begun to be understood. There is overwhelming evidence indicating that repeated antigenic stimulation, mostly viral challenge, is one major cause of down-regulation of CD28 expression in T-cells [15, 16]. More recently, homeostatic cytokines such as IL-15 are also capable of induce down-regulation of CD28 expression in CD8 T-cells [17, 18].

2.1 Antigenic Stimulation Induced $CD28^-$CD8 T-cells

An increasing number of publications shows that increase of $CD28^-$CD8 T-cells are found in patients with a variety of viral infections including human immunodeficiency virus (HIV) [19, 20], cytomegalovirus (CMV) [21, 22], Epstein-Barr virus (EBV) [23, 24], and Hepatitis C virus (HCV) [25, 26]. A common feature of these viral infections is relative persistent in the host and their interaction with immune system is often long lasting and results in varing degree of increase of effector T-cells, particularly in the CD8 T-cells. In the CD8 T-cell compartment, most of these responding CD8 T-cells are $CD28^-$CD8 T-cells. The notion that these $CD28^-$CD8 T-cells are derived from their precursor $CD28^+$CD8 T-cells after viral

stimulation is supported by several findings. (1) CD28$^+$CD8 T-cells stimulated in vitro loss CD28 expression to become CD28$^-$CD8 T-cells [4]. The loss of CD28 expression in these viral antigen primed CD8 T-cells appears stable, which is different from a transient down-regulation of CD28 expression on T-cells occurs after antigenic stimulation [27].

2.2 Cytokine Mediated Loss of CD28 Expression in CD8 T-cells

Recently, down-regulation of CD28 expression in T-cells by cytokines sharing the common γ-chain receptors has been reported [17, 18]. Although Borthwick showed that IL-2, IL-7, and IL-15 were capable of down-regulation of CD28 expression in T-cells after a short term culture, it is unclear if such down-regulation is transient or stable and what mechanisms are responsible for these cytokine-mediated down-regulations of CD28. In addition, TNF-α, a proinflammatory cytokine secreted by various types of cells including T-cells, has also been shown to down-regulate CD28 expression in CD4 T-cells [28]. However, the relationship of cytokines of the common γ-chain family and the TNF family in down-regulation of CD28 expression is not fully understood.

Loss of CD28 expression in memory CD8 T-cells under homeostatic cytokine IL-15 in a longer term of culture has been analyzed in more detail [18]. In general, CD28 expression was relatively stable during the initial few rounds of cell divisions under IL-15 but a significant loss of CD28 expression occurred after the fifth cell division. The average ratio of CD28$^-$ to CD28$^+$CD8 memory T-cells is 0.43 for the cells that had undergone fewer than five cell divisions while this CD28$^-$ to CD28$^+$CD8 memory T-cell ratio increases to 1.4 in cells undergone five or more cell divisions. Further analysis to determine if loss of CD28 expression was limited to the surface expression or occurred at the transcription level, we found that CD28 mRNA was absent in CD28$^-$CD8 memory T-cells, suggesting that the down-regulation of CD28 expression under IL-15 is at transcriptional level. Finally, the loss of CD28 expression in CD8 memory T-cells is quite stable under IL-15-culture and there is no obvious re-gain of CD28 expression in those CD28$^-$CD8 T-cells over a month of culture. These findings suggest that IL-15-mediated down-regulation of CD28 expression occurs primarily in actively dividing CD28$^+$CD8 memory T-cells and that IL-15-induced loss of CD28 expression in CD8 memory T-cells is stable under continuous IL-15 stimulation.

How does IL-15 induce down-regulation of CD28 expression in CD8 memory T-cells? We found that IL-15 induced production of TNF-α in CD8 memory T-cells and blocking TNF-α effect with the neutralizing anti-TNF-α antibody reduced CD28$^-$CD8 T-cells by approximately 15% (p=0.002, n=12) after 14-day IL-15 culture [18]. More dramatically, supplement of recombinant TNF-α(200 ng/ml) in IL-15 culture induced significantly more CD28$^-$CD8 T-cells than that of the control cultures (IL-15 alone) at day 14 (195% increase, p= 7.1×10^{-6}). The loss of CD28

expression in CD8 memory T-cells induced by exogenous TNF-α is time and dosage-dependent. Supplement of recombinant TNF-α at the beginning of culture accelerated CD28 down-regulation in CD8 memory T-cells as early as 7 days of culture. The effect of TNF-α on down-regulation of CD28 expression in IL-15 cultured CD8 memory T-cells is seen as low as 50 ng/ml of TNF-α. Together, these findings indicate that IL-15 induced down-regulation of CD28 expression in CD8 memory T-cells is partially through production of TNF-α.

2.3 Transcriptional Regulation of CD28 Expression in CD8 T-cells

Loss of CD28 expression in $CD28^-$CD8 T-cells appears to be regulated at the transcription level [29, 30]. Analysis of the promoter of CD28 reveals that an inoperative transcriptional initiator (INR) consisting of two motifs α and β at the proximal region of CD28 promoter is involved in the regulation of transcription of CD28 [30]. Loss of α and β bound complexes is found in $CD28^-$ T-cells and two proteins, nucleolin and heterogeneous nuclear ribonucleoprotein-D0 isoform A (hnRNP-D0A), bind to the α motif of INR [31]. The binding of these proteins to the α motif of INR is required for transcription of CD28 as lack of nucleolin and hnRNP-D0A at the α site INR site appears to be associated with the loss of transcription of CD28 in $CD28^-$ T-cell lines [31]. Because these findings were derived from cell lines, it remains to be confirmed if the same regulation works in normal/primary T-cells during chronic infection and replicative senescence. Equally important is to understand how the chronic stimulation and/or replicative senescence lead to the loss of the α/β INR complexes in the promoter of CD28 gene.

3 Gene Expression Analysis of $CD28^-$CD8 T-cells

3.1 Experimental Design

Memory phenotype CD8 T-cells that are $CD28^+$ and $CD28^-$ were isolated from peripheral blood of healthy adults based on the surface markers CD8, $CD45RA^-$ and CD28 by cell sorting. The purity of sorted $CD28^+$ and $CD28^-$ memory phenotype CD8 T-cells was over 95%. Total RNA were extracted immediately from half of the sorted cells or after 5-day culture with human recombinant IL-15 (50 ng/ml, Peprotech, Boston, MA) of the rest of sorted cells. The quality and quantity of total RNA were analyzed by an Agilent Bioanalyzer (Agilent Technologies, Palo Alto, CA) and only the high quality RNA were used in the microarray experiment and in real time quantitative RT-PCR. To minimize the potential differences among individuals, RNA was pooled from 2–3 donors and a total of three RNA pools were generated for microarray experi-

ments and for real time quantitative RT-PCR analysis. A fourth RNA pool was made for additional real time quantitative RT-PCR analysis to ensure the changes identified here were common between $CD28^+$ and $CD28^-$CD8 memory T-cells.

The microarray gene chips were purchased from Agilent Technologies (Whole Human Genome Oligo Chip). This Whole Human Genome Oligo Chip consists of the vast majority of the genes and transcripts in human genome (36,866) on a single slide. The targets on the chip were 60-mer oligonucleotides which offer an overall excellent balance between sensitivity and specificity. The two-fluorescent dyes detection system with a standard universal reference RNA was used in the signal detection to allow a uniformed comparison among different chips. As only three biological replications in this experiment, we applied a conservative error model to reduce the false positives. Statistical significance was determined using the false discovery rate (FDR). The FDR was set to 0.05, which corresponds to the average proportion of false positives = 5% in combination with the pair-wise mean comparison of the signal intensity difference was set to be greater than 2 fold. Finally, real time RT-PCR was applied to independently confirm these selected significant genes. Most of them were confirmed by real time RT-PCR, and the agreeable rate was 85%.

3.2 Gene Expression Changes in CD28⁻CD8 Memory T-cells

Overall, $CD28^-$ and $CD28^+$CD8 memory T-cells expressed similar number of genes at the comparable levels. A small number of genes (58 out of 36,866 analyzed) displayed significant difference in mRNA level between $CD28^-$ and $CD28^+$CD8 memory T-cells. The majority of these differentially expressed genes are known genes (78%, 45 out of 58 genes) and they serve a wide range of functions and are discussed below.

3.2.1 Expression of Co-Stimulatory Receptors in CD28⁻CD8 T-cells

The CD28 co-stimulatory receptor family consists of five known members, CD28, CTLA-4 (CD152), inducible costimulator (ICOS), program death-1 (PD-1), and B and T Lymphocyte Attenuator (BTLA) [8]. The CD28 family transmembrane proteins have a single extracellular IgV domain and a cytoplasmic tail. CD28 is constitutively expressed on the cell surface of most T-cells and plays a primary role in augmenting TCR signals upon activation. The expression of CD28 decreases after activation. CTLA-4 increases expression after activation and serves as an inhibitory receptor [32, 33]. ICOS expression increases after activation and may play a role in sustained stimulation of effector functions of T-cells [34]. PD-1 and BTLA are both expressed on T and B cells and serve as inhibitory receptors [35, 36]. Among the five members of CD28 family, we found that only CD28 expression was significantly diminished in $CD28^-$CD8 memory T-cells compared to $CD28^+$ counterparts.

CD40L and CD70 are members of the TNF superfamily and both serve as co-stimulatory receptors during T-cell activation. The expression pattern of CD40L is similar to CTLA4 during CD8 T-cell differentiation. CD70 is a ligand for CD27, a receptor that is member of the tumor necrosis factor receptor (TNFR family). The signal generated from CD27/CD70 interaction is temporally or spatially segregated from CD28 during T-cell activation [37]. The T-cell activation/survival signals generated by different co-stimulators have some functions in common and yet distinct from each other in other aspects to allow effectiveness and longevity of the T-cell response and survival. The levels of CD27 and CD70 are stable from naive to memory ($CD28^+$ to $CD28^-$) cells. Decreased CD27 expression associated with increased CD70 expression are found in the effector memory CD8 T-cells. The significance of this altered balance of CD27/CD70 expression remains to be determined. It is clear, however, that the parallel loss of CD27 and CD28 expression has profound impact on CD8 T-cell function.

Not all co-stimulatory receptors were down-regulated in $CD28^-$CD8 memory T-cells. Two co-stimulatory receptors (4-1BB and SLAMF7) express higher in $CD28^-$CD8 memory T-cells. 4-1BB (CD137) belongs to the TNFR gene family and plays a key role in activation-induced cell division, survival, and effector function of CD8 T-cells [38, 39]. An increased 4-1BB expression along with a diminished expression of CD154 coexists in $CD28^-$CD8 memory T-cells, suggesting that an elevated 4-1BB could facilitate the growth and survival of $CD28^-$CD8 memory T-cells in vivo. If this is true, 4-1BB might facilitate the age-associated accumulation of $CD28^-$CD8 T-cells. CD2-like receptor activating cytotoxic cells (CRACC, SLAMF7) also belongs to the SLAM gene family and is expressed on cytotoxic T-cells, activated B cells, and mature dendritic cells [40]. Engagement of SLAMF7 activates NK cell-mediated cytotoxicity [40]. The mRNA level of SLAMF7 was highly expressed in ex vivo $CD28^-$CD8 memory T-cells and was stable after IL-15 treatment. Although the mRNA level of SLAMF7 was lower in ex vivo $CD28^+$CD8 memory T-cells, the level of SLAMF7 was similar between $CD28^-$ and $CD28^+$CD8 memory T-cells after IL-15 treatment.

Alteration of co-stimulatory receptors expression in $CD28^-$CD8 memory T-cells appears to be complex. While loss of expression of some receptors (CD28 and CD154) was apparent, elevated expression of other co-stimulatory receptors (4-1BB and SLAMF7) may provide a compensatory measure for the co-stimulatory function. The questions are: How are these different co-stimulatory receptors regulated in CD8 memory T-cells, particularly in $CD28^-$CD8 memory T-cells? Can an elevated expression of 4-1BB and SLAMF7 compensate the loss of CD28 and CD154? Further studies are required to address these issues and to better understand the activation associated defects of $CD28^-$CD8 memory T-cells and the mechanisms of the age-associated decline of immune function.

3.2.2 Expression of NK Cell Receptors in $CD28^-$CD8 T-cells

The NK cell receptors are initially identified on the surface of NK cells and NK T-cells. Based on their structures, NK cell receptors can be divided into (1) the Immunoglobulin-

like NK cell receptors including natural cytotoxicity receptors (NCR), killer immunoglobulin-like receptor (KIR), and CD244, and (2) the C-type lectin-like NK cell receptors including the killer cell lectin-like receptor (KLR) [41]. According to their functions, NK cell receptors can be divided into inhibitory and stimulatory receptors. While engagement of the inhibitory receptors prevents NK cells and CD8 T-cells from killing target cells, interaction of stimulatory receptors results in the trigging of NK cell or CD8 T-cell-mediated cytotoxicity. Expression of NK cell receptors on CD28⁻ CD8 T-cells have been reported [42]. Here we discuss the expression of seven NK cell receptors: KIR2DL2, KIR3DL2, NCR1, CD244, KLRD1, KLRF1, and KLRG1 during CD8 T-cell differentiation identified from microarray analysis.

KIR2DL2, KIR3DL2, NCR1, and CD244 belong to the Ig-like NK cell receptor family. KIR2DL2 (NKAT6) and KIR3DL2 (NKAT4) bind to the polymorphic MHC class I molecules and inhibits lymphocyte cytotoxicity. In contrast, NCR1 and CD244 are stimulatory NK receptors that activate NK-mediated cytotoxicity. The engagement of CD244 (2B4) with its ligand (CD48) or with an anti-CD244 antibody results in enhanced production of interferon gamma (IFN-γ) and cytotoxicity in CD8 T-cells and NK cells [43, 44]. Despite their opposite function, the expression patterns of these four NK cell receptors are similar: all of them are expressed in naïve cells, down-regulated in CD28⁺ memory T-cells, increased in CD28⁻ memory T-cells, and elevated in effector memory cells. After IL-15 treatment, all of them are down-regulated in CD28⁻CD8 memory T-cells [45]. As NCR1 is considered to be exclusively expressed in NK cells, the role of its elevated expression in effector memory T-cells remains to be determined. It has been shown that CD244 level is elevated in CMV-specific effector CD8 T-cells while absent in naïve CD8 T-cells [44]. This enhanced expression of CD244 in effector memory cells agrees with the elevated effector function of the CMV specific CD8 T-cells.

KLRD1, KLRF1, and KLRG1 belong to the C-type lectin-like NK cell receptor family. KLRD1 (CD94) forms heterodimers with KLRC3 (NKG2E) or other members. The KLRD1/KLRK1 (CD94/NKG2D) heterodimer is expressed primarily in NK cells and CD8 T-cells. KLRF1 (NKp80) is expressed in all NK cells and CD56⁺ T-cells and cross-linking of KLRF1 results in induction of cytolytic activity. KLRG1 is a newly identified member of the KLR family and is expressed in NK cells and a subset of T-cells. Although all of them are highly expressed in CD28⁻CD8 T-cells, the patterns of their expression differ. A down-regulation of expression from naïve to memory (CD28⁺) is observed for KLRD1 and KLRF1 but not for KLRG1. The identification of elevated expression of different NK cell receptors in CD28⁻CD8 memory T-cells suggests that NK cell receptors may play roles in CD28⁻CD8 T-cell function. The physiological significance of acquiring these NK cell receptors in CD28⁻CD8 T-cells is not clear and will require further study.

3.2.3 Expression of Cytolytic Molecules in CD28⁻CD8 T-cells

The function of cytotoxic CD8 T-cells is inducing rapid apoptosis of intracellular pathogen-infected or transformed cells. This cellular killing is mediated by two

distinct pathways: the granule exocytosis pathway that releases perforin and granzymes from the granule cores and the Fas ligand (FasL)/Fas pathway [46]. The granule exocytosis pathway consists of secretory granules that contain perforin and granzymes. Perforin is expressed only in cytotoxic T-cells and form a pore structure on the targeT-cell membrane to facilitate the entry of granzymes [47]. Granzymes are proteinases that consist of five members in humans: A, B, H, K and M. Each member of granzymes has a different substrate specificity [46]. Granzyme A (GZMA) and granzyme B (GZMB) are expressed in CD8 CTL, γδ T-cells, and NK cells [48, 49], granzyme H (GZMH) and granzyme K (GZMK) appear to be expressed mainly in CD8 CTL [50, 51], and granzyme M (GZMM) is expressed mainly in NK cells [52].

Perforin is detected in freshly isolated CD8 memory T-cells and is up-regulated after in vitro stimulation by TCR crosslinking or by treatment with IL15 [53]. The levels of perforin mRNA was higher in $CD28^-$CD8 memory T-cells than their $CD28^+$ counterparts [13, 45]. After culture with IL-15, there is no obvious increase of perforin mRNA levels in $CD28^-$CD8 memory T-cells but significantly increased perforin in $CD28^+$CD8 memory T-cells. The increase of proforin mRNA in IL-15 treated $CD28^+$CD8 memory T-cells is compatible to the level of freshly isolated $CD28^-$CD8 memory T-cells.

GZMB and GZMH share a high degree of similarity in amino acid sequence [50]. However, the expression patterns of GZMB and GZMH are quite different. The GZMB level is low in freshly isolated T-cells, but increases after activation [54]. The GZMH level is low in both freshly isolated and activated T-cells [55]. In $CD28^-$ CD8 memory T-cells, both GZMB and GZMH are highly expressed, resembling a mixed feature of activated T-cells and NK cells. GZMA and GZMK are functionally overlapping as up-regulation of GZMK has been found in GZMA deficient mice [51]. The levels of GZMA mRNA are similar between $CD28^-$ and $CD28^+$ CD8 memory T-cells, but a low level of GZMK is found in $CD28^-$CD8 memory T-cells compared to their $CD28^+$ counterparts. The level of GZMM expression was similar between $CD28^-$ and $CD28^+$CD8 memory T-cells. Following culture with IL-15, the expression of both GZMA and GZMB were increased in both CD8 memory T-cell subsets. Although activation by antigen do not significantly increase the expression of GZMH [55], IL-15 treatment induces up-regulation of GZMH in $CD28^+$CD8 memory T-cells. But $CD28^-$CD8 memory T-cells still have higher levels of both GZMB and GZMH than $CD28^+$CD8 memory T-cells. This indicates that $CD28^-$ CD8 memory T-cells possessed more cytolytic granule enzymes than $CD28^+$ counterparts before and after IL-15 culture, providing a molecular basis for high levels of cytotoxicity of $CD28^-$CD8 memory T-cells.

The Fas ligand (FasL)/Fas pathway provides another means of T-cell cytotoxicity, which applies not only to regular target cells such as intracellular pathogen infected and transformed cells but also to immune cells as a negative feedback regulation to the generation and expansion of CD4 and CD8 T-cells [46, 56]. It has been reported that FasL can block expression of CD28 at the transcriptional level in Jurkat cells [57], suggesting the role of FasL/Fas in the age-related decline of CD28 expression. The level of FasL mRNA appears higher in $CD28^-$CD8 memory T-cells than in

$CD28^+$ counterparts, and IL-15 treatment did not increase FasL expression in $CD28^-$ CD8 memory T-cells but increased in $CD28^+$CD8 memory T-cells. Together, the elevated expression of key molecules in both the granule exocytosis pathway and the FasL/Fas pathway indicates an enhancement of cytolytic capability in $CD28^-$ CD8 memory T-cells.

3.2.4 Expression of Cytokines, Chemokines and Their Receptors in $CD28^-$CD8 T-cells

Cytokines and chemokines are secreted proteins and play essential roles in many aspects of immune functions. In lymphocytes, cytokines or chemokines can promote their survival or death through strict regulation of their expression and their receptor expression during lymphocyte development and differentiation. Activation of lymphocytes induces production of a variety of cytokines and chemokines in turn these cytokines and chemocykes influence the effectiveness or determine the consequence of an immune response. Therefore, alteration of expression of cytokines and chemokines and their receptors could lead to mild or even severe defects of immune function [58].

Changes in cytokine and chemokine production in $CD28^-$CD8 T-cells after in vitro stimulation have been previously reported [10, 12, 59]. In freshly isolated $CD28^-$CD8 memory T-cells, the mRNA levels of interleukin 12A (IL12A), interleukin 13 (IL13), chemokine (C-C motif) ligand 4 (CCL4, MIP1-β), chemokine (C-X3-C motif) receptor 1 (CX3CR1, CCRL1), and chemokine-like receptor 1 (CMKLR1) are more highly expressed than do $CD28^+$CD8 memory T-cells. In contrast, the mRNA levels of interleukin 3 (IL3), interleukin 23A (IL23A), interleukin 7 receptor (IL7R), and interleukin 12 receptor β2 (IL12RB2) were more highly expressed in $CD28^+$CD8 memory T-cells compared with the $CD28^-$ cells.

IL-12 and IL-23 are cytokines that are composed of two subunits, one common subunit (IL12B, p40), and one unique subunit IL12A (p35) and IL23A (p19) for IL12 and IL23, respectively [60, 61]. Functionally, IL-12 induces the production of IFN-γ in NK and T-cells, facilitates Th1 differentiation, and serves as a bridge between non-specific innate resistance and antigen specific adaptive immunity [60]. In contrast, IL-23 participates in the proliferative signal in memory T-cells [60, 61]. At the mRNA level, IL12A is higher in $CD28^-$CD8 memory T-cells ex vivo but down-regulated after IL-15 treatment. In contrast, IL23A is highly expressed in $CD28^+$CD8 memory T-cells ex vivo, but was not changed after IL-15 treatment. The increased level of IL12 in $CD28^-$CD8 memory T-cells could contribute to the cytotoxicity of these cells while decreased levels of IL23A may affect the proliferative response of $CD28^-$CD8 memory T-cells.

IL-13 is produced primarily by Th2 cells and NK cells and promotes survival, differentiation, and proliferation of hematopoietic progenitor cells [62]. It also exerts immunoregulatory functions including anti-inflammatory effects, Th2 cell development, and B cell proliferation and IgE production [63]. By regulating cell-mediated immunity, IL-13 modulates resistance to several intracellular organisms [63]. IL13 mRNA level was higher in $CD28^-$ than in $CD28^+$CD8 memory T-cells

ex vivo. After IL-15 culture, IL13 mRNA level does not increase in CD28$^-$CD8 memory T-cells but increases in CD28$^+$CD8 memory T-cells. The precise role of IL-13 in CD28$^-$CD8 memory T-cells requires further study.

IL-7 is an essential cytokine during T-cell development and also plays a key role in homeostasis of memory CD8 T-cells [64]. IL-7 receptor is a dimmer that consists of IL-7 unique α receptor (IL7R) and the common γ chain. The function of IL7 depends on the expression of IL7R, which appears to be regulated in T-cells by the availability of IL-7 [65]. The mRNA level of IL7R is lower in CD28$^-$CD8 memory T-cells than in the CD28$^+$CD8 memory T-cells and is further down-regulated in both subsets after IL-15 treatment. These findings suggest that IL-7 may not be a key survival cytokine for CD28$^-$CD8 memory T-cells.

The primary function of chemokines is regulating lymphocyte migration but they are also involved in lymphocyte development, differentiation, and effector function. Like cytokines, different expression patterns of chemokines and their receptors were also observed between CD28$^-$ and CD28$^+$CD8 memory T-cells. CD28$^-$CD8 memory T-cells express higher levels of CCL4 (MIP-1β) and CX3CR1 compared to CD28$^+$ counterparts. Both are involved in the regulation of adhesion and migration of T-cells and NK cells [66, 67]. In addition, the expression of CX3CR1 is found in CTL and NK cells [68, 69]. Interaction of CX3CR1 with its ligand, CX3CL1 (Fractalkine), induces the adhesion function as well as promotes subsequent migration to the secondary chemokines such as CCL4 or IL-8/CXCL8 [69]. After IL-15 treatment, the mRNA levels of CCL4 and CX3CR1 are increased in both subsets of memory cells. In addition, the mRNA levels of chemokines XCL1 (lymphotactin-α) and XCL2 (lymphotactin-β) are induced to significantly higher levels after IL15 treatment in CD28$^-$CD8 memory T-cells compared to their CD28$^+$ counterparts. Since they induce both T-cell and NK cell migration [70], elevated expression of XCL1 and XCL2 may facilitate migration of CD28$^-$CD8 memory T-cells. Three chemokine receptors, CCR2, CCR6, and CCR7, express more highly expressed in CD28$^+$CD8 memory T-cells than in CD28$^-$CD8 memory T-cells. After IL-15 culture, the mRNA levels of CCR2 and CCR6 are increased while the level of CCR7 was decreased in both subsets of memory cells.

3.2.5 Differentially Expressed Transcription Factors in CD28$^-$CD8 T-cells

The interaction between T-cells and other cells at various lymphoid compartments mediated by different ligands/receptors on the cell surface is an ongoing process throughout the life of T-cells. The consequence of these interactions depends on the specific interaction, the strength of the interaction, and the states of interacting cells, which are essential for the development, differentiation, and function of T-cells. One of the consequences of the surface ligand/receptor interaction is activation of transcription factors. Here, we will discuss four transcription factors that are differentially highly expressed either in CD28$^-$ (TBX21, EOMES, and MYC) or in CD28$^+$ (CEBPD) CD8 memory T-cells.

T-box 21 (TBX21, T-bet) is a member of T-box containing gene family and is involved in initiating Th1 lineage development from naive precursor cells and

regulation of Ig class switching in effector cells [71, 72]. In addition, it is also involved in regulation of the effector function by promoting IFN-γ production and cytotoxicity in CD8 T-cells [73, 74]. The level of TBX21 mRNA is higher in CD28⁻CD8 memory T-cells than in the CD28⁺ counterparts but there is no significant difference in the levels of IFN-γ and other Th1 cytokine genes between CD28⁻ and CD28⁺CD8 memory T-cells. Thus, it is plausible that elevated expression of TBX21 may serve as a regulator behind the elevated cytotoxicity in CD28⁻CD8 memory T-cells.

Eomesodermin (EOMES) is also a member of the T-box containing gene family within the same subfamily of TBX21. EOMES has been shown to induce IFNγ, perforin, and GZMB in CD8 T-cells [75]. The level of EOMES is higher in CD28⁻CD8 memory T-cells than in their CD28⁺ counterparts. After IL-15 treatment, the levels of EOMES are decreased only in CD28⁻CD8 memory T-cells but did in CD28⁺CD8 memory T-cells. As EOMES shares similar function with TBX21 in regulation of effector functions of CD8 T-cells, their elevated expression in CD28⁻CD8 memory T-cells provides a transcriptional basis of enhanced cytotoxicity in CD28⁻CD8 memory T-cells.

MYC and its family transcription factors are key regulators of cell growth and proliferation as well as inhibition of terminal differentiation and induction of apoptosis [76]. Dysregulation of MYC expression leads to unlimited cell growth and ultimately development of tumors [77]. MYC is up-regulated after T-cell activation and is also involved in the induction of apoptosis [78]. The level of MYC mRNA is higher in freshly isolated CD28⁻CD8 memory T-cells than their CD28⁺ counterparts. After IL-15 culture, MYC mRNA levels are highly increased in both CD28⁻ and CD28⁺CD8 memory T-cells. However, the difference of MYC mRNA level remained significantly higher in CD28⁻CD8 memory T-cells compared to their CD28⁺ counterparts. As previously studies showed CD28⁻CD8 memory T-cells are resistant to apoptosis, MYC in CD28⁻CD8 memory T-cells may facilitate cell division and resistant to apoptosis.

CEBPD is a member of the CCAAT/enhancer-binding protein (C/EBP) family that contains a highly conserved of leucine zipper DNA binding motif [79]. Members of the C/EBP family have been shown to regulate the differentiation of myelomonocytic marrow cells [80]. CEBPD is also involved in regulating the expression of IL6 that plays an important role in regulating immune and inflammatory response [81].The level of CEBPD mRNA is higher in CD28⁺CD8 memory T-cells than in CD28⁻CD8 memory T-cells. Although CEBPD expression is tightly regulated in G(0) growth-arrested mouse mammary epithelial cells (MEC) [82], IL-15 induced proliferation does not appear to affect the levels of CEBPD mRNA in either CD28⁻ or CD28⁺CD8 memory T-cells. It remains to be determined the significance of down-regulated expression of CEBPD in CD28⁻CD8 memory T-cells.

4 Conclusion

Studies of the generation of CD28⁻CD8 T-cells indicate that both antigenic stimulation and homeostatic proliferation are causes for loss of CD28 expression in CD28⁺ CD8 T-cells. Thus, it is likely that age-associated accumulation of CD28⁻CD8

T-cells is the combinational consequence of antigenic stimulation and homeostatic expansion of memory T-cells. Genome-wide analysis of gene expression profiles between $CD28^-$ and $CD28^+CD8$ T-cells reveals the molecular changes in $CD28^-$ CD8 memory T-cells. The gain and loss of these specific gene expressions in $CD28^-$ CD8 T-cells may reflect an adaptive process of the immune system in which an induced cytotoxicity is replaced by a constant cytotoxicity in CD8 memory T-cells in compensation of the inability of robust proliferation. Further characterization of the regulation and function of those differentially expressed genes in $CD28^-$ CD8 T-cells will help us to better understand this age-associated change in T-cell function and may open new avenues of clinical intervention to slow or reverse this aging-associated process.

Acknowledgment The author want to thank Monchou Fann, Kevin Becker, and William Wood III for conducting and assisting microarray experiments; Karen Chiu and Jason Godlove for the study of IL-15 induced down-regulation of CD28 expression, Robert Wersto, Joe Chrest and Coung Nguyen for cell sorting, Karen Madara and her staff at the NIA Apheresis Unit for processing the blood samples. This research was supported by the Intramural Research Program of the National Institute on Aging, National Institutes of Health (NIH).

Role of Regulatory Subsets During Aging

Piotr Trzonkowski

Contents

Abstract: Efficient immune response requires both vigorous effector responses and regulation via regulatory subsets. Any disturbances in the balance between these two opposite activities of immune system result in either autoimmunity or excessive immunosuppression. Undoubtedly immunosenescence contributes to this balance as it affects the majority of populations taking part in immune response. This chapter describes activities of regulatory subsets, alterations associated with their ageing and clinical consequences of these changes.

Keywords: CD25+CD4+ Treg cells • Tr1 cells • Th3 cells • Interleukin 10 (IL10) • Transforming growth factor β (TGFβ) • Tolerogenic dendritic cells • CD28-CD8+ T suppressor cells • NKT cells

1 Introduction

Aggressive action of immune system against alien agents has to be strictly controlled in order to prevent destruction of self tissues. There are several subsets within lymphoid system which are responsible for the control of selective targeting of alloanti-

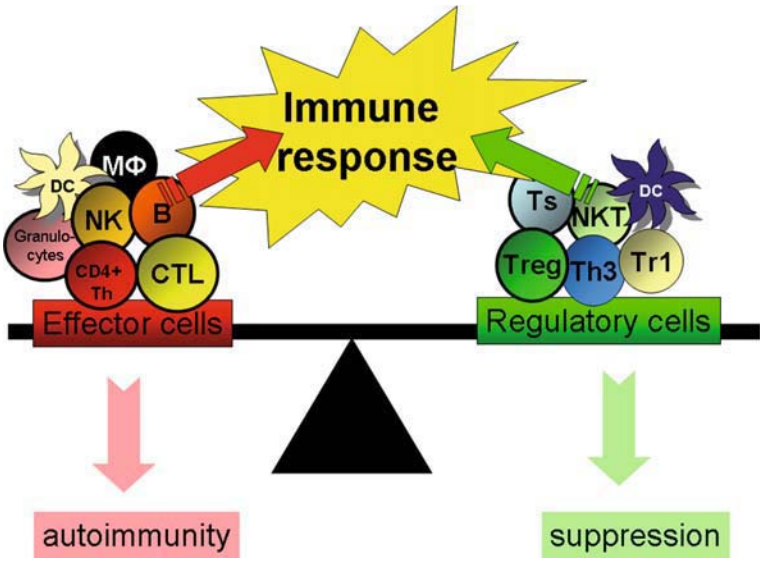

Fig. 1 The balance is required for efficient immune response. Coordinated function of effector and regulatory subsets guarantees efficient immune response. Imbalance in this regulation results is either autoimmune phenomena or exaggerated immunosuppression

gens and, at the same time, keeping the immune system neutral to autoantigens. The awareness of such immunosuppressive subsets started with Owen's notion, who found that the intraplacental transfusion of blood in cattle caused that each dizygote twin tolerated skin transplants from the other (Owen RD 1945). Soon after, Medawar performed a series of excellent Nobel Prize awarded experiments with infusion of alloantigens to newborn mice inducing selective alloantigen tolerance during their adulthood (Billingham RE 1953). The leading role of T-cells in tolerance induction was proved in 70s and 80s (Gershon RK 1970; Fujimoto S 1975; North RJ 1984); however, a detailed phenotype of those cells has been discovered only recently. In 1995, Sakaguchi reported that deficiency of CD4+ T-cells with expression of IL2Rα (CD4+CD25+), so-called T regulatory cells (Treg), in mice was associated with multiple autoimmune diseases (Sakaguchi S 1995). Without any doubt, different subsets of Treg cells have taken a central stage in immunology since that time. Nevertheless, induction of tolerance is much wider than Treg cells as some other subsets, such as CD28-CD8+ T suppressor cells (Ts), NKT cells, and some dendritic cells, were also found to confer it in immune system. Making the story even more complex, recent reports have suggested that efficient regulation of immune response is not limited to immunosuppressive cells, but it is more a balance between suppressive and proinflammatory effector cells. Interestingly, having opposite activities, at least some of those cells have common origin. Thus, keeping adequate proportions between aggressive effector phase of immune response and self-limitation of immune response is probably the best definition of the function of all the above mentioned regulatory subsets.

2 $CD25^{high}CD4^{+}$ T Regulatory Cells (Treg)

2.1 Biology

CD4+ T-cells play the central role in T-cell mediated regulation. There are two main subsets of CD4+ Treg cells in the body: naturally occurring and adaptive ones. As the discovery of Treg cells is relatively fresh, it is very often difficult to distinguish between these lineages due to their common features. Naturally occurring or intrinsic Treg cells (nTreg) in humans can be defined as $CD25^{high}$FoxP3+CD4+ T-cells. The expression of CD25 receptor is related to their high dependency on IL2, and FoxP3 is a transcription factor that drives intracellular signals which results in suppressive abilities of nTreg cells. Of note, FoxP3 is currently considered as the most characteristic intracellular marker of nTreg cells (Baecher-Allan C 2001; Hori S 2003). nTreg cells originate from the thymus. Maturing nTreg cells are self-reactive with intermediate to low affinity to autoantigens and yet they escape from central deletion. It is distinctive feature of their development in the thymus. Probably, they do not only arise as a result of the presentation of self antigens through TCR-dependent process but also by means of some other not well understood mechanisms. It has been only recently discovered that their intrathymic lineage commitment is maintained by interactions with medullary thymic epithelial cells expressing the autoimmune regulator AIRE (Aschenbrenner 2007). Intracellular mechanisms related to the maturation of Treg lineage are still far from final conclusions. The studies with *Scurfy* mice, that is, mice without active Treg cells due to the knockout of FoxP3 gene, revealed that these animals suffer from severe lymphoproliferative autoimmune disease (Fontenot JD 2003). Similar defect, so-called IPEX (IPEX–Immune dysregulation, Polyendocrinopathy, Enteropathy, X-linked syndrome) was also found to be caused by mutations in FoxP3 gene in men (Bennett CL 2001). Genome-wide profiling revealed that transcription factor FoxP3 can bind to around 700 genes imposing phenotypic features of nTreg cells (Zheng Y 2007). Although FoxP3 takes a part in both differentiation and functioning of these cells, it appears that its action solidifies only pre-established features acquired by developing nTreg cells in the thymus as it has been shown that inactive nTreg may develop in the thymus even in the absence of FoxP3 (Gavin MA 2007; Wan YY 2007). Moreover, early stage of activation may be associated with transient expression of FoxP3 in T effector cells (Kretschmer K 2005). Despite self-specificity, nTreg do not damage own tissues at the periphery as they are highly anergic. The anergy might by explained by high differentiation of nTreg cells. It has been revealed that the expression of many surface markers locate them within memory phenotype, their proliferation is very much limited, they are characterised by short telomeres and easily undergo apoptosis (Taams LS 2001, 2002). The most important function of nTreg cells is the suppression of other immune cells. Autoreactive cells are not the only targets for nTreg cells. They are also highly efficient suppressors of alloresponses. Broad range of responses inhibited by nTreg cells caused that they were initially thought to be non-specific. However, more recent data, mainly from in vitro nTreg expansion experi-

ments, proved that their suppressive effect can be directed against responses driven by specific antigens (Masteller EL 2006). This inconsistency might have come from low affinity of their receptors and the phenomenon of bystander regulation exerted by nTreg cells, *i.e.* nTreg cells specific to particular antigen may impose tolerance to other antigens when activated (Waldmann H 2006). At first, only CD4+ T effector cells were described to be inhibited by nTreg cells (Suri-Payer E 1998). Twelve years after the discovery Treg cells were found to interfere with CD8+ T-cells, NK cells, NKT cells, monocytes, dendritic cells, and granulocytes (Piccirillo CA 2001; Trzonkowski P 2004; Taams LS 2005; Lewkowicz P 2006). Upon stimulation, which usually occurs at the site of inflammation as well as in the local lymphoid tissue, nTreg interact with effectors in a direct cell-to-cell manner suppressing their proliferation and effector activities (Taams LS 2001; Trzonkowski P 2004). Although nTreg cells were found to produce suppressive cytokines, such as IL10 or TGFβ, direct contact with other cells is regarded as the most important way of their action. The most important receptor of Treg cells cooperating in the immune synapse with both CD4+ and CD8+ T effector cells is CTLA-4 molecule (Cytotoxic T lymphocyte antigen 4, CD152). Engagement of this receptor in the presence of TCR ligation triggers suppressive activity of nTreg cells (Takahashi T 2000; Sansom DM 2006). There are several mechanisms of this suppression. Initially, it was postulated that nTreg cells may physically interfere with the interaction of effector T-cells with APCs by competing for the costimulatory molecules on APCs (Takahashi T 2000). It might be possible as, in comparison to the ligands expressed on T effectors, CTLA-4 has higher affinity for B7 family receptors on APC (Linsley PS 1992). In addition, nTreg cells express variety of adhesive molecules, such as ICAM-1 (CD54) and integrins LFA-1 (CD11a/CD18), α4β7 (LPAM-1), αEβ7 (CD103) and α4β1 (CD49d/CD49), that may additionally give Treg cells the advantage of cell-to-cell interaction with APC that is stronger than the interaction of APC with effectors (Takahashi T 2000; Stassen M 2004; Marski M 2005). Another explanation is that the interaction between CTLA-4 on nTreg cells and B7 family receptors on APC, notably in dendritic cells (DC), induces the expression of enzyme indolamine 2,3-dioxygenase (IDO) in the latter (Grohmann U 2003). IDO changes metabolic pathway of tryptophan to kynurenines, which suppresses T-cell responses (Mellor AL 2002). It has been also described that the engagement of CTLA-4 on nTreg induces secretion of TGFβ that subsequently strongly suppresses T effector cells (Chen W 1998). Apart from T-cells, cell-to-cell interactions were also described in the regulation of other immune cells by nTreg cells. Membrane-anchored TGFβ on nTreg cells is crucial for the inhibition of NK cells and TLR receptors expressed on nTreg cells are prerequisite for the regulation of the activity and survival of granulocytes (Ghiringhelli F 2005; Lewkowicz P 2006). The competition between nTreg cells and T effectors is not limited to the binding of surface receptors of APC. nTreg cells are highly dependent on IL2 but devoid of capabilities of its production. Thus, they compete with effector cells for IL2 which decreases the amount of IL2 available at the site of immune reaction and therefore tempers activities of T effectors (Thornton AM 1998). Moreover, despite dependency on IL2, Treg cells suppress production of IL2 by CD4+ T effectors which additionally decreases availability of

the cytokine during immune response. The most extreme pathway of the regulation revealed during research upon nTreg cells is their cytotoxicity. Namely, it has been found that these cells upon stimulation kill autologous cells by means of secreted cytotoxic perforin and granzymes (Grossman WJ 2004; Gondek DC 2005).

Peripherally induced or adaptive Treg cells constitute another subset of CD4+ Treg cells. It is a small number of cells generated during each and every immune response from activated naïve CD4+ T-cells at the periphery (Karim M 2004). These cells are antigen-specific as they arise in response to specific antigens and their activation is dependent on expressed TCR receptors. Importantly, it is a source of Treg cells independent of the thymus. Apart from that, basic characteristics of these so-called adaptive Treg cells, including the most important marker FoxP3, are similar to thymic-derived nTreg cells (O'Neill 2004).

There are also some other subsets of adaptive CD4+ Treg cells induced at the periphery. In contrast to nTreg cells, these cells do not suppress in cell-to-cell mode and their action is dependent mainly on secreted suppressive cytokines. Based on secreted cytokines at least two different groups may be distinguished—Tr1 cells, which function relies on secreted IL10 (Groux H 1997), and Th3 cells, which produce mainly TGFβ (Fukaura H 1996). Apart from cytokine-dependent mode of suppression, their basic characteristics are also different from nTreg cells. Tr1 cells are anergic mainly due to autocrine action of IL10. These cells seem to be dependent on IL2 family of cytokines as they constitutively express high levels of IL2 family receptors IL2Rβ (CD122) and IL2Rγ (CD132) and can be expanded in the presence of IL2 and IL15. On the other hand, normal level of IL2Rα (CD25) on Tr1 cells can be achieved only upon TCR-mediated stimulation (Battaglia M 2006). Also the expression of FoxP3 in Tr1 is not constitutive but can be upregulated upon activation (Vieira PL 2004). The most consistent intracellular protein postulated as a marker of Tr1 cells is the repressor of GATA-3 (ROG); however, its expression was also noted in T effectors (Cobbold SP 2003). The most important inducer of IL10-producing Tr1 are immature DC (Levings MK 2005). IL10 secreted during interaction of Tr1 with DC limits the production of IL12 and TNFα by DC and macrophages which subsequently quenches induction of Th1 and Th2 responses (Moore KW 2001). Tr1 cells were found to promote tolerance to both auto- and alloantigens. Their suppressive role was described in allotransplantations of bone marrow and solid organs, down-regulation of immune responses in rheumatoid diseases and other autoimmune pathologies, allergies and, inflammatory bowel diseases. On the other hand, their deficit was found to facilitate chronic course of some infections (Battaglia M 2006). It might be important in ageing that IL10 is secreted not only by Tr1 cells but also by other T-cells, monocytes, macrophages and nonlymphoid cells. IL10 from all those sources is often treated as a counterbalance to proinflammatory cytokines, notably to IL6 (Saurwein-Teissl M 2000; Ye SM 2001; Hacham M 2004).

Like Tr1 cells, TGFβ-producing Th3 cells are distinctive in several aspects. First of all, their function is linked mainly to oral tolerance. This aspect is of great importance as Th3 cells generated with orally administered antigens might exert bystander regulation, which has implications in pathology as well as in potential

therapeutic strategies (Ochi H 2006). Unlike other Treg cells, the generation of Th3 cells is dependent on IL4 (Fukaura H 1996; Hafler DA 1997). Also TGFβ on its own, or augmented by IL10, may generate Th3 cells from naïve T-cells (Chen W 2003; Kitani A 2003). Immunosuppressive action of TGFβ secreted by Th3 cells is directed against Th1 responses as it downregulates expression of IL12R and transcription factor T-bet in Th1 cells (Kitani A 2000; Gorelik L 2002). TGFβ may work as soluble cytokine but also as membrane-anchored receptor. The action of the latter form, in relation to TGFβ type 1 on Treg cells, was initially described as an important tool of cell-to-cell regulation of T effectors, B cells (Nakamura K 2001) as well as NK cells (Ghiringhelli F 2005). Membrane-anchored TGFβ seems to work as an executor of several pathways of regulation as its function can be activated by several factors, for example, latency-associated protein (LAP) or thrombospondin (Faria AM 2005). Like the system associated with IL10, TGFβ-dependent regulation appears to be much wider than Th3-mediated effects. The cytokine is fully capable of suppression of T-cells responses when produced by nonlymphoid lineages, such as macrophages or enterocytes (Barnard JA 1993; Galliaerde V 1995).

2.2 Ageing

The regulation of immune responses through Treg cells in ageing appears to have some distinctive features. When compared to younger subjects, the elderly are characterised by higher number of Treg cells but per-cell activity of those cells seems to be altered.

Several laboratories reported increased frequency of Treg cells in aged individuals (Trzonkowski P 2003; Gregg R 2005; Gottenberg JE 2005). The percentage of $CD25^{high}CD4+$ T-cells in the peripheral blood is surprisingly high at birth reaching in some cases even 9.5% of total CD4+ T-cells in cord blood (Godfrey WR 2005), but then decreases during childhood and remains on a stable level not exceeding 5% of total CD4+ T-cells in young and middle aged subjects (Cao D 2004; Beyer M 2005; Gottenberg JE 2005). In more advanced age the number of Treg cells gradually increases and, in the extreme, it may be even fivefold higher than that noted in earlier phases of ontogeny (Trzonkowski P 2006). There might be several sources which give rise to the increased number of Treg cells with ageing. First of all, longer life means longer time when the cells can be generated. Although thymic involution causes reduced output of naturally occurring Treg cells with age, adaptive Treg cells may be generated continuously at the periphery throughout entire lifespan. To a great extent, this idea was confirmed in animal model. Shimizu's group found that age-associated increase in FoxP3+ T-cells with regulatory properties was mainly attributed to CD25-CD4+ T-cells and not to the classical thymus-derived nTreg cells (Shimizu J 2003). In humans, FoxP3+ Treg cells were shown to arise from rapidly dividing, highly differentiated memory CD4+ T-cells (Vukmanovic-Stejic M 2006). Since both memory and regulatory subsets in particular subjects were revealed to share the same TCR repertoire, the authors of this report concluded that every chal-

lenge with specific antigen generates both memory and regulatory cells. This finding, consistent with other reports (Cobbold SP 2006), is of special importance in quantitative studies upon Treg cells in aging as it gives a link between the number of immune responses and potency of regulation in particular subject. It seems to be logic that aged individuals have had higher chance to be challenged with higher number of pathogens than the young, simply because they live longer. Thus, as it comes from Akbar's studies, the elderly are not only characterised by increased number of memory cells but also those regulatory (Vukmanovic-Stejic M 2006). Consistently with this view, when the number of Treg cells was compared between subjects of the same age, the higher number was found in those with the history of more frequent inflammatory events and exposures to higher number of antigenic challenges (Trzonkowski P 2003). Thus, it is not surprising that frail elderly with inflammatory burden (Pawelec G 2005) are characterized by higher number of Treg cells than their healthy counterparts (Trzonkowski P 2006). Preferential accumulation of Treg cells in unhealthy individuals may be recognized as a kind of "vicious circle," when Treg cells arising during particular responses make the patient more susceptible to subsequent infections and these infections induce more Treg cells. It may be especially detrimental in aged subjects as their "vicious circle" lasts for a long time and therefore the number of Treg cells is exceptionally high in frail elderly (Trzonkowski P 2006).

It has to be highlighted that the estimation from peripheral blood might not correlate with total number of Treg cells in the body as Treg cells are capable of efficient trafficking through lymphoid tissues where their level may be substantially higher than that measured in the peripheral blood. For example, Treg cells in mice were found to constitute 40% of CD4+ T-cells in the bone marrow or even more, in terms of absolute numbers, in the spleen (Hoffmann P 2002). Moreover, the trafficking through the tissues seems to be crucial for the function of Treg cells as the expression of receptors allowing them to enter lymphoid tissues, such as CD62L or CCR7, was associated with higher capabilities of immunosuppression (Fu S 2004; Taylor PA 2004; Ermann J 2005). Since the expression of these receptors declines with age on T-cells, it might be the reason that Treg cells in the elderly are not capable of extravasation and their level is increased in the peripheral blood but not in the tissues. These receptors are also markers of naïve cells which implies that Treg cells, like other T-cells, may be on different levels of their differentiation. Indeed, "naïve" CD45RA+FoxP3+CD4+ T-cells, which characteristics are close to other naïve T subsets, was described as a subset of Treg cells in humans. The percentage of these cells was shown to be substantially reduced with age (Valmori D 2005). Initially, no difference in ex vivo suppressive activity was found between CD45+ and CD45RA- Treg cells (Valmori D 2005; Seddiki N 2006). Nevertheless, it might have been dependent on incomplete phenotyping and assessment based on single sampling of the probands. More recent study, in which authors followed phenotype of Treg cells over time during ex vivo expansion, proved superiority of Treg cells derived from CD45RA+ precursors above those CD45RA- (Hoffmann P 2006).

Bearing in mind that the majority of Treg cells in the elderly are highly differentiated and their development, to some extent, is parallel to memory/effector cells, it

might be possible that their accumulation might be an attempt of the counteraction to the process of "shrinkage and filling up of the immunological space" hypothesized initially by Franceschi's group (Franceschi C 2003). The theory is based on the observation that lymphoid system in aged individuals is filled with expanded clones of anergic CD8+ T-cells that block proper immune responses to new challenges (Ku CC 1997). Homeostatic proliferation seems to be an important phenomenon responsible for the generation of CD8+ T clones during ageing (Ku CC 2000; Surh CD 2000; Goronzy JJ 2007). The process has not yet been fully understood but it is known that it is regulated by homeostatic cytokines IL15, IL7, CCL19, CCL21, and MHC-signaling which allow T-cells for rapid expansion in the absence of any external stimuli. Interestingly, recent reports have proved that Treg cells are important players in the limitation of homeostatic proliferation of nonregulatory T effector cells (Shen S 2005). Moreover, Treg cells do not undergo homeostatic expansion on their own (Liu W 2006; Seddiki N 2006). In the light of these facts, their accumulation with age might be surprising as the logic indicates that homeostatic proliferation should preferentially give rise to the increased number of CD8+ T clones and, at the same time, keep the number of Treg cells low. The explanation comes from the nature of resistance of Treg cells to the homeostatic mechanism. Namely, Treg cells are devoid of the expression of IL7R (CD127; Liu W 2006; Seddiki N 2006) and therefore, in contrast to other CD4+ T-cells, they do not require IL7 for survival. The level of this homeostatic cytokine declines with age together with the shrinkage of its main producer, the stroma of the thymus and other lymphoid organs (Fry TJ 2001; Aspinall R 2002). Thus, independence from IL7 may be the reason that CD4+ Treg cells, in contrast to non-regulatory CD4+ T-cells, accumulate with age. Making the image complete, CD8+ T clones are able to accumulate in a homeostatic manner even more vigorously than Treg cells because they are not very much dependent on IL7 and utilize IL15 instead (Chiu WK 2006). Importantly, IL2 is prerequisite for Treg cells to inhibit homeostatic proliferation of other T-cells (Murakami M 2002). In this regard, the role of Treg cells in the suppression of homeostatic proliferation might be somewhat ambiguous as, on the one hand, Treg cells require IL2 for the limitation of homeostatic proliferation of other cells but, on the other hand, they inhibit production of this cytokine by CD4+ T effectors (Piccirillo CA 2001). It might be possible that beyond some threshold the accumulation of Treg cells may be the reason of self-limitation of their activity due to deprivation of IL2. Reaching this point, Treg cells no longer prevent from homeostatic proliferation of T effectors. Indeed, frail elderly seem to "cross the threshold" as they are characterized by extremely high number of Treg cells concomitantly with deep deficiency of IL2 (Trzonkowski P 2006). It seems that the regulation of homeostatic proliferation by Treg cells was designed by the evolution for short-living individuals. Long-lasting or repetitive stimulation, such as continuous stimulation with pathogens like CMV described widely during ageing, might be capable of destabilization of this regulatory circuit which subsequently results in detrimental expansion of oligoclonal CD8+ T-cells found preferentially in frail elderly.

It is not a long time since the discovery of Tr1 and Th3 cells was made and therefore the data specifically on these two subsets in ageing are scarce yet. Up to date,

many questions related to these two suppressive subsets of CD4+ T-cells remain not addressed. In many cases, it is not possible to split up the function of different regulatory subsets of CD4+ T-cells in a given experimental model. Performed studies very often suggest overlapping between phenotype and function of different subsets. The main suppressive cytokines, TGFβ and IL10, are not only secreted by CD4+ T-cells but also by other lymphocytes and nonlymphoid cells and they do not only exert action on immune system but also on other tissues. IL10, in particular, is associated with regulation in ageing as it is often contrasted with proinflammatory activities of IL6 and other proinflammatory cytokines reported to be overexpressed in the elderly. Polymorphic variant -1082GG of IL10 gene, which is associated with high production of IL10 (Persico M 2006), was found to be preferentially spared in centenarian males (Lio D 2002). Interestingly, animal studies suggest surprisingly well preserved secretion of IL10 in old animals versus young ones in epithelial organs such as intestine and kidney (Hacham M 2004). This finding is consistent with previous reports that IL10, also secreted by Tr1 cells, modulate preferentially mucosal immune responses (Nakagome K 2005; Uhlig HH 2006). The cytokine secreted by Tr1 cells might be also involved in aging of cardiovascular system. High levels of IL10 were found in hearts from old mice during their healthy ageing (Hacham M 2004). Increased expression of IL10 in the wall of aorta after adoptive transfer of Treg cells was found to be an agent slowing down atherosclerosis in apolipoprotein E-knockout mice (Mor A 2007). Involvement of IL10 in the circulatory system was also described in humans where low levels of IL10 were associated with complicated recovery after coronary artery bypass grafting (Wei M 2003). Some other studies did not find age-related differences in the levels of IL10 but pointed at increased levels of soluble form of TGFβ in plasma of the elderly (Forsey RJ 2003). Increased secretion of TGFβ type 1 was revealed in response to elevated levels of IL6, being a counterbalance to proinflammatory activity of the latter (Villiger PM 1993). Both TGFβ type 1 and 2 were found to interfere with IL7 in thymopoiesis which might contribute to faster involution of the thymus (Chantry D 1989). At the periphery, TGFβ was described to suppress many different cells. It seems that apart from inhibitory action on T-cells (Letterio JJ 2000), TGFβ is involved in the inhibition of macrophages, which might be of great importance in the prevention of inflammageing (Erwig LP 1998). High levels of TGFβ in aged individuals appear to be consistent with increased expression of CTLA-4 on T-cells reported in this age group (Wakikawa A 1997; Leng Q 2002). Reciprocal interrelation between TGFβ and CTLA-4 may have some functional implications. Cross-linking of CTLA-4 results in the secretion of TGFβ by CD4+ T-cells (Chen W 1998). On the other hand, TGFβ accelerates the expression of CTLA-4 on T precursors which facilitates transformation of CD4+CTLA-4+ T precursors to adaptive Treg cells (Zheng SG 2006). As mentioned above, TGFβ secreted by regulatory cells must be separated from other sources as, for example, locally decreased production of this factor by fibroblasts was linked to impaired wound healing in the elderly (Kudravi SA 2000). Moreover, soluble form of the cytokine is significantly less functional than that membrane-bound and the level of the latter was found to drop down quite early in life in animal model (Gregg RK 2004). Nevertheless, we still

lack the knowledge about age-related differences in the expression of membrane-bound TGFβ in humans.

Despite many efforts, there is no certainty that the accumulation of Treg subsets with age results in oversuppression of the immune system in the elderly. For example, inflammageing, one of the most commonly accepted theories of ageing, contradicts exaggerated immunosuppression in the elderly. Indeed, some reports suggest that the activity of Treg cells declines with age (Tsaknaridis L 2003). Importantly, these studies compare suppressive ability of equal numbers of highly purified Treg cells sorted from either elderly or young subjects in various in vitro suppression assays. In fact, lower responsiveness of Treg cells from the elderly, as compared to the young, in these tests may simply illustrate an impairment of aged Treg cells on a per-cell basis. If the quality of single Treg cell taken from aged subject is not as good as that from the young, it is not surprising that the same number of Treg cells taken from the elderly and the young does not reveal similar suppressive abilities in the assay. The suggestion that per-cell Treg activity from older subject is lower than that from the young is of great importance in the light of reports that local rather than systemic level of Treg cells is associated with clinical outcomes (Liu W 2006). As such, small proportion Treg cells trafficking to the place of local inflammation, might be effective enough in the young but insufficient in the elderly. Bearing in mind this quality issue, the accumulation of Treg cells reported in the elderly may be not necessarily associated with high suppressive abilities but rather recognized as a compensation for their per-cell impaired functioning. Indeed, altered phenotype of Treg cells with age, manifested as low proportion of CD45RA+ naïve Treg cells, seems to prove this hypothesis. Another example of impaired "molecular hardware" of aged Treg cells is their inability to undergo apoptosis. It was described mainly in frail elderly and was recognized as a reason of Treg cell accumulation with age (Trzonkowski P 2006). Of note, although the level of Treg cells was revealed to be extremely high in frail elderly, they were unable of efficient action as those patients were the most affected by detrimental effects of inflammageing (Trzonkowski P 2003). It clearly indicates that aged Treg cells are somehow defective. It is possible that prolonged exposure to environmental factors throughout the lifespan might be responsible for defects of Treg cells. Such environmental influence in the elderly was already described as a cause of damage of naïve CD4+ T-cells (Haynes L 2002).

Although accumulation of Treg cells was not found to be faster in any gender, some specific physiological milestones of human life were linked with sudden increase or decrease in the suppressive activity of Treg cells, notably per-cell Treg cell activity. The best described effects are associated with pregnancy when Treg mediated suppression increases in order to tolerate foetal tissues (Aluvihare VR 2004; Somerset DA 2004). However, slightly increased suppressive activity can be also detected during each and every luteal phase of menstrual cycle being interpreted as an action facilitating implantation of the embryo (Mysliwska J 2000; Trzonkowski P 2001). It is very likely that protolerant action of Treg cells towards embryonic tissues is the most pronounced locally. For example, primary idiopathic infertility is associated with low density of Treg cells in endometrium (Jasper MJ

2006). Obviously, the activity of Treg cells in these phenomena is driven by sex hormones, notably oestradiol (Prieto GA 2006). No surprise, fading hormonal activity around menopause is associated with loss of per-cell Treg activity that tips the effector/suppressor balance in favor of the former (Rachon D 2002; Arruvito L 2007). For example, a peak of some Th1-dependent autoimmune diseases associated with menopause in women, such as rheumatoid arthritis, might be triggered by decreased per-cell activity of Treg cells (Ehrenstein MR 2004). Somehow similar effects, but less clear, were also described for androgens (Page ST 2006). Importantly, also other steroid hormones, both endogenous and administered as drugs, are known to keep proper physiological activity of Treg cells (Fattorossi A 2005).

In general, the discussion about suppression in immune system should take into account effector/suppressor balance rather than suppressors only. It might be of special interest in the elderly, where the activation of immune system is prolonged and elevated. Namely, it was found in animal model that Treg cells generated throughout life regulate weak to moderate immune responses mediated by T effector cells. On the other hand, strong stimulation of T effector cells could not be stopped by endogenous Treg cells and only adoptive transfer of relatively high number of Treg cells specific to the stimulus was able to limit the response (Billiard F 2006). Are these conditions adaptable in humans? Would it be possible that we are able to control our immune responses to some level and when the input of activatory signals is too high or too long, like in the case of inflammageing and CMV, endogenous Treg cells are no longer capable of control over T effectors? Some experimental data answers in the affirmative. Some factors associated with inflammation may turn the effector/suppressor balance in favor of exaggerated effector responses. Proinflammatory cytokines, such as TNFα and IL6 were described as strong inhibitors of Treg cell function (Valencia X 2006; Wan S 2007). Bearing in mind that inflammageing is associated with extremely high production of TNFα and IL6, it is not surprising that above some threshold Treg cells in the elderly are no longer able to counteract inflammation. Moreover, recently discovered strong proinflammatory subset of CD4+ T-cells, Th17 cells, were found to have common ties with Treg cells on a very early stage of development. Th17 cells exert their actions mainly through secreted members of IL17 family cytokines, which are very strong stimulators of inflammatory responses (Veldhoen M 2006). In the extreme, as it comes from animal models, they may be involved in the development of chronic inflammation and autoimmune diseases (Romagnani S 2006). Pathways leading to transition of precursor cells to either Treg cells or Th17 cells were proved to have some common features. Like in the case of adaptive Treg cells, the generation of Th17 cells requires TGFβ (Bettelli E 2006; Veldhoen M 2006). However, the transition to Th17 cells needs also the addition of IL6. The secretion of IL6 by DC stimulated with lipopolysaccharide, in the presence of TGFβ, was necessary to generate Th17 cells. Interestingly Treg cells could be a source of TGFβ in this process and secretion of TGFβ by Treg cells in the presence of IL6 results inevitably in the generation of Th17 cells and not Treg cells. Other inflammatory stimuli, TNFα and IL1, were not necessary but strongly enhanced this process (Veldhoen M 2006). Moreover, activated Treg cells could themselves differentiate into Th17 cells in the presence of IL6 (Xu L

2007). This mechanism of regulation is of special importance in the elderly, where inflammageing phenomena may easily add inflammatory stimuli to those secreted by Treg cells and generate Th17 cells and disturb effector/suppressor balance. Ironically, accumulation of Treg cells in frail elderly would not prevent from inflammageing but rather gave more signals necessary to generate Th17 cells.

2.3 Infectious Diseases

The accumulation of Treg cells with age is an attractive explanation of commonly known susceptibility to infections and high incidence of some tumours among the elderly. However, regulation mediated by suppressive mechanisms should not be always treated as a "pure evil." Effective regulation seems to be inevitable to focus immune response on the pathogen clearance and not on unnecessary exaggerated inflammation leading to destruction of self tissues. For example, lack of IL10-dependent regulatory circuit, as shown in IL10-deficient mice, was responsible for high sensitivity to lysteriosis (Deckert M 2001), gram-negative peritonitis (Sewnath ME 2001) or chronic active *Helicobacter pylori* gastritis (Chen W 2001). TLR4-defective mice were also found to be highly susceptible to infection with *Bordetella pertussis* due to low production of IL10 (Higgins SC 2003). In all those models immune response was fulminant and led to a damage of self tissues and not to elimination of invading pathogen.

Of note, TLR-dependent activity is the example of yet another way of regulation of antipathogen responses by Treg cells. It has been only recently found that Treg cells are able to directly sense pathogens through expressed TLR receptors (TLR4, TLR5, TLR8 in humans; Caramalho I 2003). Signals received by Treg cells through at least some of those receptors (TLR2 in mice and TLR8 in humans) were found to decrease suppressive abilities of those cells at the time of acute infection which allowed for effective immune response. However, the same signals promoted proliferation of Treg cells. Thus, it is hypothesized that TLR-dependent regulation makes the activity of Treg cells low during pathogen clearance and, at the same time, promotes the generation of expanded clones of Treg cells that attenuate potentially harmful responses of residual T effectors left when the infection is gone (Peng G 2005; Sutmuller RP 2006). The delay in TLR-stimulated activity of Treg cells, as compared to other subsets regulated by TLR stimulation, comes from the fact that Treg cells need much stronger signals (more microbial products) than other immune cells to be activated via TLR receptors (Raghavan S 2005). In the light of this mechanism, repetitive infections may explain accumulation of suppressive Treg cells with age. It might be relevant in the clinic as some authors tempt to speculate that the protection from atopic diseases in adults might be linked to increased frequency of regulatory cells generated during frequent infections with some pathogens during childhood (Braun-Fahrlander C 2002; Yazdanbakhsh M 2002). It is possible that it is yet another example of "short-sightedness of evolution," when the mechanism good for young individuals might be disastrous in the elderly. At some

point, accumulation of Treg cells may become detrimental as it leads to insufficient responses to new infectious challenges, which results in chronic nature of infections in the elderly or, in the worst case, can prove fatal.

As already mentioned, Treg cells are capable of inhibition of the variety of immune cells. The suppression of effector cells, when affects somehow deteriorated T-cells in the elderly, might be a reason of too weak effector responses. Looking into the spectrum of cells suppressed by Treg cells it is not surprising that Th1 responses are the most depressed. Treg cells suppress efficiently cells with abilities to exert cytotoxic effect, such as CTL, NK and macrophages. Thus, infections that are cleared by cellular type of immunity, where cytotoxic activity is crucial, are more difficult to control in patients with increased activity of Treg cells. It is very much important in the elderly. Treg cells, mainly nTreg cells, make infections chronic by decreasing cytotoxic abilities of effectors as revealed in persistent infections caused by *Hepatitis C virus, Herpes simplex virus* and CMV (Boettler T 2005; Vahlenkamp TW 2005). Involvement of those cells was also described in some other infections known to be associated with deteriorated immunity in ageing, such as candidiasis (Netea MG 2004), tuberculosis (Chen X 2007) or pneumocystis pneumonia (McKinley L 2006).

2.4 Tumors

Increased frequency of tumors is recognized as another consequence of increased frequency of Treg cells in the elderly (Sharma S 2006). The presence of Treg cells associated with tumors might be extremely dangerous in aged individuals as a high proportion of those cells recognize self-antigens. As such, these cells mediate tolerance also to aplastic self tissue of growing tumors, which additionally hampers immune response compromised already by ageing. Accumulation of Treg cells was revealed in a wide variety of tumors of different origin (Betts GJ 2006). Some of the studies managed even to correlate increasing level of Treg cells with disease progression and patient survival (Curiel TJ 2004; Wolf D 2005). Importantly, high number of the studies reported increased number of Treg cells in cancer, predominant type of tumors in the elderly (De Pinho RA 2000). The most convincing link between Treg cells and tumor immunity comes from the studies on NK cells. NK cells are one of the most important elements of immune surveillance against tumors. It is remarkable that aged individuals characterized by low activity of NK cells are at higher risk of cancer onset when compared to those with high NK activity (Imai K 2000). It has been described that Treg cells, mainly nTreg cells, are strong inhibitors of NK cells (Trzonkowski P 2004). Utilizing membrane-bound TGFβ, Treg cells inhibit cytotoxic activity of NK cells in the site of tumor as well as in local lymph nodes and peripheral blood. Importantly, the effect appeared to be quite universal as it was found against gastrointestinal stroma tumors (GIST), melanoma, different types of cancer and, leukaemia cells in both humans and animals (Wolf AM 2003; Ghiringhelli F 2005; Smyth MJ 2006). Apart from NK cells, also CD8+ T-cells were found to be directly inhibited by Treg cells within the tumor mass (Curiel TJ 2004).

It might be also possible that tumor environment on its own is able to induce regulatory cells from naïve precursors. For example, it is widely known that many tumors secrete TGFβ necessary to transform naïve T-cells to Treg cells. Consistent with this finding, tumor-infiltrating Treg cells are mainly Tr1 and Th3 cells which suppress effector cells via secreted cytokines (Chacrabarty NG 1999; Liyanage UK 2002). Moreover, some tumor cells and tumor-infiltrating inflammatory cells secrete chemokines, such as CCL22, attracting Treg cells to the site of tumor (Curiel TJ 2004).

Some anti-tumor drugs were confirmed to have an impact on Treg cells. Small dose of cyclophosphamide was confirmed to induce selective apoptosis of Treg cells in humans and animals (Ghiringhelli F 2004; Lutsiak ME 2005). Similar effect was also described after administration of another oncological drug, fludarabine (Beyer M 2005). There are also attempts of more specific immunotherapy targeting Treg cells. For example, depletion of those cells resulted in a better immune response to tumors or when performed prior to the administration of ant-itumor vaccines, enhanced effects of anti-tumor vaccines against cancer cells in animals (Dannull J 2005; Nair S 2007). It is of special importance in the elderly as the effectiveness of anti-tumor vaccines in preclinical models was revealed to be low at this age and there are suggestions that age-associated accumulation of adaptive Treg cells might have been responsible for this effect (Gravekamp C 2007).

2.5 Autoimmunity

The role of Treg cells in the elderly is intriguing when autoimmunity is taken into account. It is surprising that there is an accumulation of Treg cells and, at the same time, the incidence of autoimmune phenomena during ageing is higher than during earlier ontogeny (Stacy S 2002). Nevertheless, there are few characteristic features of autoimmunity in aged individuals, which may explain this apparent paradox. First important feature is the hormonal introduction to senescence. Menopause, and less evident andropause, are associated with a peak of incidence of some autoimmune diseases, mainly those Th1-dependent like rheumatoid arthritis or Hashimoto's thyroiditis. As already mentioned, lack of hormonal protection starting with menopause (and to a lesser extent with andropause) might be associated with a decrease in regulatory function of Treg cells which facilitates the onset of such disorders (Arruvito L 2007). Later phases of senescence are more associated with Th2-dependent autoimmunity. Shrunk naïve compartment and cytokine balance skewed towards Th2 cytokines makes B memory cells the leading cause of autoimmune phenomena in the elderly. Of note, the control provided by Treg cells over B cells, notably over B memory cells, is very much limited. It is rather indirect suppression as Treg cells regulate mainly CD4+ T helper cells cooperating with B cells (Guay HM 2007). Moreover, as B memory cells are less dependent on signals from CD4+ T helper cells than their naïve precursors, therefore B memory cells are the least affected by Treg cells. Hence, a wide variety of autoantibodies can be found

in the elderly (Stacy S 2002). Streaking feature of these autoantibodies is that the vast majority of them is not linked to any autoimmune disease and seem to be not interfering with the health status (Xavier RM 1995; Nilsson BO 2006). It might be possible that, like during earlier life, crucial immunodominant self antigens are still protected from autoaggression in the elderly. Obviously, accumulation of Treg cells is relevant for this regulation but it is not the only event contributing to this phenomenon (Specht C 2003). Increased proportion of CD5+ B1 cells and elevated level of antiidiotypic antibodies together with low affinity and avidity of autoantibodies in aged individuals is probably more important in this regulation (Doria G 1978; Arreaza EE 1993; Zhao KS 1995).

Although high incidence of autoimmune diseases is noted in the elderly, many of these diseases have started earlier in life and their presence in aged individuals simply reflects the fact that nowadays medicine allows affected individuals reaching the age ≥ 65 years. It has to be stressed that the characteristics of late-onset autoimmune diseases, *i.e.* diseases starting mainly in the elderly, differs from those starting earlier. For example, pernicious anaemia, Sjögren syndrome, myasthenia gravis are relatively slowly progressing as compared to a dramatic course of, occurring mainly in children, diabetes mellitus type I. Taking into account that the pressure of autoimmune phenomena in the elderly is thought to be much higher than that in the young, it seems that immunoregulatory mechanisms in aged individuals might be surprisingly well-preserved. Is it due to the accumulation of Treg cells? Obviously, Treg cells are only a small piece of the puzzle.

2.6 Interventions—Vaccinations

Prophylaxis with vaccines in the elderly is one of the most important medical interventions protecting from exacerbation of symptoms of various medical conditions which very often complicate infections at this age. The most advised for the elderly are anti-influenza and pneumococcal vaccines. As a leading goal of this form of therapy is to transform naïve lymphocytes into specific memory/effector cells, immune alterations associated with immunosenescence make it more difficult than in the young. The accumulation of Treg cells should be considered as a one of such harmful alterations. Treg cells were found to limit postimmunization effector and memory cell numbers (Toka FN 2004; Belkaid Y 2005). Consequently, depletion of Treg cells in animal model resulted in improved immune responses to variety of vaccines (Moore AC 2005). It is clinically relevant in geriatrics as Treg cells accumulate the most in frail elderly, that is, patients at the highest risk of complications, if the vaccination did not protect them from infection (Trzonkowski P 2006). Both serological and cellular protection achieved after anti-influenza vaccination was found to be the lowest in such individuals (Trzonkowski P 2003). The association, at least in case of cellular response, was not a co-incidence but proved interrelation as in vitro studies revealed that the addition of Treg cells to the cultures of CTL or NK cells resulted in the suppression of responses to the vaccine antigens. Cell-to-cell interactions were revealed

as the leading mechanism of this suppression (Trzonkowski P 2004). However, in some experimental types of vaccinations, IL10 secreted by Treg cells was the master regulator of immunization efficiency (Stober CB 2005). It has to be mentioned at this point that surprisingly low efficiency of vaccines against some pathogens, mainly parasites, is highly attributed to the effect of immune evasion that involves Treg cells. Namely, parasites protects themselves utilizing host Treg cells that suppress the action of the host effector mechanisms. Such situation during immunization against parasites results in low clinical effectiveness of anti-parasite vaccines (Belkaid Y 2005). Some indirect effects might be also very much relevant to the final outcome of the vaccination. For example, Treg cells may limit production of specific antibodies via suppression of CD4+ T helper cells cooperating with B cells during antigen encounter. As a result, the titer of specific protective antibodies after vaccination is low in patients characterized by high number of Treg cells, that is, mainly frail elderly (Trzonkowski P 2003). Also the fact, that Treg cells are consumers of IL2 might additionally decrease effectiveness of the immunization as this cytokine is necessary to generate protective post-immunization immune memory (Effros RB 1983; Provinciali M 1994). Again, Treg cells make the deficit of IL2 more severe in the group of patients characterized already by the lowest levels of this cytokine, *i.e.* in frail elderly (Trzonkowski P 2003). High number of Treg cells prior to the vaccination is not the only obstacle for efficient responses. It has been shown that immunization on its own, due to the challenge with administered vaccine peptides, generates vaccine-specific Treg cells which may additionally decrease immunization efficiency (Bauer T 2007). Specificity of Treg cells seems to be a key point in obtaining good post-immunization responses. For example, low response of CTL after immunization with immunodominant peptide of *Herpes simplex virus* was attributed to antigen-specific Treg cells. Namely, Treg cells isolated from mice chronically infected with *Herpes simplex virus* were much more potent in the suppression of *anti-herpes* CTL responses than Treg cells obtained from healthy mice (Suvas S 2003). In contrary, there are experimental data from mice which proves that very potent graft-specific Treg cells that keep operational tolerance to transplanted organs in recipient animals are not the obstacle in efficient cytotoxic responses to the challenge with influenza virus antigens as these antigens are different from those expressed by the graft (Bushell A 2005).

Interestingly, in some models Treg cells were required to receive efficient postimmunization responses. For example, depletion of Treg cells was associated with poor antibody responses to the vaccination and subsequent challenge with *Borrelia burgdorferi* (Nardelli DT 2006). Another interesting mode of regulation, in which regulatory T-cells are necessary to maintain post-immunization immune memory, is provided by the hypothesis of anti-idiotypic T-cells. This theory states that after a challenge with a given peptide, CD4+ T-cells create a network of idiotypic /anti-idiotypic T-cells (to some extent it is similar to Jerne's idiotypic network of antibodies; Nayak R 2001). According to this theory, antiidiotypic T-cells were in fact antigen-specific Treg cells, which presence was necessary to maintain long-term immune memory within both B and T subsets (Nayak R 2001; Lal G 2006). Some dysfunctionalities in this complex network over years of life might have been responsible for insufficient responses to vaccines in the elderly.

2.7 Interventions—Transplantation

Modern medicine has reached the point when the barrier of age is less important and even high-level invasive medical procedures are considered to be applied in the elderly. It is the most obvious in transplantation, which significance in geriatrics increases parallel with increasing number of elderly patients that received transplanted cells or organs. It is not a long time since modern drugs harnessed the major problem in transplantation, that is, incidence of acute rejections. Yet, their action is associated with many severe adverse effects which limit their use. It is of special importance in the elderly, in whom their administration may additionally deteriorate existing medical conditions or, in some cases, it is precluded due to insufficiency of organs taking part in their metabolism. Thus, dose reduction, application of novel less toxic drugs or tolerance induction strategies are one of the primary goals of nowadays transplantation. Fortunately, immunity compromised with age can be considered as an ally in these strategies. There are number of organs which have been reported to be better tolerated in the elderly as compared to the young after transplantation. Lower incidence of acute rejections in the elderly was reported in kidney, liver, heart, lung and corneal transplantations (Renlund DG 1987; Snell GI 1993; Vail A 1997; Zetterman RK 1998; Bradley BA 2000). While the majority of these studies are based on limited number of patients, renal transplantations can be analyzed with great statistical accurateness due to the widespread of this procedure. The analysis of around 80, 000 cases from the United Network of Organ Sharing (transplant registry in the US) fully confirmed that the level of acute rejections is lower in the elderly and the dose of immunosuppressive drugs in the elderly might be reduced (Bradley BA 2001, 2002). The need for reduced immunosuppression protocols in the elderly is urgent as the majority of posttransplant deaths at this age is associated with exacerbated circulatory diseases, tumors and infections, which are clear adverse effects of overimmunosuppression (Bradley BA 2001; Dębska-Ślizień A 2007). No doubt, accumulation of Treg cells with age may contribute to the deterioration of immunity and better transplantation outcomes in the elderly. Importantly, the action and number of Treg cells is modified with the use of particular immunosuppressive drugs which might have implications in establishing of immunosuppression protocols. For example glicocorticosteroids and mTOR inhibitors have been found to increase the number and function of Treg cells (Fattorossi A 2005; Game DS 2005), while calcineurin inhibitors depressed the activity of those cells (Zeiser R 2006). Of note, mTOR inhibitors are superior above other immunosuppressants as they have less adverse effects. This feature can make mTOR inhibitors a "drug-of-choice" in the elderly (Halloran PF 2004). Also the dose of strong and toxic calcineurin inhibitors can be reduced in the elderly as it was found that aged T-cells activated with alloantigens are less resistant to these drugs than T-cells from young recipients (Bradley BA 2001b). Surprisingly, the incidence of chronic rejections, currently known as chronic allograft nephropathy (CAN), is higher in the elderly than in the young. The most widely described cause of CAN is oversecretion of TGFβ (Suthanthiran M 1997). As already mentioned, the level of this cytokine is increased in the elderly but, apart from lymphocytes, it is secreted by a variety

Table 1 Regulatory subsets in humans

Subset	Phenotype	Mechanism	Origin
Naturally occurring CD4+ T regulatory cells	CD3+CD4+CD25^{high}FoxP3+ CD127-*	Cell-to-cell contact	Thymus
Adaptive CD4+ T regulatory cells	CD3+CD4+FoxP3+	Cell-to-cell contact	Conversion from nonregulatory CD4+ T-cells at the periphery
CD4+ Tr1 cells	CD3+CD4+IL10+ROG+	via IL10	Conversion from non-regulatory (usually naïve) CD4+ T-cells at the periphery
CD4+ Th3 cells	CD3+CD4+TGFβ+	via TGFβ and sometimes IL10	Conversion from non-regulatory (usually naïve) CD4+ T-cells at the periphery
CD28-CD8+ type 1 T suppressor cells	CD3+CD28-CD8+	Cell-to-cell contact, DC-dependent	Terminally differentiated CD8+ T-cells (generated in vitro by multiple rounds of stimulation with APC)
CD28-CD8+ type 2 T suppressor cells	CD3+CD28-CD8+IL6+IFNγ+	via soluble factors, IL6 and IFNγ required	Terminally differentiated CD8+ T-cells (generated in vitro in 1-week coculture with monocytes, GM-CSF and, IL2)
CD28-CD8+ type 3 T suppressor cells	CD3+CD28-CD8+IL10+	via IL10	Conversion of naïve CD8+ T-cells by IL10-producing plasmacytoid DC
NKT cells	'Classical' NKT: CD56+ CD3+TCRαβ(Vα24i) +'Nonclassical' NKT: CD56+CD3+TCRγd(Vγ9/ Vd2)+	via IL10, IL13	Thymus
Immature dendritic cells	Lin^{neg}HLA-DR+CD80^{low} CD86^{low} CD83^{low}	Cell-to-cell contact, IL10 and tryptophan deprivation (IDO)	From myeloid and lymphoid precursors
Plasmacytoid dendritic Cells	Lin^{neg}HLA-DR+CD11c^{low}CD123^{high}	Cell-to-cell contact, IL10 and tryptophan deprivation (IDO)	From lymphoid precursors
Cytokine-modulated mature dendritic cells	Lin^{neg}HLA-DR+CD80^{high} CD86^{high}CD83^{high}	IL10, TGFβ, TNFα, GM-CSF, G-CSF, M-CSF, VIP, IL21, thymic stromal lymphopoietin	From immature DC

* Other markers suggested but also expressed on other subsets: GITR+, CTLA-4+, neuropilin1+, CD45RB-, CD103+, CD62L+, CD54+, CD122+, CD134+, CD137+

of nonimmune cells. In transplanted kidney affected by CAN, TGFβ secreted by fibroblasts is suspected to be responsible for fibrosis, medial hyperplasia and therefore vessel narrowing. It is very much possible that proinflammatory activity in the elderly may contribute to CAN as proinflammatory cytokines directly stimulate production of TGFβ and activate mononuclear cells facilitating their trafficking and infiltration of the graft (Bradley BA 2002). Not to mention, that synergistic action of TGFβ and proinflammatory cytokines results in the generation of highly inflammatory Th17 cells. However, it has to be highlighted that pathogenesis of CAN is complex and consists of plenty, also non-immune, factors.

2.8 Interventions—Perspectives

Adoptive transfer or depletion of Treg cells is recognized as a manoeuvre suppressing or improving immune response, respectively. Bearing in mind that one of the major features of immune risk phenotype is a low level of dysfunctional CD4+ T-cells, intervention affecting CD4+ T-cells might be of interest in geriatrics. In theory, depletion of Treg cells can be specifically obtained using anti-CD25 antibody, the drug commonly used during allogeneic transplantations in humans. Although initially confirmed, the depletion was subsequently denied by other reports (Kreijveld E 2007). It was reported in some oncological studies that the administration of the antibody improved anti-tumor responses but did not kill but rather blocked the activity of Treg cells (Fecci PE 2006). On the other hand, the use of other antibodies in humans, such as anti-CD3, anti-CD52, anti-lymphocyte globulin preparations, was reported to induce different subsets of Treg cells (Belghith M 2003; Ciancio G 2005; Lopez M 2006). Currently, a lot of effort has been put into attempts of ex vivo large-scale generation of Treg cells which might be subsequently used as immunosuppressive medication (Tang Q 2006). Apparently, in the light of the fact that Treg cells accumulate in aged subjects, these attempts seem to be irrelevant for the elderly. Nevertheless, aged population is a substantial consumer of various immunosuppressive drugs and therapy with Treg cells is thought to be substantially less toxic alternative to those drugs.

3 Other Regulatory Subsets

3.1 Dendritic Cells

Although CD4+ T-cells are robust in their regulatory abilities, it is not the only subset having such potential. It is not surprising that DC are also considered as they are often the first sensors of pathogen pattern. Their action directs all subsequent responses of the immune system. While mature DC trigger mainly robust effector responses, immature DC have the capability of immunosuppression in

order to protect self tissue against uncontrolled effector activity of immune system. DC might be of importance as they seem to be relatively slightly affected by age (Agrawal A 2007). Some known age-dependent alterations in DC functioning, such as low expression of MHC receptors and costimulatory molecules (Shurin MR 2007), make the phenotype of aged DC close to immature tolerogenic DC. Namely, it is widely known that immature DC, that is, DC with low expression of MHC and costimulatory molecules, are capable of induction of anergy in effector T-cells and transition of naïve T-cells to adaptive subsets of Treg cells (Steinbrink K 1997; Steinbrink K 1999; Jonuleit H 2000; Vigoroux S 2004). Immature DC are so effective in this process as they have become a laboratory tool in expansion of Treg cells for therapeutic purposes (Yamazaki S 2006). The mechanism of action of tolerogenic DC is associated with release of IL10 (by DC and adaptive Treg cells stimulated by DC) and expression of indoleamine 2,3-dioxygenase (IDO; Steinbrink K 1999; Munn DH 2002). The latter mechanism is very intriguing as increased expression of this enzyme in immune cells of aged individuals was described as predictive for mortality (Pertovaara M 2006). As lymphocytes require tryptophan for their proper functioning, its deprivation triggered by IDO is recognized as ``immunosuppression by starvation of immune system'' (Mellor AL 1999). In addition, IDO in DC metabolises tryptophan to kynurenines and these products suppress T-cells. To a great extent, anergy of T-cells in such environment is dependent on upregulation of GCN2 kinase in T-cells and induction of adaptive Treg cells (Munn DH 2002; Mellor AL 2003). The activity of the enzyme was found to be increased in late-onset autoimmune diseases and chronic infections (Mellor AL 1999; Pertovaara M 2005). Interestingly, the activity of IDO, including the isoform expressed in immune cells, is associated with serotonin deficit in depression (Cubala WJ 2006). There are assumptions that the enzyme might be an important link between chronic stress, inflammation and neurohormonal alterations in this disease (Muller N 2007). As depression is one of the most important medical conditions in the elderly and serotonin deficit is the target for a very potent group of antidepressive drugs (SSRI), the research upon IDO will for sure find its continuation in the elderly. Recently, a growing attention in the field of immune regulation has been given specifically to immature plasmacytoid DC (PDC or DC2) which were found to be extremely powerful regulators of immune responses. Utilizing IDO-related mechanisms, immature PDC significantly reduce antigen presentation, which leads to immunosuppression (Munn DH 2004). Induction of anergy of CD4+ T-cells by immature PDC occurs in direct cell-to-cell interaction between MHC and TCR receptor which prevents from upregulation of CD40L, and possibly other costimulatory molecules, on T-cells (Kuwana M 2001). Particular relevance of these cells for the clinic comes from the fact that the presence of immature PDC promotes vigorous progression of tumor growth and significantly decreases efficiency of anti-tumor vaccines (Munn DH 2004; Shurin MR 2007). While there is single study that reported no difference in the activity of PDC between young and adult mice (Dakic A 2004), there is still no convincing data on the activity of PDC in aged humans (Shurin MR 2007). It has to be mentioned that mature DC, in some specific conditions, are also capable of immunosuppression. It is mainly due to the action of various cytokines, such as

IL10, TGFβ, TNFα, GM-CSF, G-CSF, M-CSF, VIP, IL21 and, thymic stromal lymphopoietin, that modulate activity of mature DC (Rutella S 2006).

3.2 CD28− CD8+ T-Cells

CD28-CD8+ T-cells, described elsewhere in this book as a substantial burden for immunity in ageing, have some regulatory abilities when cooperate with other immune subsets. Because of that they are often described as T suppressor cells (Ts). Thus, anergy of these cells should be also evaluated in the context of regulation of particular immune responses. First of all, CD28-CD8+ Ts cells are heterogeneous with at least three subsets distinguished already (Filaci G 2002). Ts type 1 cells trigger anergy of CD4+ T effector cells through interaction with DC presenting specific antigens to these effectors (Liu Z 1998). As such, the inhibition is MHC-restricted. Anergy occurs due to the inhibition of expression of CD40 receptor on the surface of DC, which further prevents from upregulation of B7 molecules on DC. Ts type 1 cells also upregulate expression of the immunoglobulin-like transcripts ILT3 and ILT4 on DC (Chang CC 2002). The expression of these transcripts upon stimulation with Ts type 1 cells not only is responsible for anergy of CD4+ T effector cells but also for promotion of adaptive Treg cells (Suciu-Foca N 2005). Ts type 2 cells were generated from CD8+ T-cells in vitro in the presence of monocytes, exogenous IL2 and GM-CSF (Balashov KE 1995). These cells are capable of suppression of cytotoxic cells via secreted cytokines in MHC unrestricted way (Filaci G 2002). Interestingly, IL6 and IFNγ secreted by Ts type 2 cells were indispensable in this mode of suppression (Filaci G 2001). Finally, Ts type 3 cells can be generated by the stimulation of naïve CD8+ T-cells with IL10-producing PDC. Ts type 3 cells acquires then the ability to secrete IL10 on their own and suppress other naïve, but not effector, CD8+ T-cells. IL10 secretion, rather than downregulation of CD28 receptor, is the characteristic feature of Ts type 3 cells. Despite IL10-dependent mode of action, the inhibitory effects appear to be antigen-specific and limited to the antigens presented initially by PDC to Ts type 3 cells (Gilliet M 2002).

Like in the case of many other elements of immune response, generation of CD28-CD8+ T-cells might be considered profitable during particular infections as these cells control effector cells and prevent from damage of self tissues. On the other hand, frequent infections, accumulation of infectious episodes throughout life or chronic form of infections may result in continuous generation of CD28-CD8+ T-cells which skews effector/ suppression balance during aging towards suppression (Pawelec G 2005). Important way of escape from this age-dependent dysregulation, a kind of "rescue circuit of regulation," might be acquired expression of KIR receptors on CD28-CD8+ T-cells (Abedin S 2005). Unlike the level of intrinsic NKT cells, the level of NK-like T-cells expressing KIR receptors is increased in aged individuals (Tarazona R 2000; Peralbo E 2007). The expression of KIR receptors is not a constant feature of CD28-CD8+ T-cells and becomes evident at late phase of their differentiation (Arlettaz L 2004). Diversity and function

of KIR receptors implies that the expression of some of them make CD28-CD8+ T-cells tolerant towards self antigens, while the others are capable of triggering their cytotoxic response. Thus, it is probable that the expression of different sets of KIR receptors might be responsible for fine tuning of the function of CD28-CD8+ T-cells (Abedin S 2005).

3.3 NKT-Cells

Intrinsic NKT-cells are another subset with regulatory abilities. NKT-cells merge the characteristics of T-cells and NK-cells but the facts that the repertoire of their TCR is restricted (invariant Vα and limited diversity of Vβ) and they recognize very limited range of glycolipids, via CD1d on APC cells classically, place them on the border between acquired and innate immunity (Biron CA 2001; Kinjo Y 2005). Their proportion in peripheral blood is small and reaches not more than 2–3% of T-cells. In peripheral tissues they preferentially migrate to the bone marrow and liver, where they constitute 10–20% and 30–40% of T-cells, respectively (Emoto M 2003). The most classically, NKT cells are generated in the thymus and traffic mainly to the liver (Abo T 2000). The number of NKT-cells was found to be increased in aged mice but diminished in the general population of the elderly humans with exception of very old subjects. It might be important for aged immune system that the liver can serve as a site of extrathymic development of NKT-cells which results in increased number of those cells in centenarians (Watanabe H 1996; Miyaji C 2000). Regardless of number discrepancies, it is altered function of NKT-cells that influences substantially the activity of immune system (DelaRosa O 2002; Faunce DE 2005; Peralbo E 2007). On the one hand, NKT-cells were found to control autoimmune diseases, such as diabetes mellitus type I, rheumatoid arthritis, inflammatory bowel disease, systemic sclerosis (Sumida T 1995; Hong S 2001; Lee PT 2002; van Kaer L 2005) and promote tolerance to transplanted organs (Jiang X 2005, 2007), but on the other hand, they significantly improve anti-tumor responses and potentialize efficiency of vaccines (Cui J 1997). These ambiguous results might be explained by the mechanisms of their action, which suggest their regulatory activity (Kronenberg M 2005). When stimulated, they produce both Th1 and Th2 cytokines. Production of Th1 cytokines, mainly IFNγ, is responsible for augmented anti-tumor and viral responses via stimulated NK cells (Cui J 1997), while Th2 cytokines, mainly IL4 and IL10, are responsible for NKT-mediated suppression (Kronenberg M 2005). Ageing is associated with decreased secretion of IFNγ by NKT cells, which is recognized as an important reason of deficits in antiviral and antitumor responses in the elderly (Miyaji C 2000; Mocchegiani E 2004). On the other hand, the secretion of Th2 cytokines, like IL10, remains unchanged or even increases with age (Faunce DE 2005). It seems to be a powerful regulatory mechanism as the secretion of IL10 by NKT cells was found to be a major inducer of tolerance to many allotransplants (Oh K 2005; Jiang X 2007). Moreover, increased suppressive activity of NKT cells stimulate secretion of IL10 by CD4+ and CD8+ T-cells and DC (Jiang X 2007;

Wahl C 2007). NKT cells were also found to suppress CD8+ T-cells via secreted IL13 (Terabe M 2000). However, the most convincing proof of the regulatory activity of NKT cells comes from the fact of reciprocal influence of NKT cells and Treg cells. Some NKT cells were found to secrete IL2 stimulating proliferation of Treg cells (Jiang S 2005). In several models, NKT cells were found to promote oral tolerance via induction of adaptive Treg cells which secreted IL10 and TGFβ (Roelofs-Haarhuis K 2004; Kim HJ 2006). Also the shift towards Th2 cytokines produced by gut-associated NKT cells was revealed to be associated with local increase in the number of Treg cells (Ronet C 2005). In contrary, Treg cells were found to suppress activity of NKT cells in cell-to-cell manner (Azuma T 2003). It is probably relevant in the clinic as the interference of Treg cells with NKT cells was proved to promote enhancement of some tumors (Nishikawa H 2003).

B Cells

Transcription Factors in Mature B-Cells During Aging

Daniela Frasca, Richard L. Riley and Bonnie B. Blomberg

Contents

Abbreviations

AID	activation-induced cytidine deaminase
ARE	adenylate/uridylate-rich elements
BAFF	B-cell-activating factor
BCMA	B-cell maturation antigen
bHLH	basic helix loop helix
BSAP	B-cell lineage-specific activator protein
CSR	class switch recombination
EMSA	electrophoretic mobility shift assay
HEB	E-box binding protein
Ig	Immunoglobulin
MZ	marginal zone
NF-κB	nuclear factor-κB
RAG	recombination activating enzyme
RT-PCR	reverse transcription-polymerase chain reaction
SL	surrogate light (chain)
TACI	transmembrane activator and CAML interactor
TdT	deoxynucleotidyl transferase
TD	thymus-dependent
TI	thymus-independent
TTP	tristetraprolin
UTR	untranslated region

Abstract: The purpose of this chapter is to give an overview of the age-related changes in the expression and function of the major transcription factors regulating mature B-cells. We also summarize our recent work and show that the age-related defects in Ig class switch are directly related to the decrease in the transcription factor E47 which controls the expression of AID, needed for CSR. The age-associated effects on the expression and function of the transcription factors NF-κ B and Pax-5 are also described. Blimp-1 seems not to be modified by aging. For other transcription factors relevant for mature B-cell functions, such and IRF4 and Notch2, no effects of aging have been reported so far. The defects presented herein for aged B-cells should allow the discovery of mechanisms to improve humoral immune responses in both humans and mice in the near future.

1 E Proteins

Class I basic helix loop helix (bHLH) proteins, also known as E proteins, were first identified based on their ability to bind with relatively high affinity to the palindromic DNA sequence CANNTG, referred to as an E-box site (Ephrussi et al. 1985; Henthorn et al. 1990; Quong et al. 2002), found in the promoter and enhancer regions of many B lineage-specific genes, such as the enhancers in the immunoglobulin (Ig) loci and the promoters of mb-1, λ5 and RAG-1 (Quong et al. 2002). The E protein family includes E12, E47, HeLa E-box binding protein (HEB), and E2-2, in vertebrates, and the Drosophila gene product, daughterless (Massari and Murre 2000). E12 and E47, arising through differential splicing of the exon encoding for the HLH domain of the *E2A* gene (Murre et al. 1989), regulate a plethora of processes involved in B-cell commitment and differentiation. In particular, they initiate Ig rearrangements; and regulate the expression of the surrogate light (SL) chain, the recombination activating enzymes RAG-1 and RAG-2, the enzyme terminal deoxynucleotidyl transferase (TdT), the IL-7Rα chain, which together with the common γ chain (γc) comprises the high affinity IL-7 receptor (IL-7R), and the genes encoding the signal transduction molecules Igα (mb-1) and Igβ (B29; Schlissel et al. 1991; Sigvardsson et al. 1997; Massari and Murre 2000; Kee et al. 2002). E2A also induces the expression of EBF, which acts in synergy with E2A to promote SL chain transcription.

In B lymphocytes, the active DNA-binding complex consists of E47 homodimer, as opposed to E12/E12 or E12/E47 complexes, whereas in the bone marrow pro-B/early pre-B cells the predominant form is E12/E47 (Frasca et al. 2003). The formation and the function of the homodimer or heterodimer depend on the balance between the *E2A*-encoded proteins, other class I bHLH proteins (HEB and E2-2) and the E protein inhibitory proteins, Id 1-4, which lack the DNA-binding domain and function as dominant negative inhibitors of E proteins (Rivera and Murre 2001). The paradigm of HLH function is that an ubiquitously expressed class I bHLH protein dimerizes with a tissue-specific class II factor, such as MyoD (skeletal muscle) or NeuroD (neurons), to regulate cell-specific gene transcription. E2A-deficient

mice display a complete block in B lineage development at a very early stage prior to the onset of IgH DJ rearrangement, whereas myeloid development is normal. Transgenic introduction of either E47 or E12 restores B lymphopoiesis in E2A-deficient mice, although E47 promotes pre-B cell differentiation more effectively, likely because it has a higher DNA-binding affinity than does E12 (Shen and Kadesch 1995). Mice expressing a transgene for Id proteins, the inhibitors of E protein activity, have a phenotype similar to the $E2A^{-/-}$ mice (Quong et al. 2002). These mice display the same block in B-cell development, and its severity is dependent on the level of expression of the transgene.

E2A activity is necessary for class switch recombination (CSR; Quong et al. 1999; Sugai et al. 2003), as the E47 transcription factor has been shown to be important in transcriptional regulation of *Aicda*, the gene encoding the activation-induced cytidine deaminase (AID; Sayegh et al. 2003), the enzyme responsible for breaking the DNA in the switch regions, the first step in the CSR process. Briefly, it has been shown that ectopic expression of Id3 in splenic activated B-cells inhibits CSR (Quong et al. 1999) because of reduced AID transcription and overexpression of E47 can directly induce *Aicda* gene expression both in a B-cell line and in splenic B-cells activated in vitro (Sayegh et al. 2003). A cis-regulatory element (E-box) in the *Aicda* locus has been identified and shown to be activated by E-proteins. Ectopic expression of AID in splenic activated B-cells retrovirally transduced with Id3 only partially rescues the ability of these cells to undergo CSR. The Authors concluded that the efficient induction of *Aicda* expression is dependent on E-proteins, but also suggest that E-proteins have roles in CSR in addition to their induction of *Aicda* expression. However, the level of restoration of AID was not complete in these experiments and therefore an alternative interpretation of these results would be that optimal E47, which would induce optimal AID, would itself completely restore CSR. Our data showing no decrease in germline μ transcripts in old or in $E2A^{+/-}$ B-cells support this hypothesis (Frasca et al. 2004a).

In senescent mice, we have previously shown that in vitro stimulated splenic B-cells are deficient in production of multiple class switch isotypes (IgG1, G2a, G3, and E), and CSR (Frasca et al. 2004a, b). This occurs concomitant with decreased induction of E47 and AID. The reduced CSR observed in old splenic activated B-cells is not the consequence of defective B-cell proliferation, as B-cells from old mice can be effectively activated in vitro, but their capacity to undergo CSR is impaired. Our results are in line with the findings that expression of the receptors for CD40, and IL-4 are unaffected by aging in mice and humans, as already reported (Whisler et al. 1991; Song et al. 1997; Zheng et al. 1997; Bergler et al. 1999). Although it is known that there are defects in T as well as B-cells during aging, our studies indicate that an intrinsic B-cell defect may not be able to be rescued by modifying/enhancing T-cell activity alone by itself in aged individuals. Both DNA-binding (EMSA) and expression (Western blot) of E47 are decreased in stimulated splenic B-cells from old mice. We have previously shown (Frasca et al. 2003) that the endogenous E47 DNA-binding is low, and importantly, twofold lower than that in unstimulated young spleen cells in the majority of aged mice individually tested (65%). Activation of B-cells up-regulates E47 DNA binding in

young and to a significantly lower extent in old mice. Therefore, both basal and activated levels of E47 are decreased in splenic B-cells in aged mice. These findings suggest that the down-regulation of this transcriptional regulator may help explain not only decreased CSR in activated splenic B-cells from old mice, but also age-related changes in affinity maturation and SHM affecting the quality of the Ab response. Other results from our laboratory showing that CSR is perturbed in $E2A^{+/-}$ mice further support the important role of this transcription factor in the generation of Abs with different isotypes (Frasca et al. 2004a).

In order to determine a mechanism for the age-related decrease in the amounts of E47 protein in nuclear extracts, we found that E47 mRNA levels were decreased in stimulated splenic B-cells from old as compared with young mice. RNA stability assays showed that the rate of E47 mRNA decay was accelerated in stimulated splenic B-cells from old mice, but E47 protein degradation rates were comparable in young versus aged B-cells, indicating that the regulation of E47 expression in activated splenic B-cells occurs primarily by mRNA stability (Frasca et al. 2005b, 2007b). In contrast with splenic activated B-cells, E47 mRNA expression is comparable in bone marrow-derived IL-7-expanded pro-B/early pre-B cells from young and old mice (Van der Put et al. 2004). Thus, the reduced expression and DNA-binding of the E12/E47 transcription factor in aged B-cell precursors is not transcriptionally regulated, but is due to reduced protein stability (Van der Put et al. 2004; King et al. 2007) mediated presumably via the ubiquitin–proteasome pathway (Kho et al. 1997; Huggins et al. 1999). This instability is largely due to PEST (proline, glutamic acid, serine, threonine) residues common to degradation domains (Huang et al. 1998).

The stability of labile mRNA may be controlled by signal transduction cascades, where the final product of the cascade phosphorylates a protein which interacts with adenylate/uridylate-rich elements (ARE) in the 3′ untranslated region (UTR) of mRNA and modifies its stability (Chen et al. 1995; Bevilacqua et al. 2003). ARE sequences have been found in the 3′-untranslated region (UTR) of many mRNAs, including those for transcription factors. ARE motifs have been previously classified into at least three categories based in part upon the distribution of AUUUA pentamers. Class I AREs, found in early response gene mRNAs like c-fos and c-myc, contain multiple isolated AUUUA motifs; class II AREs, found exclusively in cytokine mRNAs, contain two or more overlapping copies of the AUUUA motif; class III AREs contain no AUUUA motifs but generally contain U-rich or AU-rich regions and possibly other unknown features for their destabilizing function. The E47 mRNA is a class I/III mRNA, because it has one AUUUA sequence and multiple AU/U-rich regions. At least part of the decreased stability of E47 mRNA seen in aged B-cells is mediated by proteins. We have found that tristetraprolin (TTP), a physiological regulator of mRNA expression and stability, is involved in the degradation of the E47 mRNA. Because many studies have shown TTP expression and function in macrophages, monocytes, mast cells and T-cells, but little is known about the expression and function of TTP in primary B-cells, we have investigated TTP mRNA and protein expression in splenic B-cells from young and old mice. Our recently published results (Frasca et al. 2007b) show that TTP mRNA and protein levels are higher in stimulated splenic B-cells

from old as compared with young mice. TTP has been described to be directly phosphorylated by p38 MAPK in macrophages (Carballo et al. 2001; Chrestensen et al. 2004; Cao et al. 2006). We show that inhibition of the p38 MAPK signaling pathway significantly reduces TTP protein expression in B-cells. Old B-cells in response to LPS make less phospho-p38 MAPK (Frasca et al. 2007b) and therefore, as would be expected, make less phospho-TTP. This leads to an increase in the amount of TTP bound to the 3′-UTRs, and therefore decrease mRNA stability (of E47) in old B-cells. Our studies demonstrate for the first time that TTP is regulated in activated B-cells during aging, that TTP is involved in the degradation of the E47 mRNA, and show the molecular mechanism for the decreased expression of E47, AID and CSR in aged B-cells.

2 NF-κB

The transcription factor, nuclear factor-κ B (NF-κB), has also been shown to be important for Ig class switch (Snapper et al. 1996). NF-κB has been shown to be strongly activated by anti-CD40/IL-4, but not by anti-CD40 or IL-4 stimulation alone in splenic B-cells and to be involved in CSR to IgG1/IgE in both humans (Jeppson et al. 1998) and mice (Tinnell et al. 1998; Pioli et al. 1999; Kaku et al. 2002). It has also been shown to be the key transcription factor in mouse or human B-cells undergoing CSR in response to BAFF, the B-cell-activating factor, also called BLyS, TALL-1, THANK, ZTNF4 or TNF13B (Litinskiy et al. 2002; Castigli et al. 2005; Yamada et al. 2005).

We have recently investigated the ability of BAFF/IL-4, as compared to anti-CD40/IL-4, to induce CSR to γ_1 in splenic B-cells from young and old mice (Frasca et al. 2007a). We found that anti-CD40/IL-4 is a better CSR stimulus than BAFF/IL-4 in young B-cells, as measured by RT-PCR of postswitch transcripts and flow cytometry. CSR is reduced in old B-cells with both stimuli, but the suboptimal CSR seen in young mice to BAFF/IL-4 shows less reduction in the old B-cells. AID and γ_1PSTs are significantly reduced in old B-cells stimulated with anti-CD40/IL-4, and less reduced with BAFF/IL-4 stimulus. BAFF receptor mRNA expression (BAFF-R, TACI, and BCMA) is not affected by aging. The age-related decrease in CSR induced by anti-CD40/IL-4 is primarily associated with a decrease in E47, whereas the less affected response to BAFF/IL-4 is associated with decreases in both E47 and NF-κB. Therefore, NF-κB is not involved in the decreased response of old B-cells to anti-CD40/IL-4. These differences in B-cell responses to CD40/IL-4 and BAFF/IL-4 may help to explain at least a partial maintenance of TI (more BAFF/IL-4-dependent) versus TD responses in senescent mice (Smith 1976; Weksler et al. 1978).

The mechanisms by which NF-κB controls CSR are known only in part. Recent results show that signals delivered via CD40 that activate NF-κB synergize with signals delivered via the IL-4 receptor that activate Stat-6 to induce optimal AID gene expression (Dedeoglu et al. 2004). The importance of Stat-6 and NF-κB in induction of AID expression by IL-4 and CD40 was demonstrated in studies of Stat-6$^{-/-}$ and p50$^{-/-}$ mice. However, in this study (Dedeoglu et al. 2004) the ability of

CD40 ligation to induce AID expression and to synergize with IL-4 in AID induction in B-cells was only partially impaired in $p50^{-/-}$ mice, suggesting that NF-κB is only one of the transcription factors involved in inducing AID expression and CSR in B-cells. Our studies show that the defect in aging seen in CSR is due primarily to E47 and not to NF-κB (Frasca et al. 2007a).

3 Pax-5 (BSAP)

Pax-5, also called B-cell lineage-specific activator protein (BSAP), is critical for B-cell lineage commitment, B-cell development and CSR in GC B-cells, but it is not expressed in terminally differentiated B-cells (Max et al. 1995; Nutt et al. 1998, 1999; Linn et al. 2002; Gonda et al. 2003). B-cell-specific target genes for Pax-5 are λ5, CD19, mb-1, blk, RAG-2, J-chain, and IgH genes (Kozmick et al. 1992; Neurath et al. 1994; Zwollo et al. 1994; Michaelson et al. 1996; Lauring and Schlissel 1999). Binding sites for Pax-5 have been identified in the promoters of multiple genes as well as at multiple sites within the IgH locus (Neurath et al. 1994; Michaelson et al. 1996). Pax-5-dependent repression of X box binding protein-1 (XBP-1) is probably critical for inhibiting plasmacytic differentiation in the GC (Shaffer 2002). It has recently been demonstrated that a putative regulatory region in the *Aicda* gene contains both E2A- and Pax-5-binding sites, and the latter site is indispensable for AID gene expression (Gonda et al. 2003). Id proteins have been shown to interact with Pax-5, and inhibit its DNA-binding (Roberts et al. 2001; Gonda et al. 2003). E2A proteins have been described to regulate Pax-5 not directly but through its regulation of EBF (Kee and Murre 1998). Consistent with these observations is the finding that the Pax-5 promoter contains functional EBF binding sites (O'Riordan and Grosschedl 1999).

Pax-5 DNA-binding activity (for the active Pax-5a isoform) has been shown to be strongly reduced in resting splenic B-cells from aged mice, whereas protein levels did not change significantly (Anspach et al. 2001). Decreased Pax-5 binding activity is not the result of decreased levels of Pax-5 RNA transcripts or overall protein levels, as shown by RNase protection and Western blot analyses, suggesting a posttranslational mechanism affecting Pax-5 activity in aged B-cells, possibly involving its oxidation status (the oxidative form does not bind to DNA; Tell et al. 1998). Unlike E2A, Pax-5 is regulated posttranscriptionally in splenic B-cells. Preliminary results from our laboratory have shown that in splenic activated B-cells Pax-5 may also be regulated by mRNA stability (Landin, Frasca and Blomberg, work in progress).

4 Blimp-1

Blimp-1, encoded by the *prdm1* gene (Lin et al. 2003), is a transcriptional repressor which represses proliferation and induces maturation of B-cells into antibody-secreting plasma cells. It blocks the alternative GC B-cell fate by inhibiting Bcl-6,

Pax-5, BCR signaling, E2A, EBF, CSR, activation and homing to follicles (Lin et al. 2002; Shaffer et al. 2002; Johnson and Calame 2003, Calame et al. 2003). Blimp-1 has been detected in plasma cells, but not in early bone marrow B-cells, splenic memory B-cells in spleen, and GC B-cells (Tunyaplin et al. 2004).

As demonstrated by Han et al. (2003), there is a substantially higher number of antibody-secreting cells in the spleens of old mice than in the spleens of young mice. Therefore, we measured Blimp-1 mRNA expression in cultures of splenic B-cells from young and old mice activated for different times with LPS. We also determined the percentages of plasma cells ($CD138^{+}B220^{low}$) in cultures of LPS-stimulated B-cells from young and old mice. The expression of mRNA for Blimp-1 is induced by LPS and suppressed by IL-4 (Knodel et al. 2001). Our results (Frasca et al. 2004b) showed that Blimp-1 mRNA was undetectable in unstimulated B-cells, increased at days 2 and 3, reached the optimum levels at day 4 and then decreased at day 7 in both young and old mice. Blimp-1 mRNA expression was comparable in young and old splenic B-cells. These results again point to the main defect in aged stimulated B-cells being at the level of CSR, and not due to differentiation to antibody-secreting (plasma) cells.

5 IRF4

IRF4, also called Pip, LSIRF, ICSAT or MUM1 (Iida et al. 1997) is a member of the interferon-regulatory factor family of transcription factors characterized by a specific DNA-binding domain and by the ability to bind to regulatory elements in promoters of interferon-inducible genes. In the B lineage, IRF4 is expressed in immature B-cells in the bone marrow, is absent from proliferating centroblasts and then is re-expressed in plasma cells (Lu et al. 2003; Klein et al. 2006). IRF4, together with Blimp-1, is required for the generation of plasma cells, both transcription factors acting upstream of the transcription factor XBP-1 (Klein et al. 2006). No aging effects have been reported so far for IRF4.

6 Notch2

The Notch family of receptors plays an important role in the development of hematopoietic cells (Maillard et al. 2005). Notch1 regulates T-cell development, whereas Notch2 is preferentially expressed in mature B-cells (Saito et al. 2003). Conditionally targeted deletion of Notch2 results in a defect in marginal zone (MZ) B-cells and their precursors (Kuroda et al. 2003). Among Notch target genes, the expression level of Deltex1 is prominent in MZ cells and strictly dependent on that of Notch2, suggesting that Deltex1 may play a role in MZ cell differentiation. No aging effects have been reported so far for Notch2.

7 Conclusions

In conclusion, particular transcription factors have been shown to be decreased with age in activated murine B-cells, *e.g.* E47, or in resting B-cells, *e.g.* Pax-5. The stage of differentiation as well as activation of the cell types studied appears to be important as our data on E2A in murine bone marrow versus the spleen has shown decreases with age but using different molecular mechanisms (Frasca et al. 2005a; Riley 2005). Further studies should help to better determine the molecular mechanisms for these suboptimal expression of transcription factors, their molecular consequences, and provide avenues for correction of the immune deficiencies created by them.

B-Cell Repertoire Changes in Mouse Models of Aging

Jean L. Scholz, William J. Quinn III and Michael P. Cancro

Contents

Abstract: Changes in the antibody repertoire are a well-established feature of immunosenescence. These reflect an aggregate of age-associated alterations in the generation, numbers, and proportions of B-cell subsets; as well as the homeostatic and selective processes governing them. A basic understanding of these relationships, coupled with integrated assessments of how they change with age, should reveal mechanisms underlying the immunosenescent phenotype. Mouse models provide powerful tools for these analyses, allowing controlled manipulation of key genetic, cellular, and microenvironmental factors. Here we summarize current understanding of how primary and antigen-experienced murine B-cell repertoires are established, as well as how they shift with age.

DOI 10.1007/ 978-1-4020-9062-2_20,

1 Introduction

Immunosenescence, the progressive dysregulation of immune function with age, reflects a mosaic of genetic, epigenetic, and microenvironmental changes [10, 11, 34, 42, 44, 77, 101, 102, 125–127, 158]. This complexity confounds minimal explanations of the overall phenomenon, and underscores the need to exploit systems whereby defined factors can be deliberately manipulated. Accordingly, mouse model systems, which have been refined as immunologic experimental tools, should yield insights into the underlying mechanistic relationships.

Altered clonotype repertoires are a consistent feature of immunosenescence. This is anecdotally evident from the shifts in immune responsiveness, increased autoimmunity, and clonal expansions that accompany age; and is corroborated through empirical evidence in human and animal models. For example, both the frequency and clonotypic composition of hapten- and virus-specific primary B-cells change with age [76, 112–114, 136, 182, 184, 185]; and nearly all laboratory mouse strains display an age-associated appearance of autoantibodies [29, 30]. Most observations addressing these age-associated repertoire shifts are based on assessments at single time points. While these can *identify* repertoire changes, the underlying mechanisms resist interrogation via such static sampling approaches, because lymphocytes comprise multiple, dynamic populations under stringent selective and homeostatic controls.

Lymphocyte dynamics involve the continuous generation and corresponding loss of cells, such that relatively constant numbers are maintained. Thus, the stability of lymphocyte numbers disguises underlying and ongoing cellular and molecular processes. For example, commitment rates to the B lineage per se, as well as the entrance rates and lifespan of B-cells in different functional subsets, can vary. Further, these compartments not only play differing immunological roles, but also can interact with and impact one another's behavior. Finally, selective events based on B-cell receptor (BCR) specificity, innate ligand responsiveness, and homeostatic factors are superimposed on this dynamically changing landscape. Accordingly, effective interrogation of repertoire changes—including those associated with advancing age—requires simultaneous, longitudinal assessments of lymphocyte generation, homeostasis, and selection.

Indeed, the size, proportions, and dynamics of nearly all progenitor and mature B lineage subsets shift with age in the mouse, so overall changes in clonotype frequency and composition likely reflect the aggregate of these shifts. Understanding age-associated repertoire changes therefore requires an appreciation of the molecular and cellular mechanisms governing primary and antigen-experienced repertoires. Herein we review currently accepted notions about the identity and relationships of B lineage subsets and their progenitors, emphasizing the selective and homeostatic processes impacting repertoire composition. With this as background, age-associated changes in these parameters and their potential relationship to repertoire shifts in primary and antigen-experienced B-cell subsets are discussed. A schematic summary of these overall changes is provided in Fig. 1.

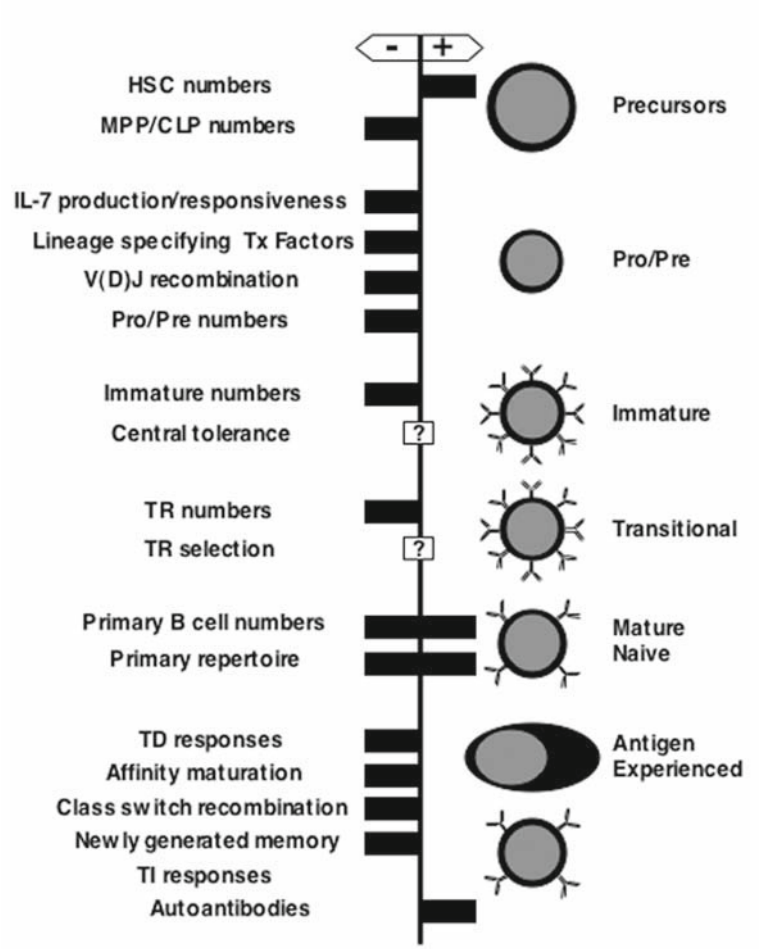

Fig. 1 Changes in B-cell traits with age. Major B-cell subsets are shown at right with characteristic traits and/or processes at left. Bars indicate changes in aged mice compared to young adults. Bars left-of-center denote age-associated reductions, while bars right-of-center indicate age-associated increases, of a characteristic. Disparate or mixed results are indicated as bi-directional bars, and currently unexplored issues are signified by a central question mark.

2 Primary Repertoire Development

2.1 Lineage Commitment and Developing Bone Marrow B-Cell Subsets

In adults, B-cells are generated in the bone marrow (BM), where pluripotent hematopoietic stem cells (HSCs) give rise to multipotent progenitor (MPPs) that initiate lymphoid-restricted gene expression. This yields common lymphoid pro-

genitors (CLPs) [65], a population enriched for B lineage specified precursors that subsequently become committed to the B lineage [2]. Several transcription factors and cytokine receptors comprise a regulatory network for B lineage specification and commitment [16, 66, 90, 106, 117, 151] (also see Frasca et al., this volume). For example, Ikaros is expressed in all hematopoietic lineages and controls the emergence of lymphoid progenitors [68, 111]; the proto-oncogene PU.1 is critical for both myeloid and lymphoid differentiation [149]; and the transcriptional repressor Bcl11A is essential for normal B- and T-cell development [72]. The E protein family members E2A and EBF coordinately activate the expression of B-cell specific genes, especially those governing pre-BCR production and function [64, 66, 119, 150] and also regulate Pax-5 [140], a key mediator that activates B lineage-specific genes and represses genes associated with other lineages [16, 17]. IL-7/IL-7R is a key cytokine axis for early B lineage development, promoting both survival and differentiation [2]. Complex interplay between cell intrinsic and extrinsic signals characterizes the regulation of these transcriptional systems [26, 90, 150].

Although these transcriptional and signaling events occur prior to antigen receptor gene rearrangement, they can nonetheless influence repertoire composition in several ways. First, they dictate the rate of lineage commitment, thus impacting B-cell production rates and shifting downstream homeostatic demands. Second, they influence the rate and specificity of key intracellular events, thus coloring the likelihood and nature of heavy and light chain gene rearrangements.

Subsequent to lineage commitment, B-cell differentiative stages are characterized according to surface markers and Ig gene rearrangement status [46–48, 94, 121, 122, 138]. In the pro-B stage, cells rearrange their Ig heavy chain genes [40, 180]. This is followed by surface Ig heavy chain expression with surrogate light chain and BCR signaling molecules, delineating onset of the pre-B-cell stage. Surface pre-BCR expression and signaling are required for transit from the pro- to pre-B-cell stage [61, 92, 93, 123, 133, 134, 164, 165], and result in a proliferative burst characteristic of the large pre-B-cell compartment. Light chain gene rearrangement during the late pre-B-cell stage leads to the expression of a complete BCR, defining the immature (IMM) BM B-cell. Once in the IMM subset, cells either die or exit the BM to complete maturation [6, 7].

2.2 Peripheral Maturation and Primary B-Cell Subsets

Recent marrow émigrés have been dubbed transitional (TR) B-cells [73], and can be further divided into subsets termed T1, T2, and T3 [1]. While historically viewed as a linear progression from the IMM marrow stage through the successive TR compartments, it now appears that branched, asynchronous models for transit into and through these subsets are more likely [5, 91, 145, 153]. Cells that successfully complete TR differentiation enter the mature peripheral B-cell pools.

Mature follicular (FO) B-cells, also termed B2 or “conventional” B-cells, encompass the majority (>80%) of peripheral B-lymphocytes, and are the progeni-

tors of both primary antibody forming cells and memory B-cells. Additional subsets of mature B-cells include marginal zone (MZ) B-cells, which are phenotypically, functionally, and anatomically distinct from FO B-cells and play a major role in responses to T-cell independent (TI) antigens. In peritoneal and pleural cavities the B1 subset predominates (reviewed in [52]). B1 B-cells appear first in ontogeny and are maintained by self-renewal [48, 49, 53]. The MZ and B1 subsets share several functional attributes, particularly participation in TI immune responses [63, 74, 75, 83]. The derivation of B1 B-cells, though distinct from the other B-cell subsets, is not yet entirely clear [1, 14, 52, 54, 74, 104, 176]. However, in the context of age-associated repertoire shifts, it is noteworthy that while production from BM B2 progenitors predominates in young adults, this wanes in aged mice. Therefore, if B1 progenitors are stable and distinct from B2 progenitors, the B1 lineage may wax with advancing age; thus altering the combined B-cell repertoire [104, 105].

2.3 Selection and Homeostasis Among Emerging and Primary B-Cells

Although they occur before complete BCR expression and perforce cannot be specificity-driven, heavy and light chain gene rearrangement processes, as well as heavy chain selection at the pre-BCR stage, will influence the incipient B-cell repertoire. For example, only heavy chains with structural characteristics affording surrogate light chain pairing are selected for further differentiation [81, 95]. In addition, heavy and light chain gene rearrangement processes rely on multiple factors, including the expression of appropriate enzyme and targeting complexes, accessibility and marking of heavy and light chain loci, and the activity of DNA damage resistance and repair systems (for reviews see [32, 59, 62, 107, 108, 139, 142–144]).

The interaction of homeostasis and selection powerfully impacts all B-cell subsets downstream of BCR expression, directly determining repertoire composition. A critical notion emerging from appreciation of this interplay is that events acting upstream of mature B-lymphocyte pools can impact downstream populations. Since advancing age is accompanied by substantial shifts in both B-cell generation and the success rate of IMM and TR differentiation, distinguishing primary lesions from homeostatic compensation is critical to a mechanistic understanding of age-related changes [19, 99, 131].

Stringent specificity-based selection occurs at the IMM stage, where high avidity interactions yield secondary Ig gene rearrangements or death [21, 22, 41, 109, 110, 115, 116, 128–130, 162]. These central tolerance mechanisms result in the loss of ~90% of all IMM cells formed [7, 120]. While it is possible that the IMM pool is governed by homeostatic mechanisms to preserve its size, this remains speculative and does not seem tied to BCR-mediated negative selection. Instead, BCR signal strength is the major, if not sole, determinant of survival at the IMM stage.

Specificity-based selection continues to act on newly formed cells that exit the marrow to join TR pools. Whereas high avidity BCR interactions lead to cell death, a lack of minimal BCR signaling precludes maturation and entrance to mature

peripheral pools [20, 23, 33, 51, 82, 169]. While BM negative selection depends on BCR signal strength (and is therefore cell-intrinsic), the likelihood that a given cell completes TR differentiation to join a mature B-cell subset is based on both BCR signal strength and the availability of B-lymphocyte stimulator (BLyS, also termed BAFF). BLyS is the limiting resource for which TR, FO, and MZ B-cells compete (reviewed in [18] and [100]). Through this competitive mechanism, steady state numbers of mature B-cells are governed by ambient BLyS levels that vary the proportion of TR cells completing maturation, as well as the lifespan of FO and MZ B-cells [50, 57]. This connection between BCR specificity and fitness for interclonal competition indicates that BLyS availability, within the context of the emerging clonotypic cohort, will determine thresholds for TR selection. This relationship has recently been confirmed in several transgenic systems [56, 70, 161].

The relationship between BLyS availability, antigen receptor specificity, and TR selective stringency makes several implications relevant to age-associated changes in the primary repertoire. First it implies that BCR- and BLyS-mediated signals must be integrated, possibly via cross-talk between intracellular signaling systems [154]. Although the molecular details remain the subject of intense research, age associated perturbations of any of these systems may influence primary repertoire diversity. Moreover, decreased B-cell generation rates in BM—a feature of the aging immune system—might permit a broader array of clonotypes, including autoreactive cells, to enter peripheral pools as competition wanes [100].

3 Antigen-Experienced Pools

3.1 Establishing and Maintaining Antigen-Experienced Subsets

Antigen-experienced subsets contain the descendants of primary B-cells recruited into immune responses, and thus include activated cells themselves, as well as the resulting effector and memory pools. Humoral immune responses are generally characterized as T-dependent (TD) or T-independent (TI), depending on their requirement for cognate T help. In general, protein antigens engender TD responses, reflecting the requisite for MHC class II restricted presentation that affords delivery of costimulation. These responses primarily involve FO B-cells, and typically lead to long-term humoral immunity. A key characteristic of TD responses is the formation of germinal centers (GCs), where proliferating B-cells undergo class switch recombination, as well as the somatic hypermutation (SHM) and affinity-based selection processes that culminate in cells producing high-affinity antibody [86]. In contrast, TI responses do not require cognate help, although T-cell derived cytokines may promote limited isotype switching [15]. TI responses elicit little if any memory, lack substantial hypermutation or affinity maturation, and consist predominantly of IgM. Two classes of TI antigens exist: TI-1 responses are induced via pattern recognition receptors [148]; whereas TI-2 responses are generated by antigens with densely repeating epitopes. Both TI-1 and TI-2 responses preferentially arise from

B1 and MZ B-cells. Whether this reflects intrinsic bias in the pre-immune repertoires of these cells or more extensive expression of pattern recognition receptors [58, 84]—both of which are empirically observed—remains debated.

Antigen activation yields a series of short-lived cells, which are detectable for only days or weeks following antigen challenge; as well as several subsets of long-lived cells, which persist for months or years [80, 141, 163]. During TD responses, antigen activated B-cells become either GC B-cells, or short-lived plasma cells (PC), in a differentiation decision dictated by BCR affinity [124]. Short-lived PC arise in the first few days of an immune response, congregating at the T/B-cell interface and extrafollicular regions of secondary lymphoid organs [86]. The critical relationship between BCR repertoire and recruitment into long-lived pools has been revealed using transgenic systems [24, 25]. For example, B-cells with low initial affinity for antigen can participate in GC reactions when higher affinity competition is eliminated, suggesting that initial repertoire can shape the pool of antigen-reactive B-cells that ultimately succeed and contribute to immune responses. Long-lived antigen-experienced populations include a group of long-lived PC, as well as a separate group termed memory B-cells [79, 87]. The delineation of these groups based on surface markers is debated; however, a clear functional difference is that long-lived PC secrete antibody, while memory cells do not [9, 28, 78, 85, 87–89]. The lineal relationships between various antigen-experienced subsets are unclear. For example, whether long-lived populations are generated from cells within the generally short-lived populations, or instead differentiate from distinct progenitors through a separate selective mechanism, is debated.

3.2 Homeostasis in Antigen Experienced Subsets

The concept of a biological niche for naïve B-cells is well established, with the BLyS/BR3 ligand/receptor axis playing a central role. In contrast, knowledge of factors governing the size and composition of antigen-experienced B-cell subsets is more limited. As with naïve pools, interplay between homeostasis and selection seems likely in the establishment and maintenance of antigen-experienced subsets. Multiple steps in the generation of effector and memory B-cells rely on selective decisions. These include the relationship between BCR affinity and recruitment into the extrafollicular PC pool versus the GC [124]; affinity maturation per se; as well as commitment to long-lived PC versus memory B-cells [8, 31].

Homeostatic controls, while evident in antigen-experienced pools, also remain poorly understood. While neither short-term effectors or long lived antigen experienced populations compete with primary B-cells for survival, the trophic factors and relationships are only now being explored. Recent evidence suggests that additional BLyS family receptors or ligands, such as TACI, BCMA and APRIL likely play a role. In support of this idea, TACI is associated with activated B-cells and regulates some TI immune responses [163, 168], whereas BCMA is required for survival of long-lived PC in BM [118]. Further, ongoing immune responses appear to create

temporary homeostatic niches for short-lived populations, while leading to little change in long-term protective memory pools [132]. Finally, long-lived BM PC survival is competitive [78–80], possibly involving cell extrinsic stromal factors, as well as Fc-gammaRIIb expression [177].

4 Age-Associated Changes in Progenitor and Primary Pools

An extensive literature suggests the primary repertoire shifts with age. For example, the phosphorylcholine-specific repertoire shifts from one predominated by the T15 clonotype to a more diverse pool [113, 114, 136, 185]. On the other hand, overall diversity in the primary pool is not altered extensively, as assessed by fine specificity analyses [113, 183]. Nonetheless, clonal expansions in both the B and T-cell pools suggest that some specificities can be inordinately expanded. Understanding the basis for these changes requires considering all events likely to impact repertoire generation, selection, and maintenance. These include changes in the size and behavior of generative pools, as well as changes in the primary pools themselves.

4.1 B-Cell Generative Rates and Subsets Change with Age

Age-associated changes in B lineage development include reductions in precursor frequencies, lowered expression of critical regulatory genes, diminished pro- and pre B-cell numbers, and damped responsiveness to differentiation cues [35, 39, 60, 69, 97, 136, 146, 156, 157, 166]. Together, these observations indicate overall diminution of B-cell generation and throughput.

The impact of aging is first manifested in HSCs and CLPs. Somewhat paradoxically, while HSC numbers are maintained and possibly expanded in aged mice [179], the MPP/ELP and CLP pools are reduced [3, 97, 98]. Although the basis for this remains unclear, correlations with age-associated reductions in stromal IL-7 production [156]; as well as reduced expression of E2A and EBF and genes they control, suggest these may contribute [35, 39, 147, 166, 167]. As might be expected from these changes in upstream pools, pro-B-cell numbers are reduced, with an even greater proportional reduction in pre-B-cell numbers [4, 131, 135]. This decline in part reflects reduced IL-7-mediated proliferation at the pro- to pre-B transition [103, 155]. Hormonal changes may be another important extrinsic factor, since pregnancies delay the age-associated reduction in BM B-cell production [12].

The dynamics of developing B-cells also change with age. In vivo BrdU labeling studies [60, 67, 69] showed reductions in successful pro- to pre B-cell transit, yielding a fourfold drop in pre-B-cell numbers, and a corresponding decrease in the IMM B-cell generation rate. However, the throughput of pre-B-cells increased, so a twofold greater proportion of pre-B-cells enter the IMM pool. In addition, residency

within the IMM pool is longer. Together, these apparent compensatory features result in an IMM pool that is only about twofold smaller than in young adults.

4.2 Dynamics and Proportions of Peripheral Subsets Change with Age

Reflecting the upstream reductions in IMM B-cell numbers, TR pools are reduced in throughput and size; however, because residency time is extended, TR cell numbers are not significantly reduced. Similarly, the FO pool's turnover rate is reduced in aged mice [60, 67, 131], so FO pool size is maintained in the face of reduced marrow production. Despite this fairly stable overall size, B-cell clonal expansions are more prevalent in aged mice [13, 171, 172]. In contrast, the MZ and B1 pools are unaffected or even enlarged in aged mice, but this may vary by strain [4, 131, 171].

Whether the homeostatic mechanisms controlling primary B-cell numbers change with age has not been extensively interrogated. However, several recent observations suggest this is likely. For example, in young adults, emerging cells expressing high levels of the BLyS receptor, TACI, are selected during TR differentiation. This process is dampened in aged mice, allowing cells with lower TACI levels to join the mature FO pool [131]. In addition, FO B-cells from aged mice more effectively capture BLyS-mediated survival signals in vitro, although the underlying mechanism is unclear. These observations suggest a model whereby selection at the marrow-periphery interface is relaxed in aged mice; yet competition among mature B-cells may be more severe, reflecting lifelong selection for optimally fit clonotypes [131].

4.3 Developing and Primary Repertoires Change with Age

Alterations in the BM pre-selection repertoire might be expected, given the numerous age-associated changes in cytokine and transcription factors, many of which are involved in Ig gene rearrangement [39, 69, 146, 147, 156]. There is a correlation between the age-associated reduction of pre-B-cell numbers and reduced RAG gene expression, V(D)J recombinase activity, and V to (D)J rearrangement [69, 159, 160]. Evidence for age-associated, intrinsic shifts in V gene segment use are suggested by studies showing an increased frequency of phosphorylcholine-responsive cells arising from sIg^- BM cells in aged BALB/c mice [185]. These increases included clonotypes bearing VhS107 (T15) as well as other Vh segments.

The interplay of intrinsic and microenvironmental changes in aged BM could affect the pre-selection repertoire in several ways. Shifts in heavy chain allele choice at the pre-BCR stage or in light chain choice at the pre-B stage could alter repertoire

composition. Decreased pre-B-cell production may mean that fewer B-cells of different clonotypes are generated. However, this effect may be at least partially offset if extended residency time in the IMM stage affords greater opportunity for receptor editing or Vh gene replacement. Finally, the existence of multiple B differentiation lineages whose Vh gene preferences differ and whose dominance varies with age might underlie some of these observations.

There is ample evidence for age-associated shifts in the primary repertoire, but whether these act to generally expand or contract diversity is uncertain. The phosphorylcholine-specific response in young BALB/c and B6 mice is dominated by VhS107/Vk22 gene segments, whereas aged mice use a broader range of Vh and Vk segments [112, 113]. Moreover, phosphorylcholine-binding monoclonal antibodies generated from aged mice show greater polyreactivity. In contrast, while the frequency of NP-responsive cells is about twofold lower in aged mice, there is no accompanying change in repertoire diversity or clonotype distrubution [184]; and repertoire diversity to influenza hemagglutinin is similar in aged and young mice [183]. Finally, the autoreconstituting repertoire that emerges after irraditaion- or drug-induced lymphopenia is truncated in aged mice, when assessed by CDR3 length heterogeneity [71].

5 Immune Responses and Antigen-Experienced Pools Change With Age

Some age-related changes in immune responses may be related to shifts in the preselection or primary repertoires, while others may be the result of alterations that are observed as or after responding cells have encountered antigen. Immune responses in aged mice sometimes—but not always—involve reduced antibody production and/or antibody of lower affinity in comparison to young mice; however, overall diversity of the responding repertoire is retained or enhanced. Short-lived PC responses and pools are normal to increased in aged individuals, whereas long-lived PC and memory cell numbers are reduced. All of this suggests that the antigen-experienced repertoire is different in quality and possibly quantity in aged mice.

Extensive age-associated changes have been reported in TD immune responses. These include impaired GC formation and kinetics, defective cellular interactions, and deficiencies in SHM and affinity maturation (reviewed in [187]). The antibody response to NP-CGG in aged B6 mice is impaired in terms of primary response kinetics and the amount of antibody produced; moreover, the average affinity of NP-binding antibodies is sixfold lower than in young mice [96]. Although GCs form in aged mice, their number and size are significantly reduced, their kinetics are delayed, and there is no detectable SHM. In apparent contrast, some experimental systems suggest that SHM yields increased diversity of serum Igs in aged mice [175]. These different results are not necessarily contradictory, as SHM may occur even when B-cells are activated outside of GCs [173, 174]. Microenvironment may play an important role: Peyer's patch GC B-cells from aged B6D2F1 mice were

similar in frequency and activation phenotype to those observed in young mice, yet showed higher somatic mutation frequencies [137].

Cellular interactions are also altered with age [43, 152, 178]. T-cell intrinsic changes may account for some of this; for example, a decrease in IL-2 production with age leads to reduced CD40L expression as well as a general CD4+T-cell population shift away from a naive phenotype and towards either a memory or a regulatory phenotype [55]. The proportion of antigen-responsive B-cells to DNP-specific stimulation is decreased in aged mice, and T-cells from aged mice can down-regulate B-cell responsiveness [181, 182]. In an Igh^b *scid* chimera system with donor lymphocytes from young or aged mice, where the primary response to NP is highly restricted to use of Vh186.2/lambda-1 gene segments, aged donor helper T-cells—but not aged B-cells—are less effective at inducing GC formation, and shift Vh gene segment use away from Vh186.2 to include higher proportions of others, particularly C1H4 [178]. In addition, SHM in GC B-cells was reduced in frequency with aged donor T- or B cells. Thus, both germline repertoire use and SHM are likely altered in aged mice; and immunosenescence likley results from changes in both B- and T cell compartments.

Class-switch recombination also appears impaired in aged mice [36–38]. B-cells from old BALB/c mice stimulated in vitro with optimal levels of CD40L and IL-4 display a reduced ability to isotype switch [38]. Defects in isotype switching as well as SHM are associated with an age-related downregulation of E47, which leads to reduced expression of the activation-induced cytidine deaminase (AID) [37].

Mirroring the spectrum of observations in primary repertoire analyses, whether age impacts the magnitude or diversity of antibody responses depends on the model antigen employed, as well as the strain of mice studied. For example, the magnitude of the antibody response to *S. pneumoniae* vaccine and TNP-BA differ in B6 and BALB/c mice, indicating a role for genetic factors in the immune response [113]. However, the clonotypic diversity of the response to both antigens and to phosphorylcholine is greater in aged mice of both strains [112, 113]. In contrast, both primary and secondary responses to DNP-BGG are reduced in aged mice [43, 170]. A study of the IgM component of the primary response to TNP-KLH shows that the peak IgM response is delayed in aged mice but the spectrum and affinity of antibodies are similar to those seen in young animals [186].

Several studies have shown decreased affinity or avidity of antibodies produced by aged mice in TD responses, in some cases along with evidence for a role for altered T-cell responses [27, 43, 114, 170, 186]. When mixtures of phosphorylcholine-specific antibodies from young or aged donor mice are injected into recipients that subsequently receive a lethal dose of *S. pneumoniae*, only antibodies from young donors allowed survival [114]. Moreover, the average affinity of antibodies from aged donors is lower than that of young donors for free PC hapten [114]. Thus the efficacy of antibodies produced by aged mice may be quite different from those produced by young mice. In accord with this overall picture, aged mice challenged with NP-CGG show a higher antigen-forming cell (AFC) response than young mice, but smaller and fewer GCs [45]. Most of the AFC in old mice were low-affinity IgM producers, and the number of high-affinity AFC

was half that of young controls. There were significantly fewer AFC in BM of aged mice following immunization, and reconstitution experiments demonstrated that aged BM was defective in supporting AFC. Thus, the spleen may prove the primary source of the antibody response in aged mice, in contrast to BM in young mice. This shift in AFC location could reflect several potential age related defects in the B-cell response including potential BM homing problems, an altered antigen specific precursor frequency, reduced capacity for AFCs in the BM environment, or a combination of these and other factors. Due to the unclear relationship between naïve B-cells and long-lived PC generation, it is difficult to determine whether impaired humoral immunity in the aged is due to a failure to generate cells capable of seeding the BM and becoming PC memory, or if the defect is downstream. It has been proposed that long-lived PC occupy a highly specialized, tightly regulated niche, and it is possible that this niche is unable to support the entrance of newly formed long-lived PC in old mice, due to intensive competition for survival factors [132].

Only a few studies have addressed TI responses in aged mice. Zharhary [186] made a direct comparison of the IgM response following immunization with TD versus TI forms of the TNP hapten. While the peak IgM response was delayed in aged mice for the TD antigen, there was no delay for the TI antigen. Similarly, Weksler [170] reports that TI responses are generally less impaired than TD responses in aged mice.

It is tempting to speculate that because TI responses are largely B-cell-intrinsic, they will be less severely impacted by age-related changes in T-cell function. Moreover, TI responses may be further preserved by the age-associated persistence of MZ and B1 cells [131], which are largely responsible for antibody production to TI antigens. Thus, the comparative resilience of TI responses may increasingly impact repertoire composition with advancing age.

6 Summary and Perspective

Assessing the nature and basis for repertoire changes is a first-order consideration in our understanding of immunosenescence. Multiple processes appear to act in concert to alter repertoire with age. These include reduced B-cell generation, shifts in V gene choice, and altered subset dynamics and selection overlaid with compensatory homeostatic mechanisms. Murine model systems are attractive routes to interrogate the underlying mechanisms, not only because of their substantial similarities to age associated shifts in human immune responsiveness, but also because they provide an opportunity to approach basic questions experimentally. Some important questions include why and how BM B-cell generation decreases with age, and how this impacts repertoire; whether the stringency of central or TR tolerance change with age; and how B-cell repertoire shifts and impaired immune responses in aged individuals are linked.

1 Role of B-Cells in Age-Associated Susceptibility to Infection

It has been well established that the efficiency of the immune system declines with increasing age. Immunosenescence causes increased susceptibility to infectious diseases, and infection is, in fact, the third leading cause of mortality in people aged 65 and over [1]. As is clearly apparent from the other chapters of this book, there are many components of the immune system that can change with age, and are crucial to maintaining an effective immune system. The humoral immune system interacts with the other components, both as part of its own development and via its effector mechanisms. The most important function of B-cells is to produce antibodies, the indispensable soluble effectors of many functions. There are a number of different stages of development for B-cells and their antibodies (Fig. 1).

In the primary B-cell response antibodies that recognize pathogen, although not necessarily with high affinity, are rapidly produced. They may include the so-called "polyspecific" antibodies, which have the ability to recognize multiple antigens [2]. The first antibodies are of the IgM isotype and are crucial for opsonizing pathogens, inducing phagocytosis and activating the complement cascade. These

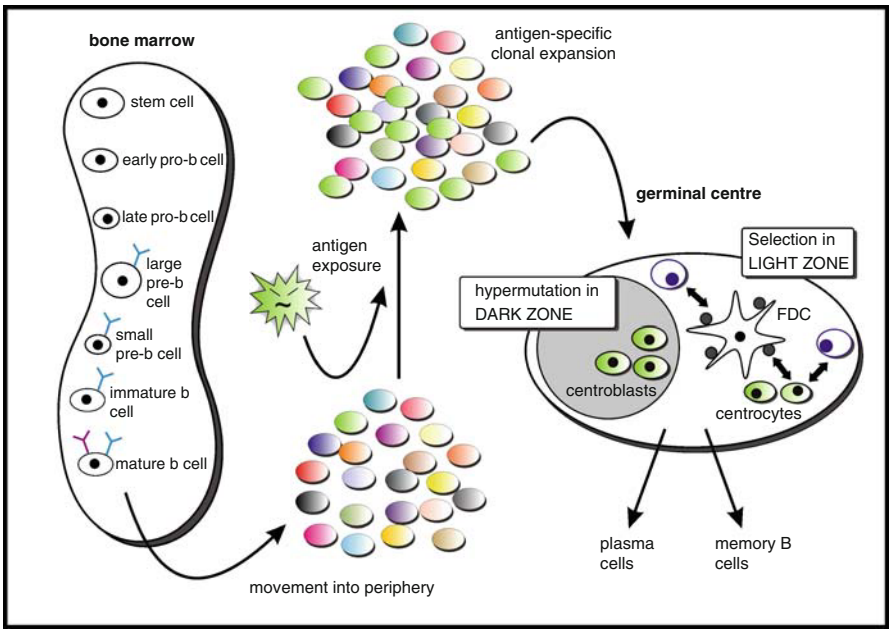

Fig. 1 B-cell development. The humoral immune response is mediated by antibodies produced from plasma cells. These plasma cells are the end point in B-cell development, which is characterized by (a) generation of a huge diversity of different B-cells, each carrying a different antibody gene in the bone marrow and (b) selection processes using the affinity of the membrane-bound form of the antibody (the B-cell receptor) for it's antigen as the selection criteria. Diversity is generated by a process of gene rearrangement early on in the development of the cell, in the bone marrow prior to antigen encounter. The selection processes are twofold. Firstly B-cells are selected for survival, or not, on the basis of their antibody recognition—to eliminate inappropriate self-reactivity and encourage reactivity with foreign pathogens. Secondly there is a mutation step in development, and the resultant B-cells carrying improved antibodies are selected—this occurs in the germinal centre of secondary tissues, after encounter with antigen, and serves to increase the affinity of the antibody for the relevant antigen. Both generation of diversity and selection of antibody are complex processes that are crucial for an effective humoral immune system. A clear understanding of these processes, and how they are affected with age, is needed in order to comprehend the etiology of age-related inflammatory and infectious disease

antibody functions, and the rapidity of this primary response, have been shown to play a vital role in protection from extracellular bacterial pathogens [3]. Antibodies afford protection against viral infection by neutralizing the virus particles; binding and blocking key molecules involved in cellular infection. Similarly they can also neutralize toxins. Later maturation of the B-cells in the immune response is slower but results in the generation of more highly specific antibodies, which may be of a different isotype, following a process known as affinity maturation. In addition to the neutralizing and opsonizing functions of antibody, B-cells are also important as modulators of inflammation [4, 5], regulators of the immune response [6] and as antigen presenting cells and activators of T-cells [7–10].

The elderly are susceptible to infections by a wide variety of pathogens, all of which involve B-cells and antibodies in the normal course of the immune response (Table 1). The lungs are, in common with other mucosal surfaces of the gastrointestinal and genito-urinary tracts, particularly vulnerable to infection by virtue of their exposure to the environment. As is illustrated in Table 1, pulmonary infections are common in older people. The elderly are usually the first to be affected by annual epidemics of respiratory infections, and frequently suffer the worst clinically. Mortality figures attributable to influenza and pneumonia are confused by the fact that influenza is very often followed by a secondary infection—most notably by *Streptococcus pneumoniae*. Some would argue that this confounding factor results in a two to threefold underestimate of influenza mortality [23]. It is also argued that mortality due to influenza is negligible and it is the secondary bacterial infection that causes almost all deaths [24, 25]. Whichever way round, it is generally agreed that older people are the worst affected by these diseases. It has been reported that 90% of all pneumonia and influenza deaths and 88% of respiratory syncytial virus-associated deaths occur in those aged over 65 years [26]. In the oldest old (85 years and over) there was a 32-fold increased chance of mortality from influenza or influenza-associated pneumonia compared with those aged 65–69 years [26]. According to the Department of Health, in the UK there are more than 18,000 hospitalizations resulting from pneumococcal pneumonia each year in those aged 65 years and over [27]. There is also an increased incidence of pneumococcal septicemia in old people associated with *S. pneumoniae* infection [28].

Table 1 Pathogens found frequently in elderly subjects with respiratory or urinary tract infections. (adapted from [1])

Organ system	Pathogen found frequently	B-cell role in immune response to pathogen
Respiratory tract (upper and lower)	Bacteria	
	Streptococcus pneumoniae	B-cells are crucial to the TI-II response [11]
	Hemophilus influenza	Mucosal IgA has a protective role independent of serum antibody levels [12]
	Legionella pneumophila	B-cells are required for opsonization [13]
	Chlamydia pneumoniae	Neutralization by antibody [14]
	Viruses	
	Rhinoviruses	Antibody-mediated neutralization [15,16]
	Coronaviruses	
	Influenza	
	Respiratory syncytial	
Urinary tract	Bacteria	
	Escherichia coli	IgA secretion and antigen-specific Ig inhibits attachment of bacteria [17,18]
	Proteus	An increase in IgM and IgA aids protection [19,20]
	Klebsiella	
	Pseudomonasaeruginosa	Opsonization [21]
	Enterococci	Antibody alone not hugely effective, but effective in the presence of complement [22]

It is known that specific antibodies, generated during a T-dependent B-cell response, are crucial for protection against influenza. Ineffective influenza-specific antibody, as assessed by the Haemagglutination inhibition (HI) test, is associated with lowered protection from the disease [29]. Studies have shown that 25% or more of the elderly fail to develop HI titres of a protective level following vaccination [30, 31]. In vivo studies in mice have shown that higher levels of B-cells and IgG2a antibody confer increased levels of protection [32]. It has been said that an age-related decrease in influenza protection can be solely accounted for by the reduced T-cell help available in the diminished elderly T-cell repertoire. However, this does not take into account the fact that the CD4+ T-cells themselves may rely on fully functioning B-cells for their activation [7, 10].

In other areas of humoral immunity the B-cells are even less reliant on T-cells for help. Pneumonia is a bacterial infection, caused by a number of different organisms (e.g. *Streptococcus pneumoniae* [33], *Staphylococcus aureus* [34], *Streptococcus pyogenes* [35]) although *S. pneumoniae* is the major cause [33]. Immunity against *S. pneumoniae* is particularly reliant on a healthy B-cell population. This is because the antigenic portion of *S. pneumoniae* is a capsular polysaccharide and a T-independent type II (TI-II) antigen. Unlike a T-dependent B-cell response, where the maturation of the B-cell antibody relies on T-cell help and therefore any failure to respond could be attributed to a failure of T-cells, the TI-II response is independent of direct T-cell help. Therefore a failure to protect against *S. pneumoniae* is more likely to be a failure ascribable to deficits in the B-cells themselves.

In children a reduced pneumococcal response can be explained by a lack of marginal zone B-cells in the spleen, where the main TI-II responding B-cells are thought to reside. However, older people appear to have a fully functioning splenic marginal zone [36] so the lack of effective pneumococcal protection in the elderly still remains a mystery. One good candidate for further study is the IgM response. It has been shown, in mice, that the classical complement pathway, partially mediated by binding of natural IgM to bacteria, is vital for innate immunity to S. pneumoniae [3]. Human studies have also shown that antibody of the IgM isotype is vital in providing efficient protection against S. pneumoniae [37], although this has been mainly attributed to "IgM memory," with mutated IgM genes. The exact roles and relationships between natural antibody, IgM memory and class switched memory in the pneumococcal response remain to be determined.

The immune response of the elderly to RSV is less well studied than that against other pulmonary infections. Recent data shows that the senescence accelerated mouse has a severely compromised cellular immune system and produces less virus-specific local IgA in response to RSV infection [38].

Although pulmonary infections of the elderly are the most notable, by virtue of the fact that they cause the most mortality, there are also significant increases in morbidity and mortality from other infections. Bacterial infections of the skin, urinary tract, soft tissue, and gastrointestinal tract are all increased with age [1]. The exact role of the humoral response in this declined protection has yet to be elucidated.

2 Vaccination in the Elderly

Vaccines are an extremely important tool in preventing deaths from infection, and since they are routinely administered as part of a normal health care routine they are the main source of data on immune responses in man. It has been consistently shown that the effectiveness of vaccines is severely diminished in older people. The most commonly studied vaccine is that against influenza. The cellular response, i.e. T-cells and release of cytokines, macrophages and natural killer cells, is decreased with age [39]. In terms of the humoral response the antibody titre, in the form of IgG, is significantly lower [39–41]. While vaccination of the elderly against influenza is widely accepted as a valid health strategy to reduce disease incidence, and studies support this, [42–44] other studies suggest that influenza vaccination does not significantly decrease influenza-related mortality in older people [45, 46]. The age-related reduction in specific antibody production also occurs in response to other vaccines, such as against hepatitis B [47], tetanus and tick-borne encephalitis (TBE) [48]. Data on some of the less common vaccines is more scarce, but gradually becoming available with the advent of an older population which travels more widely. Some travel vaccines, such as hepatitis A, also show a reduced specific antibody response [49], while others such as yellow fever seem to show an undiminished antibody response but have an increased risk of adverse events in the elderly [50].

A possible explanation for a decrease in specific antibody is that the process of affinity maturation is defective. During one study on influenza vaccine it was discovered that an age-related decrease in specific antibody was accompanied by an increase in antibodies against double stranded DNA—indicative of self reactive/polyclonal B-cells [51]. Polyclonal B-cells are often associated with naive B-cells that have not been through the affinity maturation process and are reacting in either a low-affinity manner to specific antigen, or in a non-specific manner by virtue of their innate pattern recognition responses. It was this finding that led to the idea that perhaps humoral immunity in the older person was better represented by the T-independent response. However, as mentioned above, there is a large T-independent component to immune protection against *S. pneumoniae* and general protection is decreased with age. Cross-reactive antibodies certainly appear to be increased in older people treated with the polysaccharide pneumococcal vaccine [52], although the failure of the vaccine to adequately protect against pneumonia [53–57] implies that they are not adequate compensation for the reduction in specific antibody that is also seen [52].

3 Autoantibodies and Age

There is a well-documented shift towards self-reactive antibody production with age. One of the most common autoantibody types, frequently associated with disease, is antinuclear antibodies (ANAs). These have consistently been found to be

increased in the old (over 65) in the absence of disease; a prospective study showed persistence of these raised levels throughout older life [58]. The significance of this increase has not yet been determined, and attempts to relate these antibodies with general levels of disease and frailty have shown no associations. The Swedish longitudinal NONA immune study [59] showed significantly higher ANA levels in the oldest old (86–95 years) but found there to be no association nor any correlation to other immune risk factors (e.g. CD4/CD8 T-cell ratio, CMV seropositivity). These findings are echoed by a Finnish study, where ANA positivity at the age of 90 did not show any correlation with survival, or with the levels of serum markers of inflammation [60]. It has even been suggested that an increase in ANA antibodies may have beneficial effects by virtue of a possible anti-tumor activity [61].

ANAs are not the only auto-antibodies to increase with age. The study by Xavier et al. [58] also noted an increase in the frequency of anti-ssDNA antibodies, as have other studies [62, 63]. Increases in antibodies against many other auto-antigens have been reported, for example against cardiolipin, dsDNA and rheumatoid factor, [62–65] although, again, there were no associations found with mortality [62]. The Danish study by Andersen-Ranberg et al. [65] did find a correlation between autoantibodies and comorbidity and disability, although this was only for the organ-specific antibodies, indicating that these were more likely a result of age-associated disease.

Although the aetiology of Rheumatoid arthritis (RA) is not yet fully elucidated, it is an age-related inflammatory autoimmune disorder. Coincidentally, as reported above, there is also an increased incidence of rheumatoid factor (RF) with age—regardless of whether the subject has RA or not [62–65]. There has been a decline in incidence of the disease that has been observed over the last 40 years [66] which has been attributed to environmental factors. One possible contributor to this is the gradual decrease in the number of smokers. Recent evidence has shown that the presence of another auto-antibody, anti-cyclic citrullinated peptide (anti-CCP) is associated with smoking and a higher risk of RA [67]. The successful use of therapies such as Rituximab, which utilize an anti-CD20 monoclonal antibody to ablate peripheral B-cells, is ample evidence that B-cells play an important part in the disease process of RA [68]. In addition to the obvious mechanism of depleting auto-antibody producing cells, there is increasing evidence for a role of B-cells in RA as antigen-presenting cells, activating T-cells, and producing and responding to cytokines [69]. A further complication in understanding the role of B-cells is the fact that B-cells have recently been shown to be capable of immunosuppression—including in animals models of arthritis [70, 71].

4 Immunodysregulation of B-cells in Aging

The above observations are all evidence that the humoral immune system is dysregulated in older people. At first glance it would appear that there is no easily identifiable quantitative defect in the humoral immune system with age. However, although the range of B-cell numbers, as a percentage of peripheral blood lymphocytes, varies greatly between individuals, it has been reported that there is a slight decline in the

number of CD19+ B-cells in old age [72–75]. It has also been reported that having a higher number of CD19+ B-cells is associated with better survival [76, 77]. When CD20 is used as a marker for B-cells no age-related change could be found [78]. The number of antibody molecules circulating in the periphery of older adults remains relatively stable [79, 80]. Similarly, studies have been conducted on the ratio of different Ig isotypes in the elderly and most show no significant change during later life [75, 81, 82]; although it has been reported that an increase of the mucosal IgA antibody in the serum can be a predictor of mortality [83]. In general the picture is one of a qualitative change in the antibody repertoire rather than a quantitative one [84].

4.1 Generation of High Affinity Antibodies

Since the lack of high affinity antibodies is a key feature of the older immune system, and our expertise is in the study of Ig genes, we initially investigated the affinity maturation process. Affinity maturation occurs in the germinal centre (GC) and involves the expansion of antigen-specific B-cells, mutation of their Ig genes (resulting in altered antibody function), followed by selection of the B-cells producing the best antibody [85–87]. Contained within the dynamic microenvironment of the GC are B-cells, T-cells, and follicular dendritic cells (FDCs) all in close proximity to allow the exchange of costimulatory molecules and cytokine signaling.

Following antigenic stimulation, selected B-cells migrate and converge on the GC FDCs, making contact with their long processes [88] and differentiating into centroblasts. The FDCs are the stromal cells of the GC and play a key role in regulating the humoral immune respone [89]. Unlike antigen presenting cells (APCs), FDCs present intact antigen–antibody complexes on their cell surface [88], in the form of immune complexes which are highly immunogenic, and assist GC B-cell proliferation [90–92]. Proliferating GC B-cells are known as centroblasts. During centroblast proliferation, in the dark zone of the GC, hypermutation of the immunoglobulin (Ig) genes encoding antibody occurs. The B-cells move into the light zone, as centrocytes, and will die through apoptosis unless they receive rescue signals conditional on efficient recognition of the antigen by the newly formed B-cell receptor. Rescue signals are provided by FDCs and T-cells [93]. The helper T-cells in the GC are a particular subset of CD4+ T-cells, expressing CD57. These cells have unique characteristics that have yet to be fully elucidated [94]. Since FDC and T-cell help is limiting there is competition between B-cells and therefore selection of those B-cells with the highest affinity for antigen occurs. The resulting B-cells can switch the class of their antibody, from IgM to IgG/IgA/IgE, and this also requires T-cell help. B-cells with high affinity antibody differentiate into either memory B-cells, to provide for an efficient recall response, or plasma cells to secrete antibody. We have addressed the possible age-related changes in the GC reaction in three main areas: proliferation of B-cells, hypermutation of the Ig genes, and selection of high-affinity, antigen-specific, antibodies.

4.2 Proliferation

A defect in B-cell proliferation would have severe consequences for the GC reaction, since the loss of cells due to deleterious mutations acquired by hypermutation is extremely large and the pool of B-cells required to counter this is therefore also large. For some cell types proliferating cells can reach replicative senescence—where the telomeres at the ends of the chromosomes erode at each division and therefore there is a limit to the amount of proliferation one cell line can undergo set by the length of the telomere [95]. It has been shown that telomere length decreases with age in T-cells, and to a lesser extent in B-cells [96, 97]. However, we do not believe that the proliferative capacity of B-cells in the GC is impaired in this way as a result of old age. Telomerase, the enzyme that elongates telomeres, is upregulated in the GC, being high in centroblasts and higher still in centrocytes. This results in B-cells leaving the GC for the periphery with substantially longer telomeres than when they first entered, up to 4 kb longer as determined by Southern blotting [98]. Further to this, memory B-cells have telomeres on average 2 bp longer than naïve B-cells [97].

There has been much debate as to whether the overall size and number of GCs decrease with age. Several studies have pointed to this though they have all been conducted in rodent models [99–101]. Immunohistochemical studies measuring the size and overall number of B-cell follicles in human spleen, Peyer's patches [36] and lymph nodes [78] have not shown any age-related difference. However, there have been two studies of human tonsil, performed by flow cytometry rather than measuring individual GC sizes, which have both reported a decrease in GC B-cells with age [99, 102]. Tissue specific differences may account for these discrepancies and further work would be needed to clarify the issue.

4.3 Hypermutation of B-Cells

As outlined above, somatic hypermutation occurs following activation of the B-cells by antigen and entry into the GC reaction. The mutations introduced are generally point mutations, though some insertions and deletions may occur, and tend to be in areas containing hotspot motifs [103–105].

There is conflicting opinion regarding whether there is a quantitative change in hypermutation in the ageing individual. Reports have indicated no change [106–108], a decrease [109, 110] or increase [99, 111, 112] in mutation with increasing age. The fact that these studies do not agree is hardly surprising as they do not take into account patient health history i.e. prior immune responses. The tissue origin of samples can also make a significant difference to the number of mutations observed, for example we have shown consistently that B-cells of mucosal origin have a higher level of mutations than those from, say, spleen or blood [113].

We addressed these issues by attempting to quantitate the frequency of hypermutation in individual B-cell GC expansions. We microdissected histologically-defined

areas of GC from the spleen and Peyer's patch follicles of young and old humans so that only the mutations in that particular GC reaction were counted [114, 115]. Individual B-cell expansions were identified by their Ig gene characteristics; by identifying Ig gene sequences that have the same CDR3 region we can identify related B-cell clones (Fig. 2, *see* later for a more detailed explanation of Ig gene rearrangement). Furthermore, we can draw a lineage tree of individual B-cell clonal expansions (Fig. 3) by analyzing the order of accumulation of mutations in the hypermutation process [114, 115]. In this way we look at the number of mutations that occurred within that particular clonal expansion, and can compare lineage trees from subjects of different ages. We have shown that there was no difference in the frequency of mutation occurring in human GC reactions in the spleen and Peyer's patch with age.

4.4 Selection of High Affinity B-Cells and Class Switching

Lineage tree construction can furnish information on the affinity maturation dynamics by measurement of lineage tree shape parameters. The shape of the lineage tree can help indicate the degree of selection that has taken place. For instance, a 'pruned' tree (few branches) indicates high selection pressure whereas a 'bushy' tree (many branches), indicates less selection (Fig. 3). Since a failure of adequate selection

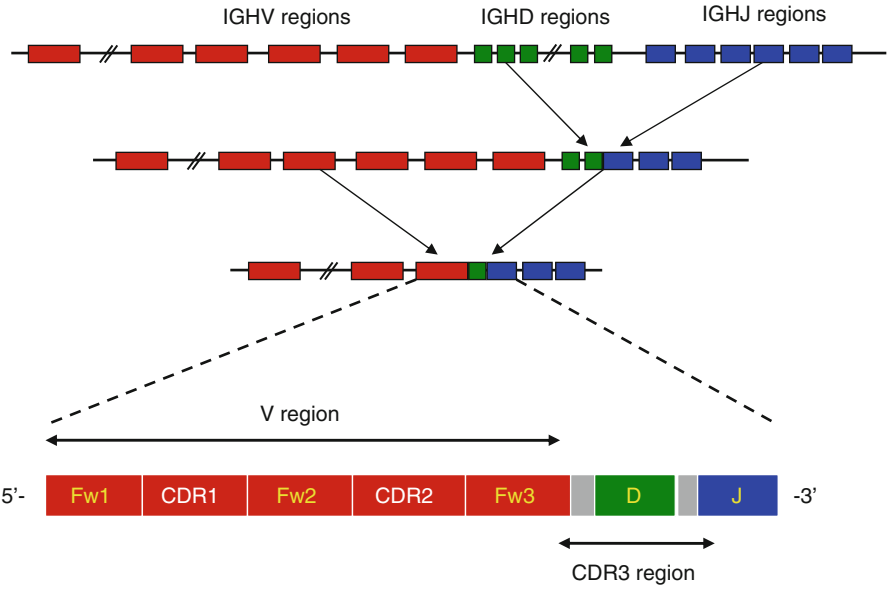

Fig. 2 Immunoglobulin heavy chain gene structure and the complementarity determining region (CDR) 3 region. The rearranged immunoglobulin gene contains 3 CDR regions (that form the antigen binding site) and 3 framework (Fw) regions (that provide structural integrity). During germline Ig gene rearrangement, a variable (V) region is joined to a diversity (D) region and a joining (J) region. During the rearrangement process, random N-nucleotides (N) are inserted into the junctions to form a unique CDR3 sequence

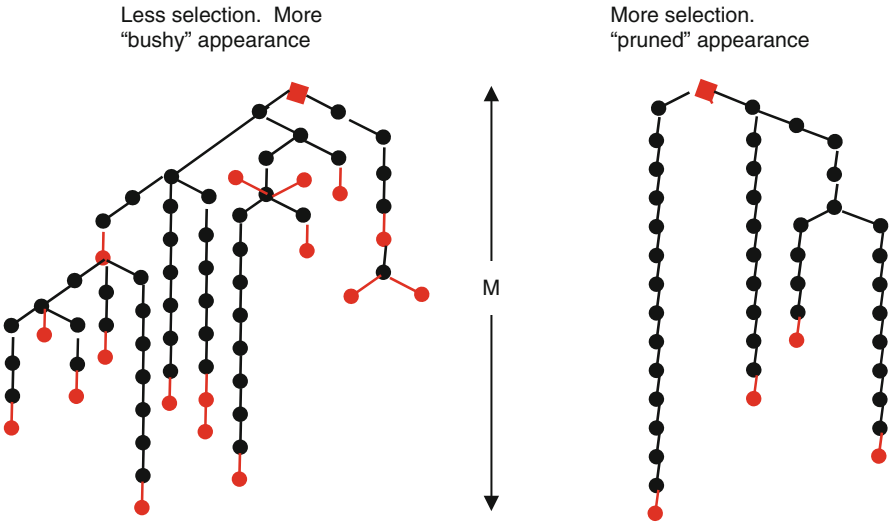

Fig. 3 Representations of lineage trees from clonal expansions of B-cells in the germinal centre reaction. Each node (round) represents one mutation away from the germline sequence (square). The shape of the lineage tree reflects the degree of selection acting on the clonal expansion as shown. The relative frequency of mutation in each lineage tree is compared by comparing the distances between the top and bottom of the lineage trees (M)

could result in the production of a population of cells with low affinity, such as is seen in the elderly, we investigated lineage trees from GC reactions in samples from patients of different ages for selection differences. We found a significant decrease in the degree of selection pressure acting on GC B-cells in the Peyer’s patch of the gut (but not the spleen). These data were confirmed by further analysis of the distribution of mutations within the Ig gene. A high level of replacement mutations in the complementarity-determining areas of the gene (relative to the more conserved Framework areas, Fig. 2) is expected in a selected Ig gene, and is indeed seen in the younger Peyer’s patch GC samples but not the old [114, 115].

An explanation for these apparent changes in selection is still elusive, but several factors could contribute. It may be solely a failure of the quality of B-cells in terms of specificity or signaling function. However, since FDCs and T-cells are important in the selection process they are also good candidates to investigate for the failure of selection pressure.

There is a well-documented age-related decline in thymus size and a reduced T-cell output. Homeostatic regulation in the face of reduced levels of naïve T-cells causes skewing of the T-cell repertoire which may reduce the availability of appropriate T-cell help for B-cells. Immunohistochemically stained human tissue sections have illustrated changes in T-cell populations in B-cell follicles [36,102]. The CD8+ T-cell numbers decline with age resulting in an increased CD4+/CD8+ ratio. Since it is CD4+ cells that are important in the affinity maturation process the significance of these findings is not known. There is, as yet, no information on whether the GC-specific T helper cells (CD4+ CD57+) are changed with age. CD40 ligand on GC

T-cells interacts with CD40 expressed on B-cells and this relationship is critical to T-cell dependent activation of B-cell proliferation, memory formation and class-switch recombination in the GC. Aged CD4 T-cells in mice have shown reduced CD40L expression [116] and in these animals there is a decrease in IgG levels reminiscent of the decreased IgG production in response to influenza vaccination in humans [40,41].

It has been suggested that the function of FDCs declines with increasing age [101, 117, 118]. Defects may be intrinsic to the FDCs themselves, or may be a failure of the FDC-B-cell interactions. FDCs have Fc receptors (FcR) and complement receptors 1 and 2 (CR1 and CR2) on their surface which retain antigen as immune complexes [119], and these interactions are crucial for the signaling and activation of antigen-specific B-cells. The immune complexes coat the FDCs to form bodies known as iccosomes. Aged FDCs have been reported to produce few to none of these iccosomes [117]. This may be due to the apparent down-regulation of FDC-FcγRII expression by FDC-bound immune complexes demonstrated in the GCs of old mice [120]. The resulting decrease in immune complex retention and presentation to B-cells would lead to lowered B-cell activation in the GC.

Although there is clearly a role for accessory cell failure in the age-related changes in GC responses, changes intrinsic to the B-cell itself are also responsible. The key enzyme in affinity maturation of B-cells is Activation Induced Cytidine Deaminase (AID) which is directly responsible for both hypermutation of Ig genes and class switching. Class switch recombination, from IgM to either IgG, IgA or IgE isotypes, creates antibodies with the same antigen specificity but different effector functions (e.g. complement fixing, secretory, opsonizing). AID expression is regulated by the E2A-encoded transcription factor E47. It has been shown, in mice, that E47 and AID expression is reduced in old B-cells [121], and that this reduction is due to a failure in the CD40 signaling pathway (indicative of T-dependent interactions) and the BAFF signaling pathway (indicative of T-independent reactions) [122]. Preliminary results also suggested that there was a similar decrease of E47 and AID in human peripheral blood B-cells [121].

4.5 Diversity of the B-Cell Repertoire

Evidence from our lineage tree studies on individual GCs indicated that in some instances the founder B-cells of a GC may have already been mutated. This occurred more often in the older samples and led us to postulate that B-cells which have previously been through the affinity maturation process might be being re-used in subsequent immune responses. If the starting population of B-cells has already been modified in response to a different antigen, then its ability to effectively change to accommodate a new antigen may be compromised. This could partially explain the compromized selection noted above. Naive B-cells are characterized by their IgD expression, and memory B-cells are characterized by having mutated Ig genes and expressing CD27 on their surface. It has been shown in mice that the older B-cell

population is made up of a greater number of B-cells carrying mutated Ig genes—i.e. memory B-cells [123]. Observations of an increased number of CD27+ B-cells in humans concur with this [124,125]. A change in serum IgD, which may also reflect an increase in the proportion of IgD-, memory, B-cells, has also been noted [84]. It is now well established, in mice, that naïve B-cell output into the periphery decreases with age [see p. 395 Scholz et al.]. There is, as yet, no evidence that human bone marrow B-cell output decreases with age, although it is known that children reconstitute B-cell function after bone marrow transplants more rapidly than adults do [126]. Therefore, if the overall number of B-cells is not drastically reduced, and there are less naive cells being produced, an increased proportion of memory B-cells is a logical conclusion [127]. Since B-cell memory appears to be maintained by proliferation [125] it is possible that proliferating memory B-cell clones make up for any shortfall in immunological space caused by lower naive B-cell input. However, a decrease in the number of memory B-cells with age has also been reported [128], so it would seem that this issue is still not completely resolved.

Our postulation, that GC reactions in the older samples were using "second hand" B-cells, lead us to further investigate B-cell diversity. A diverse and functional repertoire of antibodies is essential to produce an effective humoral immune response. If the repertoire of B and plasma cells is reduced, then the ability to recognize foreign antigen is severely compromised. B-cell diversity and antibody specificity are defined during the early stages of B lymphocyte differentiation, where the Ig genes are formed. The remarkable way in which gene segment rearrangement forms a complete Ig gene from different segments (Fig. 2) results in millions of different B-cells, each with a unique Ig sequence capable of producing antibody with distinctive specificity. Briefly, the Ig molecule consists of both heavy and light chains. There are three types of gene segments, variable (V), diversity (D, heavy chain only) and joining (J). The segments are randomly recombined to generate a V(D)J for the heavy chain (Fig. 2) or VJ for the light chain. Thus a germline repertoire of just 165 different V,D or J genes can result in a possible 8,116 different gene rearrangements. Combination of the heavy and light chains results in a possible 2,643,840 combinations. The region where the junctions join together is further diversified by an incomplete joining process. Addition and deletion of nucleotides by terminal deoxynucleotidy transferase (TdT) activity at these joints leads to junctional diversity. The VDJ joining region of the heavy chain, the CDR3 region, is so highly variable that it can be considered to be a fingerprint for that particular gene and the B-cell (and its progeny) that carries it.

There have been a number of studies which have looked for an age-related change in diversity by investigating the gene segment usage in Ig genes. The studies vary in design (looking at specific gene families only, or at specific isotypes, or only in response to a particular challenge) which may account for some of the discrepancies between them. The earliest report is probably the most comprehensive in terms of VH repertoire, although limited in the number of different subjects used (five old and one young) [106]. They showed an increase in usage of certain IGHV genes, in particular of the IGHV4 family [106]. However, this has since been contradicted. In another sequencing-based study of the IGHV4 repertoire in elderly human tonsil

Kolar et al. did not find any change [99]. The IGHV repertoire has also been analyzed, in a small group of individuals, using a family-specific PCR-based approach. This showed consistency in the IGHV repertoire between samples of the same individual at time points 10 years apart [107]. IGHV family specific studies alone may not pick up functionally significant differences in the repertoire. Although the IGHV3 family usage in response to pneumococcal polysaccharide vaccination showed no overall difference between the elderly and young adults, there was a significant loss of focus in the elderly response as evidenced by a loss of oligoclonality [52]. Furthermore, in the same experiments, a difference in Ig light chain usage was observed [129].

Other studies of B-cell diversity have concentrated on the CDR3 region. This, being the most variable region of the gene and having importance in antigen binding, has traditionally been an area used to define monoclonality and oligoclonality in pathology [130]. However, due to the cumbersome nature of sequencing and identifying V-D-J regions, the numbers of patients studied have generally been low, or limited to particular subsets of genes. For example, one study by Xue et al. [131] looked at D and J

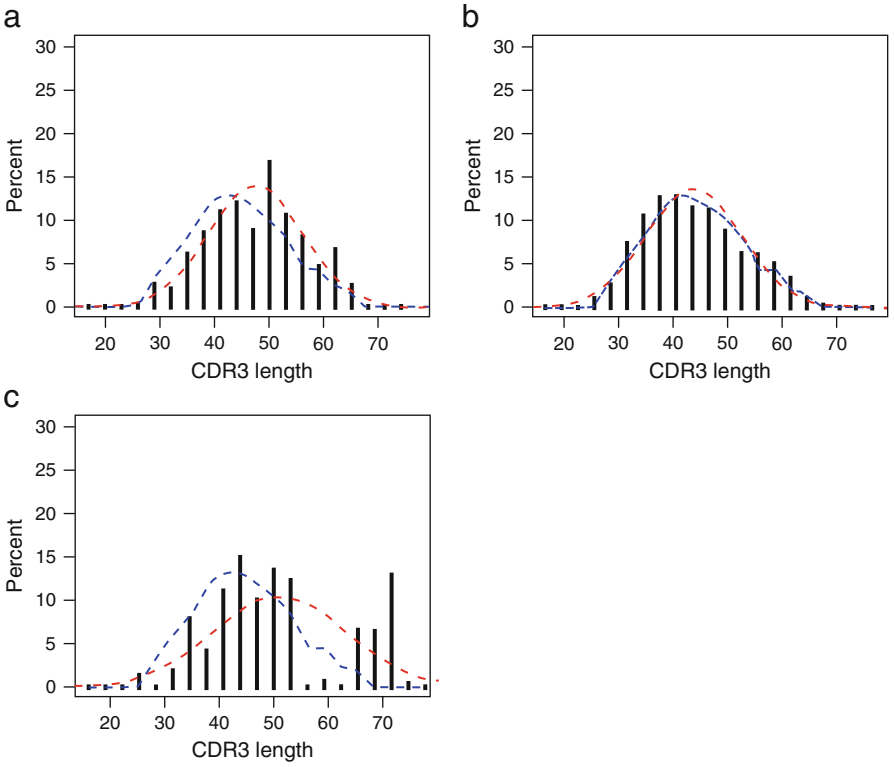

Fig. 4 Three different spectratype profiles. All are from old individuals (>88 years). Black bars represent the percentage of cdr3 regions of each different length. The red line represents the mean distribution for the young controls. The blue line shows the best fit for the individual sample data shown. A shows some B-cell repertoire restriction, B shows normally distributed cdr3 lengths, C shows an individual with very restricted B-cell repertoire. Approximately one-third of the old blood samples analyzed show restricted IgH repertoire along the lines of the spectratype in C

region usage as determined by sequencing and found no difference between younger and older samples. However, they had only seven young and seven old samples and only studied the CDR3 regions of IGHV5 family IgM genes. A more tractable method of looking at CDR3 diversity was also employed by them, using PCR to amplify all CDR3 regions and look at the spread of different sized fragments. This method of spectratyping has also been used in the analysis of T-cell repertoires [132–134] and enables the study of a much greater number of samples. We performed B-cell spectratyping on samples from peripheral blood of 33 old and 24 young subjects. The old samples are from the Swedish NONA Immune Longitudinal Study [135], from patients over 86 years of age. Preliminary data has shown that the B-cell repertoire is indeed restricted in a subgroup (approximately one third) of older people (Fig. 4).

4.6 Association of Monoclonal B-Cell Expansions With Age

Skewed B-cell spectratypes of the kind we have observed may have a number of aetiologies. It may indeed be true that a decreasing naïve B-cell output in the face of homeostatic mechanisms to keep the total number of B-cells the same has resulted in the repertoire being increasingly made up of antigen-experienced expansions of cells. Alternatively there may be pathological monoclonal expansions of B-cells, such as are seen in leukemia or lymphoma. Usually, these are diagnosed conditions, and individuals with this sort of medical history are excluded from studies on B-cell diversity. However, it might be possible that a pre-clinical condition exists in some people. An increase in monoclonal expansions of B-cells, both of CD5+ and CD5- phenotype, has previously been reported in older people [136]. Monoclonal gammopathy of undetermined significance (MGUS) is a predominant plasma-cell disorder [137] and has been shown to increase with age in both humans [137,138] and mouse [139]. It is characterized by an increase in presence of serum monoclonal Ig. MGUS is not found in young subjects, is prevalent in around 2% of over 50s and has been reported to vary in the elderly from 11% to 38% [138,140]. There is an association between MGUS and onset of multiple myeloma or related malignant condition with average risk assessed at about 1% per year [141]. Questions still remain as to what significance these populations have in the aging human. Obviously there is the possibility that MGUS accounts for some of the observed repertoire restriction with increasing age. However, our data does not suggest a high prevalence of such monoclonal expansions, and the restricted repertoires often have a more oligoclonal appearance.

5 Summary

We have outlined the different factors that are involved in making and maintaining an effective humoral immune response and how these may be affected by increasing age. It is clear that the ability to produce high affinity antibody with age is diminished

but there are many possible explanations as to why this might be. We have identified the most likely areas as being a decrease in the ability to select B-cells producing high affinity antibodies, and a decrease in the available repertoire in the first instance.

Many of the studies on B-cells in old age are carried out in mice and the data in humans is sadly lacking. Hopefully this situation will change in the future and maybe the advent of the use of B-cell depletion therapies for the treatment of autoimmune disease can help provide more human data on B-cell dynamics in individuals of different ages.

Neutrophils

Neutrophil Granulocyte Functions in the Elderly

Peter Uciechowski and Lothar Rink

Contents

Abstract: The immune response weakens during aging. Especially, the altered functions of the lymphocytes of the adaptive immune system have been extensively studied. Aged persons >65 years display a predisposition to inflammation and infection combined with an increase in morbidity and mortality than younger individuals. In the past few years it has been discovered that certain functions of the innate immune system, which build the first line of defense against pathogenic microorganisms, are altered with aging. Among the cells of the innate immune system, neutrophilic granulocytes (polymorphonuclear leukocytes, PMN, neutrophils) eliminate invaded bacteria and fungi and play an accepted important role in regulation of the immune response. In vitro studies demonstrate that neutrophilic functions such as phagocytosis, generation of reactive oxygen species (ROS), intracellular killing, degranulation, and possibly chemotaxis are changed in elderly persons whereas the number of circulating neutrophils are unaltered compared to young persons. However, the reported data of different investigators regarding the above-mentioned functions are sometimes controversial. This may result from the use of different isolation methods of neutrophils, the degree of contaminating cells and preactivation of neutrophils during isolation. It could be shown that most of the adhesion surface molecules and receptors of neutrophils are not impaired in function and expression with age. But there is increasing evidence that age-related changes affect receptor-dependent signal transduction and membrane content and fluidity, which in turn lead to a decline in function and in inhibition of apoptosis. Further research

1 Introduction

Elderly persons are more susceptible to microbial infections with an increase in morbidity and mortality due to declining immune status, termed immune senescence. In general, age-related changes include a decreased response to vaccination, increased incidence of inflammatory and autoimmune diseases and cancer. There are many efforts to clear up the molecular and cellular changes surrounding immune system dysfunctions. However, other factors such as nutrition, fitness, social components and diseases influence immunity of elderly persons making it difficult to detect single, age-dependent changes. To exclude those factors, the SENIEUR protocol was created to clearly separate age-related from nonage-related alterations of the immune system [1, 2]. This protocol sets the criteria in order for a healthy elderly person to participate in immunogerontological studies. The effects of aging are well-documented for the adaptive immune system, e.g. the alterations in T-cell count, phenotype, and function as well as reduced ability of B-cells to synthesize high affinity antibodies. But in the meantime, the importance of the innate immune system in fighting invading microorganisms and the cooperation with the adaptive immune system to ensure optimal immune response has become more widely accepted. Neutrophils display alterations of function, surface molecule expression, apoptosis and signal transduction with aging. These changes and their effect on the attenuation of neutrophil functions will be summarized and discussed by reviewing the literature.

2 Neutrophils

Polymorphonuclear leukocytes (PMN or neutrophils) are key effector cells of the innate immune system. They are the first cells to migrate rapidly to sites of infection and recognize and engulf microorganisms by phagocytosis. Neutrophils destroy and degrade invaded pathogenic bacteria and fungi via the release of reactive oxygen species and antimicrobial and proteolytic granule proteins, which are delivered to the phagosomes and to the extracellular environment. Additionally, neutrophils produce chemokines and cytokines that recruit and regulate the inflammatory response of macrophages, T-cells and neutrophils themselves. Finally, activated neutrophils

initiate an apoptotic programme where they are digested by macrophages without causing tissue damage and necrosis and therefore support the resolution of the inflammatory response [3].

Neutrophils are short-lived cells and die by apoptosis spontaneously within 12–24 h of their release from the bone marrow. The adult bone marrow has to produce $1–2 \times 10^{11}$ neutrophils per day to sustain a sufficient cell number to efficiently fight infections [4]. This continuous production is controlled by granulocyte colony-stimulating factor (G-CSF), granulocyte/macrophage colony-stimulating factor (GM-CSF) and interleukin-3 (IL-3). To maintain the function of neutrophils summoned to infected tissue, "survival" factors such as lipopolysaccharide (LPS), hypoxic environment, complement and pro-inflammatory cytokines counteract apoptotic programs in neutrophils (Fig. 1) [5–8]. To fulfill their tasks in the defense against bacterial and fungal infections specific functions are regulated by specific receptors. These receptors are formyl-methionyl-leucyl peptide (fMLP), GM-CSF, complement, IgG Fc and interleukin-8 (IL-8) receptors [9]. Additionally, pattern recognition receptors, e.g. toll-like receptors (TLR), binding conserved molecular structures of most microorganisms, participate in the inflammatory response of PMN and other cells of the innate and adaptive immune system [10].

Historically, the role of neutrophils and their immune response has been underestimated and their function has been reduced to being only phagocytic active cells. In the past few years the views on the ability of neutrophils to bridge and regulate innate and adaptive immune responses have been shifted [11]. Using an isolation method to acquire highly purified human neutrophils without preactivation it was shown that neutrophils synthesize only a limited pattern of cytokines released, mainly IL-8, after stimulation [12, 13]. In addition, neutrophils produce large amounts of the antiinflammatory interleukin-1 receptor antagonist (IL-1RA) after stimulation or after high accumulation of neutrophils [14, 15]. Interestingly, neutrophils do not synthesize proinflammatory cytokines such as interleukin-1ß (IL-1ß), tumor necrosis factor-α (TNF- α) and interleukin-6 (IL-6) as described by others [16], which may be explained as a result of monocyte contaminations in the PMN isolates. Therefore, neutrophils not only recruit other immune cells to sites of infection but are also able to create an antiinflammatory environment that helps resolve inflammation.

3 Neutrophils and Aging

It is well-known that aging results in a predisposition to inflammation as well as to infections, which is associated with higher rates of mortality and morbidity [17, 18].

One might assume that impaired defense against invading pathogens such as fungi and bacteria is accompanied by a reduced amount of neutrophils as seen within the T- and B-cell system of elderly persons. But there are no alterations in the number of precursor cells in the bone marrow or of circulating neutrophils [19, 20]. Moreover, neutrophils have been described to be significantly increased in the aged [21]. Neutrophil precursor cells show a reduced proliferative response to G-CSF only (Fig. 1),

normal release of neutrophils

whereas responses to GM-CSF and IL-3 are not affected [19]. Elderly persons also display a normal neutrophilia during infection [22], indicating that GM-CSF and IL-3 mediate sufficient neutrophil production. However, loss of apoptotic rescue and a normal recruitment of neutrophils by G-CSF during infection might promote an impaired immune response with age (Fig. 1). In the case of severe chronic infection, neutropenia can be observed in the elderly, suggesting that persistent infection in the elderly impairs neutrophil recruitment [20].

4 Function

Although neutrophil count is elevated and adherence to endothelia is unchanged in elderly persons, impaired neutrophilic functions can be seen including a decline in phagocytic capacity in healthy elderly individuals accompanied by reduced intracellular killing [22–24]. This decline in function may contribute to increased susceptibility to bacterial infections in the elderly population. In contrast, aged persons fulfilling the SENIEUR criteria who also exhibit elevated numbers of granulocytes are functionally normal [25–28].

Studies that analyze phagocytosis of opsonized bacteria or yeast and opsonized zymosan by neutrophils have all demonstrated a significant impairment in phagocytic function in the elderly [29–33]. Additionally, the antibody-dependent phagocytosis mediated by Fc-receptors is also decreased [33]. Interestingly, the functions of these receptors are not changed, immunoglobulin and complement levels are normal and serum from elderly donors opsonize bacteria normally so that phagocytosis itself is impaired [32–34]. Butcher et al. [33] have shown that one of the receptors involved in recognizing antibodies on the surface of bacteria, CD16 (FcγRIII), is significantly reduced with age and may contribute to the observed decline in neutrophil phagocytic function with age [33].

After phagocytosis of pathogenic microorganisms, the phagosomes fuse with lysosomes containing bactericidal substances and build the phagolysosome. Therein the pathogen will be intracellularly killed. Besides other destructive components contained within the phagolysosome, intracellular killing is dependent on the generation of ROS, termed respiratory burst. This respiratory burst causes production of superoxide, hydrogen peroxide, and hypochloric acid, which are all toxic to microbes. Contradictory findings describing the respiratory burst after fMLP stimulation in neutrophils of the elderly have been reported. Some groups determined decreased respiratory burst activity after either fMLP [35–38], GM-CSF, or LPS stimulation [39, 40]. Wenisch et al. [32] showed a significant reduction in generation of ROS after stimulation with

Fig. 1 Recruitment and apoptosis of neutrophils during infection
a) After phagocytosis of invading microorganisms the apoptosis of neutrophils in young individuals is blocked via the release of survival factors. Additionally, G-CSF induces the release of a large number of neutrophils from the bone marrow leading to physiological neutrophil leukocytosis.
b) In elderly persons the inhibition of apoptosis of neutrophils is impaired and the recruitment of neutrophils from the bone marrow is not enhanced. This might result in an exhaustion of neutrophils and consequently lead to a reduced immune response with age.

Staphylococcus aureus (*S. aureus*) in contrast to no reduction after stimulation with *Escherichia coli*. These results are in concordance with the reported reduced ability of elderly to fight infections caused by gram-positive bacteria [41], since *S. aureus* frequently causes postoperative sepsis in the elderly.

Others studies using SENIEUR selected persons could not detect a difference in respiratory burst compared to younger persons even after stimulation with fMLP [22, 23]. The application of different stimuli led to various results, based on the assumption that distinct pathways of neutrophilic activation are involved. An early report by Tortorella et al. [42] showed that signal pathways may be impaired. Neutrophils obtained from elderly humans and stimulated with GM-CSF displayed a significant reduction in phosphorylated ERK1/2 levels and an even larger decrease in ERK1/2 activation. No changes in GM-CSF-induced p38 MAPK phosphorylation were observed [42]. This coincides with Larbi and colleagues reporting that p38 signaling is not involved in GM-CSF delayed apoptosis in any age-groups [43]. There are few reports about intracellular killing of fungi and bacteria in elderly people. They described that the capability of stimulated and unstimulated neutrophils to destroy *Candida albicans* is reduced by 10–50% in the elderly, and *E. coli* killing is 44% lower than that of young persons [39, 44]. The reason for impaired intracellular killing in neutrophils of the elderly is not clear yet. Although Piazzolla postulated that cytoskeleton affecting compounds are responsible for the alteration of fMLP stimulated superoxide generation [45], this does not illuminate the selective discrimination of one stimulant against the other. It is possible that triggering various signal transduction pathways after recognition of the pathogen and consequent activation of the neutrophil are responsible for an impaired defense towards one pathogen whereas the response to another remains unaltered in the elderly.

Neutrophils respond to various chemotactic products released either by the host or by the invading organism [46, 47]. Chemotaxis results from the initial contact and adhesion of PMN to endothelial cells through cell adhesion molecules, followed by migration through the endothelium following a chemotactic gradient to inflamed sites. Some investigators reported that chemotaxis remains largely unaltered in the elderly [34] or at least display a normal reaction after stimulation with fMLP [22, 23]. Other research groups found impaired chemotaxis when using other chemotactic substances and complement [32, 48, 49]. The consequence of the latter is that a fast recruitment to sites of infection is functionally restricted. That might explain the occurrence of severe wound infections by elderly persons since small numbers of pathogens cannot be efficiently eliminated. Corberand et al. [50] reported significantly decreased chemotaxis in people over the age of 80 years, and no significant difference in 60- to 70-year-old compared with young persons. Curiously, Niwa et al. [49] presented contrary results. They found a correlation between 60- and 70 year-old volunteers with diminished PMN chemotaxis and respiratory burst and mortality 7 years after the initial study. No difference between people older than 80 years old and the young could be seen. The explanation they offer was that there was no difference between the over-80-year-old persons and the younger ones because individuals with the more suitable neutrophils survived into the oldest age group [49, 50]. Similar data have

been obtained for degranulation and superoxide production in response to stimulants such as fMLP [31, 38].

5 Apoptosis

Apoptosis is involved not only in differentiation, development of tissue and homeostasis, but also in neurogenerative and immune diseases and cancer. Neutrophils display a fast apoptotic rate in vitro as well as in vivo. Apoptosis has to be well-balanced to ensure their survival and production; if the balance is shifted, the risk of chronic inflammatory diseases is enhanced.

The regulation of apoptosis of neutrophils is important to maintain longer survival in inflamed tissue or the resolution of inflammation. Without stimulation, the susceptibility of neutrophils to apoptosis is either slightly increased in the elderly or unaffected by aging [51–53].

It has been shown that the functions and the rescue from apoptosis by survival factors G-CSF, GM-CSF, IL-2 and LPS of PMN diminish with aging. In comparison to younger persons only GM-CSF alters apoptotic neutrophils slightly in the elderly [53]. Increased apoptotic rates of neutrophils at the site of infection might cause decreased bactericidal function (Fig. 1). DiLorenzo and coworkers reported a significant age-related decrease of formation of O^{2-} and chemotaxis whereas no significant correlation between age and the expression of the death receptor CD95 (APO1, Fas) on the granulocyte membrane could be detected. The authors suggest that an increase of CD95-mediated apoptosis of neutrophils might play a minor role in the impairment of neutrophilic function [54]. Fulop et al. [55, 56] investigated the role of antiapoptotic Mcl1 and pro-apoptotic Bax in decreased apoptosis inhibition in PMN of the elderly. The authors found that the expression of Bax was unchanged in elderly and young persons; also treatment with GM-CSF could not modulate the Bax expression. Similar results were obtained by examining Mcl1, which was upregulated after GM-CSF stimulation in young persons, whereas in the elderly no difference was found between stimulation and spontaneous apoptosis. By comparing the Bax/Mcl1 ratio after GM-CSF stimulation in younger and aged persons there was only a slight difference in the Bax/Mcl1 ratio in the elderly, whereas Mcl1 expression was increased relative to Bax in neutrophils from younger individuals. These findings indicate an important role of Bax and Mcl1 in the survival of neutrophils mediated by GM-CSF. The Janus tyrosine kinase (Jak)2-signal transducer and activator of transcription (Stat)5 signal transduction pathway is also modulated in elderly persons [44, 56]. Since Jak2 is related to the expression of antiapoptotic Bcl-2 there might be a possible link between Jak2 and Mcl1 being involved in the decreased rescue of neutrophils from apoptosis (Fig. 2) [56]. Larbi et al. [43] presented evidence that a modulation in the p42/p44 (ERK1/2) mitogen activated protein kinase (MAPK) activation occurs in PMN of elderly subjects under GM-CSF stimulation and is in part responsible for the decreased apoptotic decline of PMN in the elderly. This might be the reason why GM-CSF was not able to down-regu-

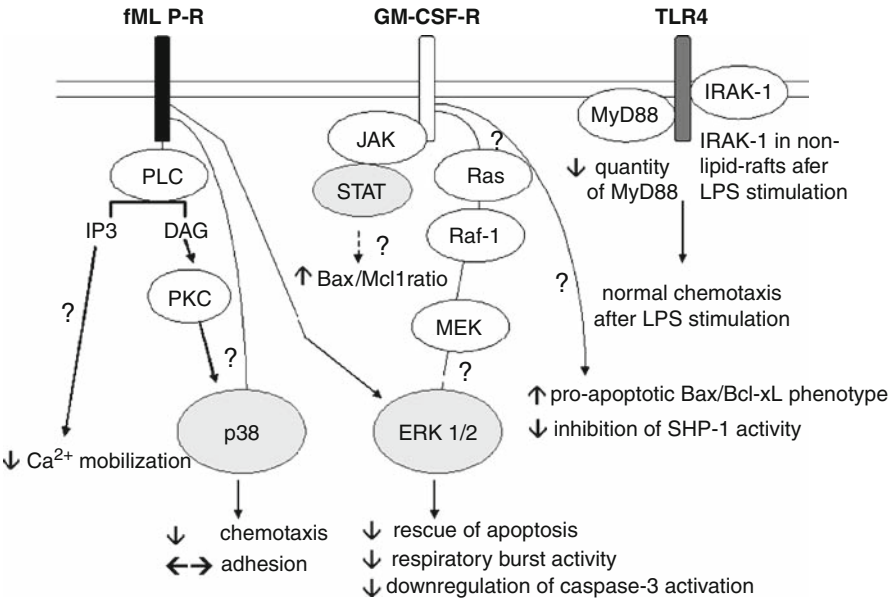

Fig. 2 Signaling in neutrophils of the elderly
Age-related impairment in intracellular signaling after binding of the appropriate ligands to their receptors leading to altered functions of neutrophils. Question marks display defects in different signal pathways associated with age (modified and adapted from Fulop et al. [56]). PLC, phospholipase C; DAG, diacylglycerol; IP3, inositol triphosphate; MEK, MAPK (mitogen-activated protein kinase)/ERK kinase; PKC, protein kinase C.

late caspase-3 activation in neutrophils of elderly persons. Interestingly, the authors observed that GM-CSF changed the proapoptotic phenotype to an antiapoptotic phenotype by alteration of the bcl-2 family members Bax and Bcl-xL in young neutrophils in an MAPK independent way whereas this could not be seen in aged neutrophils [43]. Taken together, these modulations might be responsible for the creation of a proapoptotic environment and could explain the increased incidence of infections in the elderly (Figs. 1, 2).

6 Signal Transduction

Activation of the fMLP receptor via phospholipase C (PLC) leads to the production of diacylglycerol (DAG) and inositolphosphate 3 (IP3), the latter initiates the enhancement of intracellular Ca^{2+}. DAG induces the membrane translocation of protein kinase C (PKC) and phosphorylation of MAPK family members. Intracellular Ca^{2+} is decreased in stimulated neutrophils from elderly persons (Fig. 2), suggesting that there is an impairment in Ca^{2+} flux during cell signaling [53, 56–59]. Interestingly, resting neutrophils of elderly subjects show an enhanced level of intracel-

lular Ca^{2+} [32, 57, 60]. Preactivation, modulation of the aged plasma membrane followed by altered receptor and adapter protein linkage and defects in the early phase of signal transduction might lead to the impairment of Ca^{2+} mobilization of aged neutrophils after fMLP stimulation. By investigating the impaired Ca^{2+} mobilization in aged neutrophils, Klut et al. [61] found heterogeneity of the examined neutrophils concerning time and magnitude of the response. A reduced number of neutrophils in the elderly were able to generate an effective reaction, hinting at a possible subpopulation [61].

After fMLP stimulation, PKC might also activate the p38 signal pathway, which is involved in regulating gene transcription, chemotaxis and adhesion. The ERK1/2 signal pathway is also triggered after fMLP stimulation playing a role in adhesion and respiratory burst activity. Defects in the signal cascades of both pathways and the decrease in activation and phosphorylation levels of p38 and ERK1/2 MAPKs are suggested to affect impaired neutrophilic functions in the elderly (Fig. 2) [56].

GM-CSF is able to activate the JAK/STAT pathway, the Ras-Raf-1-MEK-ERK1/2 pathway and phosphatidyl-inositol 3 kinase (PI-3K) triggered signaling [56]. Investigating the role of protein tyrosine phosphatases (PTP), especially Src homology domain-containing protein tyrosine phosphatase-1 (SHP-1), Fortin et al. [62] suggested a differential effect of GM-CSF on phosphatase activity in modulating neutrophil functions with aging. SHP-1 is a negative regulator of signal transduction and can negatively regulate Src kinases, such as the Jak or Lyn kinase, elicited by GM-CSF in PMN. When recruited to the plasma membrane and activated, SHP-1 dephosphorylates proteins activated by receptors, and inhibits cell activation. The authors could show that SHP-1 phosphatase activity cannot be down-regulated after short stimulation with GM-CSF in the neutrophils of the elderly persons in contrast to neutrophils of young. In lipid rafts from neutrophils of elderly, SHP-1 is continuously present, whereas in the neutrophils of young donors, SHP-1 is rapidly dissociated after stimulation by GM-CSF and is recruited back during a longer period of stimulation. In contrast to younger persons, SHP-1 is constantly recruited to Lyn, which cannot be relieved by GM-CSF. These modulations together with the above-mentioned changes in the Jak2-Stat5 and ERK1/2 signal pathways might contribute to the decreased GM-CSF effects on neutrophils [62]. Fig. 2 summarizes the effects of aging in signal transduction.

7 Adhesion, Surface Molecules and Receptors

After receiving a chemotactic signal, the rolling neutrophil adheres via integin molecules to endothelial cells and migrates through the endothelium (diapedesis) towards the site of infection. Adhesion appears not to be impaired in the elderly. After stimulation with fMLP, zymosan, phorbol myristate acetate (PMA), or calcium ionophores, human neutrophils from young and elderly persons displayed no difference in adhesion to plastic, gelatin, and bovine aortic endothelium [37, 44].

Additionally, a normal or enhanced adherence of neutrophils to endothelia or thrombocytes has been described, but it is not clear whether this has an effect on increased tissue migration in vivo. One might argue that increased adherence is caused by slightly enhanced expression of CD15 (Lewis X) and CD11b (Mac-1, complement receptor 3) on neutrophils [31]. In contrary, no increase of CD11b and CD15 but a decrease of CD62L (L-selectin) was observed by others [33, 63]. Interestingly, the expression of the other two integrins, CD11a (leukocyte function antigen, LFA-1) and CD11c (p150, 95) involved in cell adhesion, is not affected [22, 23, 31, 33].

De Martinis et al. [64] compared the expression of CD50 (ICAM-3; a ligand for CD11a/CD18) and CD62L adhesion molecules in peripheral blood granulocytes and monocytes between healthy elderly and young persons. They found a decrease in the percentage of granulocytes and monocytes expressing CD62L in the elderly but no alteration in the density expression on both cell types suggesting a preactivation which might contribute to the proinflammatory status in aging. The authors described a downregulation of the density expression of CD50 at a per cell level on granulocytes and a decrease of CD50 density expression on monocytes but an expansion of CD50 positive cells in elderly persons. This indicates that the loss of CD62L on granulocytes leads to impairment in cell adhesion and likely contributes to the enhanced susceptibility to acute infections in elderly persons.

Noble et al. [65] observed a significantly lower recruitment of early activation marker CD69 from the vesicles to the plasma membrane after stimulation with PMA in elderly people (fulfilling the SENIEUR criteria) than in younger persons. fMLP in contrast had no influence in different expression of CD69 in young and elderly persons, suggesting again the impairment of distinct pathways within aging. Interestingly, also the CD69 expression in natural killer (NK) cells is decreased [66].

There is growing evidence that aging is accompanied by changes in receptor signaling pathways and membrane fluidity [22, 24, 37, 43, 56, 62]. In contrast to other cells the fluidity of the PMN membrane increases with age, caused by alterations in the cholesterol/phospholipid content of the membrane [56, 67, 68]. These modulations result in changed function of lipid rafts, which directly influence TLRs and GM-CSF signaling. Additionally actin, which may play a role in cell-surface receptor movement and expression, has been indicated to contribute to the changed ROS production [69]. In summary, these alterations in signaling may impair the effector functions of neutrophils in aging.

After stimulation, the fMLP receptor which is coupled to a Pertussis toxin-sensitive G protein induces the production of superoxide anion, hydrogen peroxide, nitrite oxide (NO) and an increase in intracellular free calcium. The influence of aging on the release of free radicals has been investigated by different laboratories for a long period of time (reviewed by Ref. 24). Some investigators reported a decreased synthesis of free radicals by neutrophils of elderly persons, but found no change in the expression of fMLP receptor number, [37, 38, 56] whereas others could not confirm those data [22]. A recent study by Fulop et al. [56] examining

neutrophils isolated from young and aged persons who met criteria defined by the SENIEUR protocol, showed a significantly lower production of superoxide anion under fMLP stimulation and/or GM-CSF priming in PMN from elderly persons compared with younger ones. Fulop et al. [56] postulate the existence of a subpopulation of neutrophils in aged persons, which seems to be responsible for a significantly higher superoxide anion production after 48 h when compared with younger PMN, although they found a reduced superoxide anion production after 24 h stimulation with fMLP and GM-CSF in elderly persons. The authors suggest that PMN from elderly persons might act heterogeneously to down-regulate responses to stimulation than PMN from younger persons, which react more efficiently.

Toll-like receptors belong to the family of pattern recognition receptors and have a specificity to bind substances consisting of conserved motifs of bacteria, fungi and virus. To date, ten different human TLR have been identified, including three intracellularly located types. After ligand binding, the central adapter molecule, myeloid differentiation primary response protein 88 (MyD88), transduces signals into the cell by recruiting a cascade of serine–threonine kinases and IL-1 receptor-associated protein kinases (IRAKs), leading to nuclear factor kappa B (NF-kB)-dependent transcription of proinflammatory genes. Although there is a MyD88 independent way, stimulation via TLR leads to the release of pro-inflammatory cytokines such as interleukin-1, IL-6 or TNF-α. The additional production of chemokines and upregulation of surface molecules through TLR signaling build a bridge between innate and adaptive immune responses. Few reports about the influence of age on TLR exist at present. Renshaw et al. [70] described that LPS (ligand for TLR4, gram- bacteria)-stimulated macrophages from aged mice synthesize less IL-6 and TNF-α than younger ones. This study was confirmed by Boehmer [71]. Additionally, a lower TLR4 mRNA level compared with those of younger macrophages was found in aged macrophages by Renshaw et al. [70, 71], whereas others did not observe a variation in TLR4 surface expression with age. These results are not compatible with the situation in elderly human beings where elevated levels of circulating proinflammatory cytokines are generally observed; especially since elderly monocytes after LPS stimulation produce significantly higher amounts of IL-6 and TNF-α [24, 72, 73].

By studying the expression of TLR2 (ligand: components of gram+ bacteria) and TLR4, Fulop et al. [56] did not observe any changes in the proportion of neutrophils expressing TLR2/4 nor in the expression of both receptors on the surface of neutrophils. They also observed no differences of fMLP and GM-CSF receptor expression with aging [56]. What they found was an increase of TLR4 expression in unstimulated raft and nonraft fractions and no redistribution after LPS stimulation in elderly persons in contrast to younger individuals.

Although the TLR2 and TLR4 expression remains unchanged, one key component of the TLR signaling, IRAK-1, was not found to be associated with lipid-rafts after stimulation with LPS. Additionally, the main adapter protein of the TLR signal pathway, MyD88, was significantly reduced in the plasma membrane of elderly persons (Fig. 2). These observations confirm the thesis that age-related

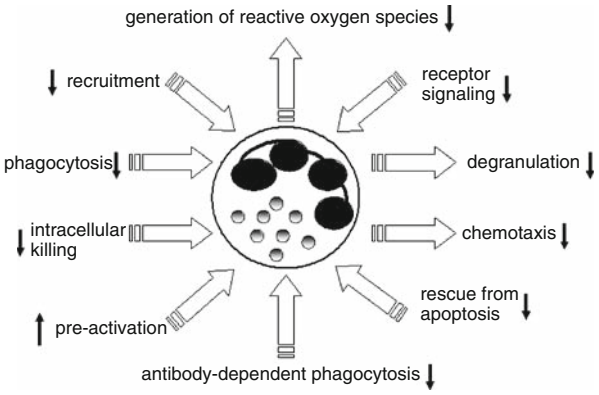

Fig. 3 Overview of impaired neutrophilic functions with aging

alterations influence receptor-driven signal transduction but do not explain normal LPS mediated chemotaxis of neutrophils of elderly persons. One might speculate that other signal pathways are involved or a nonreceptor-driven function of LPS might exist [56, 72].

The views regarding the importance of neutrophils in immune responses have been changed over the past few years. In immunogerontological studies, contradictory data may result from different isolation techniques of neutrophils, distinct amounts of contaminating cells, preactivation of neutrophils during isolation, and selection criteria of aged persons.

Taken together, the neutrophils are also affected through aging. The changes are found in decreased chemotactic functions which may be associated with the loss of CD62L. Therefore, CD62L-mediated migration might be hampered and this might lead to increased infection. The shedding of CD62L from the cell surface of neutrophils is also a sign of preactivation as postulated by other groups [17, 18] and conforms well to the observation of enhanced Ca^{2+} flux in elderly persons. Yet, one has to be cautious with regards to the purification process of neutrophils since some substances may cause a decrease in CD62L expression [12, 13, 24]. With the exception of CD62L, CD50 and CD16 other surface molecules such as CD11a, b, c/CD18 were not found to be modulated in aged persons when compared to younger individuals. Recent publications indicate a decline in signal transduction as being responsible for receptor-mediated responses and apoptotic rescue mechanisms. Additionally, altered plasma membrane content and fluidity of neutrophils in the elderly appear to influence signal transduction. It should be pointed out that different PMN isolation techniques and monocyte contaminations cannot be excluded as a possible explanation for the controversial results published by distinct groups of investigators [24]. The importance of purity and preactivation of PMN preparations in defining and differentiating PMN signals from those by others could be demonstrated recently [13, 14]. By investigating cytokine production of neutrophils in the elderly, one must also take into account that aged monocytes produce significantly more proinflammatory cytokines after stimulation than those of younger persons [72, 74].

Table 1 Age-related changes of neutrophils

Parameter/function	Stimulants/targets	Reported effect
Number of circulating neutrophils		←→19, 20 ↑21
Number of precursors in bone marrow		←→19
Proliferation of neutrophilic precursors in response to	G-CSF	↓19
	IL-3	←→19
	GM-CSF	←→19
Phagocytosis	Opsonized bacteria, yeast	↓29–33
	Antibody-dependent CD16-mediated	↓33
Respiratory burst	fMLP	↓ 35–38←→ 22, 23
	GM-CSF, LPS	↓39, 40
	Gram positive bacteria	↓32, 48
	Gram negative bacteria	←→32
Degranulation	fMLP	↓31, 38
Chemotaxis	fMLP, GM-CSF, LPS	↓32, 48–50←→22, 23, 34
Intracellular killing	Gram negative bacteria, fungi	↓39, 44
Adhesion	Endothelia, thrombocytes	←→37↗31
	CD11a-c/CD18	←→33, 63, 65↗31 (CD11b)
	CD15	←→63↗31
	CD50	↘64
	CD62L	↓64
Apoptosis		←→51, 52↗53
rescue by	IL-2, LPS, G-CSF, GM-CSF	↓51, 53
CD95 induced apoptosis; expression of CD95		←→54
down-regulation of caspase-3 activity	GM-CSF	↓43
Bax/Mcl1	GM-CSF	↑55, 56
Antiapoptotic phenotype	GM-CSF	↓43
inhibition SHP-1 activity	GM-CSF	↓62
Jak2-Stat5 pathway	GM-CSF	↓56
Signal transduction		↗42, 56
intracellular Ca^{2+} level		↑32, 57, 60
intracellular Ca^{2+} mobilization	fMLP	↓57–59
ERK1/2 MAPK pathway	GM-CSF	↓42
p38 MAPK pathway	GM-CSF	←→42, 43
plasma membrane fluidity	Receptor signaling in relation with lipid rafts	↓56, 67, 68
Expression of surface molecules		
	CD69	↓65
	fMLP-R	←→ 37, 38, 53↘22
	GM-CSF-R	←→ 56
	TLR2, 4	←→ 56

↓, decreased; ↘, slightly decreased; ↑, increased; ↗, slightly increased; ←→, unchanged

8 Conclusions

Although neutrophilic counts are normal or slightly increased in aged persons compared to young individuals aging influences the functional properties of neutrophils. The changes affect phagocytosis in neutrophils from elderly subjects where significant reduction along with decreased antibody-dependent phagocytosis was observed. Also, the other toxic mechanisms to destroy pathogenic microorganisms such as ROS generation, degranulation and intracellular killing, are impaired by age. Studies of chemotaxis have shown contrary results, so it has to be clarified if migratory responses of neutrophils from healthy, elderly persons are in fact altered. The decline in functionality, impaired Ca^{2+} mobilization and delayed rescue from apoptosis during aging appear to arise from defects of several signaling pathways, altered plasma membrane components and modulated protein tyrosine phosphatase activity. The molecular mechanisms responsible for those alterations in signal transduction and why distinctive stimuli cause different effects are still poorly understood. Fig. 3 and Table 1 summarize the age-related changes in neutrophils.

Further research is required since neutrophils display more features than formerly assumed, it would spread light on the deficiencies that occur during the aging process and could be beneficial to the elderly in the future.

Signal Transduction Changes in fMLP, TLRs, TREM-1 and GM-CSF Receptors in PMN with Aging

Carl F. Fortin, Anis Larbi, Gilles Dupuis and Tamas Fulop

Abstract: It is well known that the immune response is decreased with aging leading to a higher susceptibility to infections, cancers and autoimmune disorders. The most widely studied alterations are relative to the adaptive immune response. Recently, the role of the innate immune response as first line of defence

against bacterial invasion and modulator of the adaptive immune response has been widely recognized. One of the most important cell components of the innate response is neutrophils. It is now accepted that neutrophil functions are changed with age however the degree of these changes is still debated. With aging there is an alteration of the receptor driven functions of human neutrophils, such as superoxide anion production, chemotaxis and apoptosis. One of the alterations underlying these functional changes is the decrease of the receptor signalling elicited by specific receptors. Alterations were also found in the neutrophil membrane lipid rafts. These alterations in neutrophils functions and signal transduction occurring with aging might contribute to the increased infections with aging.

1 Introduction

Neutrophils, also known as polymorphonuclear leukocytes (PMN), are the first cells to arrive at the site of an aggression (Medzhitov and Janeway, 2000). Their role is to eliminate the aggression in a non specific way to prevent ongoing tissue damage and in the mean time regulate and determine the adaptive immune response. They are very efficacious to combat the bacterial and fungal infections (Lehrer et al. 1988). The neutrophils are very short lived cells except if they receive a proinflammatory signal. These signals may prolong the survival of neutrophils to be more effective in eliminating pathogens. Neutrophil functions with aging are changing, mainly those of chemotaxis, free radical production and adherence. Most of these functions are mediated through the engagement of a receptor including formyl methionyl leucine peptide (fMLP), granulocyte macrophage colony stimulating factor (GM-CSF), interleukin-8 (IL-8) receptors (Fulop and Seres, 1994). Recently, novel class of receptors emerged and, they have profound impact on the functions of human PMN. Among them, the pattern recognition receptors (PRRs), including at least 10 toll like receptors (TLRs) which recognize conserved molecular structures, related mostly to pathogens, were described and extensively studied (Medzhitov 2001; Krishnana et al. 2007). Furthermore, the triggering receptor expressed on myeloid cells-1 (TREM-1) is a recent addition to the growing members of activating receptors that are members of the Ig superfamily and, is up-regulated at the surface of PMN and monocytes in infection and LPS-induced sepsis in mice (Bouchon et al. 2000; Bleharski et al. 2003; Gibot 2006). Over the past few years, it has been demonstrated that PMN-specific receptor-driven effector functions are altered with aging (Fulop et al. 1997; Varga et al. 1997; Fulop et al. 2004). One of the causes of these decreased functions could be the alteration of signalling with aging via various receptors of neutrophils (Fulop et al. 1985a,b; Vlahos and Matter, 1992; Wenisch et al. 2000; Lord et al. 2001; Schröder and Rink, 2003; Fulop et al. 2001; Biasi et al. 1996; Seres et al. 1993). This chapter will describe our present knowledge concerning the signal transduction pathways in neutrophils with aging elicited by fMLP, GM-CSF, TLR and TREM-1 ligands.

2 Neutrophil Function Changes with Aging

PMN are short-lived cells that play important roles in both host defence and acute inflammation. They represent the first line of defence against an assault. They are committed to die in circulation within 18 hours unless activated (Akgul et al. 2001). This activation results in the initiation of an inflammatory response leading to chemotaxis via adhesion to endothelial cells, migration and the development of effector functions such as free radical production (Babior 2000). The adhesion (Butcher et al. 2001) and migration (Biasi et al. 1996) functions of PMN were found unchanged with aging. Recent data on chemotaxis indicate a decrease during aging towards fMLP and GM-CSF as chemoattractants (Fulop et al. 2004). The inability of GM-CSF to prime PMN of elderly for superoxide anion production was also described (Seres et al. 1993). It is of note that the number of receptors involved in PMN chemotaxis has not been found to change with aging. We have demonstrated some time ago that the production of free radicals by PMN of elderly subjects was decreased under fMLP stimulation while the number of fMLP receptors did not change (Fulop et al. 1985a, 1989) and, this was also found by many laboratories (Braga et al. 1998; Biasi et al. 1996), while others found no changes (Lord et al. 2001). It is of note that the variations in PMN superoxide production with aging were dependent on the stimuli indicating different pathways of neutrophil activation. It was shown that gram positive pathogens induce a decreased production, while gram-negative ones induce no reduction (Wenisch et al. 2000). Insofar, these pathogens modulate PMN functions through different TLRs (Hayashi et al. 2003).Certain proinflammatory cytokines, or other molecules, were shown to prolong the life span and the functional survival of PMN (Whyte et al. 1999). Among these molecules are GM-CSF, LPS and IL-6. Other bacterial products such as fMLP, LPS, lipoteichoic acid modulate the effector functions of neutrophils. We and others have found that the PMN of elderly subjects can not be rescued from apoptosis by various agents known to be very effective for PMN of young subjects (Fulop et al. 1997; Tortorella et al. 1998, 2001).

Thus, we can hypothesize that alterations of the signal transduction pathways of the various receptors are involved in the altered neutrophil functions with aging (Fulop and Seres 1994; Fulop et al. 2001). This altered signal transduction can be related to changes in the physico-chemical properties of the PMN membrane with ageing determining its fluidity. It has been shown that changes in membrane fluidity affect PMN functions, such as chemotaxis, superoxide anion production (Yuli 1982; Alvarez et 2001). An age-dependent decrease in plasma membrane fluidity has been shown in various cell types (Rivnay et al. 1980; Shinitzki 1987) including T-lymphocytes (Larbi 2004a,b), whereas in neutrophils an increase was observed in the membrane fluidity (Fulop et al. 2004). These data suggest that either of these changes in membrane fluidity with aging could be deleterious for cellular functions. It should be remembered that PMN are very short lived cells in contrast to all the others studied, explaining the differential changes of membrane fluidity with aging. Very recently, the presence of lipid rafts in PMN cell membrane has been

described and an important role in PMN signal transduction has been suggested for them (Kandzelskii et al. 2004; Sitrin 2004; Fortin 2007b, c). Changes in membrane fluidity will affect the function of lipid rafts (Simons and Ehehalt 2002; Simons and Ilkonen 1997), which are special membrane microdomains for signalling that are playing an important role in cellular functions, including chemotaxis (Ibanez 2004). Thus, age-related changes in the cell membrane affect the membrane properties, which in turn determine the signal transduction leading to altered effector functions, such as chemotaxis, superoxide anion production and apoptosis. This might influence the sequence of all the other effector functions of PMN with aging. We will review herein some specific receptor signalling changes with aging.

3 Signal Transduction Changes and Lipid Rafts in Neutrophils in Relation to fMLP, GM-CSF and Toll-like Receptors with Ageing

There are rather few data concerning the signal transduction in PMN with aging as compared to those in T-lymphocytes (Larbi et al. 2004a). Nevertheless, accumulating data suggest that aging cause alterations of specific receptor signalling pathways in PMN (Fulop and Seres 1994; Fulop et al. 2004; Lord et al. 2001; Schröder and Rink 2003; Tortorella et al. 2007). The recent description of lipid rafts in PMN membrane will also rapidly improve our understanding on PMN signalling pathways and permit their extension to a better investigation of the PMN signal transduction with aging.

3.1 fMLP Receptor

Formyl peptides engage receptors that belong to the seven transmembrane G protein-coupled receptor (GPCR) family and trigger neutrophil responses, i.e., chemotaxis, up-regulation of surface receptors, release of proteolytic enzymes from granules and, ROS production (Varga et al. 1988; Mcleish et al. 1989; Varga et al. 1989; Rabiet et al. 2007). These responses are largely inhibited by Bordetella pertussis toxin, indicating that signal transduction is dependent on a heterotrimeric G protein of the Gi type. We will review current knowledge about the peptide-induced activation of chemoattractant receptors and their regulation, with special emphasis on the human formyl peptide receptor family (FPR, FPRL1, and FPRL2). Upon chemoattractant binding, receptors undergo a conformational change that enables them to interact with the Gi2 protein thereby triggering both the exchange of GDP to GTP in the G protein α subunit and, the dissociation of the $\beta\gamma$ complex from the α subunit (Gierschik et al. 1989). Following its dissociation from the α subunit, the G protein $\beta\gamma$ subunits activate the phospholipase Cβ2 (PLCβ2) (Camps et al. 1992) and the phosphoinositide 3-kinase γ (PI3Kγ) (Stoyanov et al. 1995). PI3Kγ

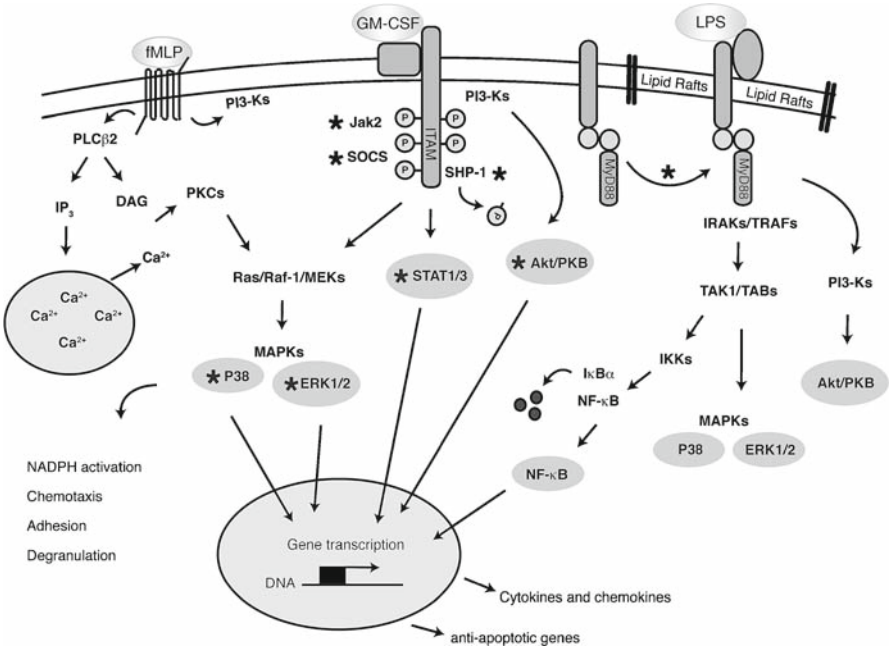

Fig. 1 Alterations in the receptor-mediated signal transduction in human neutrophils with aging. In neutrophils, fMLPR engagement leads to activation of PI3-K and PLCγ2, this in turn leads to the production of DAG and the influx of Ca^{2+} to the cytosol where they activate the PKCs. The PKCs activate the downstream MAPKs P38 and ERK1/2 through Ras. The ligand of GM-CSFR, for its part, induces the phosphorylation of residues in the ITAM of the common β-chain These events will induce the recruitment of various signalling molecules to the GM-CSFR and, will lead to the activation of the MAPKs P38 and ERK1/2, the Jak2-STAT1/3 and the PI3-K-Akt/PKB signalling pathway. The down-regulation of the GM-CSFR is mediated by phosphatases, like SHP-1, that removes phospho-groups on the ITAM, or the SOCS family of protein, which bind Jak2 and other activating upstream kinases thereby impeding the recruitment of signalling molecules on the receptor. Upon engagement, TLR4 is recruited into lipid rafts and, with the accessory molecule MyD88, leads to the activation of the MAPKs P38 and ERK1/2 and the transcription factor NF-κB through the IRAK/TRAFs and TAK1/TABs complexes. It also activates the PI3-K-Akt/PKB pathway through largely unknown mechanisms. The downstream kinases and the transcription factors elicited by these receptors mediate, in the cytosol and in the nucleus, the functional responses of human neutrophils such as respiratory burst, chemotaxis, degranulation and production of cytokines and chemokines. The asterisks indicate impairment that have been found in the signalling pathways of these receptor with aging in human neutrophils. One can appreciate the work that remains to be done as the absence of asterisk indicates that potential alterations were not studied in the elderly for these signalling molecules

converts the membrane phosphatidylinositol-4,5-bisphosphate (PIP_2) into phosphatidylinositol-3,4,5-trisphosphate (PIP_3) which is required for both the directed migration of neutrophils in a gradient of fMLP and the generation of superoxide mediated by the stimulation of chemoattractant receptors. The activation of PLCβ2, which induces the production of IP_3, leads to an increase of intracellular free calcium and of DAG, which result in the translocation of PKC to the membrane and,

leading to the phosphorylation of members of the MAPK family (Chang and Wang 1999). Neutrophils express the classical PKC isoforms (α, βI, and βII), the novel PKC isoforms δ and the atypical PKC isoforms ζ. The activation of PKC isoforms play a role in the regulation of NADPH oxidase activity. The extracellular signal-regulated kinases (ERK1/2) and the stress-activated p38 MAP kinase are activated by chemoattractants in neutrophils. These two signalling pathways are thought to participate at different degrees in adherence, chemotaxis and superoxide production. PLA_2-α is phosphorylated by MAP kinases and is translocated to the plasma membrane in a calcium-dependent manner where it produces free fatty acids and lysophospholipids.

Stimulation of the cells by fMLP induces, via the production of IP_3 and the opening of calcium channels in the membrane, an increase in intracellular free calcium. This increase is normally very rapid and returns to the prestimulation level relatively quickly. There is a slight difference between young and elderly subjects in the intracellular free calcium kinetics stimulated by fMLP in PMN (Biasi et al. 1996). The amount of the intracellular free calcium inside the cells is higher under fMLP stimulation in PMN of young than elderly subjects, while it was higher in the PMN of elderly at unstimulated status (Fulop and Seres 1994). This indicates a slight activation status of PMN with aging due to the low grade inflammation occurring with physiological aging (Franceschi et al. 2000; Meyer et al. 1998). The return of the intracellular free calcium must be tightly regulated, because if it remains high this could lead to cell death via the activation of certain intracellular proteases such as calpains or endonucleases. These data indicate that aging is associated with a decrease in the early phase of signal transduction in PMN.

The induction of PKC via the ras pathway in turn induces the activation of MAPK family members when the PMN are stimulated by fMLP (Zu et al. 1998). MAPKs are a family of serine/threonine kinases that are activated by a cascade of protein kinase reactions (Kyriakis and Avrach 1996), which are not completely elucidated in human neutrophils, even after fMLP stimulation. In rat neutrophils the activation of Lyn is associated with binding to the Shc adaptor protein and allows the G protein-coupled receptors to modulate the activity of the Ras/ERK cascade (Chang and Wang 1999). Nevertheless, investigations of human neutrophils have suggested that p38 MAPK is involved in an intracellular cascade that regulates stress-activated signal transduction. The p38 MAPK can phosphorylate transcription factors, thereby regulating gene expression and, can also phosphorylate other proteins to stimulate NADPH oxidase activity, adhesion and chemotaxis (Kyriakis and Avreach 1996; Zu et al. 1998; Heuertz et al. 1999; Yagisawa et al. 1999; Chang and Wang 2000). fMLP has been shown to induce the activities of ERK1 and ERK2, thus playing a role in neutrophil adherence and respiratory burst activity as well as inducing p38 and contributing to chemotaxis and superoxide anion production (Zu et al. 1998). Recent data obtained in our laboratory (Larbi et al. 2005) indicate that aging is associated with a decrease of ERK and p38 tyrosine phosphorylation in PMN under fMLP stimulation, suggesting a decreased activity of these MAPKs. These alterations could explain the decrease found in effector functions of PMN with aging such as superoxide anion production, as well as chemotaxis. Altogether we assist to an alteration of the human fMLP receptor signalling with aging.

3.2 GM-CSF Receptor

GM-CSF is a powerful modulator of granulopoiesis and the priming of mature PMN to a second stimulation such as fMLP. GM-CSF is able to rescue PMN from apoptosis by interacting with its specific receptor on the PMN plasma membrane. The receptor for GM-CSF is a member of the superfamily of cytokine receptors (Miyajima et al. 1992). Its structure consists of a receptor-specific α subunit and a β subunit (βc) that is shared by the receptors for IL-3 and IL-5 (Miyajima et al. 1993). Although the GM-CSF receptor is not endowed with intrinsic protein kinase activity, its occupation triggers the phosphorylation of its βc subunit on tyrosine residues, most probably by Jak2 (Quelle et al. 1994) and, the phosphorylation of a host of cytoplasmic proteins on tyrosine residues, the expression of early response genes and the proliferation of hematopoietic cells. GM-CSF has been shown to activate three distinct pathways in various cells: 1. the JAK/STAT pathway, 2. the Ras-Raf-1-MEK-MAP kinase pathway and, 3. the PI3-kinase intracellular signalling events (Sato et al. 1993; Watanabe et al. 1997). Recently, the MAPK and PI3K pathways were suggested to be involved with the GM-CSF antiapoptotic effect in PMN (Klein et al. 2000). These signalling pathways modulate the executioner phase of apoptosis, mediated by a family of cysteine proteases, the caspases, as well as members of the bcl-2 family, which are key players in the regulation of apoptosis.

Our recent studies suggest that aging is accompanied by a decrease in GM-CSF-signal transduction (Fortin et al. 2007a). PMN functions were shown to decrease with aging, as well as the antiapoptotic effect of GM-CSF (Fulop et al. 2004). Thus, we also investigated whether the Jak/STAT pathway in PMN under GM-CSF stimulation could be altered with aging. We have demonstrated that activation of the Jak/STAT pathway is altered in PMN of elderly subjects under GM-CSF stimulation. Neither short, nor sustained phosphorylation of Jak2 could be demonstrated and this inability of GM-CSF to induce Jak2 activation was translated in the decreased activation of STAT3 and STAT5. Moreover, the density of GM-CSF receptor β subunit did not change with age. The unchanged βc-subunit expression would assure an equal possibility of signalling in PMN of young and elderly subjects. This is supported by the fact that the physical association between the GM-CSF receptor β subunit and Jak2 did not change neither with aging, nor with GM-CSF stimulation. One other explanation could be an alteration in the membrane composition rendering difficult the mobility of the receptors to facilitate the phosphorylation of Jak2 (Fulop et al. 2004). Recently, the presence of lipid rafts in the cell membrane of PMN was demonstrated (Sitrin et al. 2004; Kindzelskii et al. 2004). These lipid rafts are privileged microdomains in the membrane enriched in cholesterol, sphyngolipids and various proteins, such as signalling proteins (Simons and Ikonen 1997). We found with aging a significant alteration in the composition and properties of lipid rafts of T-cells (Larbi et al. 2004a). In PMN, our group showed in a recent paper an over activation of the protein tyrosine phosphatase SHP-1, a negative regulator of signal transduction, in the lipid rafts with aging. This over activation caused the defects in the activation of the Src Kinase Lyn and contributed to the impaired functions of PMN with aging (Fortin et al. 2006). Moreover, an over activation or a deregu-

lated termination of Jak2 negative regulators, including SOCS, with aging cannot be ruled out and is currently under investigation by, among others, the group of Tortorella (2007). They demonstrated that both SOCS1 and SOCS3 levels were significantly higher in unstimulated neutrophils from elderly individuals than in their younger counterparts and, unlike the neutrophils of young subjects, they did not further increase following GM-CSF stimulation. As a result, a more effective SOCS1 and SOCS3 binding to either the GM-CSF receptor or Jak2, which would largely account for the GM-CSF dependent defect of PI3-K/Akt/ERK activation, might occur in senescent neutrophils. This finding is in line with recent demonstration of elevated SOCS3 levels in resting lymphocytes from elderly donors. Therefore, the increase in this class of inhibitory molecules may be considered as a general phenomenon associated with aging (Tortorella et al. 2007).

We also investigated whether this alteration in the activation of the Jak/STAT signalling pathway could be linked to the decreased antiapoptotic effect of GM-CSF in PMN of elderly subjects. We found that GM-CSF was unable to modulate the Caspase-3 activity in the elderly subjects (Fortin et al. 2007a). Moreover, our results show that AG490 could not modulate the already decreased anti-apoptotic effect of GM-CSF. It is difficult to determine what the exact contribution of the Jak/STAT pathway is, but these results indicate that it plays an important role in the GM-CSF failure to rescue PMN of elderly subjects from apoptosis. Thus, PMN of elderly subjects seem to be in a dominant negative status leading to a decreased response to GM-CSF. This also precludes that if the Jak2 activation is decreased, other downstream signalling pathways could be also altered, such as the PI3-kinase pathway (our unpublished results and Tortorella et al. 2007). Thus, Jak2 might play an upstream and essential role in the signalling cascade to provide survival signal to STATs and other signalling pathways.

PI3-K and the downstream serine/threonine kinase Akt/protein kinase B (Akt/PKB) have a central role in modulating neutrophil respiratory burst activation, chemotaxis and apoptosis. Tortorella et al. (2007) studied the functional activity of the neutrophil PI3-K/Akt pathway in the elderly and found, similarly to the ERK1/2, higher baseline levels of phosphorylated Akt forms and lower GM-CSF-induced phosphorylation of Akt with respect to younger subjects. The link once more between these signalling alterations and the age-related inability of GM-CSF to prolong neutrophil survival emerged from observations using various pharmacological inhibitors such as PD98059, LY294002 or wortmannin. These alterations in the PI3-K/Akt pathways could explain the alterations in the MAPK ERK1/2 activation, as they seem to be activated in succession. In fact, others and we have showed significant alterations in the GM-CSF induced ERK1 and ERK2 tyrosine phosphorylation and, even a higher decrease in ERK1/2 activation with respect to baseline in PMN from elderly subjects compared to young subjects (Larbi et al. 2005). The p38 MAPK pathway was also found altered in PMN from elderly under GM-CSF activation (Larbi et al. 2005).

It is of note that bypassing the GM-CSF receptor by direct inhibition of Caspase-3 was able to rescue PMN from apoptosis in both groups of age (Fortin et al. 2007a). This further indicates that the GM-CSF inability to rescue PMN of elderly

from apoptosis is linked, in part, to the alteration of the signalling pathway that leads from GM-CSFR to Caspase-3. However, it is not the sole factor as there is a significant fraction of residual procaspase-3 in the PMN of the elderly donors after 18h of culture. Moreover, after 18h of culture with GM-CSF there is even a larger fraction of inactive procaspase-3 in the elderly. These results would be surprising if the inhibition of Jak2 by AG490 did resulted in a complete cleavage of procaspase-3 in the elderly as it did in the young donors. We can only hypothesize that the inability of GM-CSF to rescue PMN of elderly from apoptosis is not mediated by the cleavage of procaspase-3 but rather by other mechanisms, especially as the Caspase-3 enzymatic activity has been found to be higher in this paper (Fortin et al. 2007a). Others mechanisms include an altered ratio of antiapoptotic vs. proapoptotic members of the Bcl-2 protein family, such as Bax, BclXL, Bad and A1 (Fulop et al. 2002; Fulop et al. 2004) and, deregulation of the activity of negative regulators of GM-CSF signal transduction like SHP-1 (Fortin et al. 2006). Supporting this notion, GM-CSF has been shown to up-regulate the expression of the antiapoptotic Mcl-1 (Moulding et al. 1998) while interferon-α/γ had similar surviving effects by increasing the expression of the cIAP2 protein (Sakamoto et al. 2005)**.** Moreover, the failure of GM-CSF to sustain STAT3 phosphorylation in the elderly may promote PMN apoptosis by not counteracting the proapoptotic effects of activated STAT1, as it is the case for Mel80 cells. Moreover, these observations in elderly subjects bear a resemblance to the phenomenon observed in T-cells. The T-cell receptor (TCR) signalling is altered leading to deficient proliferation with aging, while bypassing the TCR by PMA and Ca2+ ionophore stimulation restore their proliferative capacity. This could be of importance when we consider the increase of infections with aging and the modulation of PMN function might go through a nonspecific manner.

The Jak/STAT, PI3-K/Akt and MAPK pathways were found to be altered with aging in PMN upon GM-CSF receptor stimulation (Fortin et al. 2007a; Larbi et al. 2005; Tortorella et al. 2007). However, there is no decrease in the GM-CSFR number with aging. The primary alteration could be the Jak/STAT pathway as it seems to regulate all the others. Not only the positive signalling events but also the negative signalling events are altered under GM-CSF stimulation in PMN with aging. This leads to an altered functioning of the PMN with aging concerning apoptosis, chemotaxis and free radical productions.

3.3 Toll-like Receptors

Toll-like receptors (TLRs) are pattern recognition receptors that recognize conserved molecular patterns on microbes and link innate and adaptive immune systems. There exists actually of 10 different TLRs. Ligands for the TLR2 are gram-positive bacteria, while gram-negative bacterial product, LPS, is a ligand for TLR4 and, both of them are found on neutrophils (Remer et al. 2003; Kurt-Jones et al. 2002). The signalling pathways activated by TLRs are broadly classified into MyD88-depend-

ent and independent pathways (Takeda and Akira 2005) as MyD88 is the universal adapter protein recruited by all TLRs, except TLR3. The MyD88-independent pathway of TLR4 signalling is not used in human PMN (Tamassia et al. 2007). The major pathways activated by TLR engagement are using IκB kinase (IKK), MAPK and phosphatidylinositol 3-kinase (PI3-K)/Akt pathways. These pathways regulate the balance between cell viability and inflammation. There are currently four cytosolic adaptor proteins that are thought to play a crucial role in specificity of individual TLR-mediated signalling pathways. Amongst them, TLR4 signalling involves all four adapter proteins, MyD88 (myeloid differentiation primary response gene 88), MyD88 adapter like [MAL; also known as TIRAP (TIR domain-containing adapter protein)], TIR domain-containing adapter protein inducing IFN-β [TRIF; also known as TICAM1 (TIR domain-containing adapter molecule 1)], and TRIF-related adapter molecule [TRAM; also known as TICAM2 (TIR domain-containing adapter molecule 2)] (McGettrick and O'Neill, 2004). The differential recruitment of these adapter proteins by different TLRs form the basis for the specificity in the signalling process activated by them. However, the signal transduction pathway initiated by these interactions is mediated initially by an adaptor molecule, MyD88, recruiting various serine-threonine kinases, IRAKs and finally leading to NF-κB translocation (Kobayashi and Flavell 2004). Among IRAK family proteins IRAK-4 and IRAK-1 play major roles in signal transduction under LPS stimulation. This interaction ultimately results in the secretion of pro-inflammatory cytokines (Cloutier et al. 2007) that recruit the cells of adaptive immune response. That is why the function of TLRs is very important not only for an adequate innate, but also for the adaptive immune response. Moreover, there exists a synergy between TLR2 and GM-CSF receptors (Hayashi et al. 2003).

There exists almost no data concerning the TLRs receptor number and signal transduction in PMN in relation to aging. Renshaw et al. (2002) reported impaired TLR expression and function with aging in mice macrophages. A recent comprehensive evaluation of TLR function in monocytes from older adults was conducted using a multivariable mixed statistical model to account for covariates (van Duin and Shaw 2007). It found that cytokine production after TLR1/2 engagement, which is essential for the recognition of triacylated lipopeptides found in a variety of bacteria, is substantially lower in monocytes from older adults. The up-regulation of costimulatory proteins such as CD80, essential for optimal activation of T-cells, on monocytes from older adults was less for all TLR ligands tested than for cells from young individuals and, the extent of CD80 up-regulation predicted subsequent antibody response to influenza immunization. These and other consequences of aging on human TLR function may impair activation of the immune response and contribute to poorer vaccine responses and greater morbidity and mortality from infectious diseases in older adults. That is why we investigated the TLR4 and TLR2 receptor numbers on PMN of young and elderly subjects by flow cytometry. We found that there is no change in the percentage of PMN expressing TLR4 and TLR2 with aging. Similar results were obtained when we measured, by comparing the Mean Fluorescence Intensity (MFI), the amount of TLR4 or TLR2 receptors expressed by PMN in each age groups (Fulop et al. 2004). These results show that there is no change with aging in the expression of TLR2 and TLR4 receptors on PMN.

One other element, as mentioned above, which recently changed our comprehension of the signalling mechanism through the membrane is the existence of specific signalling microdomains in the membrane, called lipid rafts (Simon and Ilkonen 1997). These were demonstrated in numerous cells and recently in PMN too (Shao et al. 2003). These microdomains, enriched in sphyngolipids, cholesterol and signalling molecules either are parts of, or are recruited to the signalling complexes of the cell membrane. Presently, a few data exist in relation to aging on the existence of these lipid rafts in PMN membranes and how these lipid rafts could be structured and functioning (Fortin et al. 2006, 2007b, 2007c). Therefore, we also studied, whether the unchanged number of TLRs found by FACScan is reinforced by the study of the expression of TLR2 and TLR4 in the PMN membrane lipid rafts. We showed for the first time that LPS not only increases the expression of TLR4 in PMN of young subjects, but increases also its recruitment in the rafts and nonrafts fractions. In contrast, the expression of TLR4 in rafts and nonraft fractions were increased with aging already at the basal status compared to that of PMN of young subjects while no-redistribution occurred after LPS stimulation. It is of note that the apparent increase at basal status of TLR4 expression in the membrane of PMN of elderly could be in accordance with the slight stimulated status of PMN with aging, as already demonstrated (Fulop and Seres 1994). This is also in accordance with the low-grade inflammation present with aging as stated by the inflamm-aging theory of Franceschi et al. (2000). It is of note that no significant changes in TLR2 recruitment occurred in rafts and nonrafts fractions of PMN under LPS stimulation in either young subjects or elderly subjects. These results indicate that even if the number of receptors seems not to change with aging the differential recruitment between raft and nonraft fractions could induce an altered signalling of the receptors, mainly in case of TLR4 under LPS stimulation with aging.

We also studied the early signal transduction events elicited by LPS through the TLR4. The signal transduction of TLR4 under LPS stimulation is mediated at the early phases by MyD88 and IRAKs (Kobayashi and Flavell 2004). We studied the expression of MyD88 and IRAK-1 under LPS stimulation in membrane rafts and nonrafts fractions of PMN. MyD88 was evenly distributed before and after LPS stimulation in the rafts and nonrafts fractions of the membranes in young and elderly subjects. Thus, no differences in the MyD88 distribution could be found with aging, however the quantity of MyD88 in the membrane of PMN of elderly subjects was significantly decreased after stimulation (Fulop et al. 2004). MyD88 is an adaptor protein found very close to the membrane, which could explain that no change in its physical distribution can be observed under stimulation. In contrast, there is a recruitment of IRAK-1 molecules from nonrafts fractions to lipid rafts in PMN of young subjects under LPS stimulation while this recruitment is totally absent in PMN of elderly subjects. It is of note that IRAK-1 was already in the rafts fraction at basal status, in accordance with the slightly activated status of PMN with aging. All these results suggest an alteration in the signal transduction of TLR4 under LPS stimulation with aging either in the redistribution of IRAK-1 signalling protein among rafts and nonrafts fractions, or in the quantity of the MyD88 molecule between rafts and nonrafts fractions. These results provide evidence for a lipid rafts dependant activation of neutrophils via the Toll-like receptor pathway. However,

they cannot explain why the LPS was efficient for chemotaxis of PMN with aging. We can only speculate that either this function is mediated through different signalling pathway(s) or this is a nonreceptor dependent function of LPS, playing the role of a nonspecific chemoattractant.

Altogether, the studies on signal transduction pathways elicited by the stimulation of various PMN receptors suggest that there exists an altered signal transduction in PMN with aging. These alterations does not seem to arise from a change in the receptor number, but most probably from an alteration related to the cell membrane physico-chemical status with aging. We and others have found that the fluidity of PMN with aging, in contrast to other cells, is increasing due to the alteration in the membrane cholesterol/phospholipid composition (Yuli et al. 1982; Alvarez et al. 2001). The cholesterol content does not change while the phospholipid content is increasing. These changes affect the functionality of lipid rafts which are important microdomains for the receptor signalling, as was shown in the case of TLRs and GM-CSF receptors. A dysfunction of the signalling due to age-related changes in actin cytoskeleton function (Rao et al. 1992) has been also suggested to be a contributing factor. Ultimately these changes in signalling decrease the effectors functions of PMN with aging.

3.4 TREM-1

This receptor is a recent addition to the growing members of activating receptors that are members of the Ig superfamily and, is up-regulated at the surface of PMN and macrophages in infection and LPS-induced sepsis in mice (Bouchon et al. 2000). This family mediate their signal transduction with an adapter molecule, for TREM-1 the adapter is DAP12, to elicit a number of common signalling molecules (Bouchon et al. 2000; Klesney-Tait et al. 2006; Tessarz and Cerwenka 2007). Its ligand is still unknown, but the functional responses elicited by the engagement of TREM-1 on monocytes/macrophages and PMN is well known. TREM-1 triggers the release of cytokines and chemokines, ROS production, degranulation and phagocytosis (Bouchon et al. 2000; Bleharski et al. 2003; Radsak et al. 2004; Fortin et al. 2007b). Of note, stimulation of PMN with both TREM-1 and TLR ligands resulted in a synergistic effect on functional responses (Bleharski et al. 2003; Radsak et al. 2004; Fortin et al. 2007b) hence amplifying the inflammatory response and, suggesting potentially aggravating consequences in infections with aging. Inasmuch, our group recently found that TREM-1 and TLR4 colocalized in human PMN upon stimulation with LPS (Fortin et al. 2007b) and, silencing of TREM-1 in macrophages with siRNA resulted in down-regulation of key signalling molecules of the TLR4 pathway (Ornatowska et al. 2007). Thus, emerging data are showing an unsuspected link between the TLR4 and TREM-1 and, it is possible that multimeric complexes are responsible for the recognition of noncytokines mediators of inflammation such as the ligands of TREM-1 (Klesney-Tait and Colonna 2007). We have already evoke the possibilty of an innateosome, which would be responsible for the recognition of LPS and TREM-1 ligands in human PMN, when we showed that stimulation of

either receptors lead to the phosphorylation of IRAK1 and the colocalization at the membrane of TRL4 and TREM-1 (Fortin et al. 2007b). Furthermore, the importance of soluble TREM-1, the shedding of TREM-1 occurs in sepsis or with LPS stimulation of macrophages, in a clinical context it is established that this is a relevant marker for human sepsis and, the use of decoy TREM-1 with blocking ability favored a positive outcome of the resolution of sepsis (Gibot 2006).

So far, only our group studied the impact of aging on the TREM-1-induced functions on cells of the immune system. PMN from elderly donors were found to have impaired response following TREM-1 engagement (Fortin et al. 2007c). Notably, TREM-1 could not prime the production of ROS in the elderly as it did in the young donors and, altered signal transduction of downstream TREM-1-elicited molecules (Akt and PLCγ) was found. Of particular interest, TREM-1 engagement could not reverse PMN survival following incubation with LPS or GM-CSF in the elderly whereas it did in the young. This particular alteration in TREM-1 response could possibly be a contributing factor in the higher incidence of sepsis-related deaths in the elderly population as resolution of inflammation requires clearance of effectors cells. Finally, TREM-1 engagement could not drive the recruitment of TREM-1 in the lipid-rafts of the elderly explaining in part the altered response. Although data exist in human relative to the amount of soluble TREM-1 found in the plasma of patient with or without sepsis, the study was carried only for one age group (mean age 60 ± 15) (Gibot et al. 2004). In keeping with the contributions of TREM-1 in inflammation and the aforementioned alterations in the TEM-1-induced functions in the PMN of the elderly, it would be extremely interesting to have data on lethal outcome of sepsis vs. age of hospitalized patients.

4 Conclusion

PMN are very important part of the immune response towards invading organisms. They are the first line defence being part of the innate immune response and, are essential modulators of the adaptive immune response. It is well known that the incidence of infections is increasing with age. Decrease in specific receptor mediated functions including free radical production, chemotaxis and apoptosis/survival of PMN with aging resulting from an alteration of the positive and negative events in the signalling pathways have been recently demonstrated. These alterations might contribute to the increased incidence of infections with aging. However, these changes in neutrophil functions remain controversial with aging. Elucidation with more rigorous and sophisticated methods of PMN function alterations with aging is needed as these changes could have a great impact on the adaptive immune response. The recent demonstration of lipid rafts in PMN, as being fundamental platforms for signal transduction, will help to better understand the mechanism of age-related signalling changes. These changes should be also taken into account when tentative is made to increase the immune response of the elderly by immunomodulating agents for improving the quality of life of elderly persons.

Synergistic Effects of Ageing and Stress on Neutrophil Function

Janet M. Lord, Anna C. Phillips and Wiebke Arlt

Contents

Abstract: Although ageing is a complex process, we now know much of what happens with age at the cellular and tissue level. In contrast, our understanding of how the various age-related changes interact to result in frailty and pathology is incomplete. For example, ageing is accompanied by a loss of immune function (Immunesenescence), an increase in the level of circulating proinflammatory cytokines (Inflammaging), a decline in adrenal androgen production (Adrenopause) whilst concurrently peripheral glucocorticoid availability increases. In this article we propose that these changes in combination increase the susceptibility of older adults to the adverse effects of physical and emotional stress, exacerbating the age-related decline in immune competence and exposing the older individual to increased risk of infections. We have focused upon the effects of stress and ageing

on neutrophil function, an element of the immune system that has received less attention from immunogerontologists, despite the primary role of neutrophils in fighting bacterial infections and the major contribution of such infections to age-related morbidity and mortality. We propose that physical and emotional stressors elicit an exaggerated response in older adults that synergises with the age-related loss of neutrophil function, to compromise antibacterial mechanisms. Moreover, the molecular basis of this effect may lie with the significant changes in tissue concentrations of cortisol and dehydroepiandrosterone in peripheral target cells including the immune compartment.

1 Ageing, Stress and Infection

It is now well established that the efficiency of the immune system declines with age and this is highlighted most obviously at the functional level by the increased risk of morbidity and mortality from infection in older adults [1–3]. The three major causes of death in the UK in those aged over 65 are cardiovascular diseases, cancer and respiratory disease (Fig. 1). Approximately 1 in 6 older adults will die as a result of the latter, the majority succumbing to respiratory infections. Older adults show a three-fold greater incidence of bacterial dysentery than younger subjects, 50% higher mortality from gram-negative bacterial sepsis, and deaths from gastrointestinal infections, pneumonia and influenza are largely confined to patients over 65 years of age [4, 5]. Age-related reactivation of latent infections previously held in check by the immune system is a further indicator of the age-related decline in immune function (immunesenescence). Thus the incidence of tuberculosis is raised in the elderly, indicating reduced functioning of macrophages [6] and reduced T-lymphocyte function is reflected by reactivation of latent Herpes viruses such as Varicella Zoster (shingles) in older age [7]. Older adults are also at increased risk of postsurgical complications such as infections, which include infections at the wound site; but are dominated by bacterial chest and urinary tract infections [8]. Furthermore, delayed wound healing with age has particular relevance in the context of surgery and has underlying contributions from senescent fibroblasts as well as senescent immune

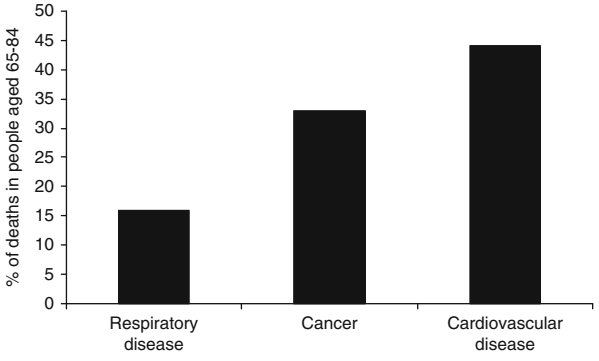

Fig. 1 The figure shows the major causes of death in adults aged 65-84 in the UK, (adapted from data presented in the House of Lords Science and Technology Committee 1st report on Ageing: Scientific Aspects, 2005, Figure 4, page 42)

cells which are key players in the wound healing response (9). The increased risk of infection following surgery may therefore reflect compromised immune and wound healing responses and underline the significant effect of physical stress upon immunity.

It is now well accepted that prolonged exposure to stress, whether psychosocial or physical, has detrimental effects upon immunity. Immune suppression associated with chronic stress has significant clinical consequences, including increased risk of illness and death from infectious disease [10, 11]. In the area of psychosocial stress there is now a solid literature showing reduced immunity, suboptimal responses to infectious agents and vaccines and increased susceptibility to infection in adults following bereavement [12–14] extended care-giving [15, 16], or low social support [10, 17–20]. In an elegant study by Cohen et al. [21] the effect of psychosocial stress on resistance to infection was clearly demonstrated. In this study almost 400 volunteers were exposed to five different respiratory viruses and incidence and severity of infection for each virus was found to be positively correlated with their scores on a psychological stress index. The reader is referred to a recent comprehensive review of this area by Kiecolt-Glaser and Glaser [22].

Moderate physical trauma is also a potent mediator of immune suppression, with 1 in 3 trauma patients succumbing to one or more infections [23]. An extensive retrospective analysis of infections in over 10,000 trauma patients revealed that 32% of patients developed respiratory tract infections and 17% had urinary tract infections [24]. In older adults the most frequent trauma results from falls leading to hip-fractures. Falls are the leading cause of admission into care homes and a frequent cause of death in the elderly population. Again, one of the major health risks associated with falls and hip-fracture is infection, such as osteomyelitis, respiratory infections and infections at the surgical wound site [24–26].

2 Ageing and Neutrophil Function

The high incidence of bacterial infections in older adults is particularly suggestive of a suboptimal neutrophil response, as these leucocytes form the primary response to bacterial, fungal and yeast infections. The preponderance of urinary tract infections in older adults would also support this conclusion. As the effect of ageing on neutrophil function is covered in detail elsewhere in this volume, this topic will be covered only briefly here to allow discussion of the combined effect of age and stress on neutrophil function.

Neutrophils are the dominant leucocyte in the circulation, making up 60% of the white cell count. They are also the shortest lived blood cell, dying by apoptosis approximately 24h after leaving the bone marrow [27, 28]. Their function can be enhanced by proinflammatory cytokines, such as GM-CSF, TNFα and Type 1 interferon, which not only amplify their basic bactericidal functions, such as generation of reactive oxygen species, but also extend their lifespan at sites of infection by inhibiting apoptosis [29, 30]. Neutrophils are recruited to sites of infection

via chemotactic signals, such as the chemokine CXCL8 (also known as IL8). Once in contact with the pathogen they uptake the microbe by phagocytosis mediated via opsonic receptors (CD11b/CD18, CD16, CD32, CD64) that detect complement proteins C3b and C3Bi or antibody coating the microbe. Once inside the neutrophil, pathogens are killed as a result of the generation of reactive oxygen and nitrogen species and the release of a range of proteolytic enzymes from cytoplasmic granules. Phagocytosis and generation of superoxide trigger the death of the neutrophil, which is then removed by macrophages leading to the resolution of inflammation [27].

Comparison of neutrophils from peripheral blood of healthy young and old adults has shown in a majority of studies that chemotaxis is not significantly affected by ageing, with adherence of neutrophils to endothelium [31, 32] and expression of adhesion molecules [31, 33] both unaltered with ageing. In contrast, bactericidal (superoxide generation and degranulation) and phagocytic function is dramatically reduced in neutrophils from older adults [34–37]. For superoxide generation, responses to the bacterial peptide fMLP and to gram-negative bacteria appear to be unaltered by ageing [31, 34, 38], whereas superoxide generation in response to a gram-positive stimulus such as *Staphylococcus aureus,* was significantly reduced in neutrophils from older donors [37]. The latter is of clinical importance bearing in mind the reduced ability of older adults to resolve infections with gram-positive bacteria [39]. The cause of reduced superoxide generation with age is not fully understood, though reduced signaling via calcium in activated neutrophils has been suggested [36] and reduced responsiveness to proinflammatory cytokines such as GM-CSF has also been shown [40, 41]. This is an important finding as cytokines such as GM-CSF prime neutrophil function leading to improved bactericidal responses to bacterial components such as fMLP. In addition, as stated above GM-CSF is also a potent neutrophil survival factor and reduced responsiveness to this cytokine would limit neutrophil lifespan extension at sites of inflammation.

Loss of phagocytic capacity has been investigated reasonably thoroughly. Neutrophils from older subjects retain their ability to phagocytose opsonized bacterial pathogens *per se*, but their phagocytic capacity (phagoctyic index, the number of microbes ingested per cell) is significantly compromised [34, 35, 42–44]. The level of expression of opsonic receptors is known to be a determinant of phagocytic capacity and our data showed a significant reduction in one of the cell surface opsonin receptors (CD16) that binds to antibody coating bacterial pathogens. Taken together these data indicate that neutrophils should be able to respond to chemotactic signals from a site of infection, but will then be severely compromised in their bactericidal function and also their ability to respond to local survival factors such as GM-CSF.

In addition to the obvious consequences of reduced neutrophil function for ability to combat bacterial infections, neutrophils also play a key role in wound healing. In response to tissue injury cytokines are released, including CXCL8, which attract neutrophils to the site. Neutrophils then aid resolution of the damage by removing microbial pathogens and restoring sterility, thus removing the inflammatory stimu-

lus. Whether neutrophils play a positive role in wound healing beyond clearance of pathogens is still a hotly debated topic. Neutrophils release cytokines important for revascularization and tissue repair, such as CXCL8 and VEGF [45], but this has to be balanced with their ability to produce tissue-damaging agents if they persist at a sterile wound site. Reduced phagocytosis of microbes will lead to persistence of inflammation and prevention of wound healing by the presence of high levels of inflammatory cytokines. Although this aspect of innate immunesenescence has received less attention, it is potentially a significant factor in the development and persistence of ulcerated wounds in the elderly.

3 Stress and Neutrophil Function

Stress, whether physical or psychological, is broadly sensed by 2 endocrine regulatory systems, the Hypothalamic-Pituitary-Adrenal (HPA) axis and the sympathetic-adrenal-medullary (SAM) system. Stress induces the release of catecholamines (adrenalin and noradrenalin) from the adrenal medulla and the sympathetic nervous system and, mediated via an increased pituitary ACTH secretion, results in an acute increase in cortisol and dehydroepiandrosterone (DHEA) release from the adrenal cortex. Catecholamines and cortisol are both immune suppressive [46, 47], whereas DHEA is a precursor to sex hormones and is generally thought to be immune enhancing [48–52], though evidence for the latter is less substantial due to lack of data generated in humans and human cell-based systems. In particular, all DHEA replacement studies in humans have been carried out in healthy older subjects only [53–55] and not under conditions of stress in which this hormone may play its vital role in counteracting the negative effects of cortisol (discussed below).

As the effects of stress on adaptive immune functions are dealt with separately in this volume, the focus here will be upon neutrophil function in response to stress.

3.1 Acute Stress

The impact of acute psychological stress on neutrophils has received little attention within the immune literature. In animals, acute psychological stress can be applied in a variety of ways including inescapable intermittent electric shock, overcrowding, or restraint in an enclosed space. Acute psychological stressors in humans usually involve brief laboratory-based tasks such as public speaking or mental arithmetic in front of an audience and/or under time pressure, or the cold-pressor test (submersion of the hand in ice-cold water), although some studies have used examination stress as a short-term stressor. Overall, the literature suggests that periods of acute stress have beneficial effects on neutrophil function. Mice that had received 2.5 hours of restraint stress showed increased infiltration of neutrophils into a surgically implanted sponge in comparison to unstressed control mice [57]. In addition, an

increase in neutrophil adhesion and aggregation has also been shown to be induced by short periods of inescapable foot shock in rats [58], an acute anticipatory stressor in healthy young adults [59, 60], and stroop and mirror tracing tasks in men aged 30–59 [61].

Acute stress has also been shown to modulate phagocytosis: periods of social conflict stress between mice for less than one day resulted in increased phagocytosis by neutrophils and other phagocytic cells in comparison to nonstressed mice [62]. When neutrophils are activated, they undergo a respiratory burst and produce toxic superoxides that kill the pathogens they have phagocytosed. In humans, a 15 minute time pressured stress task (Raven's Advanced Progressive Matrices) induced an immediate significant increase in the number of activated neutrophils relative to resting baseline and in comparison to a nonstressed control group. This increase in activation state had returned to baseline 10 minutes following the end of the stress task. A comparison of neutrophil function in students between final examination week and nonexamination weeks showed that the short-term stress of examinations was associated with an increase in neutrophil superoxide production [63, 64], and this increase was maintained at 2–3 weeks post examinations [63]. In rats, superoxide production was increased in response to 1 hour of open field stress [65]; and superoxide production at the site of inflammation following experimental *E.coli* injection was observed to be higher in rats previously exposed to inescapable tail shock in restraint tubes for two hours in comparison to non-stressed rats. In the latter study, stressed rats also showed a complete resolution of the inflammatory response to the infection two weeks faster than control nonstressed rats, potentially indicating a stress-induced elevation in neutrophil response resulting in more effective bactericidal activity [66]. This increase in neutrophil function parallels other acute stress induced changes in nonspecific immunity such as the increased production of secretory immunoglobulin A [67].

In summary, acute stress appears to have an overall positive impact upon neutrophil function, particularly when acute stress is applied in the context of an inflammatory challenge, although the mechanisms of such effects are unclear at present.

3.2 Chronic Stress

In contrast to acute stress, the effects of chronic exposure to stress are detrimental to immune function. A meta-analysis of thirty years literature on the effect of stress on the immune system concluded that chronic stress such as bereavement or physical trauma resulted in suppression of cellular and humoral immunity and increased susceptibility to infection [68]. As with acute stress there is very little information relating to neutrophil function and the research emphasis has been placed upon adaptive immune responses. However, chronic stress and depression in cancer patients is associated with neutrophilia, but also with decreased neutrophil phagocytic ability and raised cortisol levels [69]. Intense or long duration exercise is also associated with raised circulating cortisol and adrenalin, together with reduced neutrophil bac-

tericidal responses namely degranulation and superoxide generation [70]. Our own studies of the effect of physical stress (limb or hip-fracture) on neutrophil function confirmed a profound neutrophilia in response to stress, but also a significant suppression of superoxide generation in response to a bacterial peptide challenge which correlated with raised cortisol levels [71].

Glucocortoids are likely to be major mediators of the negative effects of chronic stress upon neutrophil biology and function [72]. For example, studies of the effects of cortisol infusions in humans have shown a profound neutrophilia, which is achieved in part by the inhibition of neutrophil apoptosis thus extending neutrophil lifespan in the circulation [73, 74]. Cortisol can also enhance G-CSF mediated stimulation of granulopoiesis in the bone marrow [75], further contributing to raised neutrophil numbers in response to cortisol. Unfortunately the potential benefit of an increased level of circulating neutrophils with raised cortisol is not realized, as cortisol also inhibits neutrophil chemotaxis and extravasation [76]. The clinical significance of this observation is seen in studies that reported reduced neutrophil chemotaxis in trauma patients and a strong correlation with increased incidence of infection [77, 78]. In vitro studies also suggest that the suppression of neutrophil superoxide generation after trauma is mediated by cortisol. We and others have shown that superoxide generation by cytokine-primed neutrophils in vitro was suppressed by cortisol [71, 79], though we found no effect of cortisol on phagocytic function (S.K. Butcher, unpublished data). Taken together these data indicate that raised cortisol levels will impact negatively upon neutrophil function, which could in turn increase susceptibility to bacterial infections.

The meta-analysis carried out by Segerstrom and Miller [68] also revealed that the loss of immunity in response to stress was much greater in older adults, which in turn concurs with reports of excess infection-related morbidity and mortality in older trauma patients [80–82]. Our own studies have compared responses to stress in young and old trauma patients and revealed that the detrimental effect of physical stress was most marked in older adults [71, 83], supporting an influence of age upon stress mediated suppression of neutrophil responses. That neutrophil function was affected by chronic stress in patients with cancer, an age-related disease, adds further weight to this proposal. Synergy between the effects of stress and immunesenescence on immune function, has also been proposed in relation to psychosocial stress and the immune system [22, 84] and there is now a real need to compare the differential effects of stress on a broad range of immune responses in young and old subjects.

4 Ageing and Stress Hormones

While cortisol secretion by the adrenocortical zona fasciculata appears to remain largely unchanged throughout life [85], adrenal dehydroepiandrosterone (DHEA) secretion from the adrenal zona reticularis exhibits a characteristic, age-associated pattern. Intraindividual maximum levels of DHEA and its sulphate ester DHEAS are

reached during early adulthood, followed by a steady decline throughout adult life, eventually decreasing to 10–20% of previous maximum levels by 70–80 years of age [86, 87]. This age-associated decline in DHEA synthesis has been termed "adrenopause", which is somewhat imprecise given that adrenocortical glucocorticoid and mineralocorticoid secretion is maintained without change across the lifespan. Interestingly, an age-associated secretion pattern of DHEA is only observed in humans and higher nonhuman primates [88, 89] and it is important to recognize that rodent adrenals are not capable of DHEA secretion, yielding only very low circulating DHEA concentrations of primarily gonadal origin, thereby limiting the suitability of rodents for studies on the significance of DHEA for human physiology and disease. Adrenopause is independent of menopause, and it occurs in both sexes; it shows high interindividual variability and has been suggested to be associated with a macroscopically visible decrease in size of the adrenal zona reticularis [90]. There is also a suggestion of an age related increase in senescent and apoptotic cells within the zona reticularis, though whether this contributes to loss of cells in this region of the adrenal cortex, or might influence functional activity of the zona reticularis cells, has not been established [91].

DHEA secretion exhibits a diurnal rhythm similar to that of cortisol and ongoing age has been shown to be associated with an attenuation of the diurnal rhythm and the pulse amplitude of DHEA secretion [92]. Furthermore, the adrenal stress response seems to be partially impaired with ageing, with a significant reduction of acute DHEA release following an acute exogenous ACTH challenge whilst the cortisol response remains intact [93]. In young healthy subjects it has been shown that an acute psychosocial stressor such as an arithmetic challenge or public speaking test results in an acute rise in cortisol [94], but neither the impact of this on DHEA release nor its modification in the aged has been investigated to date. We have recently shown that acute sepsis leads to an up-regulation of both cortisol and DHEA [95], however, comprehensive data on chronic exposure to physical or psychological stress are lacking.

Whilst cortisol mediates its action via the cytosolic glucocorticoid receptor that, once activated, translocates to the nucleus and initiates the transcription of glucocorticoid effector genes, the exact mechanisms underlying the actions of DHEA and its sulphate ester DHEAS still remain controversial. High affinity binding sites for DHEA have been described in murine and human T-lymphocytes [96, 97] and human vascular endothelial cells [98, 99], but their specificity as opposed to active androgens is still debated. DHEA has also been shown to have neurosteroidal properties and exerts stimulatory effects on NMDA receptors and inhibitory effects on $GABA_A$ receptors in the brain [87]. However, the current view is that the majority of its actions are mediated indirectly, via downstream conversion to sex steroids and other steroids of potentially distinct activity including the putatively immune modulatory steroids androstenediol, androstenetriol and 7α-OH-DHEA [100] (Fig. 2).

DHEA represents a paradigm for prereceptor metabolism as its action will mainly depend on the expression of enzymes responsible for its conversion to other steroids in the specific target cell of interest. Lymphocytes and macrophages have been shown previously to express steroidogenic enzymes involved in the downstream

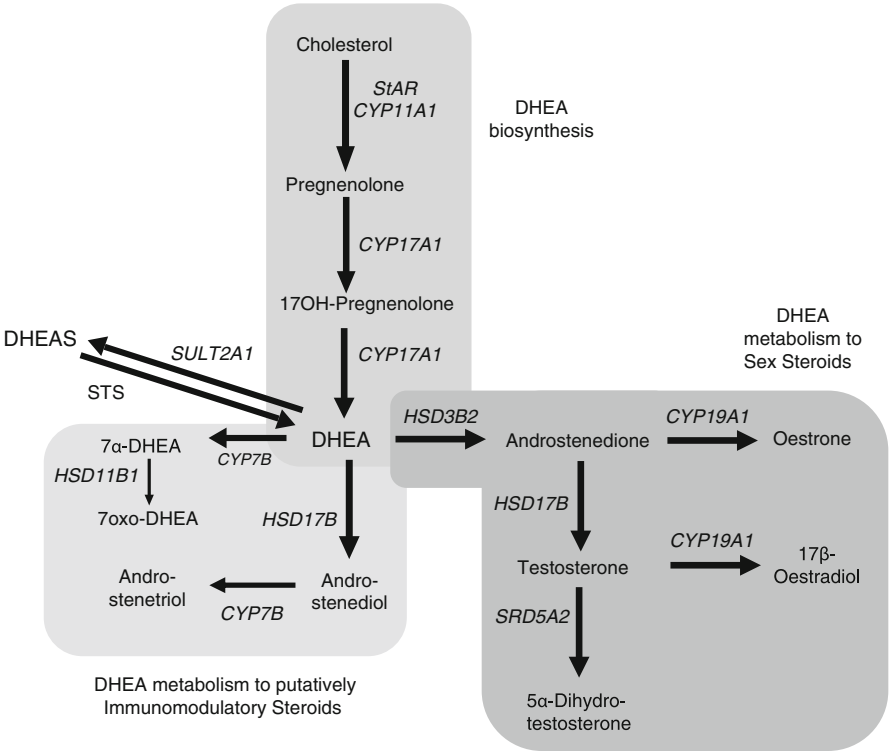

Fig. 2 Dehydroepiandrosterone (DHEA) biosynthesis from cholesterol via StAR (steroidogenic acute regulatory protein), CYP11A1 (side chain-cleavage enzyme) and CYP17A1 (17α-hydroxylase/17, 20 lyase) as well as its downstream metabolism to sex steroids and potentially immunemodulatory steroids via HSD3B (3β-hydroxysteroid dehydrogenase Type 1 and 2), HSD17B (17β-hydroxysteroid dehydrogenases), SRD5A1 (5a-reductase Type 1 and 2), CYP19A1 (Aromatase), CYP7B (7α-hydroxylase) and HSD11B1 (11β-hydroxysteroid dehydrogenase Type 1). Lipophilic DHEA can be converted to its hydrophilic sulphate ester DHEAS by SULT2A1 (DHEA sulphotransferase) and back by STS (steroid sulfatase)

metabolism of DHEA [101–103], but their presence in neutrophils has not been determined. We have recently shown that the expression level of these enzymes changes with ageing and demonstrated enhanced conversion of DHEA to androstenediol as well as increased androgen activation by 5α-reductase in lymphocytes from older men as compared to young men [104]. Concurrently circulating levels of DHEAS and testosterone were significantly lower in the older men, suggesting that the up-regulation of steroidogenic enzymes in the lymphocyte compartment may be a counter-regulatory event aiming to maintain intracellular availability of androstenediol and dihydrotestosterone.

Although circulating cortisol levels do not change significantly with aging, intracellular availability of active glucocorticoids within the peripheral target cells including immune cells may well be altered with age. The major regulatory switch controlling tissue-specific activation of glucocorticoids is the enzyme

11β-hydroxysteroid dehydrogenase Type 1 (11β-HSD1), which converts inactive cortisone to active cortisol [105] (Fig. 3). 11β-HSD1 has two activities; in vivo it mainly acts as an oxoreductase, activating cortisone to cortisol, whereas in vitro it mostly exhibits dehydrogenase activity, converting cortisol to inactive cortisone. 11β-HSD1 is anchored in the endoplasmic reticulum (ER) membrane and has its catalytic domain directed towards the lumen of the ER. Only recently it has been elucidated that its oxoreductase activity is dependent on NADPH generation by the endoplasmic reticulum luminal enzyme hexose-6-phosphate dehydrogenase (H6PDH) [106, 107] (Fig. 3). It is well established that expression and functional activity of 11β-HSD1 can be up-regulated by inflammatory cytokines, e.g., in adipose tissue and bone [108, 109]. As ageing leads to a cytokine profile that is more proinflammatory, with raised levels of IL-1β, IL-6 and TNFα [110], it can be readily hypothesized that increased activity of 11β-HSD1 would lead to increased tissue-specific glucocorticoid availability and action. A precedent for age related changes in 11β-HSD1 expression may relate to the brain, where an age related increase in 11β-HSD1 might explain why cerebrospinal fluid cortisol concentrations rise with age despite unchanged serum cortisol levels [111]. This concept has been convincingly supported by recent human in vivo data demonstrating an improvement in cognitive function by inhibition of 11β-HSD1 activity [112].

Interestingly, it has been shown that 11β-HSD1 is expressed in immune cells and that 11β-HSD1 expression is induced in monocytes upon differentiation to macrophages [113]. By contrast, intracellular glucocorticoid activation by 11β-

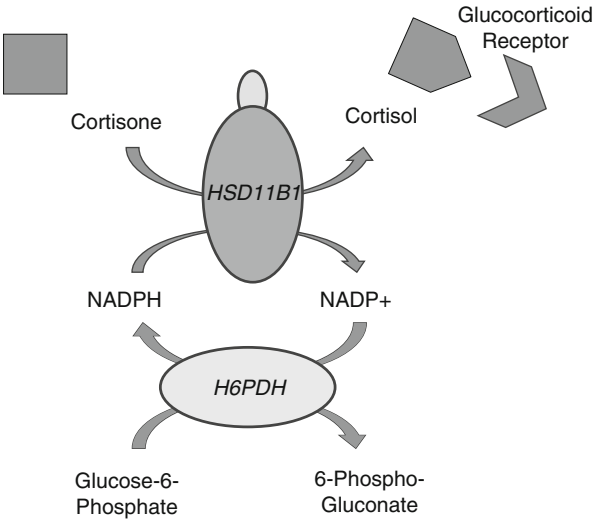

Fig. 3 The oxoreductase activity of 11β-hydroxysteroid dehydrogenase (HSD11B1) converts inactive cortisone to active cortisol that binds and activates the glucocorticoid receptor (GR). HSD11B1 is predominantly an oxoreductase *in vivo*, however *in vitro*, following disruption of the endoplasmic reticulum integrity, mainly acts as a dehydrogenase, inactivating cortisol to cortisone. HSD11B1 is anchored in the ER membrane with its catalytic domain towards the ER lumen and its oxoreductase activity is dependent on NADPH delivery by the intraluminal enzyme hexose-6-phosphate dehydrogenase (H6PD)

HSD1 oxoreductase activity sharply declines during the maturation of monocyte-derived dendritic cells [114]. Whether macrophage and dendritic cell function are differentially modulated by cortisol remains an interesting possibility. The loss of DHEA with age, accompanied by increased 11β-HSD1 in immune cells and tissues induced by inflammaging, may thus result in increased glucocorticoid activity in inflamed tissues, further dampening the immune response in older adults. In addition, inhibition of 11β-HSD1 decreases cortisol half-life [115] and the observed increase in cortisol half-life in the elderly (by as much as 40%) may be a reflection of enhanced 11β-HSD1 activity [116]. Thus we postulate that ageing represents a state of tissue specific cortisol excess in the context of normal circulating levels and that this will impair the peripheral immune response in tissues throughout the body.

5 Stress Hormones and Neutrophil Function

The vast majority of literature on this topic is focused upon the immune suppressive activity of cortisol, with little attention paid to DHEA or its downstream metabolites. Moreover, very few studies of stress hormone effects on immune cells have considered neutrophils. The active glucocorticoid cortisol exhibits a variety of immune suppressing effects [117], which appear to be counteracted by DHEA. For example, it has been suggested that DHEA and glucocorticoids have opposing effects on T-helper cell 1 (Th1)/Th2 balance [118] with evidence for protection of a Th1 cytokine profile by DHEA [119]. In rodents, DHEA antagonizes dexamethasone-induced suppression of lymphocyte proliferation and prevents glucocorticoid-induced thymic and splenic atrophy [120]. DHEA and dexamethasone may have opposing effects on dendritic cell differentiation [121]. DHEA and the glucocorticoid receptor antagonist RU486 equally reverse the suppressive effects of glucocorticoids on immune function [49]. In vitro studies utilizing human immune cells have demonstrated an increase in IL-2 secretion [52] and natural killer cell cytotoxicity [122] following exposure to DHEA. Conversely, DHEA has been shown to inhibit IL-6 release and circulating DHEAS levels have been shown to negatively correlate with serum IL-6 [123, 124]. Thus DHEA appears to counteract the changes in cytokine secretion characteristically observed with ageing, i.e. decreased IL-2 and increased IL-6 levels. DHEA replacement in patients with adrenal insufficiency and thus pronounced DHEA deficiency has been shown to increase the number of circulating regulatory T-cells [125], but this study did not provide details on functional activity.

In relation to neutrophil function, as described above cortisol is a potent suppressor of neutrophil bactericidal responses inhibiting neutrophil superoxide generation [79]. Our own work has confirmed these reports and shown that DHEAS was able to enhance neutrophil superoxide generation in vitro and to overcome the suppressive effects of cortisol on primed neutrophil superoxide generation [71]. Indirect support for the ability of DHEA to counteract the immune suppressive effects of cortisol in vivo, comes from animal studies of DHEA supplementation. For example, dietary

DHEA supplementation of rodents exposed to physical trauma resulted in reduced mortality from the trauma induced sepsis [126]. The latter may be due not only to improved neutrophil function in the presence of DHEA, but also to moderation of the shock response which can produce excessive neutrophil accumulation in tissues leading to nonspecific tissue damage. In this respect DHEA has been reported to down-regulate induction of adhesion molecule expression by LPS [127]. It is thus clear that both cortisol and DHEA appear to modulate neutrophil function, but much more research is necessary to determine the extent of these effects and their mechanisms, i.e. whether the effects of DHEA are direct or via downstream metabolites.

Peripheral actions of glucocorticoids may also be modified by DHEA. DHEA reverses glucocorticoid-associated immune changes after trauma/haemorrhage in mice, concurrently leading to normalisation of elevated corticosterone levels [128], which may suggest an effect upon the prereceptor modulation of glucocorticoids, specifically on 11β-HSD1. Down-regulation of 11β-HSD1 expression and activity by DHEA was recently demonstrated in rat hepatocytes [129], in murine adipocytes [130] and in human skeletal muscle [131]. Thus in the situation of ageing we predict an increase in glucocorticoid action in immune cells due to enhanced tissue-specific activation by 11β-HSD1 whilst the potentially counteracting DHEA pool diminishes due to the age-associated decline in adrenal DHEA production.

In summary, there is still a paucity of data generated in human based systems that informs about DHEA-induced immune effects, in particular there are few studies investigating the effect of DHEA or DHEAS on neutrophil function. The data available to date do however suggest that DHEA can counteract the immune suppressive effects of corticosteroids, including suppression of neutrophil function [132].

6 Ageing, Stress and Neutrophil Function

We propose that the age-related immune and endocrine changes outlined above have specific implications for resilience to stress in older adults. We hypothesize that the combination of adrenopause, leading to a relative preponderance of cortisol over DHEA, with increased tissue levels of 11β-HSD1 resulting in raised peripheral cortisol availability and an already reduced immune defence against infection, leave this population particularly susceptible to the negative effects of stress on immunity. For example, relative to age-matched controls, older adults exposed to the chronic stress of being the primary caregiver for a partner with dementia have

Fig. 4 Stress is sensed by the hypothalamus which secretes corticotrophin releasing hormone, stimulating the pituitary gland to produce adrenocorticotropic hormone (ACTH). ACTH acts upon the adrenal gland causing release of glucocorticoids (cortisol) and DHEA into the circulation. Cortisol suppresses neutrophil function, including extravasation, whereas DHEA counteracts the effects of cortisol and promotes neutrophil function. With age the ability to produce DHEA is reduced (indicated by the dashed line) giving a relative excess of cortisol. Raised levels of inflammatory cytokines induce 11β-HSD1 expression in peripheral tissues increasing conversion of inactive cortisone to active cortisol. The overall effect of age and stress is to diminish the antibacterial actions of neutrophils, thus increasing susceptibly to these infections in older adults

shown a variety of immunological decrements. These include a reduced response to pneumococcal pneumonia vaccination and poorer *in vitro* NK-cell cytotoxicity [133, 134]. More recently, *in vivo* assessments of immune function, such as healing rates of experimentally administered wounds and antibody response to vaccination, have been used to provide clinically relevant outcome measures of the effects of stress on immunity. These studies have supported the previous work suggesting that psychosocial stress is associated with reduced immune functioning in older populations. For example, older adults providing long-term care-giving have shown delayed wound healing in the mouth [135]. Further, experimentally induced punch biopsy wounds took significantly longer to heal in chronically stressed older caregivers and immune cells from the caregivers produced significantly less of the cytokine IL-1β in response to stimulation *in vitro* than the cells of women who were not caregivers [135]. Although an interaction between stress and ageing has not, to our knowledge, been tested directly in the context of psychological stress, there is evidence that younger care-givers of multiple sclerosis patients do not demonstrate reduced antibody responses to vaccination compared to controls [136]. In addition, influenza vaccination responses were reduced in chronically stressed older adults to a much greater extent than young adults [137].

Physical bodily trauma, such as hip-fracture, can also be considered as a chronic stressor, and is associated with decrements in immune function. For example, the experience of hip-fracture in adults aged over 65 years was associated with diminished neutrophil function (generation of superoxide) and a significant incidence (43%) of bacterial infection [83]. Interestingly, this effect of trauma on neutrophil function and infection rates was not observed in younger adults with limb fractures, suggesting that this immune impact of stress is worsened by the presence of immunesenescence. This finding supports the hypothesis that nonacute stress, whether physical [132] or psychosocial [84] exacerbates the negative influence of ageing on the immune system.

7 Conclusions and Future Directions

Ageing has been defined classically as the increasing frailty of an organism with time that reduces its ability to deal with stress, resulting in increased probability of disease and death. The age-related loss of innate immune function, including reduced neutrophil bactericidal function, contributes to such frailty by increasing susceptibility of older adults to bacterial, fungal and yeast infections. Chronic stress is also detrimental to immune function and although the literature regarding neutrophils is sparse, the negative effects of cortisol are well documented. We propose that the age-related increase in proinflammatory cytokines will increase tissue levels of cortisol via induction of 11β-HSD1, contributing to peripheral immune suppression in old age. Furthermore, the negative effects of cortisol appear to be modified by the counter stress hormone DHEA and we suggest that the loss of this

hormone with age mediates a synergistic down regulation of innate immune function by chronic stress and immunesenescence.

There is currently a paucity of experimental data concerning differential responses to stress with age and in particular the effects of stress on neutrophil function in older adults. Future intervention strategies to improve neutrophil function at times of stress may therefore usefully target the altered HPA axis, either by elevating circulating DHEA levels or by functional antagonism of cortisol at the cellular level.

Antigen Presenting Cells

Role of Dendritic Cells in Aging

Anshu Agrawal, Sudhanshu Agrawal and Sudhir Gupta

Contents

Abstract: Immunesenescence is characterized by a decline in immune functions which is responsible for majority of morbidity and mortality associated with aging. The possible consequences of this progressive aging of the immune system are an increase in autoimmune phenomena, incidence of malignancies and predisposition to infections. Innate immune system is the primary defense against invading pathogens. Moreover, it also initiates and modulates the functions of adaptive immune system. This review focuses on the age-associated changes in the functions of dendritic cells, the major antigen presenting cells of the innate immune system.

1 Introduction

The immune system is composed of two major defenses—1) innate immune or nonspecific defense mechanisms consisting of cells such as granulocytes, macrophages and dendritic cells (DCs) and proteins such as cytokines which allows an extremely rapid response to pathogens. 2) The adaptive immune or specific immune defense mechanisms consist mainly of cells such as T- and B-lymphocytes and follow the innate immune response. This response is exquisitely tailored and specific

to the particular pathogen and is responsible for generating long-term memory against subsequent challenges. These two defense mechanisms are interlinked together and the nature of innate immune response dictates the nature or quality of adaptive immune response. The proper function of both systems is thus essential for generating effective immunity. Adaptive immune functions are known to be severely compromised with increasing age and believed to be the majo r cause for immunosenescence [18, 23, 26, 27, 35, 36, 42, 44, 60]. The knowledge regarding the contribution of innate immune cells such as DCs in immunosenescence is still in its infancy. This review summarizes the findings on DC functions in aging.

2 Dendritic Cells

Dendritic cells (DCs) are the most potent of antigen-presenting cells [6, 58] of the immune system present at various portals of entry of pathogens like skin, airways etc., sensing pathogens, ready to initiate and amplify the immune response. DCs serve as critical mediators of both immunity and tolerance [6, 57, 58] by virtue of their ability to ascertain that inflammatory immune responses against commensals of the physiologic skin microflora, ingested food antigens, or inhaled airborne microorganisms are prevented while potent immune responses against harmful pathogens are sustained.

DCs can be activated by various stimuli including microbes, dying cells, and inflammatory cytokines. An array of Toll-like receptors (TLRs), C-type lectin receptors (CLRs) and intracytoplasmic NOD-like receptors (NLRs) in DCs aid them in sensing pathogens [5, 28, 50]. The sensing and capture of antigen by DCs initiates their differentiation and maturation. During maturation they lose their antigen capturing capacity and upregulate the expression of MHC and costimulatory molecules, thus becoming the efficient antigen presenting cells [6, 57, 58]. Maturation of DCs also results in the upregulation of CCR-7 which allows them migrate to T-cell areas in the lymphoid organs where antigens are presented to the T-cells, initiating an adaptive immune response. In addition to an up-regulation of various markers, activation of DCs initiates an inflammatory response through secretion of a broad array of cytokines and other inflammatory mediators which allows them to communicate between themselves and other cells of the immune system, exerting a broad influence on the immune system [6, 50]. For example, DCs can dictate the type of T-cell responses by virtue of the cytokines they secrete in response to a stimulus. IL-12 or IL-23 secretion by DCs [1, 13, 34] primes TH1/TH17 responses while IL-10 gives rise to TH2 or T-regulatory type of responses [2, 3].

Maintenance of tolerance is another key function of DCs [57, 58]. Under steady state conditions DCs continuously sample self-antigens from dying cells. However, no immune response is initiated since these do not activate DCs. These immature DCs interact with T-cells in the absence of costimulation leading to T-cell anergy or the development of T-regulatory cells. The presence of danger signals such as proinflammatory cytokines can cause DCs to mature resulting in break of tolerance. The proinflammatory cytokines and other inflammatory mediators that are increased

during aging can modulate functions of dendritic cells affecting the magnitude and quality of both innate and adaptive immune responses [10, 19, 30, 45].

3 Dendritic Cell Subsets

In humans, two major subsets of DCs [6] have been identified that function differently in both the innate and adaptive immune responses: myeloid DCs (mDCs), – interstitial DCs and Langerhans cells are found in peripheral tissue, secondary lymphoid organs and blood, and plasmacytoid DCs (pDCs) are present in the blood and secondary lymphoid organs. mDCs are professional APCs with a strong capacity to prime naive T-cells and to induce and regulate T-cell responses through secretion of IL-12. pDCs on the other hand are characterized by their plasma cell-like morphology, low phagocytic capacity and production of large amounts of Type I interferons in response to viral, bacterial and parasitic infections [38]. The two subsets of DCs differ in their expression of highly conserved microbial pattern recognition receptors (PRRs), known as Toll-like receptors (TLR). Circulating pDCs express TLR1, 6, 7, 9 and 10, but not TLR4 [29, 51], while blood mDCs express TLR1, 2, 3, 4, 5, 6, 7, 8 and 10, but not TLR9 [51].

4 DCs in Aging

Aging is associated with multiple changes in the cytokine microenvironment that could have either inhibitory or stimulatory effect on the activation and/or maturation of DCs [9, 10, 19, 30, 45, 49]. The increased TNF-α and prostaglandins would result in premature DC activation altering their antigen uptake capacity [30]. Similarly elevated IL-10 and glucocorticoid levels in aging may result in the suppression of activation of DCs [10, 45]. A change in the microenvironment such as age-associated increase in proinflammatory cytokines like TNF-α, may act as a trigger for maturation of DCs, and in combination with apoptotic cells may lead to immune activation and associated inflammation.

Studies on DCs in aging in humans have been focused primarily on the function of myeloid DC subset because it was believed to be the major DC subset involved in T-cell priming.

5 DC Numbers and Phenotype

Most studies in humans have reported no change in numbers or phenotype of DCs in aging [39, 56, 61]. In our study we found normal numbers and phenotype of circulating and monocyte-derived DCs (MDDCs) in aged humans [4]. However,

Della-bella et al. [15] reported progressive decline in the number of circulating mDCs with age while there was no change in pDC numbers. They also found that DCs from aged individuals have a more mature phenotype with an increased proportions of cells expressing CD86 and CD83 as compared to young individuals. Recent mouse studies by Grolleau–Julius et al. [22] and Tesar et al. [59] also did not report any–significant difference in the numbers and phenotype of blood or lymphoid DCs. However, HLA-DR expression on peripheral blood DCs and DCs from a strain of senescence-accelerated mouse (SAMP-1) was found to be reduced [24]. A few earlier studies in mice document a decrease in the number Langerhan cells in the skin [11, 14, 55].

6 DC Pathogen Sensing and Cytokine Secretion

H. Influenzae and *Streptococcus pneumoniae* infections account for substantial mortality [31, 41] in aged individuals resulting in increased susceptibility to infections with age. Alterations in PRR functions in aging may impair activation of the immune response and contribute to poorer vaccine responses and greater morbidity and mortality from infectious diseases. Proinflammatory cytokines are increased during aging. A greater understanding of PRR functions in aging is extremely relevant in view of the interest in TLR agonists as therapeutic agents not only for infections, but also for allergic, autoimmune, and malignant diseases.

Amongst the PRRs, TLRs are most studied in aging because of their important role in clearing viral and bacterial pathogens. Numerous studies have investigated the expression of these receptors on the innate immune cells of both humans and mice. Alterations in TLR expression pattern in aging seem to be cell specific with monocytes showing decreased expression of certain TLRs while dendritic cells appear to express similar level of TLRs as the young.

Some earlier studies [8, 48, 54, 61, 62] had reported decreased expression and function of TLRs in macrophages from aged mice; however, recent studies by Tesar et al. [59] found that TLR expression and function (in vivo) is intact in myeloid DCs and macrophages from aged mice. They found that both circulating mDCs and bone-marrow derived DCs from aged and young mice expressed comparable levels of maturation markers following activation with various TLR ligands. The levels of cytokine secretion between the groups were also comparable. In contrast, Grolleau-Julius et al. [22] reported decreased secretion of TNF-α and IL-6 and increased IL-10 secretion from bone-marrow derived DCs from aged mice. The reason for this discrepancy is presently unclear. Previous studies [39, 56] have reported comparable levels of activation and cytokine secretion by MDDCs from the aged and young subjects following TLR stimulation. Our studies [4] found no differences in TLR expression in MDDCs from aged and young subjects at the gene level (Affymatrix analyses) and protein level (TLR4). There was no difference in the expression of CD40, CD80, CD83, CD86 and HLA-DR on MDDCs before and after activation with TLR-4 ligand, LPS between

aged and young subjects. However, we observed an increased secretion of TNF-α and IL-6 from MDDCs from aged compared to young subjects, when stimulated with TLR-4 or TLR8 ligand. The levels of IL-10, IL-12p40 and IL-12p70 were comparable between the two groups. Della bella et al. [15] report decreased IL-12 secretion from LPS-stimulated circulating mDCs in humans. Unpublished data from our laboratory indicates that circulating mDCs in the aged subjects also secrete higher levels of TNF-α and IL-6 upon TLR stimulation. In summary, TLR expression and function in DCs during aging appears to be intact except an increased secretion of proinflammatory cytokines TNF-α and IL-6. High IL-6 and TNF-α levels are poor prognostic factors for a number of age-associated diseases. For example, higher IL-6 levels lead to the production of C-reactive protein which is identified as a major risk factor for myocardial infarction. Increased serum IL-6 and C-reactive protein play a major role in Type-2 diabetes; rheumatoid arthritis and osteoporosis, all diseases which show increased incidence with age [12, 16, 43]. Likewise there is positive correlation between IL-6 levels and congestive heart failure. Increase in another proinflammatory cytokine TNF-α has been found to be associated with higher incidence of arteriosclerosis in older men [47]. Thus overactivation of the dendritic cells in response to TLR may be contributing to age-associated inflammation.

7 Antigen Capture

Phagocytosis is the major mechanism used by DCs to remove pathogens and cell debris and therefore is important for maintaining both immunity and tolerance [57, 58]. Our studies [4] have shown that both, the phagocytosis of dextran beads and pinocytosis of Lucifer Yellow dye was found to be impaired in MDDCs from aged subjects when compared to young. This suggested that MDDCs from aged displayed reduced capacity to capture antigen via both receptor-dependent and independent mechanisms. In addition to foreign antigens, DCs also capture and present self-antigens in the periphery [25, 57, 58]. In fact the uptake of apoptotic cells by DCs in the periphery and presentation to T-cells in the absence of costimulation, is considered to be the major mechanism of maintenance of peripheral self-tolerance. Our investigations indicated that DCs from aged individuals were also impaired in their capacity to phagocytose apoptotic cells [4]. Impaired clearance of apoptotic cells in aging would lead to accumulation of apoptotic cells which will become necrotic and lyse to release auto-antigens such as nucleic acids, heat shock proteins, HMGB1, ATP and uric acid along with other cell debris. In contrast to apoptotic cells which are known to inhibit maturation of DCs, necrotic cells lead to activation of DCs and secretion of proinflammatory cytokines. Thus these auto-antigens can be taken up by DCs and presented to T-cells leading to inflammation and autoimmunity associated with age. Therefore, a reduction in the phagocytic capacity of DCs with age would not only result in reduced clearance of infections but would contribute to age-associated loss of peripheral self-tolerance, autoimmunity and chronic inflammation.

8 Migration of DCs

Following activation, DCs migrate to T- and B-cell areas after activation in order to induce effective cellular immune responses. Stimulation of immature DCs with TLR ligands results in the down-regulation of CCR6 and up-regulation of CCR7, which enhances their ability to migrate from the peripheral tissues to the draining lymph node. CCL21 and CCL19 both bind to the CCR7 receptor and are potent chemoattractants for mature DCs [32]. Mice deficient in CCR7 are unable to mount effective T-cell immunity [20]. Relatively few studies have addressed the question of migration of DCs in aging. We determined the migration of DCs from aged and young human subjects using a transwell system where the DCs in the upper chamber migrate through a transwell of defined pore size to the lower chamber in response to a chemokine gradient [4]. We observed that DCs from aged subjects were impaired in their capacity to migrate in response to CCL19 and SDF-1 compared to DCs from young. This was not a consequence of reduced CCR7 or CXCR4 expression. Neither did we observe a significant difference in the secretion of basal level of the chemokines from DCs between aged and young individuals. Bhushan et al. [7] observed significantly impaired migration of LCs in response to TNF-α in elderly subjects. The same group also found decreased TNF-α induced LC migration in aged animals. Choi and Sauder [11] reported decreased LCs mobilization and the subsequent accumulation of DCs in the regional lymph nodes in aged mice in response to topical challenge with a chemical agent; however, contact hypersensitivity responses were not compromised. Linton et al. [37] have reported in vivo impaired migration of DCs from aged mice to the draining lymph nodes, in a TCR transgenic mice model. They suggest it to be due to both intrinsic defect of DCs and aged microenvironment. Contrary to above studies, Pietschmann et al. [46] observed normal trans-endothelial migration of peripheral blood myeloid-enriched lymphocyte-depleted cells in elderly subjects. This could be due to the difference in the model system. Impaired migration of DCs has also been observed in mice [14, 17]. Since the migration of DCs to lymph nodes is pivotal to the establishment of the immune response, reduced migration may contribute to age-associated immune dysfunction.

9 Dendritic Cells and Adaptive Immunity

DCs play a key role in sensing and processing microbial information and directing the differentiation of naïve lymphocytes to effector cells suitable against particular types of infection. They have the unique capacity to prime naïve T-cells among the antigen presenting cells of the body, therefore they are critical for mounting immune responses against new antigens. The engagement of TLRs on DCs leads to an increased expression of MHC–peptide complexes and costim-

ulatory molecules, as well as the production of immunomodulatory cytokines, all of which have a profound effect on T-cell priming and differentiation. The up-regulation of costimulatory molecules on DCs dictates the decision between tolerance and immunity. Antigen presentation by DCs in the absence of costimulation results in the generation of anergic and/ or regulatory T-cells [25]. DCs also dictate the nature of TH (TH1, TH2, Treg, TH17) response generated through the type of cytokine secreted by them. For example, IL-12 from DCs induces T-cells to secrete IFN-γ [2] while IL-23 will induce IL-17 from T-cells [13, 34]. Secretion of IL-10 by DCs on the other hand induces either a TH2 or a T-regulatory type of response [2, 3]. It is thus clear that any alteration in the function of DCs with age, would affect T-cell responses.

There is some controversy regarding capacity of DCs in old age to stimulate T-cells. Earlier studies in aged mice demonstrated decrease in antigen presentation and T-cell priming capacity of DCs in the lymph nodes [17, 33, 55]. However, the two recent studies in mice are contradictory. Study by Tesar et al. [59] suggests the intrinsic defect in T-cells during age is responsible for the age-associated reduced T-cell function. Grollaeu-julius [22] on the other hand found old bone-marrow derived DCs less effective than young DCs in stimulating syngeneic ova–specific CD4 T-cell proliferation. They also reported a decrease in tumor regression in mice treated with the ovalbumin peptide-pulsed aged DCs than with ovalbumin peptide-pulsed young DCs.

Similar to the findings of Tesar et al. in mice [59], MDDCs from elderly subjects were not impaired in their capacity to induce T-cell responses. Steger et al. [56] and Grewe et al. [21] reported that DCs from young and aged subjects have similar stimulatory capacity to induce proliferation of T-cell lines developed in long-term cultures. Our preliminary studies with MDDCs show reduced proliferation of young T-cells when cultured with aged DCs. The reason for this discrepancy is not clear.

10 Plasmacytoid DCs and Aging

Studies described above are all focused on the mDC subset from either the blood or in vitro monocyte-derived DCs. Except for a report by Schodell et al. [53] documenting a decrease in the number and IFN-α secretion by pDCs in aging, virtually nothing is known about the functions of the pDC subset in aging. pDCs are key players in the elimination of infections and upon activation produce extremely high amounts of Type I IFNs. Type I IFN production by pDCs regulates the cytotoxic potential of NK and CD8 T-cells [38]. It also induces differentiation of B-cells to plasma cells. The NK and CD8 cytotoxicity are reduced with age along with a reduction in specific antibody responses. Studies of pDC functions with age may help in identification of mechanisms responsible for the reduced B and T-cell functions and the associated increased susceptibility to infections.

11 Conclusion

Though the numbers and phenotype of DCs are relatively unchanged during aging dendritic cell functions are altered with age resulting in an enhanced secretion of proinflammatory cytokines. This increased in proinflammatory cytokines may be due decreased sensitivity of the cells to these cytokines, a phenomenon similar to what is observed with insulin resistance. Reduced phagocytosis and migration on the other hand increases the susceptibility of the elderly to infections. Therefore, it appears that dysfunction of DCs may contribute to T-and B-cell immunosenescence and chronic inflammation associated with aging.

Phenotypic and Functional Changes of Circulating Monocytes in Elderly

Lia Ginaldi and Massimo De Martinis

Contents

Abstract: Immunosenescence has been envisaged as a situation in which the specific immune system deteriorates with age, while the innate immunity is negligibly affected and, in some cases, almost upregulated. Ageing represents a state of paradox where chronic inflammation is associated with declining immune responses. This peculiar finding, known as inflammageing, is mainly sustained by cells of the innate immunity. One of the key constituents of the innate immune system are monocytes. Therefore, although the age-related changes in the specific immunity are commonly considered the hallmarks of immunosenescence, the central role of the complex remodelling of first line defence cells, such as monocytes, is gradually emerging. For example, chemotaxis and phagocytosis, as well as antigen processing and presentation, are depressed, whereas cell activation and the secretion of inflammatory cytokines, such as IL-1, IL-6, TNF, are markedly increased. Changes in the expression of functionally important cellular receptors on monocyte surface can also contribute to the modification of immune function characteristic of the elderly.

1 Monocyte Biology and Function

One of the key constituents of the immune system are monocyte–macrophages. Monocytes originate in the bone marrow and migrate through blood to body tissues as macrophages. Monocytes therefore represent the immature macrophages when in transit from bone marrow to tissues. These cells, also known as mononuclear phagocytes, share a common precursor with neutrophils. Through the expression

of a series of transcription factors differentiation takes place [67]. Human bone marrow produces approximately 5×10^9 monocytes per day. Under the influence of cytokines, a small number of macrophages in tissues differentiate and, depending on the anatomical sites, may become osteoclasts (bone), Kupffer cells (liver), microglia (brain), etc., all of which exhibit unusual morphological features and functional capacities. Monocytes proliferate in the presence of growth factors, such as monocyte colony-stimulating factor (M-CSF), granulocyte-macrophage colony-stimulating factor (GM-CSF) or IL-3. When these cells are needed at the inflammatory loci, in order to become activated and fully functional, they must interact with interferon-γ (IFN-γ), a cytokine released by activated T-lymphocytes that interacts with the specific receptor [52, 71].

B- and T lymphocytes have specific recognition systems (immunoglobulins and the T-cell receptor, respectively), that interact with specific antigens. This mechanism allows the survival of just the small number of lymphocytes that are needed to recognize and remove foreign material. However, monocytes are members of innate immunity and thus present nonspecific systems on their cell surface to recognize and discriminate self from nonself.

Monocyte–macrophages play a crucial role in immune response and act through several mechanisms: (a) directly, by destroying bacteria, parasites, viruses and tumor cells; (b) indirectly, by releasing mediators, such as interleukin-1 (IL-1), tumor necrosis factor-α (TNF-α), etc., which can actìvate other cells; (c) by processing antigens and presenting digested peptides to T lymphocytes; and (d) by repairing tissue damage [70].

Monocyte–macrophages can produce an impressive array of cytokines, chemokines, enzymes, arachidonic acid metabolites, and reactive radicals upon activation. Many of these functions appear to antagonize or counter each other. These cells can clearly enhance or suppress adaptive immune responses. Macrophages display both proinflammatory and antiinflammatory functions, produce metalloproteinases and inhibitors of these metalloproteinases, and produce toxic radicals that contribute to tissue cell destruction as well as cytokines that promote tissue regeneration and wound healing. All of these functions are not expressed simultaneously but are thought to be regulated such that macrophages display a balanced, harmonious pattern of functions [79].

In the classic acute inflammatory response, blood monocytes enter the damaged tissue shortly after neutrophils. Encounter with bacteria, their products, and damaged tissue results in the activation of pro-inflammatory activities, such as the production of TNF-α, IL-1, and IL-6 and the secretion of metalloproteinases [102].

In addition to the inflammatory, clearance and tissue regenerative activities, macrophages also play a critical liaison role in the communication between the innate and adaptive immune systems. Macrophages can display antigen presenting activity and phenotype [46, 95] and the inflammatory milieu created by monocyte–macrophages can significantly impact the maturation of myeloid dendritic cells and thus influence the nature of the adaptive immune response that will be elicited [47, 117]. A function-polarizing synergy can develop between T-cells and macrophages wherein the functional pattern displayed by the macrophages influences the nature

of the adaptive immune response and the nature of the adaptive immune response (TH l vs. TH2) influences the functional pattern displayed by the macrophages. Th l cytokines, such as IFN-γ and TNF-α, promote inflammatory and cytotoxic activities of macrophages. In contrast, Th2 cytokines, such as IL-4 and IL-10, promote anti-inflammatory and/or tissue regenerative activities. Ligation of surface receptors such as CD40, TNF-αR, or Toll-like receptors (TLR) on macrophages initiates signal cascades that provide a strong activating stimulus for macrophage function. IFN-γ selectively upregulates LPS-induced inflammatory cytokine production and NOS and oxidase expression while down-regulating other functions, such as arginase and PGE2 and LTC4 production [75, 103, 104].

2 The Impact of Ageing on Monocyte Function

The immune system is affected by ageing, causing an increased susceptibility to infections and mortality, as well as a major incidence of immune diseases and cancer in the elderly. Because mononuclear phagocytes are an essential component of both innate and adaptive immunity, altered function of these cells with aging may play a key role in immunosenescence [98, 50].

Human immunosenescence has been envisaged as a situation in which the specific immune system deteriorates with age, while the innate immunity is negligibly affected and, in some cases, almost upregulated [46]. Aging represents a state of paradox where chronic inflammation is associated with declining immune responses [1, 107].

Inflammageing is considered the common and most important driving force of age-related pathologies, such as neurodegeneration, atherosclerosis, diabetes and sarcopenia, among others, all of which share an inflammatory pathogenesis [36]. The cell types more involved in the inflammatory processes and therefore in the inflammageing are cells of the innate immunity, such as monocytes/macrophages. For example, adhesion of monocytes to the arterial wall, via specific cell surface adhesion molecules, is an important early event in the development of atherosclerotic lesions [112]. Similarly, the increased incidence of tumours in the elderly has been related to a modified antitumour innate defence [63]. In addition, the interface between innate and adaptive immunity, implicates that many of the changes of monocytes influence the initiation of specific immune responses. Impaired ability of antigen presenting cells (APCs) to stimulate T-cells in elderly has been shown [13, 29]. Therefore, although the age-related changes in the specific immunity are commonly considered the hallmarks of immunosenescence, the central role of the complex remodeling of first line defence cells, such as monocytes, is gradually emerging. Some functions of the innate immunity are depressed in the elderly, while many other functions are upregulated, exerting a global and peculiar reshaping. For example, while chemotaxis and phagocytosis, as well as antigen processing and presentation, are depressed, cell activation and the secretion of inflammatory cytokines, such as IL-1, IL-6, TNF, or mononuclear phagocytic cell specific enzymes, are markedly increased [24, 43, 46, 66].

Healthy elderly subjects and centenarians show a decreased susceptibility of monocytes to oxidative stress-induced apoptosis [77]. The respiratory burst of monocytes during ageing decreases between 45% and 70%. Scavenger receptor activity and the expression of apolipoprotein E are reduced in healthy elderly men [37] as is the inflammatory wound healing response, which may be related to poor expression of cell adhesion molecule-1 [6].

Reports on the impact of advanced age on the recruitment of monocytes into excisional wound sites vary from observations of no significant effect to observatians of long delays in attainment of peak monocyte numbers [25].

Chemotactic activity decreases with advanced age [82, 106]. Phagocytosis and clearance of infectious organisms is also reduced with advanced age [2, 4, 12, 73]. Expression of class II MHC and antigen presentation by macrophages have been reported to be reduced in aged rodents and humans [39, 69, 118]. The production of fibroblast growth factor (FGF-2), vascular endothelial growth factor (VEGF), platelet derived growth factor (PDGF), epithelial growth factor (EGF), and transforming growth factor-beta (TGF-β) are reduced and/or delayed, as is the expression of their corresponding receptors [136]. The result is a delay and/or deficiency in reepithelialization, collagen deposition, and angiogenesis in excisional wounds of the elderly.

Haematopoietic stem cells age and have a limited functional lifespan [40]. This may explain the hypocellularìty observed in the bone marrow of elderly people [81]. Of particular interest is the decrease with age of CD68 positive cells, which are markers of macrophage population [70].

Cell lifespan may be regulated by multiple factors. Recently, telomeres and telomerase have been implicated in the regulation of replicative lifespan [56]. Several studies using peripheral blood mononuclear cells consisting of 10–15% monocytes and 60–70% lymphocytes have shown that these structures shorten with age at a rate comparable with that of purified lymphocytes. Mature monocytes do not undergo further cell division after activation. Thus, the variations in telomere length in monocytes with aging may reflect the changes in telomere length in hematopoietic progenitor cells. While mature monocytes do not express telomerase, myeloid progenitor cells do [111].

There are several potential molecular mechanisms that may affect monocyte ageing. An important and universal mechanism that leads to a wide spectrum of intracellular damage during aging are the reactive oxygen species (ROS), which are natural by-products of cellular metabolism. Exposure to ROS may lead to structural changes in macromolecules that impair their function, such as cross-linking of intracellular and intramitochondrial structural and functional proteins, carbohydrates and the oxidation of fats and lipids in membranes. A likely cause of monocyte ageing is the acquisition of defects in genomic DNA. This may occur through a reduced ability to repair even small amounts of DNA damage or very stringent requirements on DNA repair machinery for the maintenance of DNA fidelity, or both. In addition, an increased number of spontaneous mutations may occur, thereby producing DNA damage [105].

3 The Interface Between Innate and Adaptive Immunity

The complex process of immune activation is dependent on the close participation of T-cells and APCs. APCs are responsible for uptake, processing, and presentation of antigen to T-cells. Impaired ability of APCs to stimulate T-cells in elderly has been shown. Expression of costimulatory molecules that assist in the efficiency of cell to cell communication may be altered in old subjects and thus alter cytokine production by APCs, which regulates downstream T-cell effector functions [46, 48, 86]. However, some studies have shown enhanced antigen presentation by APCs from healthy elderly, associated with increased levels of IL-10 and IL-12. It is hypothesized that this upregulation in IL-12 production by APCs may be compensatory to an inherent age-related decline in T-cell function to maintain immunocompetence [46].

Antigenic presentation is a very complex phenomenon involving the formation of the immunological synapse via the activation of the T-cell receptor (TCR) and coreceptors. This interaction determines whether the interacting T-cell becomes tolerant or proliferates and differentiates into a functional effector T-cell. The capacity for immune synapse formation between APC and T-lymphocyte is altered with age. This may be partly due to an alteration in the membrane properties and costimulatory molecules of the cells of the innate immune system with ageing. The innate immune system also influences the adaptive immune response through the timing, type and strength of cytokines produced. Ageing is associated even in healthy persons with a non specific increase in the production of proinflammatory cytokines originating from monocyte to macrophages [50].

Dendritic cells (DCs) are the major APCs responsible for initiating an immune response. Agrawal et al. [1] compared the innate immune functions of monocyte-derived myeloid DCs from elderly subjects with DCs from young individuals. They showed that, although phenotypically comparable, DCs from the aging are functionally different from DCs from the young. In contrast to DCs from the young, DCs from elderly individuals display (1) significantly reduced capacity to phagocytose antigens via macropinocytosis and endocytosis as determined by flow cytometry (2) impaired capacity to migrate in vitro in response to the chemokines MIP-3β and stromal cell-derived factor-1 and (3) significantly increased LPS and ssRNA-induced secretion of TNF-α and IL-6, as determined by ELISA. Investigations of intracellular signalling revealed reduced phosphorylation of AKT in DCs from the ageing, indirectly suggesting decreased activation of the PI3K pathway. Because the PI3K-signaling pathway plays a positive regulatory role in phagocytosis and migration, and also functions as a negative regulator of (TLR) signaling by inducing activation of p38MAPK, this may explain the aberrant innate immune functioning of DCs from elderly subjects. Results from real-time PCR and protein expression by flow cytometry demonstrated an increased expression of phosphatase and tensin homolog, a negative regulator of the PI3K-signaling pathway, in DCs from the aging. Increased phosphatase and tensin homolog may thus be responsible for the

defect in AKT phosphorylation and, therefore, the altered innate immune response of DCs from elderly humans [57, 58, 83, 116].

Della Bella et al. [21] analyzed the number, phenotype and function of peripheral blood DCs from elderly subjects by using flow cytometric methods that allow cell characterization directly in whole blood samples. They demonstrated that the number of myeloid DCs progressively declines with age. This finding was accompanied by a decrease of CD34+ precursors and increase of circulating monocytes, suggesting that the entire differentiation process of APCs is partially dysregulated in the elderly. DCs from aged individuals also appeares to have a more mature phenotype and impaired ability to produce IL-12 upon stimulation [85].

The frequency of CD34+ cells progressively declines with age, suggesting that in aged subjects a reduced availability of these cells may contribute to reduce the frequency of DCs [99]. On the other hand the frequency of monocytes, that not only may differentiate into DCs but also represent another main population of professional APCs, shows a progressive increase with ageing. Therefore, the entire differentiation process of APCs is partially dysregulated in the elderly. The analysis of the plasmatic levels of factors known to affect the differentiation of monocytes and DCs from their precursors demonstrates in the elderly increased levels of TGF-β, which does promote the maturation and differentiation of monocytic cells [33]; and increased levels of VEGF, which does impair the differentiation of CD34+ cells into mature DCs [63]. The percentage of peripheral blood dendritic cells (PBDCs) expressing the costimulatory molecule CD86 and the maturation marker CD83 are slightly increased in the aged individuals. The easier explanation for this finding is that this partial activation and maturation of PBDCs may be sustained by the increased inflammatory activity that accompanies ageing [65]. The finding of higher plasma levels of TNF-α in the aged subjects seems to corroborate this hypothesis.

4 Age-Related Phenotypic Changes of Monocytes

The phenotype of monocytes in the elderly is consistently remodelled [43]. Changes in the expression of functionally important cellular receptors can contribute to the modification of immune function characteristic of the elderly [42, 45].

Our previous studies [23, 24, 44] demonstrated important cell adhesion receptor modifications on lymphocyte subsets in the elderly, related to peculiar lymphocyte dysfunctions. A significant expansion of CD14dim CD16bright subpopulation of circulating monocytes in elderly subjects, that may indicate a state of in vivo activation, has been demonstrated [96]. Cell adhesion molecules (CAMs) are surface receptors mediating cell-cell and cell-matrix interactions [102]. CAMs are essential molecules involved in chemotaxis, phagocytosis and killing of microbes and neoplastic cells. The increased susceptibility of elderly people to cancer and infections could be partly explained as a failure in such basic immune defence functions [24].

Since leukocyte adhesion molecules play important roles in mediating a wide variety of leukocyte functions, age-related changes in their expression on monocyte

surface could be partially responsible for immune dysfunctions during senescence. Chiricolo et al. [17] documented a decrease in monocyte subpopulations bearing the adhesion molecule CD11a/CD18 and an increase in CD44 antigen density on monocytes in the elderly. These changes might be an event in the mechanism leading to the decreased lymphocyte proliferative response in vitro and to other immunological dysfunctions reported in old subjects.

Considering the central role of the innate immunity in the process of immunosenescence and the involvement of CAMs in the great majority of leukocyte functions, we studied the expression of CD50 and CD62L adhesion molecules in peripheral blood monocytes in the elderly. Such adhesion receptors mediate important cellular functions. CD50 (ICAM-3) is an Ig-related molecule which functions both in cell adhesion and activation processes [20]. Moreover, ICAM-3 is important in the initial scanning of the APC surface by T-cells and, therefore, in generating the specific immune response [78]. CD62L (L-selectin) is an important leucocyte homing receptor which is required to initiate leukocyte capture, rolling and adhesive interactions. In response to inflammatory stimulation, the endothelium expresses a distinct ligand for L-selectin that is sufficient for capture of leukocytes. CD62L is up regulated on circulating leucocytes early after injury and L-selectin mediated signalling may directly initiate or amplify neutrophil activation and localization selectively at sites of inflammation. The percentages of monocytes expressing CD62L is decreased in the elderly, whereas its density expression is unchanged. CD50 expression on monocytes from old subjects show a peculiar attitude: its density expression decreases whereas the number of positive cells is expanded. CD50 is associated with tyrosine kinase activity and functions as a ligand for LFA-1 [24].

CD50 on the surface of APCs plays an important role in the initiation of the immune. Its lower expression on monocytes could therefore contribute to the impaired antigen presentation in the elderly. On the other hand, the increased number of CD50 positive monocytes in the elderly, despite its decreased density expression at a per cell level, could be interpreted as a tentative to counteract the inability to mount strong immune responses [76].

Under some conditions, engagement of surface adhesion molecules induces activation of intracellular signaling cascades (outside-in signaling) that causes altered cellular function and responses. CD50 stimulation on monocytes potently induces secretion and spreading of chemokines (MIP-1alpha, IL-8, and MCP-1 by monocytes and IL-8 by neutrophils) [62]. The increased production of chemokines in the elderly is a well known phenomenon [89]. Therefore CD50 downregulation, as the consequence of its engagement by specific ligand and consequent activation, is the first cellular step in chemokine production.

CD50 and CD62L are released to the medium upon cell stimulation. The increased proportion of granulocytes and monocytes lacking CD62L and the downregulation of CD50 intensity expression may suggest a state of in vivo activation. The presence of soluble CAMs in plasma might serve as a physiological adhesion regulatory system to prevent undesirable leukocyte cell–cell interaction or the attachment of leucocytes to endothelium [22]. Serum levels of solubile cell adhesion receptors are increased in patients with several pathologic states, as well as in the elderly. There-

fore CD50 and CD62L shedding from the cell surface of activated monocytes could be interpreted as a tentative to counteract the dangerous effects of an excessive chronic inflammation in the elderly. However, the increased proportion of CD62L negative monocytes in the elderly leads to an impairment in cell adhesion which is the first line of response to acute inflammatory stimuli. This phenomenon likely contributes to the increased susceptibility to acute infections of elderly people.

5 Hormone Modulation and the Stress Response in Senescent Monocytes

Several hormones, differentially modulated during ageing, can regulate immune cell function. For example, ageing is associated with various degrees of insulin resistance together with reduced immune cell activity. Since monocytes express insulin receptors, the perturbation of insulin pathway has been proposed as possible pathogenetic mechanism in the immune derangement in the elderly. Walrand et al. [110] measured circulating monocyte receptor expression and density using flow cytometric detection. The density of monocyte insulin receptors was not affected by age. Therefore, notwithstanding the presence of insulin receptors on monocytes, insulin dysfunction pathway has a limited action on monocyte function during ageing.

Alterations in retinoid metabolism and thyroid dysfunction occur with senescence. Vitamin A and retinoid acid have a wide variety of profound effects on growth, epithelial tissue differentiation and homeostasis, and are involved in maintaining an efficient immune system [74]. An age-related hypo-activation of the retinoid and thyroid nuclear pathways has also been demonstrated on monocytes and lymphocytes [31].

Monocytes play early roles in triggering an acute inflammatory response to many stressful conditions. The expression of leucocyte L-selectin increases during acute stress events such as injury and is temporally related to an early neuroendocrine response. Adrenaline up-regulates whereas TNF-α down-regulates the surface expression of L-selectin on monocytes [90]. The stress response in the elderly is impaired as well as the secretion of stress response hormons (cortisol, catecolamines) thus contributing to the decreased CD62L expression on both monocytes and granulocytes with consequent inhability to trigger acute inflammatory reactions. The downregulation of CD62L on the cell surface could also be the consequence of the increase of proinflammatory cytokines, such as TNF-α, which characterizes immunosenescence [24].

The effect of age in the production of heat shock proteins (Hsp) is very controversial. Hsp are highly conserved proteins and their synthesis is ubiquitous. Constitutive and stress-inducible Hsp play diverse roles in cellular function. Under normal physiological conditions constitutively synthesised Hsp act as molecular chaperones modulating protein folding, assembly, intracellular localisation, secretion, and degradation. When cells endure stress such as high temperature, exercise, oxidative stress, osmotic stress, and inflammation, the expression of inducible

Hsp is increased and these proteins participate in protein refolding and protection, in dissolving aggregated proteins, and in targeting them for degradation. Hsp27 is able to induce an increase in cellular glutathione levels, which works together with ascorbic acid and coenzyme Q as a redox buffer for cellular protection. With ageing there is a general decline in the capacity of cells to respond to stressors and oxidative insult [80].

Some investigators have reported an increase in the basal levels of Hsp with age, which is indicative of an adaptive response to cumulative intracellular stress during ageing and may be associated with increased oxidative stress. On the other hand, a decrease or no effect of age on Hsp basal levels have also been reported [30].

Njemini R et al. [80] investigated the effect of age and inflammation on the induction of Hsp27 in human peripheral blood monocytes, using flow cytometry. There is an age-related decrease in the level of Hsp27, which disappeares in the presence of inflammation. A relationship between the circulating levels of C reactive protein (CRP), IL-6 and TNF-α with Hsp27 levels exists, indicating that cytokines are able to influence the production of Hsp27. The basal level of Hsp27, measured as mean fluorescence intensity (MFI) or as percentage of Hsp27 producing cells, is inversely related to age, for both lymphocytes and monocytes.The expression of Hsp27 as well as Hsp70 is high in monocytes compared to other leukocyte subsets. Because Hsp27 is up-regulated following oxidative stress a likely explanation for this phenomenon is the higher capacity of monocytes to induce ROS and thus to promote oxidative stress. Since Hsp27 production increases with inflammation, it is possible that it exerts some antiinflammatory or immune modulatory effects on leukocytes. Inflammation results in the neutralisation of the age induced Hsp27 repression. Acute phase factors, which mediate the regulation of Hsp genes by interacting with several signaling pathways are most likely involved in this process. TNF-α might be one such factor, since there is a correlation with the percentages of monocytes producing Hsp27. This observation is compatible with the known proinflammatory tendency that is observed during ageing, and might explain the lower values for Hsp27 in the elderly compared to the younger subjects.

6 Monocyte–Macrophage Subset and Cytokine Dysregulation

Monocyte–macrophage heterogeneity has been recognized recently, and an imbalance in subsets could be a reason for the difference between the young adult versus the aged. Mononuclear phagocytes have been subdivided into M-1 and M-2 phenotypes depending on their ability to produce NO and proinfíammatory cytokines (M-1 type) or antiinflammatory agents such as IL-1RA and arginase (M-2 type), suggesting a possibility that one of these types of macrophages accumulates in the spleens of the aged [41, 75]. NOS-2 and arginase, respectively, unique to M-1 and M-2 macrophages, are reduced in macrophages from the aged. It has also been shown that macrophages can be activated by IL-4, leading to suppression of proinflammatory cytokines and enhanced expression of major histocompatibility

complex class II (MHC II) genes as well as IL-1RA [47]. As the aged have been shown to have an increased incidence of TH2 T-cells [55], it is conceivable that the macrophages in the aged have markers of IL-4 activation. Mosser and colleagues [3] identified a uniquely hyporesponsive macrophages in spleens from the aged, which has profound influences on immune responses to polysaccharide antigens and may affect the overall ability of the aged to generate an inflammatory response necessary to contain infections. Several studies have examined the capacity of phagocytic mononuclear cells to produce cytokines or chemokines [4, 79]. There are reports of increases, decreases or no effects of age on cytokine release by monocytes, either spontaneously or after LPS stimulation [80, 81]. The decreased response of monocytes from aged persons to LPS in relation to the production of IL-6 and TNF-α has been associáted with deficiencies in the activation of protein kinase C (PKC), mitogen-activated protein kinase (MAPK) and deficient expression of c-Fos and c-Jun [57, 59, 91].

Ageing is associated with progressive muscle wasting and low-grade systemic increases in cytokines such as IL-6 and TNF-α. Higher systemic cytokine levels are associated with functional decline and often cachectic disease [7, 93, 109]. Monocytes are involved in skeletal muscle repair through proinflammatory and alternative functions [49, 51]. Przybyla B et al. [88] quantified the total number of macrophages and their pro- and antiinflammatory subpopulations, as well as related cytokine expression, in muscle from young and elderly subjects before and after exercise and found that the number of macrophages within skeletal muscle from the elderly is decreased and their functional properties show defects both at rest and in response to resistance exercise, which could contribute mechanistically to age-related muscle loss [72].

The macrophage lineage displays extreme functional and phenotypic heterogeneity which appears to due in large part to the ability of macrophages to functionally adapt to changes in their tissue microenvironment. This functional plasticity plays a critical role in their ability to respond to tissue damage and/or infection and to contribute to clearance of damaged tissues and invading microorganisms, to contribute to recruitment of the adaptive immune system, and to contribute to resolution of the wound and of the immune response. Ageing alters the proportion and abundance of monocuclear phagocyte subsets. Immune cell functions, including monocyte–macrophage functional plasticity, are known to decrease with age [105].

Evidence has accumulated that environmental influences, such as stromal function and imbalances in hormones and cytokines, contribute significantly to the dysfunction of the adaptive as well as innate immune system in the elderly. A current hypothesis is that the age-associated dysfunction of monocyte–macrophages is the result of their functional adaptation to the age-associated changes in tissue environments. The resultant loss of orchestration of the functional capabilities of these cells would undermine the efficacy of both the innate and adaptive immune systems. Both the T-lymphocyte and B-lymphocyte compartments of the adaptive immune system deteriorate progressively with advancing age [34, 35, 64, 84, 108]. The implications of this hypothesis are that mononuclear phagocyte function may change with age in a tissue specific manner, that changes in macrophage function may contribute sig-

nificantly to decreased clearance of microorganisms and decreased responsiveness of the adaptive immune system.

DCs and monocytes are progressively affected during ageing. A numerical reduction of PBDCs concomitant with increase of monocytes and an impaired ability of both populations to produce IL-12 have been documented during senescence. The ability of PBDCs to produce IL-12 upon lipopolysaccharide (LPS) stimulation progressively declines with age, while their ability to produce IL-10 remains unaffected. Monocytes show the same selective impairment. Given the central role of IL-12 in the induction of protective immunity, this finding appears relevant to the increased incidence of morbidity and mortality from infections and cancer occurring in aged people. The decrease in IL-12 production may contribute to the dysregulation between the T-helper (TH)1 and TH2 subsets, characterized by a predominant production of TH2 cytokines, which has been described in the elderly [32, 34, 75].

Influenza virus-specific T-cell responses are decreased in the aged, and it is in part a result of defects in antigen presentation. The increased incidence of pneumococcal infections is a result of a defect in the production of antibodies to the capsular polysaccharide antigens, which are critical for killing of the bacteria by the phagocytic cells. This is in part a result of deficiencies in function [14].

Aged subjects are susceptible to infection with Streptococcus pneumoniaebacteria as a result of an inability to make antibodies to capsular polysaccharides. This is partly a result of decreased production of proinflammatory cytokines and increased production of IL-10 by mononuclear phagocytes. A major reason for the inability of macrophages from the aged to support B-cell responses to polysaccharide antigens is a result of a defect in secretion of IL-1 and IL-6. However, the cytokine secretion defect is not limited to IL-1 and IL-6, as other proinflammatory eytokines, such as IL-12 and TNF-α are also produced at lower levels by macrophages from the aged in comparison with young. To understand the molecular basis of cytokine dysregulation in aged mouse macrophages, Chelvarajan RL et al. [15] performed a microarray analysis on RNA from resting and LPS-stimulated macrophages from aged and control mice revealing that immune response (proinflammatory chemokines, cytokines, and their receptors) and signal transduction genes were specifically reduced in aged mouse macrophages following LPS stimulation. Accordingly, expression of IL-l and IL-6 was reduced, and IL-l0 was increased. There was also decreased expression of IFN-γ. Genes in the Toll-like receptor-signaling pathway leading to nuclear factor-kB activation were also down-regulated by IL-1 receptor-associated kinase 3, a negative regulator of this pathway. An increase in expression of the gene for p38 MAPK was observed with a corresponding increase in protein expression and enzyme activity confirmed by Western blotting. Low doses of a p38 MAPK inhibitor enhanced proinflammatory cytokine production by macrophages and reduced IL-10 levels, indicating that increased p38 MAPK activity has a role in cytokine dysregulation in the aged mouse monocyte–macrophages [8, 19]. Macrophages from the aged were not defective in IL-10 production but produced more of this cytokine than macrophages from the young. Thus, the cytokine production is dysregulated in monocyte–macrophages from the aged following LPS stimulation.

A reduction in secretion of VEGF and expression of CAMs are thought to contribute to the delay in wound healing in the aged. In contrast, peritoneal macrophages from aged mice have been shown to produce more cyclooxygenase-2 (COX-2) and prostaglandin E_2 (PGE_2) in response to LPS stimulation. Moreover, the expression of a variety of TLRs, including TLR4, is decreased in the aged, which could be the reason for a decreased response of mononuclear phagocytes from aged mice to LPS [26].

LPS stimulation not only induces expression of many genes but also represses many genes that are constitutively expressed in mononuclear phagocytes [38]. Some of these repressed genes include PPAR-γ, CCL24, and CCRl. PPAR-γ has been shown to inhibit production of several inflammatory mediators such as TNF-α, IL-1, IL-6, and inducible nitric oxide synthase (NOS) and its suppression by LPS may be a prerequisite for the induction of the LPS-induced inflammatory phenotype [103, 104]. Macrophages from aged mice have a global defect in the TLR signaling pathway and in production of proinflammatory cytokines and chemokines, and the antiinflammatory cytokines are increased, such that the splenic macrophages in the aged have an antiinflammatory phenotype.

Kang et al. [105, 106] observed an age-related increase in COX-2 expression in monocytes. Cyclooxygenase catalyses the formation of prostanoids that are crucial in maintaining homeostasis and important in inflammation. The increased COX-2 in monocytes of older humans, which is mirrored in rats, may have downstream implications in atherosclerosis and cardiovascular risk as mononuclear prostanoids are implicated in atherosclerotic plaque stability. COX-2 is the major COX system in monocytes and monocytes-derived macrophages. Upon activation, these cells are responsible for production of COX-2-derived PGE_2, which is an important signaling molecule. Therefore, increased expression of COX-2 may lead to enhanced PGE_2 production, which is known to promote atherosclerotic plaque instability by stimulating MMP-2 and MMP-9 to degrade plaque architecture. It is interesting to note that in ageing rats, monocyte COX-2 expression increase in line with COX-2 levels in vascular smooth muscle and endothelial cells, indicating that these blood elements may be a predictor of systemic status [107].

The mechanism for an age-related change in COX formation is elusive. However, one mechanism could involve histones. When histones are acetylated by histone acetyltransferase, the DNA becomes more accessible to transcription factors. Also, age-linked increases in oxidative stress, proinflammatory agents (IL-1, IL-6), and total cholesterol levels could be involved [60].

There is some controversy concerning the basis for the decline in production of inflammatory cytokines and oxidative radicals in response to LPS stimulation. Renshaw et al.[28, 92] reported that the expression of TLR on macrophages was reduced with advancing age and that this was the basis for the reduced cytokine production upon stimulation with LPS. Boehmer et al. [9, 10] reported that TLR expression was not impacted by advanced age. The influence of aging appears to be selective. Macrophages from aged mice have increased levels of COX-2 and produce elevated levels of PGE2 upon stimulation with LPS [53, 113]. LPS induction of IL-10 production also appears to be elevated in macrophages from aged

rodents and humans [96, 100]. It thus appears that aging selectively impacts LPS-induced signaling cascades such that some functions are depressed and others are elevated. Another example of a signaling deficiency that appears in advanced age is responsiveness to IFN-γ. Although expression of the receptor for IFN-γ appears to be normal, IFNγ-induced phosphorylation of MAPK and STAT-1 is reduced in aged rodents [27, 115]. Oxidative stress is hypothesized to alter transcription factors and nuclear receptors and thus alter the ability of macrophages to respond to inflammatory stimuli [68]. Antioxidants do seem to improve monocyte inflammatory function [87, 101, 114]. Neuroendocrine factors and stress hormones have also been hypothesized to contribute to the immunosenescence and decreased macrophage function. Haynes et al. [54], reported that administration of inflammatory cytokines of the innate immune system enhanced the adaptive immune response of aged mice, so that restoration of the functional balance of mononuclear phagocytes in the elderly will not only improve innate responses but, as a result, improve the function of the adaptive immune system, as well.

NK and NKT Cells

NK Cells in Human Ageing

Raquel Tarazona, Inmaculada Gayoso, Corona Alonso, M. Luisa Pita, Esther Peralbo, Javier G. Casado, Beatriz Sánchez-Correa, Sara Morgado and Rafael Solana

Contents

Abstract: NK cells are cytotoxic lymphocytes that are involved in the early defense against virus infected and tumor cells. NK cells exhibit the capacity to distinguish normal and damaged cells as well as self- and foreign cells. Besides their cytotoxic capacity NK cells also regulate the immune response by producing cytokines and chemokines that directly participate in the elimination of pathogens or activate other cellular components of immunity. NK cells express a broad range of activating receptors and their function is controlled by inhibitory receptors specific for the MHC class I molecules that are ubiquitously expressed on target cells.

Several alterations have been described in human NK cell function with advancing ageing, therefore contributing to immunosenescence. Thus whereas healthy elderly, including centenarians, have preserved NK cell number and function, a decrease in NK cell activity is associated to increased incidence of infectious and inflammatory diseases and to increased risk of death due to infection. Here, we describe recent data about the effects of ageing on NK cells.

Keywords: Ageing • Immunosenescence • NK cells • Cytokines • NK cell ceptors

1 Introduction

Although it had been generally accepted that some aspects of innate immunity, are well preserved in ageing (Pawelec et al. 1998), cumulative evidences in the last decade support the existence of age-associated changes in the cellular components of the innate immune system, including NK cells, that are important in the increased susceptibility of elderly individuals to infectious diseases (Delarosa et al. 2006; Solana et al. 2006).

2 Natural Killer Cells

Natural killer (NK) cells are bone marrow-derived lymphocytes that participate in the early defense against intracellular pathogens and tumor cells. NK cells are part of the innate immunity arsenal and have been defined as cytotoxic non-T lymphocytes. The most important characteristic that distinguishes T-cells from NK cells is the T-cell antigen receptor (TcR) which is made from rearranging genes and is clonally expressed (Parham 2006). NK cells act within hours of infection in contrast to T-cells that require several days to arise. NK cells are characterized by the expression of CD56, an isoform of the neural cell adhesion molecule (N-CAM) and/or CD16, the low-affinity IgG Fc receptor (FcγRIIIa). The discovery on NK cells of receptors for polymorphic major histocompatibility complex (MHC) class I molecules has contributed to better understanding of NK cell biology. In spite of this, NK and T-cells have much in common: cell-surface molecules, effector functions as cytokine secretion and cytotoxicity. Many of the cell surface molecules we called NK cell associated receptors (NKR) are also expressed by subpopulations of T-cells and NKR expression on T-cells has been associated to memory/effector cells (Tarazona et al. 2002, 2004; Vallejo et al. 2004; Abedin et al. 2005; Casado et al. 2005; Delarosa et al. 2006; Michel et al. 2006; Gayoso et al. 2007; Solana et al. 2007; Lemster et al. 2008).

Although NK cells have been considered for many years as being a simple, homogenous and unspecific population in comparison with T- or B cells of adaptive immunity, different subsets have been defined according to the expression of NK markers and their capacity to kill or produce cytokines. Thus, human NK cells can be divided into two functional subsets based on their cell surface density of CD56, $CD56^{bright}$ immunoregulatory cells and $CD56^{dim}$ cytotoxic cells. Both subsets have been characterized extensively regarding their different functions, phenotype, and tissue localization. The $CD56^{bright}$ NK cell subset has a distinctive role in the innate immune response as the primary source of NK cell-derived immunoregulatory cytokines (Cooper et al. 2001; Farag et al. 2003; Wendt et al. 2006). $CD56^{dim}$ and $CD56^{bright}$ subsets also differ in the expression of chemokine receptors that may contribute to cell trafficking (Cooper et al. 2001; Fehniger et al. 2003; Berahovich et al. 2006).

NK cells were long thought to respond directly to tumor or infected cells, but recent data show that NK cells acquire functionality through priming by dendritic cells (DC; Zitvogel et al. 2006; Long 2007; Lucas et al. 2007). This cross-talk between NK cells and myeloid DC also leads to DC maturation and may determine the quality and strength of the adaptive immunity responses (Vitale et al. 2005; Moretta et al. 2006).

NK cells exhibit the capacity to distinguish normal and damaged cells as well as self- and foreign cells. NK cell function is controlled by inhibitory receptors for the MHC class I molecules that are ubiquitously expressed on target cells (Table 1). In consequence, MHC class I positive targets are more resistant to NK mediated lysis. Human receptors for HLA class I molecules can be included into two structural types, those with immunoglobulin (Ig)-type domains (killer Ig-like receptors (KIR) and leukocyte immunoglobulin-like receptor) and those with lectin-like domains called CD94/NKG2 receptors. Inhibitory and activating forms of KIR and CD94/NKG2 receptors have been described. The ligands for KIRs are polymorphic determinants of HLA-A, HLA-B and HLA-C molecules whereas the ligands for the human CD94/NKG2 receptor are complexes of HLA-E bound to peptides derived from the leader sequences of other HLA class I molecules (Borrego et al. 2002; Lopez-Botet et al. 2004; Lanier 2005; Guma et al. 2006). HLA-G, a non-classical MHC class I molecule, is recognized by Leukocyte immunoglobulin-like receptor subfamily B member 1 (LILRB1/LIR1/ILT2/CD85j) and member 2 (LILRB2/LIR2/ILT4/CD85d) and KIR2DL4 (Shiroishi et al. 2006). Inhibitory receptors play a role in "missing-self" recognition, that confers to NK cells the capacity to attack cells that lose or downregulate the expression of MHC class I molecules. However, the expressions of inhibitory receptors on NK cells is not uniform and are germline-encoded by a set of polymorphic genes that segregate independently from MHC genes. Therefore, how NK cell self-tolerance arises in vivo is still poorly understood.

Licensing of NK cells by self-MHC class I has been proposed as a mechanisms for NK cell tolerance to self. This process takes place during NK cell maturation and involves inhibitory receptors that recognize target cell MHC class I molecules. This process results in two types of tolerant NK cells: functionally competent (licensed) NK cells, whose effector responses are inhibited by self-MHC class I molecules through the same receptors that conferred licensing, and functionally incompetent

Table 1 HLA class I specific inhibitory receptors expressed on human peripheral blood NK cells

Receptor	Ligand
KIR2DL1	HLA-C group 2
KIR2DL2/3	HLA-C group 1
KIR3DL1	HLA-B alleles
KIR3DL2	HLA-A alleles
CD94/NKG2A	HLA-E
KIR2DL4	HLA-G
ILT-2/CD85j	HLA-G and other HLA class I molecules
ILT-4/CD85d	HLA-G and other HLA class I molecules

(unlicensed) NK cells. Although this process has been defined for mouse NK cells several findings suggest that human NK cells also undergo this maturation process termed licensing (Kim et al. 2005; Parham 2006; Raulet 2006; Raulet and Vance 2006; Yokoyama and Kim 2006). Once NK cells acquire functional competence through "licensing'' by self-MHC molecules, the result of effector-target interactions is governed by the integration of inhibitory and activating signals that determines whether the NK cell is finally activated, secretes cytokines and lyses target cells (Gasser and Raulet 2006).

NK cells recognize infected cells or tumor cells by using different types of activating receptors (Table 2) that may act in synergy to enhance cytotoxicity or cytokine release after activation (Bryceson et al. 2006). Activating receptors expressed by NK cells include besides the well characterized receptor CD16 that binds FcγRIIIa, NKG2D, CD244, NKp80 and the natural cytotoxicity receptors (NCR) NKp30, NKp46, NKp44. Ligands for activating receptors comprise both non-self ligands and self proteins up-regulated on damaged cells.

The C-type lectin-like receptor NKG2D is unique among activating receptors in that it recognizes a wide range of ligands some of which are primarily expressed in "stressed" tissues or on tumor cells. Human NKG2D ligands are the MHC class I chain related (MIC) proteins MICA and MICB and the UL-16 binding proteins ULBP-1, ULBP-2, ULBP-3 and ULBP-4 (Eagle and Trowsdale 2007; Mistry and O'Callaghan 2007).

NKp30 and NKp46 are constitutively expressed in NK cells and NKp44 is induced after activation (Arnon et al. 2006; Bryceson et al. 2006; Gasser and Raulet 2006). The NKp46 and NKp44 receptors recognize viral haemagglutinins (Draghi et al. 2007; Ho et al. 2008; Cagnano et al. 2008) and NKp30 has been shown to bind a still undefined ligand on DCs. This binding can be inhibited by

Table 2 Activating receptors expressed on human peripheral blood NK cells

Receptor	Ligand

DNAM-1	CD155, CD112
CRACC	CRACC
NTB-A	NTB-A

* Induced after activation

the main tegument protein of human cytomegalovirus, pp65 (Arnon et al. 2005, 2006).

Along with CD244, that binds CD48, other members of the signaling lymphocytic activating molecule (SLAM) family of NK cell receptors have been identified: NTB-A and CRACC, which bind NTB-A and CRACC, respectively.

Strong stimulatory signaling resulting from increased levels of stimulatory ligands can often overcome inhibitory signals provided by MHC class I molecules expressed on target cells (Bauer et al. 1999; Cerwenka et al. 2000; Diefenbach et al. 2000).

3 Effect of Ageing on NK Cell Number and Kinetics

Several alterations have been described in NK cells with advancing age, both in animals and humans. In old humans, contradictory data exist due mainly to the different selection criteria of the elderly populations studied, a common problem when comparing studies by different research groups. Thus, whereas there are studies showing that overall NK cell number and cytotoxicity is not significantly affected in very healthy elderly people including centenarians, in other studies that have not used the same strict selection criteria, the number or functions of these cells from elderly subjects are decreased (Table 3).

In a recent study it has been shown that ageing has an impact on NK cell kinetics (Zhang et al. 2007). The analysis of NK cell homeostasis using deuterium-enriched glucose has shown that these cells are in a state of dynamic homeostasis consistent with a model of postmitotic maturation preceding circulation and with a turnover time in blood of about 2 weeks. In young healthy individuals the proliferation rate is 4,3±2,4%/day, equivalent to a doubling time of 16 days, the total production rate is $15\pm7\times10^6$ cells/l/day and the half-life is approximately 10 days. However in NK cells from healthy elderly subjects the proliferation and production rates are significantly lower (2,5±1,0%/day and $7,3\pm3,7\times10^6$ cells/l/day, respectively; Zhang et al. 2007). This study demonstrates that NK cell numbers are well preserved in healthy ageing, in spite of evidences for a reduction in total NK cell production rates of about 50%. These results suggest an increased proportion of long-lived NK cells in the elderly subjects. This may be related to the increased proportion of $CD56^{dim}$ cells, as previously reported in elderly subjects (Borrego et al. 1999).

The decreased proliferation and production rates of NK cells in the elderly can be associated to the telomere shortening observed in the elderly. Thus it has been shown that NK lymphocytes show an age-associated loss of telomeres together with an age-associated reduction of telomerase activity that was evident in individuals over 80 years of age in particular in the oldest individuals and in those with increased NK cell numbers (Mariani et al. 2003a, b).

Table 3 Effect of ageing on the NK cell compartment

	Decreased	Preserved	Increased
Percentage of NK cells			Facchini et al. 1987; Mariani et al. 1994; Borrego et al. 1999; Lutz et al. 2005

4 NK Cells and Health Status in the Elderly

An extensive analysis of NK cell number and function in elderly individuals strengthens the significance of NK cell activity in healthy ageing and longevity. Thus a decreased NK cell function in old individuals is associated with an increased incidence of infectious diseases and death due to infection in elderly humans (Ogata et al. 1997, 2001) and elderly people (aged >85 years) with low numbers of NK cells were reported to have three times the mortality risk in the first two years of follow-up than those with high NK cell numbers (Remarque and Pawelec 1998). It has been also reported that decreased NK cell activity in the elderly is also associated with increased frequency of disorders as atherosclerosis

(Bruunsgaard et al. 2001). In a similar way it has been shown that a preserved NK function is related to better health status and lower incidence of respiratory tract infections in elderly individuals and to a better response to influenza vaccination (Mysliwska et al. 2004). Additional evidences supporting the significance of NK cells in healthy ageing come from studies in centenarians, that, in general, have a very well preserved NK cell cytotoxicity (Sansoni et al. 1992, 1993; Franceschi et al. 1995). Furthermore, when NK cells are studied in nonagenarians and centenarians the results show that higher NK cell numbers and NK cytolytic activity were associated with better retained ability to maintain an autonomous life style. These parameters were also associated with higher serum vitamin D levels, a well-nourished status and balanced basal metabolism, indicating the impact of hormonal and nutritional variables on NK cell function in elderly people and again emphasizing that results on NK cells may depend to a much greater extent than T-cells on the state of health of the individual (Mariani et al. 1998b; Pawelec et al. 1998). Moreover, the percentage of NK cells has been shown to correlate with serum zinc and selenium concentrations, and with plasma vitamin E and ubiquinone-10 concentrations, confirming that micronutrients may affect the number and function of NK cells in old age (Mariani et al. 1998b; Ravaglia et al. 2000). This suggests that any analysis of biomarkers of immunosenescence must of necessity take these variables into account.

Together, these results support the fact that preserved NK cytotoxicity can be considered a marker of healthy ageing, whereas low NK cytotoxicity is a predictor of increased morbidity and mortality due to infections.

5 Effect of Ageing on the Expression and Function of NK Cell Receptors

Although the overall NK cell cytotoxicity seems not to be significantly affected in the very healthy elderly donors, it has been demonstrated that, even in these donors, there is a decreased cytotoxicity per NK cell, associated with defective signal transduction (Table 3; Mariani et al. 1998a; Solana and Mariani 2000). Thus, the maintenance of NK cell activity is probably due to a compensatory increase in the number of NK cells to accommodate a possible decrement of NK cell cytotoxicity (Mariani et al. 1994). This increased cell number has been related to a higher number of $CD56^{dim}$ rather than $CD56^{bright}$ subset containing the most cytotoxic NK cells (Borrego et al. 1999; Solana et al. 1999). Neither the binding of effector cells to the target cells nor the perforin content of NK cells is significantly different in the old and young groups. On the contrary the defective NK cell cytotoxicity is associated with a decreased capacity of NK cells to release IP3 after interacting with the target cells and a delayed hydrolysis of PIP2, indicating that the PKC-dependent pathway is affected as a consequence of ageing (Mariani et al. 1998a). However NK activation and cytotoxic granule release induced by CD16 crosslinking is not affected by ageing (Pawelec et al. 1998; Solana et al. 1999; Solana and Mariani 2000; Bruunsgaard et al. 2001; Lutz et al. 2005).

Furthermore the PI-3-kinase pathway coupled to CD16 triggering is not significantly affected in NK cells from elderly people, indicating that the transduction pathways involved in natural or CD16-dependent NK cytotoxicity are differentially affected by ageing (Mariani et al. 1998a; Solana and Mariani 2000).

Despite the maintenance of CD16-mediated killing, the decreased per-cell NK cytotoxicity against the classic target cell line K562 suggests that the expression and/or the functionality of other NK activating receptors are likely to be defective in the elderly. Very little is known about the effects of senescence on the function of NK receptors, and discrepant results have been reported in this context. Whereas it was reported that the expression of HLA-specific killer immunoglobulin-like receptors is not significantly affected in NK cells from elderly compared to young donors (Mariani et al. 1994), other study has shown that NK cells present an age-related increase in KIR expression and a reciprocal decrease in CD94/NKG2A expression, although the CD94/NKG2A inhibitory signaling pathway is intact (Lutz et al. 2005).

In relation with the expression of other NK receptors involved in NK cell cytotoxicity, our results show that NK cells from elderly donors have a decreased expression of the activating receptor NKp30 (Fig. 1). NKp30 mediates the crosstalk between NK and DCs via the recognition of an unknown ligand expressed on DCs. As summarized on Figure 1 the engagement of the NKp30 receptor can lead either to a direct killing of DCs by NK cells, or to the secretion of IFN-gamma and TNF-alpha and the subsequent maturation of DCs. Therefore NK-activated DCs loaded with tumor or virally derived antigen have an increased capacity to prime T-cells. In return, activated DCs release Th1 cytokines that further enhances NK activation (Arnon et al. 2005, 2006). The decreased expression of this receptor on NK cells

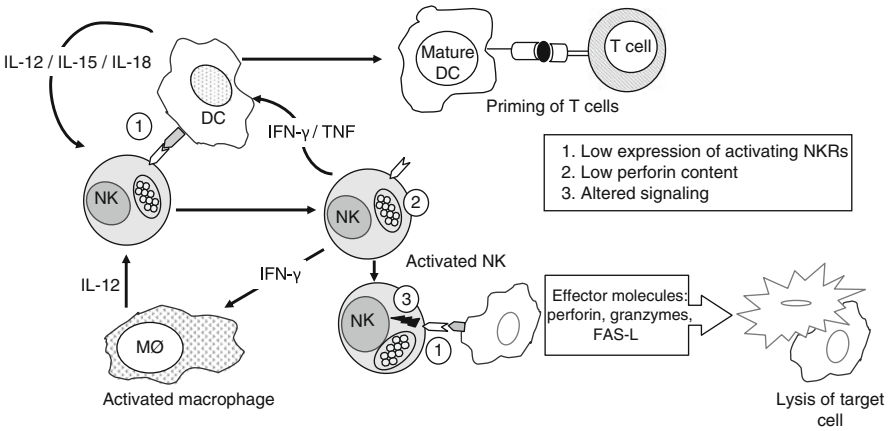

Fig. 1 Effect of human ageing on NK cell function. Cross-talk of NK cells with DCs through NKp30 receptor interaction with its unknown ligand results in inducing DCs maturation and NK cell activation. Whereas DCs collaborate with T-cells in the initiation of adaptive response, activated NK cells produce cytokines and kill target cells. Age-associated alterations in NK cell include: (1) Low expression of activating NKRs that could result in defective cross-talk with dendritic cells and defective recognition of target cells, (2) low perforin content, and (3) altered signal transduction

from elderly individuals should also affect the interaction between these cells leading to a decreased capacity to collaborate in the initiation of the adaptive immune response against virus infected or tumor cells (Fig. 1).

6 Effect of Ageing on NK Cell Response to Cytokines

Cytokine activation of NK cells results in enhanced cytotoxicity and in the synthesis and release of cytokines and chemokines. The enhancement of the cytotoxic activity of NK cells in response to IL-2, IL-12 or IFN-α and γ is well preserved in the healthy elderly. However, the capacity of these cytokine-activated killer cells to lyse the NK-resistant Daudi cell line is significantly decreased in the elderly (Kutza and Murasko 1994, 1996; Murasko and Jiang 2005). A major effect of ageing on cytokine and chemokine production by NK cells is a marked early decrease in IFN-γ secretion in response to IL-2, which can be overcome by increasing the incubation time (Murasko and Jiang 2005). In a similar way the production of MIP-1α, Rantes

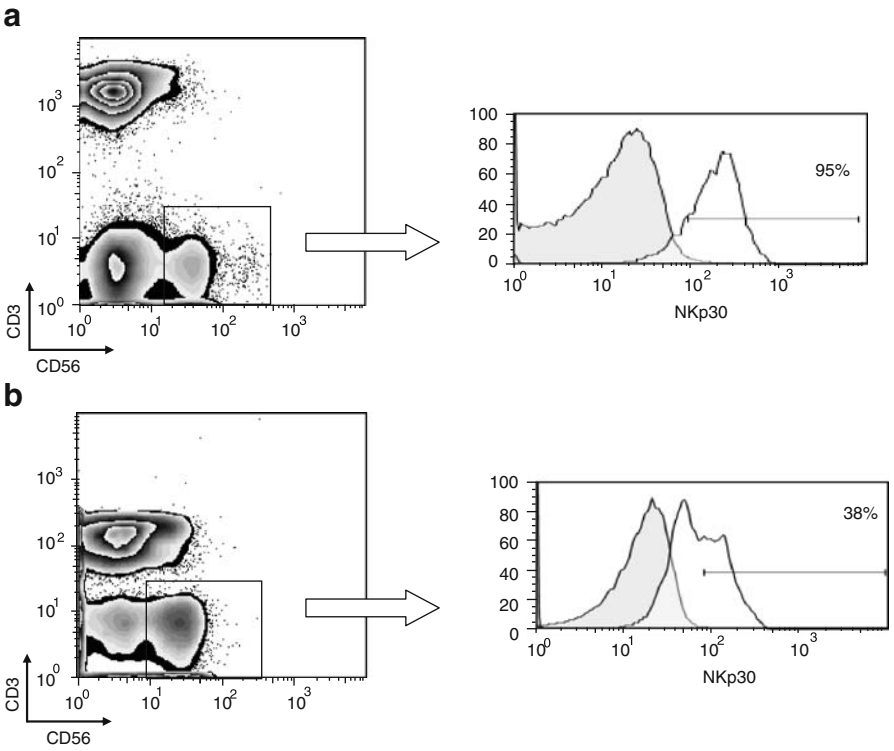

Fig. 2 Expression of NKp30 on NK cells from healthy young (a) and elderly (b) individuals. Peripheral blood lymphocytes were labeled with monoclonal antibodies against CD3, CD56 and NKp30. Results were analysed with a FACSCanto cytometer. Reduction of percentage and mean fluorescence channel of NKp30 was observed in elderly individuals

and IL-8 chemotactic cytokines by NK cells is decreased both in elderly subjects in response to IL-2 and in nonagenarians in response to IL-2 or IL-12 although these cells express the corresponding chemokine receptors. Because of the co-stimulatory role of chemokines on NK cell responses, the decreased production of chemokines can be involved in the defective functional activity of NK cells from old subjects (Mariani et al. 2001, 2002a, b).

Ageing also affects the response of NK cells to IFN-α/β both in mice and humans. This decreased response could be related to the delay in virus clearance observed in aged mice (Murasko and Jiang 2005). These results suggest that NK cells do show an age-associated defect in their response to cytokines, with a subsequent detriment both in their capacity to kill target cells and synthesize cytokines and chemokines.

7 Conclusions and Perspectives

NK cells are a key component of innate immunity in the elimination of virus infected or tumor cells. Recent evidences also support their significance in the initiation of adaptive responses by their crosstalk with DCs and subsequent activation of T-cells. NK cells can be affected by ageing, although several studies have shown a good correlation between the number and/or function of NK cells and the maintenance of an adequate health status in elderly and very elderly people (including nonagenarians and centenarians). On the contrary a decreased NK cell function is associated to increased risk of infectious diseases and risk of death due to infections, supporting the importance of the altered functions of NK cells in the age-associated deterioration of the immune system called immunosenescence.

Our recent finding that NK cells from healthy elderly individuals have a decreased expression of NKp30 receptor, important not only in NK cytotoxicity but also in regulating their cross-talk with DCs strongly support that the alterations in NK cells by ageing may have important consequences that may help to explain the association between a preserved NK cell function and the maintenance of a healthy status. Further studies on the effect of ageing on all NK cell subsets, on the expression and function of activating and inhibitory receptors and a more profound study of the molecular mechanisms involved in these processes are required to better understand the contribution of NK cell ageing to immunosenescence. Considering the increasing advances in the understanding of the mechanisms involved in NK cell interactions not only with tumor and virus infected target cells but also with other cells of the immune system the analysis of how ageing affect these different processes is mandatory.

Abstract: Natural killer (NK) cells are a lymphocyte subset in the innate immune system. These cells not only mount an early immune response to infections and neoplasia but also affect the adaptive immune system by communicating with dendritic cells. In this chapter, we review basic findings on NK-cells and then information from 1) rare patients with isolated NK-cell deficiency, 2) patients with certain malignant neoplasia, and 3) healthy middle-aged and elderly individuals. Those findings indicate that NK-cells are crucial immune components for sustaining life. With increasing age, numbers of T- and B-lymphocytes decline while the number of NK-cells increases. This is especially marked in centenarians. In terms of reduced tolerance to stress such as infections in the elderly, the power of early responders in the immune system including NK-cells may be especially important.

Keywords: Natural killer cells • Longevity • Infection • Neoplasia

1 Introduction

Studies examining healthy people showed that among the various components in the human immune system, natural killer (NK) cells are well maintained throughout life, even in centenarians. This is sharp contrast to the decline in T- and B-cell numbers with increasing age. Therefore, it is hypothesized that well-preserved NK-cell function is essential for longevity. In this chapter, we summarize basic findings on NK-cells, including recent understanding of the interaction between NK-cells and dendritic cells (DCs), and then review information so far obtained on the role of NK-cells in human longevity.

2 Overview of NK–cells

2.1 NK-cell Subsets

NK-cells were originally identified as a population of large granular lymphocytes and once considered to be a homogenous subset of lymphocytes in the peripheral blood (PB). However, NK-cells consist of heterogeneous populations. They can be divided into two subsets by the expression levels of CD56 (neural cell adhesion molecule, NCAM) and the presence or absence of CD16 antigen (FcγRIIIA),

which binds the Fc portion of IgG and mediates antibody-dependent cellular cytotoxicity (ADCC) by binding to opsonized cells [18, 43]. These two subsets, $CD56^{bright}CD16^{-}$ cells and $CD56^{dim}CD16^{+}$ cells, differ in their homing capabilities, i.e., $CD56^{bright}CD16^{-}$ NK-cells largely predominate in the lymph nodes (LNs) and comprise circa 10% of PB NK-cells, as well as in other functions including cytolytic activities, cytokine production and ability to proliferate. It was reported that the $CD56^{bright}CD16^{-}$ subset potently induces cytokine secretion, is a cytokine-responsive NK-cell subset, but has low intrinsic cytotoxicity, whereas the $CD56^{dim}CD16^{+}$ subset has little intrinsic secretory capability, but potent cytolytic activity [18, 56]. These subsets also express different receptors for chemokines, cytokines, and major histocompatibility complex (MHC) Class I ligands [67]. $CD56^{bright}CD16^{-}$ NK-cells constitutively express interleukin (IL)-2 receptors with high and intermediate affinity and increase in response to low doses of IL-2. On the contrary, $CD56^{dim}CD16^{+}$ NK-cells proliferate weakly in vitro in response to high doses of IL-2 [12]. Finally, resting $CD56^{bright}CD16^{-}$ NK-cells are large granular cells and express high levels of the CD94/NKG2 family and very low levels of the killer Ig-like receptor (KIR) family, while resting $CD56^{dim}CD16^{+}$ NK-cells contain numerous cytolytic granules in the cytoplasm and express both KIR and CD94/NKG2 receptor at relatively high levels [39].

2.2 NK-cell Development and Related Cytokines

NK-cells share a common lymphoid progenitor with thymocytes and B-cells [17]. In both humans and mice, early NK progenitors appear to be bone-marrow (BM)-derived $CD34^{+}$ cells, which express receptors for the *fms* tyrosine kinase 3 (Flt3) ligand, c-kit ligand, and IL-2 receptor β chain (CD122) shared with the trimeric receptor for IL-15, and the BM microenvironment is necessary for complete maturation of NK-cells. BM stroma-derived IL-15 in cooperation with c-kit ligand and Flt-3 ligand is a critical factor for the development of mature NK-cells from NK progenitors in the BM [22, 27]. IL-15, which is reported to protect NK-cells from IL-2 activation-induced cell death, is also important for the maintenance of NK-cells [55, 68, 79]. NK progenitors respond to early-acting, stromal cell-derived growth factors such as the c-kit and Flt3 ligands and develop into NK precursors with the $CD34^{+}$IL-2/IL-15R$\beta^{+}CD56^{-}$ phenotype. IL-15 matures these NK precursors into functional $CD56^{bright}$ NK-cells [28]. However, further studies are required to understand the regulation of $CD56^{dim}$ NK-cell differentiation.

IL-21, another cytokine that can bind the common γ-chain shared with IL-2, IL-4, IL-7, IL-9, and IL-15, plays a role in the proliferation and maturation of NK-cells [63]. IL-7 is an early-acting cytokine responsible for the generation of immature $CD56^{bright}$ NK-cells [86]. IL-2 is a growth factor for NK progenitors and mature NK-cells. In addition, IL-2 induces the production of NK effector molecules and enhances the lytic activity of NK-cells. IL-12 and IL-18 are NK-activating cytokines during late NK-cell differentiation and synergistically enhance the cytotoxicity of

and interferon (IFN)-γ production by NK-cells [34, 44]. IL-1 and IL-18 potentiate the effects of IL-12 by upregulating IL-12 receptors on NK-cells.

2.3 NK-cell Receptors

NK-cell receptors (NKRs) can be classified as inhibitory and activating [10, 53]. The MHC Class I-specific inhibitory receptors were first identified in both mice and humans. It is well known that NK-cells are able to lyse MHC Class I-negative tumors and infected cells, which are not recognized by the inhibitory receptors on NK-cells. Several inhibitory types of receptors exist, including the two main groups consisting of the KIR family (KIR2DL, KIR3DL, etc.) and the heterodimeric, C-type lectin receptors CD94-NKG2A/B, which bind to MHC Class I molecules and human leukocyte antigen (HLA)-E, respectively [10, 11]. HLA-E is a nonclassical, Class Ib molecule for which surface expression requires binding of peptides derived from the leader sequences of different HLA Class I molecules. The lack of even a single MHC Class I allele, which is a frequent event in cancer, sensitizes HLA-E to NK-cell cytotoxicity [53].

NK-cell cytotoxicity is also triggered by activating receptors including MHC Class I-specific receptors, i.e., KIR (KIR2DS, KIR3DS, etc.), C-type lectin receptor CD94/NKG2C, and non-MHC Class I-specific receptors such as natural cytotoxicity receptors, NKG2D, leukocyte adhesion molecule, and DNAX accessory molecule-1 (DNAM-1, CD226). NKG2D and DNAM-1 can recognize stress-induced ligands expressed by several tumor cell lines, such as MHC-I polypeptide-related sequence A (MICA), MHC-I polypeptide-related sequence B (MICB), and UL-16-binding protein (NKG2D ligands), and poliovirus receptor (CD155) and Nectin-2 (CD112, DNAM-1 ligands) [15, 64, 66]. Natural cytotoxcity receptors such as NKp46, NKp44, and NKp30, for which the host ligands remain unknown, mediate the lysis of many types of cancer cells. Additional receptors of NK-cell activation also comprise a series of coreceptors including 2B4, NTB-A, and NKp80 coreceptors, CD18/CD11 (β2 integrins), CD2 adhesion molecules, and Toll-like receptors (TLR) [51, 72]. NK-cell activation depends on the expression of these ligands on the target cells. These receptors provide both inhibitory and activating signals, and the balance between them determines NK-cell activation, proliferation, and effector functions.

2.4 NK-cell Function

The main function of NK-cells is host defense against tumors and infections. NK-cells can directly kill infected cells or tumor cells that have lost the expression of MHC Class I molecules. NK cytotoxicity can be triggered by viral and bacterial products directly binding to surface TLR3 and TLR9 [52, 72]. NK-cells also act as

the conductor for the activation of the immune defense along with T- and B-cells, macrophages, and immune effector cells in local sites.

NK-cells can respond to infections directly by recognizing infected cells, and indirectly by cytokine secretion and interaction with DCs expressing TLR. It has been reported that NK-cells play an important role in antiviral defense, especially in controlling the severity of Herpes virus, Hepatitis, and Human immunodeficiency virus (HIV) infections [7]. To perform this role, NK-cells require the activation of multiple effector pathways including direct cytotoxicity and the release of cytokines and chemokines. Viral infection immediately induces macrophages to produce cytokines such as tumor necrosis factor (TNF)-α, IL-12 and IFN-γ. Activated NK-cells can also secrete several cytokines, i.e., IFN-γ, granulocyte macrophage colony-stimulating factor (GM-CSF), M-CSF, TNF-α, IL-5, IL-10, and IL-13, to control the growth and spread of pathogens and tumors. Furthermore, many of the cytokines produced by NK-cells can affect the initiation and maintenance of adaptive immune responses. Although NK-cells are activated and kill virus-infected cells immediately, it takes 1-2 weeks after infection to activate adaptive immune responses, such as pathogen-specific killer T-cells and antibodies produced by B-cells.

Intrahepatic lymphocytes (IHLs) contain 37% NK-cells and that percentage in the IHL pool may increase to 90% in hepatic disease [23]. Infection with hepatotropic viruses such as Hepatitis C virus (HCV) activate liver NK-cells that play a crucial role in the recruitment of virus-specific T-cells to the liver and in inducing antiviral immunity in the site. Activated NK-cells can kill virus-infected cells by a cytolytic mechanism via the perforin/granzyme and FasL pathways and produce proinflammatory cytokines that can induce an antiviral state in host cells. Compromised NK-cell functions have been reported in chronic HCV-infected patients. To control mouse cytomegalovirus (CMV) infection, NK-cells use two main effector mechanisms: the secretion of IFN-γ and direct lysis of infected cells by exocytosis of granules that contain perforin and granzymes. TLR9 recognizes unmethylated CpG DNA, a component of bacterial and viral DNA, and delivers signals for cellular activation through the adaptor protein MyD88. TLR9-deficient or MyD88-deficient mice show an increased susceptibility to mouse CMV, indicating an important role of TLR9 and MyD88 in protection against mouse CMV [3, 20, 42, 74]. In human CMV infection, activated NK-cells produce IFN-γ and secrete lymphotoxin-α and TNF, which contributes to the NF-κB-dependent release of IFN-β from infected cells. IFN-γ and IFN-β work together to inhibit CMV replication [38].

NK-cell-produced IFN-γ might contribute to protecting humans from Influenza A and Sendai viruses. Contact between NK-cells and virus-infected macrophages induces IFN-γ production. Furthermore, the expression of MICB, a ligand for the NKG2D receptor, was up-regulated in virus-infected macrophages, suggesting the role of MICB in the activation of the IFN-γ gene in NK-cells [71]. In HIV infection, the number of $CD3^{-}CD56^{+}$ NK-cells in the PB was dramatically reduced in patients with ongoing viral replication compared with uninfected or aviremic patients. Therefore, NK-cells play an important role in controlling HIV infection. NK-cells obtained from viremic patients produce more IFN-γ and TNF-α than NK-cells from

aviremic patients [2]. A recent study has shown that the decrease in MHC Class I molecules on T-cell blasts infected with certain HIV strains was selective. The expression of HLA-A and -B was decreased in infected cells, whereas HLA-C and -E remained on the surface. HLA-C and -E bind to the KIR and CD94-NKG2A receptors, respectively, on NK-cells, resulting in inhibition of NK-cell-mediated killing of HIV-infected cells [8].

NK-cells are also activated during parasitic and bacterial infections. NK-cells produce IFN-γ in response the infection of red blood cells with *Plasmodium falciparum*, the causative agent of malaria [4]. The importance of NK-cells in protecting against bacterial infection has been controversial and may depend upon the site of infection or type of inflammatory response elicited. The expression of the activating receptors NKp30, NKp46, and NKG2D was enhanced in NK-cells after exposure to monocytes infected with the intracellular pathogen *Mycobacterium tuberculosis*. The infected monocytes upregulated the expression of the NKG2D ligand ULBP1 through TLR2 activation, and NK-cells lysed infected monocytes through NKG2D- and NKp46-dependent mechanisms [75].

2.5 Localization and Trafficking of NK-cells

NK-cells comprise approximately 5–20% of lymphocytes in the spleen, liver, and PB, and are present at lower levels in the BM, thymus, and LNs [31, 45]. Although NK-cell trafficking is not understood in detail, it was reported that chemokine secretion and chemokine receptor expression by NK-cells are dynamically regulated, and that some chemoattractants and chemokines can induce the migration of NK-cells to inflammation sites [67]. It is possible that changes in key adhesion molecules may induce the physical movement of NK-cells into sites of infection. $CD56^{bright}CD16^{-}$ NK-cells express CCR5 and CCR7 as well as L-selectin, which can attract T-cells to LNs, and $CD56^{dim}CD16^{+}$ NK-cells express CX3CR1. In addition, both of these NK subsets express CXCR3 and CXCR4 [13, 32, 67].

2.6 NK-DC Interactions

The crosstalk between NK-cells and myeloid DCs leads to NK-cell activation and DC maturation. Activated NK-cells can kill DCs that fail to undergo proper maturation; this phenomenon is called “DC editing” [53]. In vitro studies showed that NK-cells activated by IL-2 can kill immature DCs by ligation between NK-activating receptors, mainly NKp30 on NK-cells, and still unidentified cellular ligands on DCs [30, 65]. Consistent with these data, NK-cells derived from patients with acute myeloid leukemia, who frequently exhibit downregulation of NKp30 surface expression, have impaired killing of immature DCs [19, 29]. Furthermore, the NK-cell-mediated DC killing was inhibited by transforming growth factor-β, which can downregulate the

surface expression of NKp30 [14]. Recently, DNAM-1 has been shown to cooperate with NKp30 in the NK-cell-mediated lysis of DCs [64]. The expression of Nectin-2, one of the DNAM-1 ligands, is increased on immature DCs. Studies using immunohistochemistry and confocal microscopy showed that DNAM-1 ligands are expressed by DCs present in normal LNs. In general, the function of activating NKRs is under the control of inhibitory NKRs specific for HLA Class I [54]. However, immature DCs do not follow this rule. Analysis of NK clones showed that an NK subset, which lacks KIR specific for HLA Class I alleles and expresses HLA-E-specific CD94/NKG2A receptors (the $KIR^{-}NKG2A^{dull}$ phenotype), can kill immature DCs [21]. The DC editing mediated by NK-cells might be important in the selection of appropriate DCs in conjunction with the removal of DCs that fail to perform optimal antigen presentation and T-cell priming. NK-cells are not able to kill mature DCs, mainly because mature DCs express higher levels of HLA-E than immature ones.

During NK-DC interaction, NK-cells can induce DC maturation mediated by TNF-α and IFN-γ, which are released upon engagement of the NKp30 triggering receptor [77]. Semino et al showed that NK-DC interaction results in IL-18 secretion by DCs and then IL-18-activated NK-cells secrete the proinflammatory cytokine high mobility group B1 (HMGB1) [70]. HMGB1 can induce DC maturation and protect DCs from lysis. These data suggest that NK-cells mediate DC maturation by several pathways. NK-cells kill tumor cells and virus-infected cells, and subsequently prime DCs with the killed cell-derived antigens to induce specific $CD8^{+}$ T-cell responses [49, 50, 87]. After antigen uptake, DCs undergo maturation and release several cytokines, including IL-12, that enhance NK functions. NK-DC interactions also induce primary tumor rejection and long-term cytotoxic T-lymphocyte memory, bypassing the requirement for $CD4^{+}$ helper T-cells [1].

3 Contribution of NK-cells to Human Longevity

To gain insight into role of NK-cells in human longevity, we review findings 1) from patients with isolated NK-cell deficiency, 2) on the relationship between NK-cells and the development and progression of malignancies in humans, and 3) on NK-cells in the healthy elderly.

3.1 Isolated NK-cell Deficiency in Humans

Various isolated defects in human immune system have been reported, which provide valuable information on the function and importance of each component of the immune system [57]. However, primary isolated NK-cell deficiency, in which other immunologic functions are normal and which occurs in the absence of other immunocompromising conditions, is very rare. Moreover, in some reported cases, the distinction between NK-cells and T-cells expressing NK-cell markers was unclear. The

rarity of isolated NK-cell deficiency may imply the critical role of NK-cells in human life. Another explanation is that because NK-cells are an early responder in the immunogic defense system and communicate with late components in the immune system, another immune component(s) is often secondarily impaired in isolated NK-cell deficiency. In this chapter, we do not discuss patients in whom both NK-cells and other immunlogic components were compromised or unexamined [46, 82].

A girl reported in 1989 by researchers at the University of Massachusetts Medical School is probably the best-known patient with isolated NK-cell deficiency [6]. She had experienced recurrent otitis media since infancy and at the age of 13 years developed severe varicella infection and polymicrobial sepsis with *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Staphylococcus aureus* infection. Four years later, she again developed sepsis with *S. aureus* infection and interstitial pneumonia due to CMV. $CD56^+$ and $CD16^+$ cells were completely absent in her PB, along with an almost complete absence of NK-cell cytotoxicity and ADCC. She later developed aplastic anemia and died after undergoing stem cell transplantation [62]. The second patient was a 23-year-old woman who had recurrent condylomata due to human papilloma virus [5]. Her peripheral blood lacked NK ($CD3^-CD56^+$) cells but showed an increase in $CD3^+CD56^+$ cells. NK cytotoxicity was almost completely absent, which was only slightly augmented by the administration of IL-2. However, this patient appeared not to have experienced devastating infections. The third patient was a 5-year-old girl, who experienced repeated otitis media and Herpes virus infections, requiring acyclovir prophylaxis for the latter [40]. Examination of her PB showed a profoundly reduced number of NK ($CD3^-CD56^+$) cells and reduced NK cytotoxicity but normal ADCC. The fourth was a 2-year-old girl with recurrent, ultimately fatal, varicella infection [25]. Her PB also contained a markedly decreased number of NK ($CD3^-CD56^+$) cells and showed reduced NK cytotoxicity.

Another group of patients reported in the literature had a normal number of NK-cells but defective NK-cell functions. Two brothers (6 and 12 years of age), who experienced recurrent upper respiratory tract infections and otitis media, had nearly normal numbers of $CD56^+$ and $CD16^+$ cells in their PB, but NK cytotoxicity was almost completely absent, which was not improved by incubating cells with IL-2 or IFN-α [41]. A recent report has suggested that overexpression of inhibitory killer receptors is a possible underlying mechanism in such patients [33].

Information from the above patients indicates that NK-cells are important in the in vivo defense against viruses mainly in the family Herpesviridae. In patients who lack NK-cells, infections with Herpes viruses are usually life-threatening. Even in healthy individuals, an initial Herpes virus infection may be followed by latency with subsequent reactivation and, in some cases, cause malignancies including lymphoma, nasopharyngeal cancer, and Kaposi's sarcoma. Therefore, it is concluded that NK-cell deficiency in humans is associated with life-threatening diseases caused by Herpes viruses and therefore affects life span. The association between NK-cells and other viral and bacterial infections in vivo is less clear. All four reported patients who lacked NK-cells were women. Further accumulation of such patients and research on their pathophysiology including genetics will be important to understand this association.

3.2 Relationship between NK-cells and the Development and Progression of Malignancies

NK-cells may contribute to human longevity by controlling neoplastic cells in patients with malignancies. An example of data supporting this hypothesis comes from studies of myelodysplastic syndromes (MDS). MDS are malignant disorders of hematopoietic stem cells and predominantly occur in the elderly [58]. A well-designed study in the UK found that in the population aged 70 years and older, more than 50 new MDS patients are diagnosed annually per 100,000 persons [84]. MDS are composed of various subtypes and can be grouped into early-stage and advanced-stage MDS based on the percentage of neoplastic myeloblasts in the BM and PB. It is also believed that early-stage MDS is often overlooked due to the absence of specific signs and symptoms of the disorder [58]. A substantial proportion of patients with early-stage MDS progress to advanced-stage MDS and then to acute myeloid leukemia by mechanisms that have not been thoroughly clarified. MDS patients often have dysfunction in a variety of immunologic components including NK-cells [35]. NK-cell cytotoxicity, which may or may not be stimulated by IL-2 in vitro, is preserved in early-stage MDS but decreases with disease progression [24, 60]. The elevation in levels of circulating soluble IL-2 receptor [85], which can neutralize endogenous IL-2, and reduced expression of activating NK receptors such as NKG2D in NK-cells [24] may contribute to the reduced NK-cell cytotoxicity in advanced-stage MDS patients. These data suggest that NK-cells contribute to controlling disease progression in MDS and thus may affect longevity because of the high prevalence of MDS in the elderly. Similarly, NK-cells may prolong the life span of patients with other cancers by inhibiting disease progression [16, 37, 76].

Meanwhile, it is known that NK-cell activity varies significantly among healthy individuals. The question is whether differences in NK-cell activity in healthy people are involved in the development of malignancies and thus contribute to longevity. Imai et al examined NK-cell cytotoxicity in 3625 healthy Japanese, mainly in the 40-69-year-old age-group, living in Saitama prefecture [36]. They followed the cohort for 11 years to investigate cancer incidence and death from any cause. They recorded 154 cases of cancer (most frequent sites were the stomach, lung, and intestine) in the study period and found that reduced NK-cell cytotoxicity was a statistically significant risk factor for the development of cancer.

3.3 NK-cells in the Healthy Elderly

NK-cells in the healthy elderly have been examined in many studies. Sansoni et al carefully selected 138 healthy individuals, ranging in age from 4 to 106 years, and examined their immunologic parameters including lymphocyte subsets and NK-cell cytotoxicity [69]. They found that although the number of T- and B-cells

declined with increasing age, the number of cells with NK markers did not undergo an age-related decline. Instead, the number of $CD16^+$ cells and $CD57^+$ cells increased with age. Moreover, centenarians had well-preserved NK-cell activity expressed in lytic units (LU), the magnitude of which was comparable to that in healthy young people and higher than that in the healthy middle-aged.

We also selected 82 healthy individuals, aged 30 to 99 years, and investigated their immunologic parameters [61]. We confirmed that the number of T-cells declined and the number of $CD56^+$ cells increased with age and that NK-cell activity expressed as LU was maintained throughout this age range. In addition, because the number of total lymphocytes was found to decrease with age in most studies including ours, we calculated the index of absolute in vivo NK-cell activity (ALU = LU x mononuclear cell count per microliter of PB) and found that the ALU decreased as age increased. Moreover, the cytotoxic activity exerted by one NK-cell (NK activity on a per-cell basis, PCNK) decreased as age increased. When we retrospectively examined the medical records of the elderly in our cohort, it was found that low ALU and PCNK values correlated with a past history of severe infection. Therefore, we proposed that human NK-cells do not escape the aging process and that low NK-cell function is corrrelated with the development of severe infections, which may be fatal, in the elderly. Similarly, several other studies of the healthy elderly showed that the T-cell population declines while the NK-cell population increases in the PB and that the PCNK decreases [9, 26, 47, 48]. In particular, data from centenarians are striking. Miyaji et al reported that roughly 50% of lymphocytes were $CD56^+$ cells in centenarians in contrast to about 11% in the middle-aged [48]. However, it has not been fully clarified whether the NK-cell increase in the very old indicates that NK-cells result in longevity or longevity resulting from other factors causes an increase in the number of NK-cells.

Based on the above findings, we conducted a prospective study to examine whether differences in NK-cell function among the healthy elderly is related to the development of infection and infectious death [59]. Our subjects were 108 immunologically normal elderly people aged 63–99 (mean 81) years residing in nursing homes due to impaired performance status (PS). We determined counts of lymphocytes, monocytes, and neutrophils, serum albumin value, percentage and absolute number of various lymphocyte subsets ($CD3^+$, $CD4^+$, $CD8^+$, $CD25^+$, $CD56^+$, $CD3^+HLA{\cdot}DR^+$, $CD3^+CD56^+$, and $CD3^-CD56^+$ cells), and NK-cell activity. The interassay variation in NK-cell activity was minimized by examining the same control cells in each assay. We then followed the cohort and analyzed the correlation between the development of infection during the first 12 months of follow-up and the predetermined parameters as well as age and PS. Using univariate logistic regression analysis, poor PS, low albumin value, old age, and low NK-cell activity correlated significantly with the development of infection. Multivariate logistic regression analysis showed that low NK-cell activity, poor PS score, and older age were independent variables associated with the development of infection. The odds ratio for the development of infection increased

with the decrease in NK-cell activity. We next analyzed correlations between the predetermined parameters and the time until death due to infection in the 108 individuals. Eleven died of infection (all due to pneumonia) during the follow-up period. Univariate Cox proportional-hazards regression analysis showed that poor PS, high $CD8^+$ T-cell count, and low NK-cell activity correlated significantly with short survival time due to infection. Multivariate Cox proportional-hazards regression analysis showed that low NK-cell activity was an independent variable associated with short survival time due to infection. Other independent variables for short survival due to infection were poor PS and a high $CD8^+$ T-cell count. These findings support the hypothesis that well-preserved NK-cell activity is important for human longevity, at least in part because of its antiinfectious effect. The association between a high $CD8^+$ T-cell count and short survival time after infection deserves further discussion. A previous study also suggested an association between a high $CD8^+$ T-cell count and high mortality rate in the elderly [83]. One proposed explanation for this association is that clonal expansions of $CD8^+$ T-cells, which are often observed in the healthy elderly [78], are exaggerated in those with a high $CD8^+$ T-cell count. This clonal expansion probably reduces the naive repertoire of $CD8^+$ T-cells, which impairs T-cell responses and thus may be associated with vulnerability to infections.

Meanwhile, a functional relationship exists between NK-cells and T-cells. In a typical viral infection, NK-cell responses against the virus are observed during the first 1–3 days of infection [80]. These are gradually replaced with viral antigen-specific T-cell responses. When T-cell responses do not occur, as in severe combined immunodeficient mice and athymic nude mice, the increased NK-cell response is maintained for a prolonged period to defend the host [73, 81]. Considering the functional link between NK- and T-cells and the reduced T-cell count commonly observed in elderly people, the role of NK-cells in protecting against infections may be more important in the elderly than in younger individuals.

4 Concluding Remarks

NK-cells are a lymphocyte subset in the innate immune system which are early responders to infections and neoplasia. Data from isolated NK-cell deficiency, certain patients with malignant neoplasia, and healthy individuals all indicate that NK-cells are crucial immune components for sustaining life. In middle-aged people in developed countries who can overcome common infections, NK-cells may be important for defending against malignancies. In elderly people, common infections can cause significant morbidity and mortality. In terms of weakened T- and B-cell immunology as well as reduced tolerance of stress such as infections in the elderly, the strength of the early immune system response including that of NK-cells appears especially important. The role of NK-cells throughout the human life span should be studied further to confirm this hypothesis.

The Effects of Age on CD1d-restricted NKT-cells and Their Contribution to Peripheral T-cell Immunity

Douglas E. Faunce and Jessica L. Palmer

Contents

1 Introduction

Natural Killer T (NKT) cells are innate lymphocytes known for their roles in regulation of immune responses in cancer, autoimmunity, bacterial and viral infections, and the induction of immunologic tolerance [1–4]. Recently, our laboratory and others have also identified crucial roles for NKT-cells in the regulation of the host response to injury and sepsis [5–7]. As we will discuss further in this chapter, NKT-cells are now widely accepted as critical players in the initiation of maintenance of host defense, as they are uniquely poised to modulate multiple aspects of protective immunity. NKT-cells fill this position via their ability to rapidly produce significant quantities of immunomodulatory cytokines very early during the course of the immune response and can thereby influence the outcome of both innate and adaptive immune processes.

While a significant number of studies, described in this handbook and elsewhere, have identified both direct and indirect effects of advanced age on T-cells, B-cells, and cells of the innate immune system including macrophages, dendritic cells, granulocytes, etc., little is known of how NKT-cell populations might change with age and moreover, how the aging immune microenvironment affects NKT-cell function. Here, we will provide a brief overview of NKT-cells, their role in host defense, and review the limited information on the effects of age on NKT-cell biology.

2 NKT-cell Development and Restriction by CD1d, Antigen Specificity, and Tissue Distribution

Like virtually all T-lymphocytes, NKT-cells arise and differentiate from mainstream thymic precursors. Whereas conventional $CD4^+$ and $CD8^+$ T-cells differentiate and undergo negative and positive selection based upon thymic expression of self-peptide antigens and of MHC-II and MHC-I, NKT-cells on the other hand, acquire their differentiation signals and undergo thymic selection based upon thymic expression of self-lipid ligands presented on the MHC-I-like molecule, CD1d. NKT-cells arise from $CD4^+$ $CD8^+$ thymic precursors and express a canonical invariant $\alpha\beta$ TCR ($V\alpha14$-$J\alpha18$ in mouse and $V\alpha24$-$J\alpha18$ in human) that recognizes a self-lipid called isoglobotrihexosylceramide (iGb3), which is a breakdown product of the hexosaminadase-B pathway and is presented in the context of CD1d molecules expressed on thymic epithelia [8–10]. Upon engagement of the $V\alpha14$-$J\alpha18$ TCR with iGb3/CD1d complex, double positive NKT precursors down-regulate their expression of CD8. While some NKT precursors retain their expression of CD4 molecules, others eventually down regulate CD4 and become double-negative, invariant TCR-positive. As NKT-cells are so named, they acquire expression of NK lineage receptors including NK1.1, NKG2A/D, Ly49C/I in mouse and CD16, CD56, and CD161 in human.

NKT-cells are widely distributed throughout the body in both humans and mice and can be identified in the thymus, liver, spleen, lymph nodes, and circulation by either their co-expression of the invariant TCR and the above-mentioned NK associated markers or by their ability to bind lipid ligand-loaded CD1d tetramers or dimers [11, 12]. Overall, NKT-cells comprise approximately 0.5–1.0% of the entire T-lymphocyte pool. In the liver, they account for approximately 25–50% of lymphocytes (depending upon species, strain, etc.), in spleen they comprise approximately 2–3% of the lymphocyte population, while in the circulation and lymph nodes, NKT-cells make up only about 0.5–1.0% of circulating lymphocytes. Within the lymphoid compartment NKT-cells can be found in the splenic marginal zones, red pulp, PALS, and paracortical areas [13] (and Faunce et al, unpublished observations) and in the liver, they mainly accumulate in the liver sinusoids. Interestingly, the liver seems particularly adept for the recruitment and retention of NKT-cells, since they constitutively express CXCR6, the receptor for the chemokine CXCL16, which is expressed among other places on the surface of liver sinusoidal epithelium [14]. NKT-cells may also home to lymphoid organs or other sites of inflammation and immune responses via signals mediated through CCR1, CCR2, CCR4, CCR5, CCR6, and CXCR2 [13, 15].

3 CD1d Molecules and Lipid Antigens

Unlike conventional $CD4^+$ and $CD8^+$ T-cells that exhibit specificity for peptide antigens presented by MHC-II and MHC-I respectively, NKT-cells recognize glycolipid antigens presented in the context of the MHC-I-like molecule, CD1d

[1, 3, 16–18]. The CD1 family of cell surface glycoproteins is expressed by a variety of cell types, however, the CD1d isoform is expressed primarily on professional antigen presenting cells including macrophages, dendritic cells and B-cells and is expressed at the cell surface in conjunction with β2-microglobulin. In humans, five isoforms of CD1 exist, CD1a–e. In mice and rats however, only CD1d is expressed [1, 3, 16–18]. The invariant Vα14 (and Vα24) TCR only recognizes CD1d and not the other isoforms and it was the observation in the mid to late 1990's that minor T-cell subsets appeared restricted by CD1d for both function and development that led to the discovery that NKT-cells were indeed a unique subset with their own developmental restriction and antigen specificity [19–22]. Today, the CD1d-restriction of NKT-cells is exploited through the use of CD1d tetramers and dimers that are used for the specific recognition and identification of NKT-cells in both mice and humans [11, 12, 23–25].

As mentioned above, CD1d-restricted NKT-cells exhibit specificity for glycolipid antigens, rather than peptide antigens. The concept that CD1d presents lipid antigens to invariant TCRs was first considered when it was observed that the binding grooves of CD1d as well as the invariant TCR were extremely hydrophobic [20]. The first glycolipid identified as a specific activator of NKT-cells was alpha-galactosylceramide, a lipid isolate of the marine sponge *Agales mauritianus,* whose synthetic analogue KRN7000, exhibited potent anti-tumor immunity mediated by NKT-cells [24, 26–28] and is now known as a potent stimulator for NKT-cells both in vivo and in vitro [8,29–31]. More recently, it has been shown that specific microbial-derived lipids also are presented by CD1d to the invariant TCR for the activation of NKT-cells, including *Sphingomonas* GSL-1 [32], *Borrelia burgdorferi* alpha-glactosyldiacylglycerols [32], and mycobacterial phosphatidylinositolmannosides such as PIM-4 [33]. In addition to reactivity towards exogenous glycolipid antigens presented by CD1d, it is also well established NKT-cell development is restricted by thymic CD1d expression, thereby suggesting the requirement of a self-glycolipid during positive selection of NKT-cell precursors. Indeed, the glycosphingolipid isoglobotrihexosylceramide, or iGb3, appears to be a self-derived glycolipid ligand that is required for positive selection and expansion of NKT-cell precursors during development [10, 34], since β-hexosaminadase deficient mice, which as a result of this enzyme deficiency are unable to convert iGb4 to iGb3, almost completely lack invariant NKT-cells [34].

4 Effects of Age on NKT-cell Numbers and CD1d Expression

Clearly, age-related alterations in the number and/or function of NKT-cells could greatly influence the quality of the effector T-cell response. For the purposes of this chapter, we shall consider studies that have examined NKT-cell numbers and function in humans aged 59 and older and studies in mice of ages twelve months or older. Only a handful of reports have closely examined CD1d-restricted NKT-cell numbers in aged mice and humans and most agree that as age increases, so does the

number of NKT-cells in the periphery [6, 35, 36]. It is not entirely clear whether the increase represents an accumulation of cells over time versus increased expansion of newly made cells. Increased frequency and numbers of NKT-cells could also result from increased recruitment or retention. In fact, it was recently reported by Berzins and colleagues that NKT-cells are comparatively long-lived (i.e., greater than one year in mice) and are retained for significantly greater periods of time in the thymus compared to conventional T-cells [37]. Some reports describe an increase in accumulated, longer-lived hepatic NKT-cells over time in both humans and mice [35, 36]. In mice, NKT-cell number increases 2-to-3-fold in the livers, spleens, and lymph nodes of aged animals [6, 38, 39]. It could be argued that older mice are slightly larger physically and therefore might have greater numbers of cells in general, however, the relative frequency of NKT-cells as compared to conventional T-cells is also 2-to-3-fold higher in aged mice as compared to young [6]. This increase could represent an unusual effect of aging, as most immune cell populations remain static or decrease in number. Some data suggests that this age-related increase in NKT-cells actually stems from newly made cells. Using 5'-bromo-2-deoxyuridine (BrdU) labeling, ligand-loaded CD1d dimer staining and flow cytometry, our laboratory observed that the spleens and lymph nodes of aged mice (18–22 months old) contained nearly 2.5-fold greater numbers of BrdU-positive NKT-cells (Palmer and Faunce, unpublished observations). BrdU is a thymidine analog that incorporates into the newly synthesized DNA, making it an effective marker to distinguish and track newly made cells. The precise mechanisms responsible for increased output of NKT-cells in aged mice remain to be elucidated. Likewise, the reasons for the potentially greater longevity of thymic NKT-cells also require further investigation.

While the majority of observations support the concept that NKT-cells increase with age, as with most topics, the opposite has been reported in that numbers of Vα14 and Vα24 NKT-cells were found to be decreased with advanced age, particularly in the liver [40, 41].

Since NKT-cells are stimulated by lipid ligands presented by the CD1d molecule on APCs, it follows that part of the aged-related breakdown could be attributed to transitions in CD1d expression or magnitude. However, CD1d magnitude and frequency of expression is similar on F4/80$^+$ monocyte/macrophages and CD11c$^+$ dendritic cells in aged and young mice [6]. This suggests that lipid antigen presentation to NKT-cells is intact in aged animals, so changes probably lie within altered responses from NKT-cells once they are activated by ligand-bearing APCs.

5 Aging, NKT-cell Function, and Peripheral T-cell Immunity

Few studies have directly addressed the effects of age on NKT-cell biology, however the topic has been briefly reviewed by others in the recent past [36, 42]. Similarly, very few studies have made direct comparisons of CD1d-restricted NKT-cell involvement in immune function between young and aged subjects, however based on what is known (again considering mice twelve months or older), it appears that NKT-cells

modulate several aspects of T-cell function differently in aged mice compared to young. Recent studies by our laboratory demonstrated that in aged mice, NKT-cells contributed to the age-associated reduction of antigen-specific T-cell proliferation [6]. Removal of NKT-cells (Ly49C$^+$ NK/NKT) from splenic T-cell preparations prior to stimulation restored the capacity of T-cells to proliferate in response to CD3ε ligation. The same observation was made for proliferation of peripheral lymph node T-cells. Importantly, comparable T-cell proliferation in aged and young mice could also be achieved among splenocyte preparations from young vs. aged mice given anti-CD1d monoclonal antibody systemically to block NKT-cell activation in vivo. Such observations implicated NKT-cells in the age-related suppression of the T-cell proliferative response to antigen. Perhaps the most compelling evidence for a direct connection between activated NKT-cells and suppression of T-cell effector function was demonstrated in a series of experiments conducted by our laboratory that utilized delayed type hypersensitivity (DTH) responses after immunization with ovalbumin in complete adjuvant as an index of antigen-specific effector T-cell response in vivo. From studies by our laboratory and others, it is known that aged mice exhibit blunted immune responses (including DTH) in vivo [6, 42–46]. However, we observed that while aged mice given control IgG mounted DTH responses that were 30–50% less in magnitude compared to young mice, aged mice treated systemically with anti-CD1d antibody to block the activation of NKT-cells in vivo, generated DTH responses that were remarkably similar to those seen in young mice [6]. Delayed-type hypersensitivity requires adequate generation of CD4$^+$ effector T-cells during the priming phase in order for the effector arm of the response to proceed. Although aged mice and humans are known to possess fewer CD4$^+$ T-cells and a contracted effector T-cell repertoire, our studies suggested that despite fewer CD4$^+$ T-cell numbers overall, aged mice could generate adequate effector T-cell immunity in vivo when challenged with antigen and an adjuvant, provided NKT-cell activation was attenuated. The idea that blunted effector CD4$^+$ T-cell immunity observed with aging can be overcome is also supported by studies from Haynes and colleagues that used a combination of adjuvant and inflammatory cytokines to achieve results similar to ours [44]. Taken together, the current observations suggest that the decline in the quality of protective T-cell immunity associated with aged animals may be due at least in part, to a CD1d-NKT dependent active suppression of effector T-cell function.

In addition to changes in T-cell function and increased NKT-cell numbers, NKT-cell cytokine production also appears to change with increasing age. While this area of investigation needs to be explored much further, so far it has been shown that splenocytes activated by CD3ε mAb in vitro show increased IL-4 (both cytokine protein and mRNA) and diminished IL-2 output as compared to young, when measured by ELISA [6, 47]. It has also been demonstrated that CD1d-restricted NKT-cells from aged mice produce lower amounts of IFNγ both at basal levels and stimulation with IL-12 [36, 48]. This apparent NKT-cell dependent change in cytokine profile has been postulated to contribute to the overall decreased immunocompetence in aged animals although it has not been proven. Interestingly, systemic anti-CD1d treatment does not significantly decrease inducible IL-4 production [6] and it was found that in fact, memory T-cell subsets (CD44^{high}CD445RB^{low}NK1.1^{neg}) produce much of the age-associated IL-4 in

response to CD3ε-stimulation, however, they do so in an NKT-cell-dependent fashion [38, 47]. Our laboratory also reported that IL-10 production among spleen cell populations is nearly 10 times higher than the amount produced by splenocyte cultures from young mice. Unlike IL-4, the age-related increase in inducible IL-10 was significantly diminished in splenocytes obtained from aged mice that were given systemic NKT-cell blockade. There is also evidence that NKT-cells from aged mice have impaired IFNγ production, since lower baseline levels and IL-12 induced production of this important cytokine have been noted with aging [36]. Although relatively meager, the current set of data collectively support the notion that as age advances, NKT-cells shift from a more protective, IFN-γ producing phenotype (Th1), to a suppressive (Th2) type phenotype in both mice and humans by increasing IL-4 and IL-10 output.

Lastly, in addition to age-related alterations in cytokine production, NKT-cells from aged mice have also been reported to exhibit decreased cytotoxic capabilities [40, 49]. However, whether this observation applies to all CD1d-restricted NKT-cells throughout the immune compartment vs. other CD1d-unrestricted NKT-cell populations, such as those that exist in the liver, remains to be determined.

6 Summary

In summary, the effects of age on conventional lymphocyte populations have been widely studied, but age-related alterations among innate lymphocytes including NKT-cells are not as well understood. From a thorough review of the current literature that examines elderly humans and truly gerontologic mice, it appears that as age advances, the number of NKT-cells increases and their functions, particularly cytokine production, deviate away from immune protection and more toward immune suppression. The mechanisms responsible for greater numbers of NKT-cells in aged mice is also unclear, but may result from dysregulated ontologic signals that control progenitor cell development and proliferation, cell death, and homeostatic proliferation. Additionally, the possibility exists that NKT-cells, like other cells of the innate immune system may exhibit comparatively greater longevity than conventional lymphocytes. What is clear is that given their potent regulatory capacity over immune and inflammatory processes, significantly more research is required with both human cells as well as mouse models to understand how age-related alterations in NKT-cell biology might contribute to either the age-related decline in immunity or development of cancers and autoimmunity.

Stem Cells

Lympho-Hematopoietic Stem Cells and Their Aging

Hartmut Geiger and Gary Van Zant

Contents

Abstract: The lympho-hematopoietic system is largely composed of cells with short lifespans (days) and thus requires continuous replenishment of the cells lost through hematopoietic stem and progenitor cells in a process called hematopoiesis. Experimental evidence from several laboratories clearly demonstrates that hematopoietic stem cells (HSCs) harvested from young and aged animals show functional differences that are intrinsic to HSCs, implying that also stem cells in the hematopoietic system can not defy aging. We will thus discuss in this chapter the cellular phenotypes and the possible molecular mechanisms associated with aged HSCs with respect to the specific properties stem cells are endowed with, and will

investigate whether stem cell aging is inevitable or whether some of its aspects can be reverted or at least ameliorated.

Keywords: Stem cell • Aging • Hematopoiesis • Niche • DNA damage • Adhesion

1 Stem Cells

Organ or tissue attrition due to loss of cells by various means is inevitably associated with life. Thus to achieve tissue homeostasis for a long period of time, lost cells have to be replaced and/or renewed. Many, but perhaps not all tissues or organs, depend on undifferentiated stem cells to support the generation of novel differentiated cells for a given tissue. Many tissues of the major organ systems are thus composed of short-lived cells that require continuous replenishment like skin, intestine and the hematopoietic tissue as well as somatic stem cells (Potten and Morris, 1988; Morrison et al. 1995; Fuchs and Segre, 2000; Tani et al. 2000; Stappenbeck et al. 2003). Stem cells have been also identified in brain and heart, although their contribution to adult tissue homeostasis is still debated (McKay, 1997; Doetsch et al. 1999; Gage 2000; Beltrami et al. 2003; Oh et al. 2003).

Stem cells are commonly defined by two characteristics: their ability to either self-renew or to differentiate into most of the mature cells types that comprise a tissue (van der Kooy and Weiss 2000). Both processes are associated with the ability of stem cells to undergo symmetric versus asymmetric divisions (mode of the division). The regulation of the mode of division thus poses an important fundamental question in stem cell biology. The molecular determinants that influence symmetric versus asymmetric divisions of stem cells are not well understood, which still hinder rationale approaches to modulate the outcome of stem cell divisions for example for clinical purposes.

2 Hematopoiesis

The lympho-hematopoietic system is largely composed of cells with short lifespans (days) and thus requires continuous replenishment of the cells lost through stem and progenitor cells in a process called hematopoiesis. Hematopoiesis is in adults restricted mostly to the bone marrow (BM) cavities. Hematopoietic stem cells (HSCs) are the most primitive cells of the blood lineage and give, upon differentiation, rise to the entire panoply of mature blood cells. They are rare and comprise only about 0.01% of the BM cell population, but are a long-lived population that are normally not depleted during a lifetime.

The cellular differentiation pathway is organized in a functional hierarchy, in which HSCs differentiate upon an asymmetric division into progenitor cells (also called transient amplifying cells in other stem cell systems), which then differ-

entiate upon multiple steps of additional asymmetric divisions into mature blood cells. Upon differentiation and further specification, hematopoietic progenitor cells (HPCs) lose their ability to self-renew forever, and thus only true HSCs are associated with unrestricted self-renewal capacity.

In addition to their self-renewal and differentiation capacity, HSCs are also endowed with a remarkable, but still not well understood mobilization and homing ability, meaning they are able to migrate out of the BM into the bloodstream and also are able to migrate with a relatively high efficiency and specificity from peripheral blood back into the BM and to their niche, where this self-renewal and differentiation takes place. The physiological role of HSCs found in the circulation has puzzled investigators for a long time. One explanation is that these circulating HSCs are a pool of cells that help distinct sites of hematopoiesis to communicate with each other (Wright et al. 2001). Another interesting recently published explanation is that HSCs apparently circulate into and out of the lymphatic system serving an immuno-surveillance role, and it is suggested that they can via this route survey peripheral organs and foster the local production of tissue-resident innate immune cells under both steady-state conditions and in response to inflammatory signals (Massberg et al. 2007).

Thus, due to these distinct abilities, the potential of hematopoietic stem cells can be tested in a transplantation assay, which is regarded as the gold standard for testing HSCs activity in vivo. In such an assay, syngeneic animals will be myeloablated or lethally irradiated, which opens up in both cases niches for HSCs in the BM. Subsequently, HSCs that are injected into the bloodstream of these recipient mice will home to these empty niches, undergo self-renewal and differentation, and will consequently be able to contribute to the hematopoietic system of the animal for a lifetime. The relative or absolute ability of the transplanted

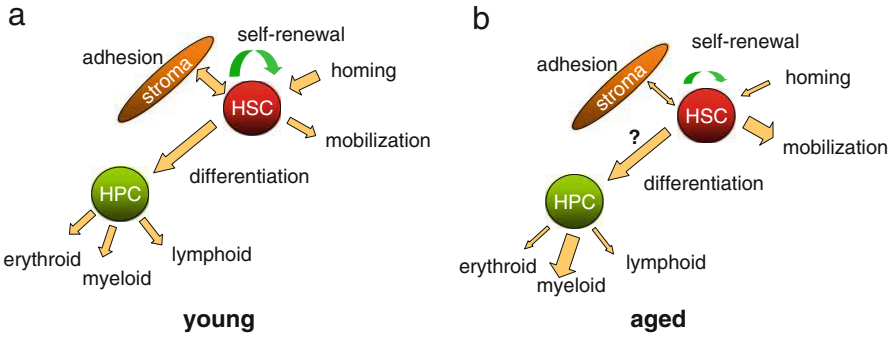

Fig. 1 Aging of hematopoietic stem cells. (a) Hematopoietic tem cells (HSCs) are defined by their ability to self-renew, to home to the bone marrow, to mobilize out of their niche into peripheral blood and their ability to adhere to stroma cells. In addition, HSCs will differentiate via hematopoietic progenitor cells (HPCs) in various distinct blood cell lineages. (b) Upon aging, HSCs present with reduced self-renewal activity, decreased homing but enhanced mobilization ability, which might be a result of the reduced ability of aged HSCs to adhere to stroma. Aged HSCs furthermore show a clear preference for myeloid over lymphoid and erythroid differentiation

stem cells to reconstitute the hematopoietic system of the recipient is regarded as a quantitative measurement of the stem cell potential.

3 How Do We Define and Isolate Hematopoietic Stem Cells?

Under a microscope, hematopoietic stem cell look actually identical to HPCs and similar to even some differentiated hematopoietic cells, including small- to medium-sized lymphocytes. So how do we identify and purify HSCs to study their biology? Over 50 years of intense research in the field of hematopoiesis and HSCs allow researchers now, at least in mice, to prospectively isolate the putative stem cells solely based on the inclusion or exclusion of distinct cell surface markers trough cell sorting via flow cytometry. HSC function and purity can then be subsequently verified in transplantation assays. Various distinct combinations of cell surface markers, which further evolved over time in complexity, but inversely resulted also in higher purity, have been used to identify HSCs. In aggregation of most of the literature, and most widely used by investigators at present, are three protocols to prospectively isolated stem cells, the LSK/CD34, the SLAM and the side population (SP) approach (Osawa et al. 1996; Kiel et al. 2005; Lin and Goodell 2006; Yilmaz et al. 2006). In the LSK/CD34 system, HSCs are defined as being negative for markers found on differentiated cells (lineage markers, and thus LIN- or L) as well as negative for CD34, but positive for the Sca-1 and the c-Kit epitopes. In the SLAM system, HSCs are defined as BM cells positive for CD150 while at the same time negative for CD48. Finally, in the SP approach a distinct cell population that does not retain the Hoechst dye 33342 (measured at two distinct emission wavelength) is highly enriched for HSCs. Although the purity of the presumed stem cell populations varies among these protocols, and each purification system might even enrich for slightly functionally distinct HSCs (Weksberg et al. 2008), all three are rigorously experimentally validated in terms of their ability to highly enrich for stem cells, and of course, there is major cell surface phenotype overlap among the purified populations (Kiel et al. 2005; Yilmaz et al. 2006; Weksberg et al. 2008).

3.1 The Aging of Hematopoietic Stem Cells

The aging process is probably best defined as a general loss in biological competence for both the individual cell and the organism as a whole. At the cellular level, it is expressed as decreasing replicative ability in proliferating cells and decreasing functional activity in postmitotic cells.

Stem cells were thought to be endowed with unlimited self-renewal capacity and thus assumed to be exempt from aging, which would result in functionally young

stem cells in a chronologically aged animal. But evidence accumulating over the past decade has now proven that there is a measurable and successive functional decline in hematopoietic, intestinal and muscle stem cell replicative activity from adulthood to old age, resulting in a decline of stem cell function (Morrison et al. 1996b; Chen et al. 1999; Sudo et al. 2000; Geiger and Van Zant 2002; Kim et al. 2003; Van Zant and Liang 2003; Rossi et al. 2005; Chambers et al. 2007). As stem cell activity is necessary to replenish lost differentiated cells in a stem cell driven tissue, it has been hypothesized that aging of stem cells leads to reduced renewal and thus reduced tissue homeostasis in aged animals, probably most obvious under stress situations (Geiger et al. 2001b; Geiger and Van Zant 2002; Van Zant and Liang 2003; Sharpless and DePinho 2004; Torella et al. 2004).Ultimately, this may determine individual longevity, although so far no lifespan extension in response to stem cell therapy has been reported. This hypothesis though is supported for example by the fact that the function of the innate immune system, which depends on stem and progenitor cells activity, is compromised in aged individuals (Ginaldi et al. 1999; Butcher et al. 2001; Lord et al. 2001).

3.2 Defining Aging of Stem Cells

Stem cells are social entities that communicate and associate with supporting cells (called stroma) in a distinct 3 dimensional space (called niche). It is believed this niche is essential for stem cell regulation (Yin and Li 2006). So immediately the question arises whether stem cells age themselves (intrinsic aging) or the niche itself ages, which as a consequence impairs the function of an otherwise young and healthy stem cell occupying this niche (extrinsic aging). In case stem cell aging was mostly driven by extrinsic clues, we would anticipate that stem cells from aged animals, when transplanted into young niches (young animals), become functionally young again. Experimental evidence though from several laboratories clearly demonstrates that HSCs harvested from young and aged animals show functional differences that are intrinsic to HSCs (Geiger and Van Zant 2002; Geiger et al. 2005; Rossi et al. 2005) and less dependent on the microenvironment, although it does not exclude extrinsic influences on stem cell aging. These data thus allow us to refer to the cells as aged HSCs and young HSCs when the age refers to the animal from which the cells were harvested. Whether or not though stem cell aging in general is mostly driven by intrinsic mechanisms is still a matter of debate, as for example in muscle, aging of muscle progenitor cells is reverted by changes in the systemic environment and thus most likely dominated by extrinsic factors (Conboy et al. 2005).

Various experimental approaches have been developed/employed to study causes and consequences of HSCs aging, and there seems to be a experimental duality in the field of aging research in general and also in the context of HSCs: Research on aging in a physiological environment and at a physiological pace in contrast to research on stem cell phenotypes in genetically modified animals which present

with accelerated aging/stem cell aging. Let us have a short detour to the car repair shop to explain the differences in more detail.

We will start with describing the ailments of old cars (old stem cells) and just list all the problems a mechanic usually finds in them and which might be the reason for why the old car might not function very well anymore. We know that the mechanic's observations are correlative, but he will eventually replace/fix the worn out part(s) he was talking about and thus will subsequently test whether he was guessing right (causative approach).

Genetically modified animals on the other hand that present with phenotypes indicative of accelerated stem cell aging (either partial or in general) are more like cars in which we messed up on purpose with let's say the water pump and of course, over time the pump and subsequently the car will break. This tells us that the water pump is an essential part for the car, it does though not prove that in most cases in aged cars that is the part that will break, or whether preventing in general water pumps from braking in old cars will reduce the fragility of old cars. Only after the mechanic that usually sees all the old cars in the repair shop agrees that water pumps in old cars are an issue and tend to break, we are convinced about the relevance of our observations in the accelerated model [*see* also (Hasty and Vijg 2004; Miller 2004; Warner 2004)]. Although the authors do not imply that one approach might be superior over the other, it is still a good idea to differentiate between these experimental approaches. We will focus in the following paragraph primarily on physiological stem cell aging, and refer to premature aging systems whenever relevant.

There is still controversy on aspects of the phenotype and function of physiologically aged HSCs. The following phenotypes therefore represent commonly agreed phenotypes for aged HSCs and supported by research conducted by multiple independent investigators (canonical aging phenotypes). We suggest that the combination of these phenotypes comprise an physiologically aged HSCs, but that of course "partial" stem cell aging might be observed under given circumstances. Aged and young HSCs differ mostly in their function, and for HSCs, this function is best measured in transplantation assays. Consequently, most of the available data characterizing functional differences between aged and young stem cells has been generated by comparing young and aged HSCs in transplantation experiments.

3.3 Changes in Function Associated With Aged HSCs

In a competitive transplant setting, when stem cells from aged mice from the C57BL/6 inbred strain are transplanted along-side young cells into a lethally irradiated recipient animal, aged HSCs are less efficient in contributing to hematopoiesis (perturbed homeostasis) compared to young HSCs (Morrison et al. 1996b; Chen et al. 2000). Whether or not aged HSCs are also reduced in their ability to self-renew is still a matter of debate, although clearly aged HSCs are functionally impaired compared to young stem cells in serial transplantation assays.

Aging also affects the differentiation potential of HSCs (Rossi et al. 2005). Many studies have demonstrated that aged stem cells have a reduced ability to support the red blood cell system, and that aged HSCs do not efficiently generate both T- and B lymphoid progeny, while they present with an increased ability to differentiate into the myeloid lineage [*see* (Linton and Dorshkind 2004) and references cited therein]. This difference in cell lineage self-renewal is emphasized by age-associated anemia and a decline in function of immune cells in aged individuals (Lipschitz and Udupa 1986; Lipschitz 1995; Ginaldi et al. 1999; Sudo et al. 2000; Butcher et al. 2001; Lord et al. 2001; Kim et al. 2003; Rossi et al. 2005). The generalized lymphoid defect has been at least in part attributed to an impaired ability of aged HSCs to differentiate into the common-lymphoid progenitor cell, the progenitor cells that will give rise to both the T- and the B-cell lineage. Thus aged HSCs are impaired in their ability to support the repopulation of the thymus and are less able to contribute to the B-cell as well as the T-cell lineage. Finally, aged HSCs are reduced in their ability to home from PB into the BM upon intravenous injection. A reduced ability to home to BM of aged HSCs was implied/speculated about in various publication and was recently experimentally confirmed by Liang et al. (Sudo et al. 2000; Kim et al. 2003; Liang et al. 2005; Rossi et al. 2005). The ability of HSCs to home to BM out of PB is clinically very important, as this is the first step to achieve successful engraftment in a HSC transplantation setting. Interestingly though, aged HSCs show enhanced mobilization proficiency upon G-CSF (Xing et al. 2006), which might in combination with the reduced homing indicate reduced cell–cell adhesion parameters for aged HSCs. Both impaired homing by old HSC and enhanced mobilization might imply "looser" niche association including dysregulated proteins involved in the HSC–niche interaction.

Comparing the engraftment properties of HSCs from various aged mouse inbred strains revealed that there are considerable differences in the rate of which stem cell self-renewal activity is reduced in aged animals, suggesting a strong genetic regulation of stem cell aging (Van Zant et al. 1990; Chen et al. 2000; Chen 2004; Geiger et al. 2005; Snoeck 2005;). Old C57BL/6 animals for example present with an increase in the number of phenotypically defined stem cells, although each of these stem cells has a clearly reduced potential upon transplantation, whereas old DBA/2 animals present with both, a reduced phenotypic number and a reduced function for aged HSCs. Thus, although overall the potential of the stem cell population decreases in the BM with aging independent of the strain, the pace with which this happens seem to be genetically restricted, adding another level of complexity to the determination of mechanisms that result in stem cell aging.

While the determination of stem cell function in the murine system via the transplantation assay can be relatively easily accomplished, our experimental tools to determine the function of human stem cells are understandably more limited. Thus investigations into the function of aged human HSCs are still in their infancy and more open to speculation, although both a reduced ability to support T-cell development as well as a reduced clonality and thus reduced stem cell number in aged humans has been so far identified [*see* for example (Wick et al. 1989; Abkowitz et al. 1998; Offner et al. 1999)]. In addition, elderly patients (similar to mice) fre-

quently present with anemia. The mechanisms for this finding are mostly unexplained. (Balducci et al. 2006; Ferrucci et al. 2007).

3.4 Molecular Phenotypes Associated With Aged HSCs

What might be the molecular mechanisms responsible for the age-associated decrease in HSC function? As obvious from the previous paragraph, there are multiple phenotypes associated with aged stem cells. We thus do not assume that there is a single, unique molecular mechanism of stem cell aging, but rather that there are most likely multiple molecular pathways that result in these phenotypes, which we will address below.

3.5 Genome-Wide Gene Expression Profiling of Aged HSCs: Finding Pathways in Aging?

Several laboratories recently undertook a global approach to identify on the genome scale changes in the transcription level of genes associated with the young/aged transition of HSCs (Chambers et al. 2007; Rossi et al. 2005, Geiger and Van Zant, unpublished results). Unfortunately, each of these experiments were performed with HSCs purified according to a different scheme and analyzed with distinct microarrays, rendering a comparative approach almost impossible. In general though, genes associated with the stress response, cell adhesion, protein turnover and signal transduction dominated the up-regulated expression profile, while the down-regulated profile was marked by genes involved in the preservation of cell adhesion, genomic integrity and chromatin remodeling. So far though no specific pathway based on these RNA expression analyses could be identified based on the collections of these differentially expressed genes, emphasizing probably one more time the complexity of aging even at the single cell level. Interestingly though, in one set of these experiments, gene products associated with myeloid leukemia were markedly upregulated, which the authors interpreted in the way that aged stem cells might be, through their altered expression profile, already intrinsically prone to leukemia, although this hypothesis will require further experimental testing (Rossi et al. 2005).

3.6 The Role of Oxidative Damage in Stem Cell Aging

An important and probably universal mechanism that leads to a wide spectrum of intracellular damage during aging is extended exposure to reactive oxygen species (Hasty 2001). Long-term exposure to these metabolic byproducts leads to structural changes in a number of cellular macromolecules that impair their function. Such changes include the cross-linking of intracellular and intra-mitochondrial structural

and functional proteins and carbohydrates, and the oxidation of fats and lipids in membranes as well as DNA damage. The multiple functional components a cell consists of form complex and interdependent physiological systems, making it difficult to determine which age-related change may be the primary cause of aging and which changes may be entrained by the primary event. Age-dependent changes in mitochondrial function and DNA integrity due to the accumulation of respiratory oxidative stress have also been reported for a variety of cell types, including liver, intestinal crypt and cardiac muscle cells (Bohr et al. 1998; Taylor et al. 2003). But the importance and frequency of mitochondrial mutations might have been overestimated compared with somatic mutations, as no increase in mitochondrial mutations in normally aged mice could be detected (Anson et al. 2000; Jacobs 2003; Khrapko and Vijg 2007; Vermulst et al. 2007). A role for reactive oxygen species and the p38 MAPK activity in limiting the self-renewal capacity and thus the lifespan of HSCs was recently experimentally demonstrated, as antioxidative treatment of HSCs resulted at least in partial reversion of the phenotypes associated with aged stem cells (Ito et al. 2006).

4 The Role of Telomere Length/Telomerase in Aging of HSCs

The hypothesis that cellular senescence is mediated via replicative exhaustion (Hayflick and Moorhead 1961; Barker et al. 1982) has received mechanistic support from the finding that telomeres may act as a mitotic clock (Vaziri et al. 1994; Greider 1998). Telomeres, the repetitive sequences at the chromosomal ends that provide chromosome stability, shorten with each round of cellular replication. When a critical short telomere length is reached, the cell enters a state of senescence or apoptoses. Some reports suggest a small, but significant decrease in telomere length in either human or murine HSCs upon aging or replicative stress post transplantation [(Vaziri et al. 1994; Brummendorf et al. 2001; Lansdorp 2008), and unpublished data Van Zant]. Since HSCs from laboratory mouse strains present with telomeres several times longer than human cells (Hemann and Greider 2000), and since stem cells synthesize telomerase to maintain telomeric length (Morrison et al. 1996a), whether natural telomere shortening by itself plays a role in HSC aging is still a matter of debate. These observations are further supported by the finding that although loss of telomerase activity clearly results in phenotypes associated with premature aging of stem cells, over-expression of telomerase in HSCs could so far not revert stem cell aging (Allsopp et al. 2003a, b).

5 The Role of DNA Damage in Aging of HSCs

A more likely cause for aging of stem cells in general, and HSCs in particular, might be age-dependent acquisition of defects in genomic DNA. HSC or intestinal stem cells show a high radiation sensitivity compared with most other cell

types (Jacobson et al. 1949; Martin et al. 1998). This radio-sensitivity implies either a reduced ability of stem cells to repair even small amounts of DNA damage, stringent requirements on the DNA repair machinery for the maintenance of DNA fidelity, or increased rates of apoptosis. These various possibilities are not mutually exclusive. Moreover, brain, liver and muscle cells from old mice have a reduced ability to repair radiation-induced damage compared to young animals (Hamilton et al. 2001). Furthermore, Dolle et al. reported a general increase in the frequency of genomic mutations in old compared with young animals. Interestingly, small intestine, the only stem cell system with a high cell turnover analyzed in these experiments, showed the highest mutation frequency in 2.5-year-old animals among other tissues like heart, brain and liver (Vijg and Dolle 2002), although recent results indicated that the majority of this increase is attributed to a specific cell type in the organ/tissue, and thus does not affect all cells (Busuttil et al. 2007). Loss of DNA integrity with age as the major cause of stem cell aging is also compatible with the finding that aging of HSCs is mostly cell autonomous (van der Loo and Ploemacher 1995; Geiger et al. 2001a; Rossi et al. 2005; Rossi et al. 2007). Research to determine DNA-repair capacity in mammalian systems has mostly been concentrated on the quantification of DNA damage in whole tissues in response to induced damage by utilizing cell culture or animal models (Gaubatz and Tan 1994; Jeng et al. 1999; Goukassian et al. 2000; Doria and Frasca 2001; Zhao and Hemminki 2002; Beausejour et al. 2003; Chevanne et al. 2003; Parrinello et al. 2003; Scarpaci et al. 2003;). Although published results are contradictory, the majority of the data supports the notion that the DNA repair capacity declines with age and that aged HSC present with elevated levels of DNA damage (Mullaart et al. 1990; Rossi et al. 2007). HSC, similar to other types of stem cells, show an increased radiation sensitivity compared to mature cell types (Jacobson et al. 1949; Martin et al. 1998) and a distinct expression pattern of DNA-repair genes (Geiger lab, unpublished). Both facts imply that stem cells might use DNA repair pathways differently compared to well-studied pathways in differentiated cells or cell lines, a hypothesis supported by research on DNA repair pathways in ES cells (Cervantes et al. 2002; Hong and Stambrook 2004). In addition, the expression of the cyclin-dependent kinase inhibitor p16INK4a, a stress/DNA damage indicator, was found to be elevated in physiologically aged HSCs and this has been shown to be causative for reduced survival of aged HSCs under stress, as loss of p16 expression ameliorated stem cells aging (Janzen et al. 2006). Taken together, changes in the DNA repair system in HSCs, together with changes in cell cycle regulation due to DNA damage with age, might be an important cause for the decrease in the functional capacity of aged HSCs or in general aging of multiple tissue. Such a connection is further supported by comparative linkage analysis of hematopoietic stem cell traits and longevity (Geiger and Van Zant 2002). Loci mapped to chromosomes 2, 7 and 11 regulate DNA repair and aging of primitive hematopoietic cells and at the same time, longevity (Geiger et al. 2001a). As so far though only partial amelioration of HSCs aging could be achieved by altering expression of DNA repair genes or by antioxidative therapy,

whether the DNA damage response plays the major role in stem cell aging will still be a matter of debate.

6 Altered Stem Cell–Niche Interactions in HSC Aging: A Novel Player in the Game

HSCs are entities that have social interactions. They reside in specialized three-dimensional microenvironments, or niches, in the BM. Cell-cell adhesion interactions between HSCs and stroma cells in the niche are believed to regulate HSC proliferation and differentiation. So far two niches, an endosteal and an endothelial niche, have been identified in the BM, and the distinct contribution of both of them to hematopoiesis is currently discussed [*see* for example (Adams and Scadden 2006; Kiel and Morrison 2006; Scadden 2006; Wilson and Trumpp 2006)]. Interactions of HSCs with stroma cells in the niche are consequently considered to be central to the biology of HSCs and have been therefore referred to as a stem cell synapses (similar to the immunological synapse; Adams and Scadden 2006; Scadden 2006; Yin and Li 2006). We recently reported that aged HSCs are impaired in their ability to strongly adhere to stroma cells [unpublished results and (Xing et al. 2006)]. This observation is supported by the fact that for example, the integrins $\alpha 4$ and $\alpha 5$ and the cell adhesion molecule VCAM-1 show lower expression on aged HSCs, whereas the expression of the adhesion molecule P-selectin and the $\alpha 6$ integrin are elevated in aged HSCs (Rossi et al. 2005; Xing et al. 2006). We could further demonstrate that physiologically aged primitive hematopoietic cells presented with elevated activity of the small Rho-GTPase CDC42, a protein tightly involved in regulating cellular adhesion (Van Hennik and Hordijk 2005; Wang et al. 2007; Yang et al. 2007). A distinct role for altered expression of adhesion molecules and thus altered adhesion in HSC differentiation was recently also suggested by Forsberg et al. (Forsberg et al. 2005), which supports a model in which unstable adhesion of aged HSCs to stroma might be causative for subsequent functional changes in aged HSCs. Whether the correlation between changes in expression of adhesion receptors and changes in the function of aged HSCs is also of mechanistic relevance though is not clear at the moment. We subsequently proposed that aged primitive hematopoietic cells are impaired in their ability to interact efficiently with stroma cells, which might result in the reduced self-renewal capacity as well as the altered differentiation ability associated with aged HSCs (Geiger et al. 2007). Elevated level of CDC42 activity detected in aged hematopoietic cells might be causative for these changes in cell–cell adhesion. These findings would further imply that also the stroma might play an important role in stem cell aging, as it too might be reduced in its ability to strongly interact with HSCs when aged. Molecular mechanisms that result in altered adhesion dynamics and altered function of aged HSCs might thus be tightly interconnected and result in an altered stem cell synapse for aged HSC. But as so many hypotheses linked to aging of stem cells, also this one is in critical need of additional experimental validation.

7 Amelioration/Prevention of Stem Cell Aging

Stem cell aging might be the underlying cause for dysregulated tissue homeostasis in aged individuals and consequently attenuation of stem cell aging will become a central to regenerative medicine. Identifying conditions under which in an aged organism aged stem cells are activated to be functionally equivalent to young stem cells could thus be a first step towards designing treatments to attenuate/revert the consequences of stem cell aging and consequently to improve age-associated imbalances in tissue homeostasis.

Studying muscle regeneration by muscle stem cells (satellite cells) in aged animals, Conboy et al. recently reported that aged muscle stem cells can be activated to repair/differentiate as efficiently as young muscle stem cells either by forced activation of Notch, or by systemic factors provided by serum from young animals (Conboy et al. 2003, 2005). They also identified that factors in serum from aged mice negatively affect muscle stem cell activation. As aging of HSCs is at least in part cell intrinsic, amelioration of HSCs aging might be more difficult to achieve. As mentioned above, loss of the p16 protein as well as antioxidative therapy both resulted in partial reversion of HSC aging. In addition, attenuation of HSC aging was also achieved by lifelong caloric restriction of mice from the BalbC inbred strain, without though further identification of a possible molecular mechanism underlying this stem cell response (Chen et al. 2003). These results are very promising and prove that it is possible to change the path of stem cell aging. More research though will be necessary to translate our knowledge on stem cell aging into therapies that promise a lifelong fountain of stem cell youth to all of us.

Acknowledgments We apologize to the authors of all the references we forgot to cite or discuss due to space limitations in addition to aging of our neurons. Work in the laboratory of Dr. Geiger is supported by NIH grants DK077762 and HL076604. Work in the laboratory of Dr. Van Zant is supported by NIH Grants AG020917, AG022859, AG024950. Implications of Developmental Switches for Hematopoietic Stem Cell Aging

Jens M. Nygren and David Bryder

Contents

Abstract: Each of the different hematopoietic cell types has their own properties and function, but only when they all act in tight synergy are they able to constitute a highly specific and efficient immune defense capable of efficient protection from invading pathogens and appropriate maintenance of blood clotting and oxygen transport functions.

All blood cell types are continuously produced in the bone-marrow by rare hematopoietic stem cells that persist throughout the life of the organism. These stem cells are influenced by their environment and developmental history and experience a range of cell intrinsic changes that over time alter their functional properties. These timed changes include alterations in fundamental processes such as self-renewal, proliferation, differentiation and gene expression, thereby being crucial for both normal maturation as well as hematopoietic aging.

1 Introduction

The blood system produce hundred of millions of new blood cells everyday to maintain oxygen transport, blood clotting and immune function [Morrison et al. 1995b]. This process is highly conserved through evolution and therefore largely similar between lower vertebrates and mammals [Laird et al. 2000; Zon 1995].

In the early 1960s, McCulloch and Till performed a series of ground breaking experiments to search for multipotent and self-renewing hematopoietic stem cells (HSC) that could sustain such extensive blood cell production throughout life. Bone-marrow cells were injected intravenously into irradiated mice and the subsequent engraftment of a rare fraction of these cells, as visible nodules in the spleens of the recipients, were evaluated. From such experiments, it was established that nodules appeared in proportion to the number of bone-marrow cells injected, and that individual nodules arose from single bone-marrow cells, named colony forming units spleen (CFU-S) [McCulloch and Till 1960]. The ability of CFU-S to self-renew [Becker et al. 1963], a cardinal property of stem cell function, provided the first true evidence that somatic HSC exists in the bone-marrow. Today, four decades later, we know that the bone-marrow is the primary hematopoietic organ by the end of fetal maturation and that seeding of HSC to the bone-marrow is a uniform process and results in homogeneous distribution to the different bone-marrow compartments, without spatial differences in hematopoiesis or HSC identity [Kiel et al. 2005]. The majority of cells in the bone-marrow are maturing blood cells and their progenitors, and thus HSC constitute a rare population of less than one in 15,000 bone-marrow cells [Lagasse et al. 2001].

2 Quiescent Hematopoietic Stem Cells

The identity of the bone-marrow HSC cannot be recognized by their morphology and phenotype alone, but rather by their unique functional properties [Lagasse et al. 2001; Matsuzaki et al. 2004; Osawa et al. 1996]. Traditionally, function is evaluated by the ability of cells to reconstitute the blood system following transplantation into hosts in which endogenous HSC have been eradicated by a lethal dose of irradiation. Similar to the CFU-S assay, reconstituting clones can be assayed by tissue sampling. The progeny from reconstituting HSC are identified by monoclonal antibodies and detected by flow cytometry to establish both level and quality of engraftment. With this assay, HSC properties can be analyzed even at a clonal level by detection of the descendants from single transplanted HSC [Osawa et al. 1996]. However, although ultimately being capable of producing all blood cells, including phenocopies of themselves, HSC remain low proliferative, presumably to limit divisional stress and any intrinsic changes that comes with accumulated cell divisions and aging. The mechanisms underlying such regulated quiescence is currently unknown but is one of many features that take place throughout development which eventually lead to the functional changes that are ascribed to the aging of HSC.

2.1 Quiescence and Cell Cycle Control

Adult HSC are largely quiescent in that their transit through the cell cycle is slow or even arrested at times. This is reflected by that as few as eight percent of the cells in the HSC pool enter cell cycle every day. Nonetheless, quiescence does not result in cell cycle arrest as most cells within a population of HSC have divided at least once within four to eight weeks [Bradford et al. 1997; Cheshier et al. 1999]. The series of events in an eukaryotic cell that are referred to as the cell cycle consists of distinct phases in which the cell undertakes sequential actions like growth and preparation of the chromosomes for replication (G_1 phase), DNA synthesis to duplicate the chromosomes (S phase), additional growth and preparation for cell division (G_2 phase) and finally, mitosis (M phase) during which the cell divides into 2 daughter cells [Steinman 2002]. This cyclic process is regulated at checkpoints [Mantel et al. 2001; Pardee 1989; Steinman 2002] during each phase-transition by cyclins that form complexes with cyclin-dependent kinases [Cheng 2004; Steinman 2002]. The cyclin-based surveillance system acts as a quality control that monitors the cell as it progresses through the cell cycle. Checkpoints can block progression through one phase if certain conditions are not met. For instance, mitosis is inhibited until DNA replication is completed or if not all chromosomes are attached to the mitotic spindle. A surveillance network of signaling molecules has been set up to instruct cells to stop dividing and to either repair the damage or initiate programmed cell death if necessary. For cells, like HSC, that persists and continues to proliferate throughout life, quiescence through tight negative control of cell cycle propagation and stringent surveillance of DNA integrity appears essential to minimize divisional stress and to ensure that damaged cells are not further propagated and do not progress into a cancerous state.

Some cells leave the cell cycle at the G_1 phase following a cell division and enter a nonproliferative G_0 stage [Pardee 1989]. Most often, G_0 cells are terminally differentiated and their exit from the cell cycle is thus permanent, whereas other cells, like HSC, are only temporally quiescent and can upon mitotic stimulation re-enter G_1 and prepare for additional cell cycles [Bradford et al. 1997]. HSC are relatively unresponsive to mitogenic stimuli [Bradford et al. 1997; Huang et al. 1999; Uchida et al. 2003] and this might reflect the fact that most cells in the HSC population are in a G_0 state. Thus, that HSC need a longer time and stronger stimulation than committed progenitor cells to respond to growth factors might reflect that they first need to get activated in order to reenter the cell cycle. Distinct regulation of the cell cycle activity of HSC by factors known to limit proliferation and differentiation [Cheng et al. 2000; Hock et al. 2004; Iwama et al. 2004; Lessard and Sauvageau 2003; Park et al. 2003; Walkley et al. 2005] is therefore presumably a key requirement to avoid exhaustion of the HSC compartment [Iscove and Nawa 1997] and should therefore represent a defining stem cell property. Active cell cycling have been suggested to exert negative effects on stem cell function [Fleming et al. 1993a; Glimm et al. 2000; Habibian et al. 1998; Jetmore et al. 2002; Orschell-Traycoff et al. 2000] although this can at least in part be an interpretation of experimental observations,

as the design of such experiments have assumed both that dividing hematopoietic stem and progenitor cells have a similar cell cycle transit time and that HSC are identifiable by phenotype alone. Most likely, HSC in cycle are functionally normal but due to their quiescent state represents a rare fraction within populations of enriched HSC in S/G_2/M stages. They are therefore outnumbered by nonquiescent and transiently reconstituting multipotent and lineage committed progenitor cells, which dominate most HSC enriched populations established to date [Nygren et al. 2006].

2.2 Quiescence but yet Hematopoiesis

As HSC divide, they can produce daughter cells of which at least one represent an identical replica of its ancestral HSC. Such self-renewing cell divisions are a hallmark of stem cells and necessary to maintain a constant HSC pool and lifelong production of all blood cell types [Becker et al. 1963]. Maintenance of the HSC pool can be the result of either asymmetrical cell divisions [Jan and Jan 1998] that results in one cell that is identical to the mother cell and one cell that is committed to differentiation, or of a balance of symmetrical cell divisions leading to either complete self-renewal or differentiation (i.e., result in either 2 HSC or 2 committed daughter cells). Nevertheless, asymmetric HSC divisions must occur at some point during cellular development and multilineage differentiation of committed cells [Takano et al. 2004] in order to appropriately generate progeny both for daily blood cell production as well as maintenance of a fairly constant number of slowly proliferating and inactive HSC. Daughter cells that do not inherit a stem cell identity loose the regulatory circuitry that limits proliferation by inhibiting mitogenic stimulation, and leave the quiescent state. Proliferation at the stages beneath the stem cells is likely to be an important regulator of differentiation as hematopoietic maturation requires signaling from the cyclin based surveillance system for proper influence on differentiation decisions [Ezoe et al. 2004].

The mechanisms that underlie and direct the multilineage commitment processes from HSC are still largely unknown, but several descriptive propositions of the differentiation processes has been established [Adolfsson et al. 2005; Katsura 2002; Kondo et al. 2001; Yang et al. 2004]. Common for these proposals is that self-renewing and multipotent long-term HSC exist throughout life as they throughout development maintain a quiescent state relative other hematopoietic cells [Nygren et al. 2006]. Their committed progeny irreversibly transit into short-term HSC that are also multipotent, but contribute to hematopoiesis for less than six to eight weeks, as such cells have lost the ability to extensively self-renew [Adolfsson et al. 2001; Yang et al. 2004]. Such transiently reconstituting HSC thereafter commit and enter progenitor states with restricted lineage potentials, to finally develop along certain cell lineage pathways with sequential restrictions in lineage potential and gene expression [Adolfsson et al. 2005; Akashi et al. 2003]. In light of the relatively short life span of a mouse (~2–3 years depending on strain), the low cell cycle

activity among HSC, with a population turnover of several months [Cheshier et al. 1999], is remarkable. If the steady state is severely disrupted, for example following manipulative treatments such as myeloablation and bone-marrow transplantation, HSC react by rapid expansion in the recipient [Allsopp et al. 2001; Iscove and Nawa 1997; Plett et al. 2002] and under the influence of exogenous growth factors, commitment, migration or even self-renewal might occur [Bodine et al. 1993; Fleming et al. 1993b; Kronenwett et al. 2000]. This argues for that the activity of the HSC needs tight negative and intrinsic regulation to fulfill the requirements in different physiological conditions and for the entire life of the organism.

2.3 Quiescence Imposed by a Stem Cell Niche

It is currently unknown whether there is a default fate regarding aspects such as self-renewal or differentiation into individual lineages from HSC. Whereas coordinated and precise control of commitment and differentiation largely depends on soluble factors, originating from within and outside of the bone-marrow, maintenance of HSC identities is believed to be mainly achieved by delicate interactions of the stem cells and their microenvironment, often referred to as the HSC niche. Identification of the factors and their signaling pathways underlying such control has been a main focus of hematological research, as knowledge on such regulation would allow manipulation for therapeutic purposes.

Extrinsic factors produced either by the stem cells themselves or by surrounding stromal cells that bind to receptors on the cell membrane of the stem cell can exert their effects long range as soluble molecules, or locally through direct cell-to-cell contact between the stem cells and adjacent cells [Attar and Scadden 2004]. Stromal cells and their products are spatially distributed into niches that differ in their HSC maintenance capacity and therefore, homing of HSC and hematopoietic progenitor cells to different niches affects their fate and the regulation of hematopoiesis [Arai et al. 2004; Calvi et al. 2003; Zhang et al. 2003]. Under physiological conditions, but more pronounced during stress, HSC migrate in and out of the bone-marrow compartment [Dorie et al. 1979]. This occurs at a very low frequency [Abkowitz et al. 2003; Dorie et al. 1979; Wright et al. 2001] by a mechanism that can be stimulated by exogenous cytokine treatment [Kronenwett et al. 2000]. The purpose and regulation of this migratory activity is not completely understood but might play a role in the seeding of HSC to other niches within the bone-marrow [Abkowitz et al. 2003; Wright et al. 2001], secondary lymphoid organs, like the thymus [Schwarz and Bhandoola 2004] or other organs [McKinney-Freeman and Goodell 2004].

The best direct evidence for stem cell niches comes from work in the Drosophila testis, where germline stem cells surround apical hub cells at the tip of the testis, which provide self-renewing signals [Kiger et al. 2001; Tulina and Matunis 2001]. As the stem cells divide, the daughter cell that keeps contact with the hub cells, and thereby continues to receive self-renewing signals, retains a stem cell identity. The other daughter cell that is relocated away from the hub cells initiates differentiation.

In the bone-marrow, similar regional patterning of self-renewing signals has been found within the endosteal zone lining the bone surface in the marrow cavity [Arai et al. 2004; Calvi et al. 2003; Zhang et al. 2003], with a gradient decreasing toward the central zone of the marrow space. In support of this, the majority of hematopoietic stem and progenitor cells has long since been known to be distributed preferentially along the bone surface [Lambertsen and Weiss 1984; Lord and Hendry 1972; Lord et al. 1975]. These findings suggest that fate determination of HSC within the endosteal zone occurs in a similar fashion as for germline stem cells in Drosophila testes, where the fate of the 2 daughter cells from a dividing HSC at least in part is determined by their attachment to or displacement from the stem cell-supportive niche [Wilson and Trumpp 2006].

2.4 Regulating Quiescence or Commitment

Asymmetry of the daughter cells derived from HSC self-renewing divisions might be due to asymmetric distribution of intrinsic factors, such as transcription factors, cellular components or DNA during cell division [Enver et al. 1998; Takano et al. 2004]. However, HSC regulation is a complex process involving both intrinsic and extrinsic factors that can be both counteracting and synergistic and hence, asymmetric cell division through asymmetric distribution of intrinsic factors might be dependent on extrinsic signals that prime HSC for the subsequent intrinsic regulation. This might explain why extensive efforts to ex vivo expand HSC so far has, with some exceptions, been fruitless [Bryder and Jacobsen 2000; Glimm and Eaves 1999; Miller and Eaves 1997; Moore et al. 1997; Quesenberry et al. 2002; Sauvageau et al. 2004; Srour et al. 1999]. Regardless of the outcome from an asymmetric HSC division, the interaction of the 2 daughter cells with their environment results in fate decisions that determine the destiny of each particular cell and such interaction continues throughout the life of the cell. The newly formed cells can either return to a quiescent state as the parental HSC, carry on a second self-renewing asymmetric (or symmetric expanding) cell division, commit to differentiate along a certain lineage pathway or migrate to a distant site that offers suitable environment for either of the fates above [Wagers et al. 2002]. If the environment does not support any of these possibilities, the cell will due to the lack of instructive signals inevitably undergo apoptosis, a process that plays an important regulatory function for hematopoietic homeostasis [Domen and Weissman 2000; Wagers et al. 2002].

Regulation of these HSC fate decisions is most likely a combination of stochastic (random) events, mainly though intrinsic regulation at the time of cell division [Enver et al. 1998; Greaves et al. 2003; Ogawa 1999; Phillips et al. 1992; Till et al. 1964], and deterministic events, mainly due to extrinsic factors in the HSC niche, that can be either permissive or instructive in their action [Metcalf 1998; Morrison and Weissman 1994; Muller-Sieburg et al. 2002]. Eliminating single or multiple hematopoietic growth factors or signal transduction pathways by genetic engineering in mice, allows determination of the type of action a factor imposes on the

HSC. The action of some factors is redundant as their removal does not result in hematopoietic phenotypes and can be compensated for [Akashi et al. 1998; Metcalf 1993; Sitnicka et al. 2002] whereas others are indispensable for certain fates [Iwasaki et al. 2005]. The first case exemplifies permissive regulation, allowing cells to differentiate along a predestined differentiation pathway, and the latter instructive regulation, instructing cells toward a specific fate [Kondo et al. 2000].

A major group of extrinsic factors in hematopoiesis are cytokines that play an important role in regulation of hematopoiesis. Most such molecules are available both in soluble and cell membrane bound forms and interact by direct binding to cell membrane receptors on the hematopoietic cells or on intermediate cells with which the hematopoietic cells interact. The early acting cytokines Stem Cell Factor and Thrombopoietin are nonredundant regulators of the HCS-pool [Zhu and Emerson 2002]. Other cytokines act on more committed cells and drive differentiation along particular pathways, like Erythropoietin for erythroid cells, granulocyte-macrophage colony-stimulating factor (GM-CSF) and granulocyte colony-stimulating factor (G-CSF) for myeloid cells and interleukin 7 (IL-7) for B-cells [Ogawa 1993; Zhu and Emerson 2002]. Signaling from membrane bound receptors on HSC is propagated through elaborate intracellular signal transduction pathways to the nucleus, where they influence the activity of transcription factors. These bind to promoter elements on the DNA and regulate together with other regulatory molecules and DNA polymerases the transcription of target genes and ultimately, fate decisions. Several transcription factors have been implicated in the regulation of HSC self-renewal (ICN/CSL, Ikaros, HoxB4 and GATA-2), whereas others participate at more downstream cellular levels by inducing commitment toward individual hematopoietic lineages [Zhu and Emerson 2002].

3 Hematopoietic Stem Cell Developmental Switches

Development of a fully functional blood system occurs early in development and the hematopoietic system thereafter continuously changes to meet the demands on the organism at each stage of development. These changes mainly occur through alterations of identities and functions of the HSC through specific and seemingly irreversible switches that are mainly cell autonomous but depend on and are influenced by variation of the cellular environment of the HSC niches throughout ontogeny.

3.1 The Primitive to Definitive Switch

Onset of hematopoiesis is an early event in embryonic development and required to meet the demands of oxygen transportation as the embryo becomes larger and to provide an early defense against pathogens. In mouse development, gastrulation starts 7.5 days post conception (dpc) and leads to the formation of ectoderm, mesoderm

and endoderm. During this process the extra- and intra-embryonic regions, the yolk sac and embryo proper, are established. In the yolk sac, cell aggregates called blood islands are formed and contain cells of both hematopoietic and endothelial lineages. These develop in close contact, and perhaps from a common progenitor cell known as the hemangioblast [Choi et al. 1998; Keller et al. 1999; Mikkola et al. 2003]. Commitment toward a hematopoietic fate occurs through the influence of various transcription factors, such as Tal-1/SCL, AML-1, Lmo2 and GATA-2, and results in the formation of committed primitive hematopoietic precursor cells [Zhu and Emerson 2002]. Such primitive precursors are primed towards myelo-erythroid lineages and mostly produce monocytes, for infectious defense in the placenta, and primitive erythrocytes, that are large, nucleated and produce embryonic globins [Weissman 2000]. This early burst of extra-embryonic erythrocyte production is necessary for oxygen transportation within the embryo at a time when oxygen diffusion from maternal circulation becomes insufficient [Cumano and Godin 2001]. The yolk sac remains a hematopoietic organ until the embryo itself can support blood cell production by around 11.5 dpc. Within the embryo, a region comprising the rudiments of the dorsal aorta and surrounding splanchnic mesoderm forms at around 8.5–10 dpc and at this site the development of definitive HSC initiates [Bertrand et al. 2005; de Bruijn et al. 2002; Godin et al. 1999]. The region, named the para-aortic splanchnopleura (P-Sp), later develops into the aorta gonad and mesonephros (AGM) at 10–12 dpc. Hematopoietic precursor cell activity can be identified by 10.5 dpc in a region of the mesenchyme surrounding and within the dorsal side of the aorta [Bertrand et al. 2005; de Bruijn et al. 2002; Godin et al. 1999]. These precursors develop into the HSC that support definitive hematopoiesis yielding small enucleated erythrocytes that express adult globins. The intra-embryonic definitive HSC are the sole precursors of the adult HSC that supply HSC activity throughout life [Cumano and Godin 2001], thus no further HSC are generated during late fetal and neonatal stages of development [Gothert et al. 2005]. The origin of the intra-embryonic definitive HSC has been under debate as to whether they really are descendants from the primitive yolk sac derived precursors or originate independently from definitive hematopoietic precursors. Studies by Moore and Metcalf in 1970 suggested that the yolk sac is required for both primitive and definitive hematopoiesis in mice [Moore and Metcalf 1970]. Culture of precirculation 7 dpc embryos from which the yolk sac had been removed developed without blood cell formation, whereas culture of 7 dpc yolk sac alone yielded abundant hematopoietic colonies. Although challenged over the years [Cumano et al. 2001; Medvinsky and Dzierzak 1996], this concept was recently confirmed by noninvasive labeling of progenitors of definitive hematopoiesis, expressing Runx1 in the yolk sac blood islands at 7.5 dpc, establishing that intra-embryonic definitive HSC can originate from extra-embryonic primitive precursors in the yolk sac of the developing embryo.

As definitive HSC in the AGM mature, they migrate and enter the blood circulation [Christensen et al. 2004; Delassus and Cumano 1996] to colonize the liver [Morrison et al. 1995a]. In the fetal liver environment, such cells gain properties changing their identity from being nonproliferating, nondifferentiating and nontransplantable, to cells that can rapidly proliferate and self-renew to expand their

numbers to meet the growing requirements of the hematopoietic system [Ikuta and Weissman 1992; Lansdorp et al. 1993; Rebel et al. 1996b]. The capacity of the fetal liver HSC for multipotent blood cell production and long-term repopulation when transplanted into lethally irradiated hosts is extensive and unprecedented throughout ontogeny [Jordan et al. 1995; Rebel et al. 1996a; Rebel et al. 1996b]. With emergence of fetal liver hematopoiesis, the necessity of yolk sac erythropoiesis (12–14 dpc) decreases and leads to disappearance of yolk sac hematopoietic precursors. However, as yolk sac and fetal liver HSC display similar globin switching, these events are unlikely to be the result of alternating cell populations, but rather represent the outcome of developmental switches of primitive to definitive hematopoiesis and thereby changes in transcription. By the end of pregnancy, hematopoiesis in the liver transfers through the migration of HSC to the bone-marrow [Christensen et al. 2004; Delassus and Cumano 1996; Potocnik et al. 2000], which remains the main hematopoietic organ throughout life [Morrison et al. 1995b]. During these developmental processes, mesenchymal progenitor cells (with osteogenic, adipogenic and chondrogenic potential) in parallel home to and develop niches supporting self-renewal in the primary hematopoietic organs (fetal liver, bone-marrow and spleen) as these tissues develop in the fetus [Christensen et al. 2004; Mendes et al. 2005; Palis et al. 2001; Potocnik et al. 2000]. Whether the colonization of niches supporting hematopoiesis during midgestation is a multiwave process or the result of a constant flow of rare HSC in the fetal blood is currently unclear [Christensen et al. 2004; Delassus and Cumano 1996; Potocnik et al. 2000]. It appears likely that low numbers of HSC are constantly circulating both before and after their expansion and maturation in the fetal liver, until a suitable environment for hematopoiesis has developed in the bone-marrow.

The distinct developmental fates of extra- and intra-embryonic progenitors in extra- and intra-embryonic niches [Matsuoka et al. 2001; Orkin and Zon 2002; Walker et al. 2001; Yoder et al. 1997] thus require intrinsic developmental switches that alter lineage priming, gene expression, function, cell cycling and the phenotype of HSC. As transplantation of primitive extra-embryonic progenitors to intra-embryonic sites directs these cells to adopt a definitive fate, it appears as appropriate instruction is also contingent on environmental cues [Turpen et al. 1997].

3.2 Fetal to Adult Switch

Both embryonic and adult hematopoiesis is hierarchical, with differentiation occurring through distinct and sequential progenitor subsets [Kondo et al. 2003]. This suggests that the molecular mechanisms underlying cell fate decisions are conserved from embryo to adult. Despite of this similarity, the properties of fetal liver HSC that migrate to the bone-marrow by the end of gestation are in many aspects different from when they have adopted adult properties and fates in the bone-marrow [Jordan et al. 1995; Rebel et al. 1996a; Rebel et al. 1996b]. This fetal to adult developmental switch occurs in the bone-marrow during the first weeks after birth in

a precise manner and involves coordinated alterations in the abilities to self-renew, proliferate, differentiate as well as in regulation of gene expression, suggesting cell intrinsic regulation rather than random environmental changes [Bowie et al. 2007b; Kikuchi and Kondo 2006].

Expansion of HSC numbers in the fetal liver occurs with cell cycle kinetics that are significantly different from those of adult HSC in the steady state bone-marrow [Nygren et al. 2006]. Following lodging to the bone-marrow environment, there is a need for reduction of the extended proliferative activity and hence switching of the regulatory circuitry into a more quiescent state [Bowie et al. 2006]. Such transformation seems to occur during neonatal week three to four after birth and completely alters the cycling behavior from a fetal high proliferative into an adult quiescent state that is maintained throughout adulthood [Bowie et al. 2006]. Fetal liver HSC have a dominating lymphoid potential [Morrison et al. 1996], differ in the factor dependence for their differentiation compared to adult HSC [Kikuchi and Kondo 2006] and support differentiation to B- and T-cell subtypes that are distinct in function and phenotype and normally not present in adults [Hayakawa and Hardy 2000; Ikuta et al. 1990]. These differences in lineage priming are changed upon adoption of adult HSC properties during the first week after birth. Whether the effects of these switches are reversible remains to be determined, but as HSC of fetal type undergo similar changes with analogous kinetics following transplantation into an adult environment they must involve intrinsic and, at least during steady state conditions, irreversible changes of the fetal HSC [Bowie et al. 2007b]. This change could involve components of c-kit signaling [Bowie et al. 2007b], in accordance with the role of the c-kit receptor in control of self-renewal in HSC [Bowie et al. 2007a]. Shorter cell cycle passage time of fetal HSC might be due to intrinsic proliferative control that favors symmetric self-renewing cell divisions. Similar intrinsic changes occurs in otherwise quiescent adult HSC that are exposed to an environment that demands a high degree of self-renewing cell divisions, for instance following serial transplantation [Allsopp et al. 2001]. That self-renewing cell divisions dominates fetal HSC cell divisions is not only reflected by an increased proliferative activity in vivo compared to adult bone-marrow HSC but also an enhanced capacity to long term repopulate the blood system of lethally irradiated recipient mice [Rebel et al. 1996a]. This can not be correlated with differences in the ability of transplanted cells to migrate to and engraft in the host bone-marrow, as fetal HSC transplanted together with a population of competitive adult counterparts maintain this property. Cells from both origins engraft similarly well in the adult recipients but the fetal donor cells out competes adult cells over time. Although fetal HSC transferred to an adult environment undergo developmental switching into an adult state, they maintain an enhanced capacity to proliferate with extended and preserved self-renewing abilities compared to adult cells having developed normally [Bowie et al. 2007b; Bowie et al. 2006; Rebel et al. 1996a]. As transition into an adult stage seems to occur with precise timing, it appears as cell autonomous molecular switches tightly regulate lineage priming during fetal and adult hematopoiesis, but depend on proper development with sequential changes of fate that cannot be sidestepped.

3.3 The Adult to Old Switch

Upon the fetal to adult developmental switch, HSC persists throughout adulthood in a relatively quiescent state compared to their progeny [Nygren et al. 2006], with more or less maintained properties and regulatory control. However, randomly occurring events impose direct wear and tear on HSC during their life span and as such changes can accumulate over time due to the self-renewal capability of HSC, it appears reasonable that they can result in phenotypic and functional changes and even a reduced capacity to maintain cellular homeostasis and survival. However, gene expression patterns of aged HSC have revealed that, compared to post-mitotic cells in other tissues, stress induced damage does not seem to play a major role on HSC aging in steady-state [Rossi et al. 2005]. This might be a result of a unique ability of HSC to maintain a quiescent state relative to their down stream progeny throughout ontogeny [Nygren et al. 2006] which would allow HSC to escape from much of the negative stress associated with life long and continuous proliferation. Furthermore, not all observed changes of HSC during aging appears to be attributed to macromolecular damage, suggesting contributions of cell autonomous changes through internal molecular switches [Rossi et al. 2007b]. In line with this, loss of immune function of aged HSC is likely due to cell autonomous changes that results in altered gene expression favoring myeloid specific genes, resulting in lineage skewing towards a myeloid fate [Rossi et al. 2005]. Thus, reduced competence of the adaptive immune system appears to be a result of an increased myeloid progenitor cell capacity, at the expense of lymphoid developmental potential. Phenotypical and functional evaluations have shown that the numbers of HSC in the aged bone-marrow are significantly increased [Rossi et al. 2005; Sudo et al. 2000]. Transplantation of HSC from young and old donors into young recipients showed that the elevated numbers of HSC in old mice were due to cell autonomous changes in the HSC leading to a higher incidence of self-renewing cell divisions with HSC aging.

Taken together, HSC that until recently were assumed to be exempt from aging show progressive alterations in many aspects upon reaching advanced age. Such changes however does not seem to occur in an as controlled and defined way as for the developmental switches that occur during early development. Although the cellular changes act in a cell autonomous manner, the actual switching of a cell from young to adult might indeed be triggered by environmental cues. Such factors would be linked to aging of the cellular environment of HSC, thereby altering the regulatory circuitry that controls on demand production of HSC progeny and in maintenance of their own quiescence. In support of this, aged HSC have been suggested to be affected by changes of the interaction with the supporting HSC niches in the bone-marrow, with a reduced ability for adhesion to stromal cells, impaired homing to the bone-marrow following transplantation and increased responsiveness to mobilizing factors [Liang et al. 2005; Xing et al. 2006]. Thus, intrinsic and environmental changes that occur within the pool of HSC collectively sets the prerequisite for cellular deterioration. With this interpretation, the developmental history of each individual cell establishes how and when the aging process will begin.

Such processes seem to be irreversible and unaffected by environmental factors once initiated, as the transfer of aged HSC to a young environment does not change their adult identity [Rossi et al. 2005; Sudo et al. 2000].

4 Aging of Hematopoietic Stem Cells

Aging are generally though of as the sum of the deteriorative effects on a cellular identity or function that accumulates over time and eventually reaches a state that leads to tissue failure. However, for the hematopoietic system it is doubtful whether the consequences of aging are attributed to changes of the actual HSC due to accumulation of wear and tear or environmental signals. Instead, many changes on function and identity of HSC might in fact constitute normal developmental steps that occur through controlled and evolutionary conserved switches. Such adaptation to changes in environment and requirement imposed in the system, begin in the developing embryo and continue throughout ontogeny.

4.1 Aging as the Result of Environment

As described earlier in this chapter, HSC are exposed to dramatically different environments during their maturation. Commitment towards hematopoiesis occur outside the embryo in the yolk sac blood islands, transit through the AGM region and fetal liver for developmental switching and expansion, and by the end of fetal development find their home in the bone-marrow where they, except from rare and transient migration into the blood system for relocation, stay throughout adult life. During this process, wear and tear of the most primitive HSC do occur but the extent of this and the importance it plays for their function remains largely unknown. Throughout adulthood, it has been proposed that the main site that supports maintenance of HSC is the endosteal bone-marrow niche, providing a sanctuary with limited damage to proteins, membranes and DNA imposed by the environment. The cell layers that comprise the endosteal zone are highly hypoxic, suggesting that it provides an environment with low pressure of cellular damage derived from reactive oxygen species [Parmar et al. 2007]. Furthermore, hypoxic conditions might be important for optimal stimulation of self-renewal and quiescence and thereby play an important role in avoiding accumulation of cellular damage by limiting proliferation [Tothova et al. 2007]. Hypoxic conditions could be entertained by a low flow of extra-cellular fluids in the HSC niche, thereby also limiting exposure to toxins, metabolic by products and toxic compounds from immune responses as seen elsewhere in the organism.

As HSC by definition persist for the lifetime of an organism, developmental marks should be accumulating and with time reach levels influencing cellular function thereby imposing changes on HSC stem cell identity. Recent studies have however

underscored that environmental influences plays a minor role in the specification of these cells as transferring of aged cells to an young environment does not alter their identity or function [Rossi et al. 2005]. This argues for that environmental cues can not alter cell intrinsic changes of HSC once established or modify the genetic control that regulate the kinetics of this process [Phillips et al. 1992]. However, environmental factors such as toxins, inflammatory cytokines and DNA interfering compounds might well act over long time to impose some of the cellular changes accompanying age. Many of these are closely linked to metabolic and proliferative activities, emphasizing the importance of avoiding such influence on HSC by maintaining quiescence at all times, including during stress responses and extensive self-renewal [Nygren et al. 2006]. As all other cells, the bone-marrow stromal cells that constitute the HSC microenvironment age and undergo changes that might affect its HSC supporting capacity [Liang 2005 #646]. An increasing number of senescent stromal cells might be one important factor that through deteriorated HSC supportive function fails to prevent or possibly by themselves drive HSC aging.

4.2 Avoiding Aging by Quiescence

Downstream progenitor cell populations that have committed to individual hematopoietic lineages consist of a limited number of clones with an extensive capacity to produce mature effector cells of each lineage. The high degree of multiplying and differentiating cell divisions that take place within these populations impose a high degree of divisional stress on each cell. However, as progenitor cells lack extensive self-renewing properties, any damage on cells or their genetic material can only spread within the progeny of that clone and will disappear as it reaches its proliferative limit [Hayflick 1965; Lemischka et al. 1986]. In contrast, HSC, which through their asymmetric cell divisions can generate all different progenitor cell subsets, must find means to avoid such accumulation of damage as they will be carried on and amplified at progenitor cell stages for the rest of the life of that HSC clone. It therefore appears likely that HSC have adapted a regulatory circuitry that limits proliferation at the HSC stage.

In vivo labeling with the thymidine analogue BrdU into the DNA of proliferating cells have established that although all HSC constantly divide and participate in hematopoiesis, they are generally quiescent, with a population turnover that is distinguishable from that of the downstream progenitor cells even during stress or extensive expansion [Bradford et al. 1997; Cheshier et al. 1999; Nygren et al. 2006]. To expand the numbers of progeny generated from each clone, a finite but extensive proliferative capacity instead occurs at downstream progenitor cell levels. Thus, clonal stability of rare HSC seems to be the general incidence, whereas clonal succession occurs within all hematopoietic progenitor cell populations as each progenitor cell has a limited life span and is eventually succeeded by a new progenitor cell.

When studying hematopoiesis during aging, any cell type will however eventually reach its end point and succumb or perhaps enter senescence. As new HSC

clones are not formed after midgestation embryogenesis [Gothert et al. 2005] loss of HSC clones can not be replenished but only substituted by expansion of similarly old clones that will eventually reach senescence or die. Senescent cells are metabolically active but have a changed pattern of gene expression and an irreversible loss of proliferative capacity. HSC senescence should normally represent a minor problem, if occurring at all, as HSC can be propagated for as long as four times the normal life span of a mouse through serial transplantation into sequential recipients [Harrison 1979]. The elements that are involved in avoiding senescence of HSC are not known but through studies of different mice strains, several genetic elements has been identified that are indispensable for controlling proliferation and thereby preservation of the HSC pool [Chen et al. 2000]. Although HSC appears to have found means to escape from proliferative stress such as through lodging to a hypoxic environment with low degree of oxidative stress [Parmar et al. 2007; Tothova et al. 2007], efficient exclusion of toxic components taken up from the environment by multidrug resistance membrane transporters [Zhou et al. 2002] and limiting genetic deterioration from repeated explicative stress [Nijnik et al. 2007; Rossi et al. 2007a], complete protection from these effects is unlikely. An example of this is the shortening of the critical telomere elements at the ends of the chromosomes following extensive proliferation.

Telomeres are the regions of highly repetitive DNA at the end of the chromosomes and functions as a disposable buffer of genetic material. Every time chromosomes are replicated, DNA polymerase complexes are incapable of continuing replication all the way to the end of the DNA strand of each chromosome, thereby leading to a gradual loss of nucleotides with each mitosis. This ultimately results in a genome with an increased chromosomal instability and, as a cellular defense mechanism, an increased predisposition to enter senescence or cell death. In some cells, including somatic stem cells, telomerase extend telomeres by adding extra repetitive DNA elements constituting telomeric sequences. However although genetic instability and functional impairment of HSC coincides with telomere shortening following extensive proliferative stress and following genetic alteration of telomerase function [Allsopp et al. 2001; Allsopp et al. 2003a; Samper et al. 2002], maintenance of telomeres is likely not sufficient by itself to avoid stem cell exhaustion [Allsopp et al. 2003b].

4.3 Avoiding Aging by Asymmetry

The quiescent stem cell specific asymmetric partitioning of cell fate during cell division of HSC into either preserved stem cell identity, or loss of such and commitment towards differentiation, limits the proliferative tension on the stem cell clone by allowing one of the daughter cells to maintain quiescence. Which elements that are unequally distributed to the daughter cells and how such partitioning takes place is not fully understood. However, displacement from a certain stem cell supporting environment within the niche might play a role [Kiger et al. 2001; Tulina and Matunis 2001; Wilson and Trumpp 2006] as well as regulated

or stochastic distribution of transcription factions, organelles, receptors and other cellular constituents and biomolecules into gradients that establish differences in cell fate [Arai et al. 2004; Rusan and Peifer 2007; Yamashita et al. 2007; Zhang et al. 2003]. It would therefore seem reasonable that partitioning of cell fates by asymmetric cell divisions might play a role for avoiding aging of the HSC clone that strive for persistence throughout life. During stem cell divisions, centrosomes can be asymmetrically inherited with mother centrosomes that always ends in the daughter cell with remained stem cell identity, arguing that also genetic material could be passed on from stem cell to stem cell in a similar fashion. The concept of such partitioning of the DNA have been hypothesized and could explain how long lived cells that proliferate extensively avoid accumulation of genetic defects acquired during replication [Nijnik et al. 2007] by using the same DNA strand as template for DNA polymerase replication and passing it along into the daughter cell that inherit stemness, whereas the newly replicated strand ends up in the daughter cell with lost stem cell capacity [Cairns 1975]. Retaining the same set of template DNA strands throughout development could help preventing adult stem cells from accumulating mutations arising from errors in DNA replication. Instead, randomly occurring mutations during replication within a HSC clone are passed on to nonstem cell daughters that soon terminally differentiate. Such mechanism would reduce the rate of accumulation of mutations in HSC that would otherwise eventually lead to serious genetic disorders or aging [Rossi et al. 2007a]. The idea of an immortal strand in HSC has however to be strengthened by experimental data, and if present, it has to be established how such stem cell specific partitioning of immortal template and mortal copy strands take place. All definitive HSC clones are established during midgestation embryogenesis and thereafter no new clones are born. Thus expansion of the HSC pool thereafter can only occur through multiplication of such HSC clones. Depending on when immortal templates would be established, not all HSC necessarily need to have the capacity to partition DNA into mother and daughter cells following replication. Similarly, asymmetric distribution of proteins and cellular constituents, an event that plays important roles in specifying asymmetry of the daughter cells from asymmetric cell divisions [Enver et al. 1998; Takano et al. 2004], could be speculated to also be operational to specify fates at a HSC level, although to date representing an under explored mechanisms to these processes.

Chromatin remodeling is critical for regulating transcription, replication, recombination and segregation of the chromosomes. Histone complexes organize chromatin and play a major role in epigenetic imprinting of the DNA, and a critical role in HSC biology for the polycomb protein Bmi-1, a transcriptional repressor that maintain repression of genes after a cell division and thereby maintain epigenetic memory, was suggested [Lessard and Sauvageau 2003; Park et al. 2003]. It appears likely that such processes play key roles in determination of stemness of daughter cells from self-renewing HSC cell divisions, although the order of such events remain currently unknown. However, as epigenetic imprinting of DNA has to be replicated onto the daughter chromatin following each cell division, it appears reasonable that accumulated numbers of cell divisions might lead to functional changes, including reductions in self-renewing ability.

4.4 Genetic Control of Aging

Aging is a multi parameter sequence of events controlled by both environmental factors and the genetic composition of the individual. As outlined above, environmental factors can influence on normal wear and tear of HSC and their development, but seem to have a subordinate role for establishing the transcriptional networks that specifies developmental switches and aging. Although the molecular mechanisms have not been elucidated in detail, it is clear that various genetic traits are involved in the modulation of life span [de Haan et al. 2002; Geiger et al. 2005; Rossi et al. 2007a]. Such modulation in HSC involves reduction of damage to the cell and its genetic components over time, and is crucial to avoid premature ageing and senescence. Damage control is not mainly supplied by repair systems that maintain the integrity of proteins, DNA and cellular components, but also accomplished through preventing metabolic stress and genetic instabilities acquired from extended divisional activity. This provides a strategy to limit the number of deleterious actions occurring within the limited and irreplaceable HSC pool, and is mainly accomplished by an in nature unique ability to constantly participate in the process of hematopoiesis, while still maintaining proliferative quiescence over time [Nygren et al. 2006].

Several genes involved in maintaining HSC quiescence and the action of their protein products have been characterized. These components form a network that signals to the stem cell to maintain stem cell properties through self-renewing cell divisions [Reya et al. 2003; Willert et al. 2003] and is believed to transfer epigenetic memory that identifies stemness to at least one of the daughter cells [Lessard and Sauvageau 2003; Park et al. 2003]. The process of self-renewal however needs to be restricted and factors are needed that interfere with cell cycle control to restrict proliferation [Hock et al. 2004] and maintain and strengthen adhesive interaction of the HSC with the niche supporting quiescence [Wilson et al. 2004; Yang et al. 2007]. However, although many components of the circuitry that signals self-renewal and quiescence in the HSC and their niche have been postulated, little direct mechanistic insights have so far been provided.

Genes and genetic elements that have a general effect on the life span of an organism suggests that molecular machineries can be activated to ensure that homeostasis is maintained at various situation of stress, thereby putting some sort of break to the aging process. Genetic information located in the mitochondria has been identified as one major heritable component involved in aging. Instabilities of the mitochondrial DNA due to damages or replication can lead to mitochondrial dysfunction, increased oxidative stress and cellular senescence emphasizing the importance of long lived cells to limit metabolic activity and proliferation [Cadenas and Davies 2000]. Studies of cellular processes in mice have been standardized to involve only a limited number of inbred mouse stains. In these a varying degree of effects on HSC function have been observed during aging, however generally HSC does not seem to loose regenerative capacity as they age [Rossi et al. 2005]. This is further supported by studies demonstrating maintenance of hematopoiesis during conditions and time spans that by far extends the normal life expectancy of the organism [Ross et al. 1982].

5 Conclusion

The constant ongoing process of cell replacement in the hematopoietic system imposes a strong degenerative stress on the cellular elements that participate in these processes. Luckily, many of these adverse effects from prolonged regeneration disappear upon cellular differentiation and are therefore present only transiently. However, as stem cells are maintained throughout life, accumulation of any damage or other heritable cellular traits that occurs along these processes and its regulatory networks will have dramatic effects due to the hierarchical structure of hematopoietic development. Limiting metabolic and divisional stress in hematopoietic stem cells is therefore key for maintaining their appropriate lifelong function and to avoid proliferative exhaustion or leukemic transformation with age.

Genetics

Associations of Cytokine Polymorphisms with Immunosenescence

Elissaveta Naumova and Milena Ivanova

Contents

Abstract: Deterioration of the immune system with aging is associated with an increased susceptibility to infectious diseases, cancer and autoimmune disorders. It has been demonstrated that immunosenescence is associated with chronic, low-grade inflammatory activity. The aging process is very complex and longevity is a multifactorial trait, which is determined by genetic and environmental factors, and the interaction of "disease" processes with "intrinsic" ageing processes. It is hypothesized that the level of immune response as well as possibly longevity could be associated with genes regulating immune functions. It is further hypothesized that the diversity of these genes might influence successful aging and longevity by modulating an individual´s response to life-threatening disorders. Several studies have focused on the role of genes encoding molecules with immune functions. In this chapter we will review the data on the role of cytokine gene polymorphisms in human longevity.

1 Introduction

Aging is a universal phenomenon affecting all animal species. This physiological process could be characterized as: inevitable consequence of being a multicellular organism; associated with a random passive decline in function; leading to a global loss of homeostasis over time and mortality increasing with aging (Helfand and Rogina, 2003). Aging is determined by a complex interaction of genetic, epigenetic and environmental factors, but a strong genetic component appears to have an impact on survival to advanced age. Among the several theories of aging proposed, the genetic theory suggests that several genes are involved in longevity (Kirkwood, 2002; Browner et al. 2004). Additionally, studies of Mitchell et al. indicated that up to 25% of the variation in human lifespan is heritable (Mitchell et al. 2001). The genetics of human longevity is quite peculiar in a context where antagonistic pleiotropy can play a major role and genes can have different biological role at different ages. Data of several studies imply that aging process may be associated with alterations in the immune system, suggesting that genetic determinants of senescence also resides in those polymorphisms for the immune system genes that regulate immune responses. Genes, encoding molecules involved in the development of protective immunity are highly polymorphic, present significant variation possibly resulting from an evolutionary adaptation of the organism facing an ever evolving environment. These genes include: HLA genes; genes encoding "unusual" HLA-like molecules (CD1); killer cell immunoglobulin-like receptor genes (KIR); leukocyte Fcγ receptor genes; cytokine and cytokine receptor genes; Toll-like receptor gene family; TNF- receptor associated factors. Several studies have focused on the role of cytokine gene polymorphisms for human longevity. The diversity of these genes might influence successful aging and longevity by modulating an individual´s response to life-threatening disorders.

In this chapter we summarize present knowledge on the role of cytokines in human longevity. Cytokines are an internal part of the immune response stimulated by antigen presentation in the context of HLA. Many studies have shown that the pathology of some infectious, autoimmune and malignant diseases is influenced by the profiles of cytokine production in pro-inflammatory (Th1) and anti-inflammatory (Th2) T cells. Additionally some authors have shown differences in cytokine levels in elderly and possible association with age-related diseases. Pro-inflammatory cytokines play a role in chronic inflammation, a phenomenon proposed to call "inflammaging" (Salvioli et al. 2006). People genetically predisposed to develop weak inflammatory activity seems to have fewer chances of developing cardiovascular diseases and subsequently live longer if they do not become affected by serious infectious diseases. Ferrucci et al. 1999, Harris et al. 1999 demonstrated that increased IL-6 serum levels could be a marker for functional disability and predictor of mortality in elderly. Increased expression levels of IL-6 were observed also in stress conditions, one of the characteristics of ageing (Heinrich et al. 2003). Elevated levels of this cytokine associated with development of frailty and susceptibility to diseases in elderly were also observed (Forsey et al. 2003). This inflammatory

marker could be involved in low-grade inflammatory that develops with age (Cohen et al. 1997; Bruunsgaard et al. 1999; Ershler and Keller 2000). Dysredulation of IL-6 has been thought to be involved in the pathogenesis of a variety of age-related diseases, such as diabetes and atherosclerosis, which have a substantial inflammatory pathogenesis (Chamorro 2004; Dandona et al. 2004). IL-8 is also considered to be a potent inflammatory agent. However, IL-8 has also been reported to serve as an organ protective factor. It seems possible that an association of an increased serum level of IL-8 and a low level of IL-6 is related to longevity (Wieczorowska-Tobis et al. 2006). Additionally in elderly was observed a decreased capacity to produce IFN-γ, IL-2, IL-4 upon stimulation (Franceschi et al. 2000). The higher levels of TNF-α also correlate with functional status and decreased chance of long-life survival in elderly (Ferrucci 1999; Harris et al. 1999; Ershler et al. 2000; Forsey et al. 2003). Moreover, dysregulation and, in particular, overproduction of TNF has been implicated in a variety of human diseases including sepsis, cerebral malaria, and autoimmune diseases such as multiple sclerosis, rheumatoid arthritis (RA), systemic lupus erythematosus, and Crohn disease, as well as cancer. Interestingly, in a very large

Table 1 Gene polymorphisms of pro-inflammatory cytokines associated with aging

Cytokine gene polymorphism	Effect	Population	References
IL-2 (-330 T/C)	No association in elderly	Irish	Ross et al. 2003
	Increased (T-low) marginally in centenarians	Italian	Scola et al. 2005

study in Italian population IL-1Ra plasma levels were increased with age in both male and female subjects (Cavallone et al. 2003). Because of the pivotal role of anti-inflammatory cytokines TGF-β1 and IL-10 in regulation of immune responses, the variability of their levels may affect low grade inflammation that develops with age. It has been shown that the elevated level of anti-inflammatory cytokines IL-10 and TGF-β in serum of elderly is associated with increased resistance against septic shock (Forsey et al. 2003). Increased ex vivo capacity of macrophages from elderly to produce anti-inflammatory IL-10 was also found. Intriguingly, the existence of "risk immunological phenotype," probably associated with lack of tight control in systemic inflammation was also discussed.

Similarly to other genes, coding molecules with immune functions, cytokine genes are highly polymorphic. Most of the polymorphic sites identified so far are located in the noncoding regions, containing regulatory sequences, while exon sequences are highly conserved. Three main forms of polymorphisms were identified in cytokine genes: single nucleotide polymorphisms (SNPs) (Kruglyak et al. 1999), variable number of tandem repeats and micro-satellites (Weber and May 1989; Bidwell et al. 2001). Although still controversial, polymorphic variants observed for some cytokine genes have been correlated to the level of gene expression. Thus the cytokine gene polymorphism may be responsible for observed inter-individual differences in cytokine production and may be one possible mechanism for perturbation of the Th1/Th2 balance. Some polymorphisms may have a functional significance by altering directly or indirectly the level of genes expression and/or its function, others may only be useful for the determination of genetic linkage to a particular haplotype associated in turn with a given clinical condition (Bidwell et al. 1999, 2001).

Although the data are limited and controversial (Caruso et al. 2000) and many discrepancies are reported likely due to population-specific interactions between gene pool and environment, interleukins could be considered as putative "longevity genes. " It has been hypothesized that longevity could be associated with cytokine gene polymorphism correlated with different level of cytokine expression and modulating immune response to several diseases (Ershler et al. 2000; Bruunsgaard et al. 2001; Volpato et al. 2001). Taking into account the internal part of cytokine genes in immune response, the regulation of cytokine expression level and their polymorphic nature, investigation the genetic variations of these loci with functional significance could be appropriate immunogenetic candidate markers implicated in the mechanism of successful aging and longevity.

Genetic variations correlating with elevated levels of pro-inflammatory cytokines have been negatively associated with ageing (Bhojak et al. 2000). Several studies showed that cytokine polymorphisms related to different level of secretion were associated with longevity. Genetic polymorphisms, associated with high level of IL-10 expression were increased (Lio et al. 2003), while polymorphisms possibly related to increased expression of proinflammatory cytokines - IFN-γ, TNF-α and IL-6 were decreased in elderly individuals (Lio et al. 2002; Bruunsgaard et al. 2004). These data confirmed the hypothesis that longevity is related to antiinflammatory genotype profile. Additionally, the pro-inflammatory cytokine profile was

correlated with decreased life span in elderly. However, in elderly with different ethnical background, investigations reported contradicting results on associations with cytokine gene polymorphism (Bonafe et al. 2001; Lio et al. 2002). Additionally, the majority of data were associated with investigation of single polymorphisms in single cytokine genes. The analysis of extended haplotypes which include several polymorphisms in the cytokine gene, as well as haplotypes which consist of SNPs in different cytokine genes will help to determine the precise immunogenetic basis of longevity.

2 Gene Polymorphism of Proinflammatory Cytokines and Aging

2.1 IL-2

IL-2 is a proinflammatory cytokine, which plays a central role in activation of T-cell mediated immune response and defects in IL-2 mediated activation induce severe immune deficiency (Demoulin and Renauld, 1998). Several polymorphisms in the promoter (position -330) and coding (position +166 and exon 1) regions were described in IL-2 gene. A promoter polymorphism -330 T/C was shown to influence IL-2 production in anti-D3/CD28-stimulated peripheral blood lymphocytes. T-lymphocytes from -330 CC homozygous subjects are able to produce higher amount of IL-2 than heterozygous or -330 TT homozygous individuals (Hoffmat et al. 2001).

Age-related decline in IL-2 production has been recognized since the early work of Gillis et al. Subsequent studies showed that IL-2 is reduced in aged subjects with associated effects on intracellular activation on nuclear transcription pathways (Rea et al. 1996; Pawelec et al. 2002). In humans, high IL-2 serum levels characterize subjects affected by Alzheimer's disease. Resent study in Italian (Scola et al. 2005) and Irish (Ross et al. 2003) elderly subjects did not showed a statistically significant effect of IL-2 -330 polymorphism in aging. However, a T allele associated with IL-2 low producer genotype was discussed to be marginally associated with aging (Scola et al. 2005). Data suggested that the genetic background favoring an increased IL-2 production might be detrimental for longevity.

2.2 IL-6

IL-6 is a pleotropic growth factor involved in different physiological and pathological processes. IL-6 is considered to be a potent inflammatory agent. It was found also to inhibit neutrophil apoptosis, suggesting that there is an autocrine or paracrine antiapoptotic role for IL-6 (Lindermans et al. 2006).

The human IL-6 gene is mapped to chromosome 7p21–24. Different studies identified three SNPs (−597G/A, −572G/C и −174G/C) and one AT polymorphism (−373(A)n(T)m) in 5′ regulatory region in the gene (Fishman et al. 1998; Terry et al. 2000; Georges et al. 2001). It was demonstrated that IL-6–174C allele was significantly associated with lower plasma concentrations of this cytokine (Terry et al. 2000).

Despite of the significant number of studies on possible role of IL-6 gene polymorphisms in different diseases, the associations still remain to be clarified (Rauramaa et al. 2000; Terry et al. 2000; Humphries et al. 2001; Nauck et al. 2002). Great amount of papers reported a positive association between some polymorphic markers of IL-6 gene and human longevity, and capacity of producing low levels of IL-6 thought life-span appears to be beneficial for longevity (Wright et al. 2003; Christiansen, 2004; Franceschi et al. 2005; Hurme et al. 2005) Most studies focused on IL-6 -174 C/G polymorphism and susceptibility to common causes of morbidity and mortality among elderly, such as type 2 diabetes, cardiovascular diseases, and dementia. IL-6-174 C/G polymorphism is predictive for longevity (Salvioli et al. 2006) Data on centenarians and elderly individuals from Italy showed increased frequency of C alleles in male centenarians and it seemed to be a gender specific effect on longevity (Bonafe et al. 2001). Correlations with the serum levels showed that men carrying the GG genotype had higher IL-6 serum levels in respect to subjects with CC or CG genotypes. The authors hypothesized that individuals predisposed to produce high level of IL-6 (men carrying GG) have a reduced capacity to reach the extreme limits of human life-span. Additionally, authors demonstrated that age-related increase of IL-6 serum levels in women is quite independent from -174 C/G genotype. It has also been shown that the proportion of IL-6 high producers (GG genotypes) was increased by individuals affected by age-related diseases with inflammatory pathogenesis—diabetes, atherosclerosis, osteoporosis, and neurodegenerative diseases. Similarly, Rea et al. (2003), Ross et al. (2003) reported decreased frequency of IL-6 -174 GG carriers in Irish octogenarian and nonagenarian subjects from the BELFAST elderly longitudinal ageing study. However, in Finish nonagenerians analysis on IL6-174, IL1a-889, IL1b-511, IL1Ra VNTR, IL10-1082, and TNFa-308 did not show any associations, alone or in combinations (Wang et al. 2001). It appears that IL-6 polymorphism does not affect life expectancy neither in the Sardinian population, nor in people from southern Italy, suggesting that the effect of IL-6 polymorphism on longevity might be population specific and dependent on gene – environment interactions (Capurso, 2004; Pes et al. 2004). Similar lack of association of IL-6 gene polymorphism with longevity was observed in the Bulgarian population (Naumova et al. 2004). These controversial data could be partly explained by population specific factors including genetic background, environmental factors and life stile. Most of studies analyzed the effect of isolated polymorphisms and this could partly contribute to the contradicting results. Recently, Terry et al. (Rauramaa et al. 2000) demonstrated that haplotype combination of promoter polymorphisms in IL-6 gene is more informative marker associated with the level of gene expression, compared with the influence of −174 G/C in isolation. Additionally, studies have demonstrated that CC or CG carriers have an increased risk of Alzheimer disease (AD) and cardiovascular diseases (Zhang et al. 2004).

2.3 IFN-γ

IFN-γ is one of the most representative type 1 cytokines, which plays a pivotal role in defense against viruses and intracellular pathogens and the induction of immune-mediated inflammatory responses. Taking into account the key role of this cytokine, its genetically controlled production is focused on investigation in several studies associated with longevity. Among numerous intronic polymorphisms in the IFN-γ gene, a variable length CA repeat sequence and polymorphism in the intron 1 at position +874 relative to the transcriptional start site has been implicated to influence the level of gene expression in vitro (Pravica et al. 1999). The single nucleotide polymorphism +874 T/A is one well-known single-nucleotide polymorphism at the 5' end of the CA repeat region in the first intron of the IFN-γ gene. Specific binding of the nuclear transcription factor-κB to the DNA sequence containing the +874 T allele has been reported and it could have functional consequences for the transcription of the IFN-γ gene and could then influence the rate of expression. Studies in Italian centenarians showed increased frequency of +874 T/T in female centenarians. On the other hand, investigations in elderly individuals from the Bulgarian population did not show significant differences in IFN-γ (+874) allele distribution compared to young controls (Naumova et al. 2004).

2.4 TNF-α

TNF-α is a pro-inflammatory cytokine involved in the immune response. This pleiotropic cytokine plays a wide variety of functions in many cell types.

The gene for TNF-α is located within the class III region of the major histocompatibility complex, which is a highly polymorphic region and its expression is tightly controlled at the transcriptional and posttranscriptional level. Several biallelic polymorphisms have been described within the TNF-α gene, including six in the promoter region at positions -1031T>C, -863C>A, -857C>T, -376G>A, -308G>A and -238G>A. Moreover, a number of studies have shown that the TNF-α promoter polymorphisms have a significant effect on transcriptional activity. Susceptibility to many diseases is thought to have a genetic basis, and the TNF gene is considered a candidate-predisposing gene. However, unraveling the importance of genetic variation in the TNF locus to disease susceptibility or severity is complicated by its location within the MHC and the strong linkage disequilibrium with other genes. Several investigations reported associations of MHC haplotypes with different TNF-α phenotypes: DR3 and DR4 haplotypes were correlated with high level of TNF-α (Jacob et al. 1990; Abraham et al. 1993), while DR2 haplotypes were associated with low expression (Bendtzen et al. 1988; Jacob et al. 1990). These finding proposed the existence of functional polymorphism involved in the regulation of TNF-α production. SNPs at position -308 have been commonly studied with respect to their influence on TNF-α expression. Transfection studies

Table 2 Gene polymorphisms of anti-inflammatory cytokines associated with aging

Cytokine gene polymorphism	Effect	Population	References
TGF-B1 (915 C/G)	Decreased C allele and C/G genotype in centenarians	Italian	Carrieri G et al. 2004
TGF-B1 (cdns 10, 25)	No associations in elderly	Bulgarians	Naumova et al. 2004
IL-10 (-1082 A/G)	Increased (G/G-high) in male centenarians	Italians	Lio D et al. 2002
	No association with longevity	Finish	Wang X et al. 2001
	No association with longevity	Irish	Ross O et al. 2003
	No association with longevity	Sardinian	Pes G et al. 2004
IL-10 (-819 C/T)	No association with longevity	Italian	Lio D et al. 2002
IL-10 (-592 C/A)	No association with longevity	Italian	Lio D et al. 2002
IL-10 (-1082G,-819C,-592C)	Increased in elderly	Italian	Lio D et al. 2002
IL-10 (-1082G,-819C,-592C)	Increased in elderly	Bulgarians	Naumova et al. 2004
IL-10 (-1082A,-819T,-592A)	Decreased in elderly	Bulgarians	Naumova et al. 2004

in human B-cell lines showed that the presence of rare TNF2 allele (A at position -308) results in higher constitutive and inducible levels of TNF expression compared with a common TNF1 allele (G at position -308), confirming the importance of this site in the transcriptional regulation of the TNF gene (Wilson et al. 1997; Makhatadze et al. 1998; Lio et al. 2001; Hajeer, 2001). The functional relevance of this SNP has been confirmed by its involvement in determining susceptibility to immune-inflammatory diseases (Makhatadze, 1998; Lio et al. 2001; Hajeer and Hutchinson 2001; Dalziel et al. 2002; Heijmans et al. 2002; O'Keefe et al. 2002; Sakao et al. 2002; Witte et al. 2002). Although the polymorphism -308 G/A associated with different gene expression is one of the most widely investigated in different diseases, no correlation of this SNP and longevity was found in centenarians from the Finnish and the Italian population (Wang et al. 2001; Lio et al. 2003). Similar results were observed for elderly individuals from the Bulgarian population (Naumova et al. 2004). In the Danish population, however decreased frequency of A allele was observed among centenarians. Positive association with the process of successful ageing was observed also in men centenarians from Italian population when the two SNPs -308 G/A from TNFA gene and -1082 G/A SNP from IL10 gene were analyzed simultaneously (Wang et al. 2001). The group of Lio D et al. reported that an anti-inflammatory genotype TNFA GG (low)/ IL10 GG (high) has a protective role in longevity. TNF-A and IL-10 have complex and opposing roles, and an autoregulatory loop appears to exist (Candore et al. 2002).

3 Gene Polymorphism of Antiinflammatory Cytokines and Aging

3.1 TGF-B1

TGF-B1 is a multifunctional cytokine that regulates cell proliferation, differentiation, and migration, and it was considered as an aniinflammatory molecule (Wright et al. 2003). In the study of Carrieri et al, the plasma levels of biologically active TGF-B1 were significantly increased in the elderly group, independently from TGF-B1 genotypes (Carrieri et al. 2004). The TGF-β1 gene consists of 7 exons and 6 introns. Until now, eight polymorphisms in the promoter (-509 C→T, -800 G→A and -988 C→T), coding (+896 T→C, +915 G→C, +788 C→T, +652 C→T and +673 T→C) regions end one deletion (713 del C) in inton 4 of the TGF-β1 gene were discovered. Polymorphisms +896 (codon 10) and +915 (codon 25), associated with different level of expression are the most commonly studied. For polymorphism +915 G/C, the presence of C allele is generally associated with lower TGF- β synthesis in vitro and in vivo. Association between the presence of particular TGF-β1 allele and the level of the product indicates that the G-800 A and C-509 T polymorphisms may also be involved in the modulation of expression of the TGF- β1 gene. The -509 T allele - has been reported to be associated with marginally higher transcriptional activity of TGF- β compared to the -509C allele. TGF-β -800 G→A polymorphism is in a consensus CREB (cAMP response element-binding protein) shalf-site. The presence of A allele was suggested to have reduced affinity for the CREB family of transcription factors, resulting in a lower level of total TGF- β1 in the circulation. Analysis of these three SNPs +915 G→C, -509 C→T and -800 G→A by the group of Carrieri G et al. observed that only +915 C allele and GC genotype with significantly lower frequency, compared to controls. Additionally they found also decreased frequency of extended haplotype G -800/C -509/C 869/C 915 and elevated level of TGF-β1 in elderly, but correlation with investigated genotypes in TGF-B1 gene was not found (Carrieri et al. 2004). Similarly no associations of TGF-B1 codons 10 and 25 genotypes with longevity were observed in Bulgarians (Naumova et al. 2004). It has been hypothesized that genetic determined cytokine profiles of TGF-β1 could be involved in mechanism of successful ageing but more data are need to confirm this results.

3.2 IL-10

IL-10 is a powerful cytokine that inhibits lymphocyte repeication and secretion of inflammatory cytokines (My-Chan Dang et al. 2006). Since one of the main functions of IL-10 is to limit inflammatory responses (Moore et al. 2001), polymorphisms in the regulatory region of this gene could be possibly related to longevity. Stimulation of human blood samples with bacterial lipopolysaccharide showed

variation of IL-10 production, suggesting a genetic component of approximately 75% (Westendorp et al. 1997). Inter person differences in the regulation of IL-10 production may be critical with respect to the final outcome of an inflammatory response.

The IL-10 gene is located on chromosome 1 at q31–32. Several polymorphisms in the human IL-10 5' flanking region and two microsatelites associated with differential IL-10 production have been identified. The most extensively investigated SNPs are in the promoter region at position -1082, -819 and -592 (Turner et al. 1997, D'Alfonso et al. 2000; Kube et al. 2001) correlating with different transcriptional activity. The three dimorphisms appear in three potential haplotypes: GCC, ACC and ATA (G/A at position -1082, C/T at position -819 and C/A at -592 correspondingly) related to different level of gene expression. The ability of individuals to produce high levels of IL-10 is evidently controlled by a G at position -1082, as this variant is found in the highest producers (Turner et al. 1997; Eskdale et al. 1998; Crawley et al. 1999; D'Alfonso et al. 2000; Kube et al. 2001; Lio et al. 2002). Several studies reported the linkage between the sites -819 and -592. The A allele of the -592 SNP was found to be associated with lower stimulated IL-10 release. In the presence of allele -1082A, stimulation of lymphocytes with concanavalin A resulted in lower IL-10 production than in allele -1082A negative cells (Turner et al. 1997; Hutchinson et al. 1999). The functional relevance of this SNP has been shown by its involvement in determining susceptibility to immune-inflammatory diseases (Hajeer et al. 1998; Crawley et al. 1999; Tagore et al. 1999; Howell et al. 2001; Girndt et al. 2002; Shoskes et al. 2002; Wu et al. 2002) The two dimorphisms -819 and -592 exhibit strong linkage disequilibrium.

The IL-10 -1082 A/G polymorphism has been reported to be a male-specific marker for longevity (Lio et al. 2002), while no differenced were found regarding the -819 and -592 polymorphisms. The -1082GG genotype, associated with high IL-10 production, was argued to confer an anti-inflammatory status (Lio et al. 2002). Studies in Bulgarians demonstrated significant differences for two IL-10 haplotypes: one of them (-1,082A,-819T,-592A), possibly associated with the low level of gene expression was decreased in elderly, while the other (-1,082G,-819C,-592C) associated with high level of cytokine gene expression was significantly more frequent among healthy elderly compared to young controls. This effect was more pronounced in GCC homozygous individuals as indicated by the analysis of IL-10 genotypes. However, studies in two other populations— Irish nonagenarians (Ross et al. 2003) and Finish nonagenarians (Wang et al. 2001) did not show any association with longevity. A possible explanation for the negative results in the Irish and Finnish studies could be the younger age of the old subjects investigated in comparison with the Italian study. Interestingly to note that the IL-10 -1082 GG genotype is much less frequent in patients affected by Alzheimer's disease (Lio et al. 2003).

In summary, the capability to maintain a lower production of pro-inflammatory cytokines appears to be favorable for reaching the extreme limits of human life span in good health conditions and could be genetically controlled. Cytokine genes related to inflammation seems particularly relevant taking into account that the

innate immunity is more involved during inflammation, and a chronic inflammatory status appears to be the major component of the most common age-related diseases, including cardiovascular diseases and infections. The emerging data on the pivotal role of additional interactions in affecting expression of some relevant cytokines (for example zinc–gene interactions) and studies in populations with different environmental background will allow to clarify further the role of cytokines in aging.

Cytokine Polymorphisms and Immunosenescence

Owen A. Ross, Kelly M. Hinkle and I. Maeve Rea

Contents

Abstract: The influence of genetics on immunosenescence is still to be resolved. Common genetic variants (polymorphism) that reside within the genes encoding cytokines are candidates to positively or negatively affect immunosenescence. Cytokines regulate the type and magnitude of the immune function. Polymorphism can influence the expression level of the cytokine protein which can subsequently cause an imbalance in the cytokine cascade.

Herein we examine the current literature with respect to cytokine polymorphisms in ageing and the age-related neurodegenerative disorder, Parkinson's disease.

Ageing studies have identified two cytokine promoter polymorphisms that have shown repeated associations IL-6 (-174) and IL-10 (-1082). Others have failed to confirm these associations. This is due in part to studies of limited sample sizes examining a restricted number of cytokine polymorphisms. The inflammatory processes that characterize the cell death that is the hallmark of neurodegenerative disorders such as Parkinson's disease, may also be influenced by cytokine polymorphisms. However as with ageing, the results to date have been inconsistent although a number of studies have suggested the IL-1β (-511) and TNF-α (-308) show significant association with Parkinson's disease susceptibility.

Given the complexity of the cytokine network, and the dynamic interplay between anti and proinflammatory aspects, cross-sectional studies examining many cytokine variants in large sample series are now warranted. Genome-wide association studies may hold promise in resolving the role of cytokine polymorphisms in the inflammatory processes in both disease and ageing.

1 Introduction

Ageing is a complex, multifactorial process which can be defined as a progressive, generalized impairment of function resulting in a loss of adaptive response to stress and an increasing risk of age-associated disease [44, 45, 51–53]. Although the specific biological basis of ageing remains obscure, molecular investigations over the last 50 years have led to a cluster of theories that attempt to resolve ageing across species. However the complexity of the ageing process has only been reflected in the numerous hypotheses that have been proposed [72].

There is increasing evidence from a growing number of studies that longevity has heritability in families. However, a familial history of longevity could also be caused by a shared environment. A study of Danish twins noted only modest heritability in the ability to reach the septuagenarian years and above; no evidence for an effect of shared family environment was found [47]. Other studies show that siblings of centenarians are shown to have a 4-fold higher survival rate to ages above 85 years compared to siblings of persons who died at the age of <75 years [89, 90]. Whereas the twin study examined correlations of age at death in those of old age, the latter study focused on those who survive to extreme old age, and was therefore more likely to detect a stronger effect if genetic factors play a role in longevity.

As the world of scientific research moves into a new era beginning with the publication of the human genome and the continual description of novel variations in genes, the prospect of greater resolution to the question of ageing is at hand. The draft publication of the human genome was released on February 16th 2001, on the day when one of the pioneers of modern science, Charles Darwin, would have reached the ripe old age of 192 years. The human genome is composed of 46 chromosomes that are estimated to encode for between twenty and thirty thousand genes (approximately 40 % of which are functionally unresolved) [56, 117]. Extensive variation has also been observed at the nucleotide level. DNA sequence variants are

estimated to occur in one in every three to five hundred base pairs and are linked with a large diversity of phenotypes, ranging from variation in traits e.g., eye colour, height, susceptibility to disease and even the variation in the rate of ageing.

Polymorphism, literally translated "multiple forms", is the term used to describe the DNA variants that exist within a species. Polymorphism in a gene may result in increased/reduced protein production or affect the level of the abnormal proteins generated, through directly influencing gene transcription [115]. There is increasing evidence to show that gene expression is regulated by complex interplay, from simple polymorphic variants in regulatory regions such as the promoter or 3' untranslated regions, to the presence of microRNA species that can work through a negative/positive feedback mechanism.

At the recent 55th American Society of Human Genetics (2005) meeting held in Salt Lake City, the International HapMap project released its Phase I data. This project's major aim was to help identify linkage disequilibrium patterns traversing the entire human genome and facilitate the identification of haplotype "tagging" single nucleotide polymorphisms (SNPs) [2, 22]. In 2006, public databases (such as dbSNP) housed data on more than nine million candidate human SNPs for which genotype data is available for nearly two and a half million of them [2]. These vast volumes of data, coupled with the incredible advances in genotyping and DNA sequencing technologies, create a situation whereby the geneticist can pinpoint a trait loci [68, 114]. Genome-wide association studies are being proclaimed as the latest, and perhaps most powerful, tool in the mapping of causative/modifying genetic loci in complex disorders such as ageing [101].

The human genome displays a considerable level of inter-individual variability from simple SNPs and short repeats to large-scale deletions, multiplications and rearrangements. Recent studies have demonstrated that large gene copy number variations (CNVs) occur frequently in the general population with for the most part no determinable disadvantage to carriers. However this phenomenon can be pathogenic and in rare cases result in severe disease phenotypes [99, 111, 121]. The severe disease state is usually caused through either a "gain or loss of function" that occurs from an altered balance in the level of the essential protein. However, the presence of variants that give rise to much milder phenotypes and produce a fractional increase/decrease in gene expression may result in the slow, progressive manner of symptoms that typify both the ageing process itself and also the numerous age-related diseases, including cardiovascular disease, cancer and neurodegenerative disorders.

Human longevity appears to be inextricably linked with optimal functioning of the immune system, suggesting that specific genetic determinants may reside in polymorphic loci in genes that regulate immune response. The deterioration of the immune system due to "immunosenescence" (age-associated immune deficiency), coupled with the associated increase in the susceptibility to infectious disease, cancer and autoimmune disorders has restricted the potential human lifespan [14, 32, 34]. However this deterioration of the immune function accompanied by an increased risk of morbidity and mortality observed in the noncentenarian elderly is in sharp contrast to the more intact immune function of centenarians [33]. Profound and complex changes within the humoral, cellular, and innate immune responses occur during the ageing

process, therefore immunosenescence is reflected in the sum of dysregulations of the immune system and its interactions with the other major systems in the human body.

Cytokines are proteins that have a key function, as intercellular messengers, during immune responses and in tissue remodelling. The cytokine network plays a pivotal role in the regulation of the specific type and magnitude of immune and inflammatory response. Consistent with the "remodelling theory" of immunosenescence, differing levels of cytokine production are reported in the elderly and centenarians [8, 9, 96–98]. A potent inflammatory response is vital in the defense against pathogens throughout life and may positively influence reproductive success, but chronic inflammation appears to be a common component in the development of major age-related diseases. This "trade-off" effect is largely predictable since advanced age does not seem to have been foreseen by evolution [14]. Many age-related diseases display altered cytokine profiles, suggesting that an inflammatory pathogenesis may be at the basis of these common causes of morbidity and mortality among elderly. It may be expected that people reaching the extreme limits of human lifespan, having escaped from major-age-related diseases, i.e. healthy centenarians, will be characterized by having genotypic combinations that produce "optimal" pro/antiinflammatory activity [32].

2 Cytokine Polymorphism in Immunosenescence

In several cytokine genes, polymorphism (mostly SNPs or microsatellites) located within the critical promoter or other regulatory regions, is reported to affect gene transcription resulting in inter-individual variation in levels of cytokine production (Table 1). Any qualitative or quantitative effect on cytokine production will ineluctably impinge upon the synthesis and secretion of effector molecules downstream in the cytokine cascade and may therefore alter the immune response. The polymorphic nature of the cytokine genes may confer flexibility on the immune response with certain alleles promoting differential production of cytokines. These then may

Table 1 Position and polymorphisms in selected cytokine genes

Cytokine	Nucleotide position	Polymorphism
IL-1α	-889	C/T

influence the outcome of viral and bacterial infections and/or increase susceptibility/resistance to autoimmune disorders. In summary, cytokines are essential in all areas of the immune response, so any age-related variation may be of crucial importance in determining whether intact immune function remains preserved. Herein we examine the current literature available investigating the frequency of cytokine polymorphism in ageing (Table 2 and 3).

2.1 Tumor Necrosis Factor Gene Cluster

The human leukocyte antigen (HLA) has been described as a gene system that regulates both the immune system and the ageing process. The HLA plays a central role in antigen presentation and immunosurveillence, and a number of studies have been carried out to investigate whether there is evidence of polymorphic association with immunosensecence [15, 16]. Studies have shown that the HLA-A1, B8, DR3 ancestral haplotype (8.1 AH) is associated with a variety of immune dysfunctions, autoimmune diseases and displays gender specific longevity association [15, 86]. Also of interest, the 8.1 AH is associated with variant immune responses and altered cytokine secretion patterns [15]. This HLA haplotype is also associated with a genetically-determined, high production setting for tumor necrosis factor-α (TNF-α) [60].

The *TNF* gene locus is found within the central HLA Class III region and determines the strength, effectiveness and duration of local and systemic inflammatory responses, as well as repair and recovery from infectious and toxic agents. *TNF* genes show strong linkage disequilibrium with HLA Class I and II genes, and with other genes in the HLA region that are factors in immunoregulation [58]. The multiple pro and antiinflammatory activities of TNF-α and related cytokines in the *TNF*

cluster make them attractive candidates along with other HLA genes for unravelling the molecular mechanism(s) underlying the development of ageing and related diseases.

The *TNF* cluster, containing both *TNF*-α and *TNF*-β genes, has numerous polymorphisms that may have an effect on transcription and ultimately protein levels. The *TNF*-α-308A/G polymorphism has been investigated in four studies that were aimed to assess its association, if any, with longevity. In studies of elderly and young subjects from Finland and Sweden there were no differences regarding the frequency of the *TNF*-α-308A/G polymorphism between the two age groups [19, 119]. In an Italian study, the frequency of this polymorphism did not vary between centenarians and younger subjects, and no significant gender difference emerged [63]. Likewise, the frequency of *TNF*-α -308A/G polymorphism in a study with Irish nonagenarians was not different compared to younger controls [105]. In the same study, no significant frequency difference for the *TNF*-β +252 A/G polymorphism between Irish nonagenarians and young control subjects was found either. Thus, these 4 studies appear to demonstrate that the *TNF*-α -308A/G polymorphism does not have a major independent effect on longevity.

2.2 Transforming Growth Factor-β

The cytokine transforming growth factor-β (TGF-β) has been shown to have an essential role in inflammation and in maintenance of immune response homeostasis. TGF-β belongs to the group of cytokines with antiinflammatory effects, due to its deactivating properties regarding macrophages [57, 120]. *TGF*-gene overexpression has been observed in human fibroblasts that displayed a senescent-like phenotype after exposure to oxidative stress [37]. Polymorphisms in the *TGF*-β gene influencing the cytokine production have been identified and subsequently linked to age-related pathologies, such as Alzheimer's disease [66].

A study by Carrieri et al. (2004) analyzed 419 subjects from Northern and Central Italy, including 172 centenarians and 247 younger controls, to examine the hypothesis that variability of the *TGF*-β gene affects successful aging and longevity [12]. The level of the active cytokine increased with age, and significant differences were found between the age groups for the genotype and allele frequencies at the +915 site but no differences were found for the other tested variants (the -800 G/A, -509 C/T and +869 C/G loci). As this +915 C/G polymorphism results in an arginine to proline substitution at codon 25 within the signal peptide that is cleaved from the TGF-β precursor, it is possible that the substitution could play a role in the efficient production of the mature growth factor or misdirection of the protein. Since TGF-β is immunosuppressive, the age-related increase of the active cytokine suggests that it could counteract/counterbalance the harmful effects of inflamm-ageing.

2.3 Interleukin-1 Gene Cluster

The interleukin-1 (*IL-1*) gene cluster is located on chromosome 2q13 and is an important mediator of systemic inflammatory responses. Genetic variation of three genes (*IL-1*α, *IL-1*β, and *IL-1Ra*) in the cluster has been investigated in ageing. Three studies to date have examined the frequency of *IL-1* variants in Finnish, Italian and Swedish populations [18, 19, 119]. These studies failed to show any association with either centenarians or elderly individuals in comparison to young controls. Promoter SNPs in this gene cluster are reported to alter gene expression and may therefore give rise to a different expression profile. Also, *IL-1* gene cluster polymorphisms are implicated in a number of age-related pathologies including neurodegenerative disorders such as Alzheimer's and Parkinson's disease [81, 95].

2.4 Interleukin-2

Interleukin-2 (IL-2) cytokine plays a pivotal role in cellular immunity by regulating the activation, differentiation and proliferation of T-lymphocytes during an immune response. In the elderly, decreased levels of proinflammatory IL-2 production and secretion have been reported, leading to a situation of limited T-lymphocyte proliferation and thus inhibited cellular response [13]. A promoter variant of the *IL-2* gene at position -330 T/G has been shown to negatively affect expression levels, demonstrating that the more common T-allele has a higher level of expression. Two studies have examined the frequency of the *IL-2* promoter polymorphism -330G in ageing populations. The first study by Ross et al. did not identify any frequency difference with this SNP and successful ageing in the Irish population [104]. The second study with Italian centenarians supported the lack of association. However, a

trend was observed suggesting that the -330G allele is increased in frequency in the second study's centenarian cohort and thus decreased levels of the proinflammatory IL-2 cytokine promotes successful ageing [109]. Interestingly, although decreased IL-2 production was reported during the ageing process, increased levels of interleukin-6 (IL-6) were found [78].

2.5 Interleukin-6

The interleukin-6 (IL-6) protein is arguably the best cytokine candidate to act as a potential marker for the overall health status of an individual [27, 67]. This is partly due to the fact that IL-6 plays a major role in inflammation and in the humoral immune response. It has been reported that healthy elderly individuals and centenarians exhibit a proinflammatory status, with a distinctive increase in IL-6 production [32]. There is increasing evidence for directly proportional association of the *IL-6* -174 C/G promoter polymorphism (Fig. 1) with production levels of the cytokine and with age [7, 30, 85].

Bonafe and colleagues (2001) published that the homozygous -174GG genotype was a disadvantage for longevity in men, reporting associated higher IL-6 serum levels. The findings of Ross et al. that an overall decrease in the -174GG in a cohort of Irish octo/nonagenarians from the Belfast Elderly Longitudinal Free-living Ageing Study (BELFAST) study group and with particular respect to the total males in comparison to the controls during the study would appear to concur with the findings by Bonafe et al. However, Olivieri and colleagues (2002) reported that their subjects containing the -174C allele showed a significant age-related increase in the capability to produce IL-6, even though this genotype is supposed to predispose these individuals to be low producers [85]. Another study by Wang et al. in Finland detected no significant change in *IL-6* frequencies

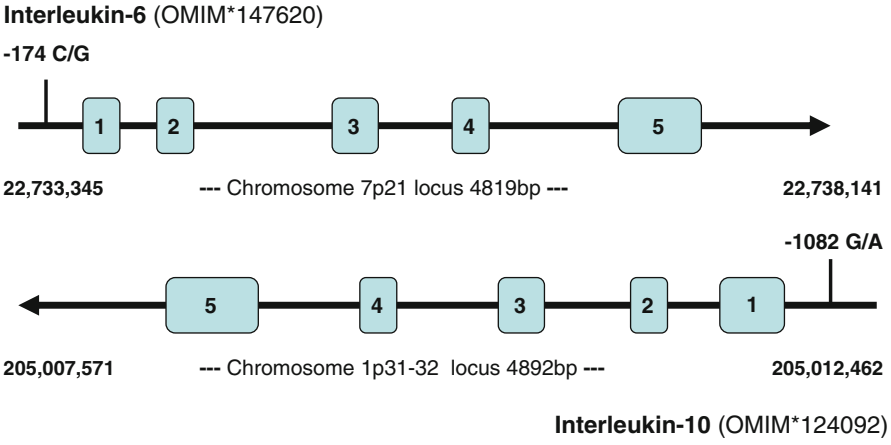

Fig. 1 Genomic structures of IL-6 and IL-10

between nonagenarians and blood donors, though a reduction of 2% was noted in –174GG frequency in comparison with their age-selected younger control group [119]. This trend for a reduction in –174GG homozygosity in elderly males in 3 countries across Europe seems intriguing since it appears to confirm in different study populations and with alternate study designs like the earlier findings obtained in the Italian population.

In later studies, there was no difference in the *IL-6* -174 C/G promoter allelic and genotypic frequencies between centenarians and controls, but the number of subjects enrolled in these studies was low [10]. A modest but significant increase in the frequency of *IL-6* –174 GG homozygotes with age was noted in a group of Danish subjects, though no analysis was carried out for gender [20]. This discrepancy may be due to racial/genetic as well as lifestyle and ethnic/cultural differences between these populations.

A total of 9 studies have now looked at *IL-6* polymorphism with respect to ageing [11, 19]. IL-6 looks like the most interesting cytokine with respect to longevity studies, separate Caucasian European elderly populations and with different selection criteria, appear to demonstrate a decrease in the *IL-6*-174GG homozygote frequency with extreme old age. Italian researchers additionally demonstrated a reduction in *IL-6* high producer allele frequency for male centenarians which was not seen in females. In conclusion, large scale studies on many diverse racial and ethnic populations are needed to clarify this important topic.

2.6 Interleukin-8

Interleukin-8 (IL-8) is defined as a “chemokine” due to the observed chemotactic activity for specific types of leukocytes. It is produced by most cell types and is important for the activation of the inflammatory response and acts as a costimulatory factor for T-lymphocyte responses. IL-8 is also a potent neutrophil chemokine that facilitates the movement of neutrophils to inflammatory sites where they limit and contain the infection. As serious infections are more common in the elderly, it has been postulated that aspects of neutrophil function might be comprised with increasing age [23]. Recently, varied levels of IL-8 production by T- and natural killer (NK)-lymphocytes were reported in an elderly Italian population [69]. Only one study to date has examined the frequency of the functional *IL-8* -251 A/T promoter variant in ageing, though the researchers did not identify any association with either allele [104].

2.7 Interleukin-10

Antiinflammatory interleukin-10 (IL-10), which affects both the T- and B-lymphocyte responses, has been reported at an increased level in the elderly [88]. IL-10 is a potent proliferation and differentiation factor for B-lymphocytes and

prevents production of proinflammatory cytokines such as IL-6 and IL-8. Along with significantly increased IL-6 and IL-10 levels, Rink and colleagues (1998) reported significantly increased production of IL-8 by leukocytes from the elderly. In the same paper, significantly decreased levels of IL-2 and interferon-γ (IFN-γ) were also reported [100]. A number of studies have investigated the association of ageing with the *IL-10* -1082 A/G promoter SNP (Fig. 1), and although the studies have not found any evidence for this, three reported an increase of *IL-10* -1082GG homozygous carriers in elderly males of Italian descent [59, 62, 63]. This may highlight a population-specific effect, although it is noteworthy that this association was not confirmed in other European Caucasian populations [91, 104, 119].

2.8 Interleukin-12

NK-lymphocytes play a central role in the innate immune response against bacterial or viral infections and tumors, and the NK-lymphocyte activities are highly regulated by numerous cytokines, particularly interleukin-12 (IL-12). IL-12 is secreted during the earliest stages of infection and inflammatory response, acting as the key immunoregulatory molecule in cellular immune responses. The critical action of IL-12 at the interface between innate and adaptive immune responses means that any age-associated alterations in expression levels are likely to have crucial functional consequences in vivo [96]. Increased levels of total IL-12, due to higher levels of the p40 subunit, are reported in the aged Irish population [96]. In the paper looking at *IL-12* polymorphisms and ageing by Ross et al., similar frequencies of the *IL-12* +16,974 A/C polymorphism in aged versus control subjects were observed. Although there was a trend for AA homozygotes to be underrepresented in elderly males with a 7% decrease in the A allele in elderly males, neither of these decreases achieved significance. Likewise, no apparent difference was present for old and young female subjects.

2.9 Interleukin-18 and Interleukin-19

Interleukin-18 (IL-18) is a proinflammatory cytokine that plays a vital role in both innate and acquired immune response [48]. IL-18 has been shown to induce IFN- γ and is implicated in a number of inflammatory diseases and neurodegenerative disorders [29, 83]. IL-18 serum concentrations are reported to be higher in centenarians compared to the younger population [38]. Frayling and colleagues (2007) reported an association of an *IL-18* SNP (rs5744292) on serum concentrations of the cytokine product and correlated these with physical functionality in the elderly [36]. These findings suggest a possible genetic association of *IL-18* with successful ageing and warrants further investigation.

Interleukin (IL)-19 belongs to the IL-10 family of cytokines, functioning to stimulate the expression of IL-10 (and the gene locus is adjacent to the *IL-10* gene). To date only one study has examined polymorphism of *IL-19* and its association, if any, to ageing. Okayam and colleagues (2007) investigated the frequency of four SNPs in the *IL-19* gene in the Japanese population. The results showed a significant association with age using logistic regression analysis. This preliminary finding requires independent replication to prove its validity.

2.10 Interferon-γ

Interferon-γ synthesis by T- and NK-lymphocytes and play a decisive role in defense against parasitic/viral infections and intracellular pathogens [82]. Proinflammatory IFN-γ was initially recognized for its antiviral activity but has since established itself as a multifunctional cytokine playing an important role in modulating almost all phases of the immune response, particularly the inflammatory response [4].

In centenarians, Lio and colleagues first reported that possession of the IFN-γ +874A allele (+847 SNP T/A is in linkage with a CA repeat microsatellite allele) was associated with longevity in Italian centenarian females likely by controlling inflammatory status [61]. Subsequently, Ross et al. could not be replicate this observation in nearly 200 Irish nonagenarians reporting similar frequencies for the CA 12 allele repeat in control and aged subjects [104]. The small decrease in the CA 12 repeat in aged, Irish, female nonagenarians was not significant but does demonstrate a similar trend to the findings in the Italian centenarian female cohort suggesting a gender-specific effect in *IFN*-γ genotypes. In Ross et al. the CA 13 repeat allele of *IFN*-γ microsatellite was similarly represented between Irish aged and young groups with no gender difference. The study also commented on a notable trend showing a decrease in the frequency of the heterozygote 12, 13 genotype within the aged subjects in comparison to the young controls (which was observed to be independent of gender).

In the aforementioned Italian study, trend of a decrease in the *IFN*-γ + 874T allele was observed among female Sardinian centenarians, however these results relate to only a relatively small number of Sardinian female centenarians, which may limit the statistical power of the study [91]. Thus, the *IFN*-γ high producer haplotype 12 CA/+874T showed a decrease in centenarian Italian females with a trend for the same change in Irish nonagenarians and Sardinian centenarians. These findings certainly warrant further replication studies and gender differences also need to be taken into account.

2.11 Gender Bias

It is postulated that cytokine allele frequencies are possibly gender- and geographically-specific, similarly to what has been proposed for other polymorphic systems

such as the human leukocyte antigen [16]. Franceschi and colleagues (2000) have postulated that gender is a variable concerning the genetics of ageing, proposing that men and women follow different pathways to extreme longevity [35]. This postulate has been demonstrated in Italian centenarian studies for the *IL-6* -174 G/C, *IL-10* -1082 G/A and *IFN*-γ +874 T/A polymorphisms, where significant frequency differences have been identified when the data was analyzed on the basis of gender [7, 62, 85].

The *IL-6* -174GG genotype frequency is reported to be decreased in elderly males in two independent studies in Italian and Irish populations [7, 104]. The *IL-10* -1082 G/A and *IFN*-γ +874 T/A polymorphism have also been reported to be gender-specific markers for longevity [61, 62]. Lio and colleagues (2002) reported an increased frequency of the homozygote *IL-10* –1082GG genotype in Italian centenarian men, and this genotype is associated with high IL-10 cytokine production, conferring an anti-inflammatory status which is postulated to increase the possibility of extreme longevity [62]. The *IFN*-γ +874T allele is reported to be in absolute correlation with the 12 CA repeat allele, where the latter is associated with increased IFN-γ production [61, 93, 94]. The group reported that possession of the *IFN*-γ +874A allele, particularly in females, conferred an overall antiinflammatory status promoting longevity.

2.12 Cytokine Polymorphism Conclusions

Due to the intricate nature of the cytokine cascade and the perpetual interaction of cytokines within the immune function, a situation is created where the overexpression of one cytokine may be either compensated for or enhanced by another. This complexity, coupled with the difficulty of clearly defining cytokine activity as anti or proinflammatory, may well have confounded the groups whose studies are reviewed in this chapter [17]. The aforementioned studies also highlight the importance of validation of significant results in either a second subgroup or independent cohort of subjects. There is also need to identify such variables as race/ethnicity, gender and age when endeavouring to fully ascertain the role(s) of cytokine polymorphisms in immunosenescence.

Genetic variants in immune response genes are certainly attractive candidates to study in the attempt to elucidate the molecular mechanism(s) that occur during immunosenescence. However, the absence of age-association for many of the cytokine gene variants, even those associated with changing expression levels, would indicate the complexity of the cytokine cascade can not be truly reflected by a small number of polymorphic markers. Future studies concentrating on compiling a genetic cytokine profile that encompasses the overall network (and working in tandem with expression levels) will aid in the resolution of the role(s) of cytokines in the aged immune function/longevity.

3 Age-related Disorders

Identification of major genetic variants affecting population mortality and extreme longevity may spur the characterization of pathways high in the hierarchy of the physiological processes that influence the onset of common age-related diseases [46]. Conversely, the study of age-related disease may provide greater insight into the molecular mechanism(s) that contribute to the ageing process. For example, Parkinson's disease (PD) is one of the most prevalent age-related neurodegenerative disorders, with approximately 1% of the population older than 50 years being affected. The question that must be asked is whether age-related disorders such as PD are a direct cause or a result of the ageing process. Unlike the study of progeriod syndromes (which are characterized by accelerated ageing), age-related disorders require more focused attention to particular aspects of the disease that mimic, or contrast with, healthy ageing.

With increasing knowledge of the complexity of the biological pathways of the brain there is growing evidence to suggest that there is an active, endogenous immune system. Glia cells are one of the most numerous cell types in the brain, and a subgroup, microglia, form the tissue macrophage population. The microglia play an important role in the growth and survival of neurons and are also critical in the inflammatory response of the brain through the production and secretion of cytokines [21]. Inflammation of the brain is postulated to contribute to the pathogenesis of a number of neurodegenerative disorders including multiple sclerosis, Alzheimer's disease and PD. The pathological, neuroinflammatory damage that is observed in these diseases has led researchers to generate hypotheses regarding their progression and susceptible neuronal populations. This hallmark neuroinflammation also provides groups with a possible avenue for therapeutic intervention and implicates DNA variants that regulate the inflammatory response in disease pathogenesis. This next section of the chapter will focus on the role of cytokine polymorphisms in PD and how genetic findings in this complex disorder can help guide future studies regarding the mechanisms influencing ageing.

3.1 Parkinson's Disease Background

The renowned French neurologist Jean Martin Charcot (1825–1893) defined the clinical syndrome "maladie de Parkinson" that has since become known as Parkinson's disease. First described by the English physician James Parkinson (1755–1824) in his milestone 1817 publication "An Essay on the Shaking Palsy", parkinsonism is characterized by the triad of tremor, rigidity and bradykinesia. PD is the most common cause of parkinsonism and the second most frequent neurodegenerative disorder, after Alzheimer's disease. Neuropathological findings in PD are loss of pigmented neurons in the brain stem, *substantia nigra* and *locus coeruleus*, with intracellular Lewy body inclusions found within surviving neurons.

Historically PD was thought to have no genetic basis and epidemiological data appeared to support this view. Cross-sectional studies by Tanner et al. and Wirdefeldt et al. suggested that either there is no genetic basis or that it is only evident in early-onset PD (age of onset <50 years), although to date twin studies have been underpowered to refute incompletely penetrant genetic causes of PD [112]. Differing disease concordance rates between monozygotic and dizygotic twins in longitudinal studies (including those using 18F-dopa positron emission tomography; PET) do support heritability in PD [92]. In fact, many clinical reports note that familial aggregation of parkinsonism and a family history of disease is the second most significant risk factor after age [110].

The etiology and pathogenesis of PD remains unclear, however, it has been suggested that PD, like ageing, may be a multifactorial disorder caused by a combination of age, genetic and environmental factors. During the last decade, contention regarding the importance of genetics in PD was challenged by the identification of several large pedigrees in which parkinsonism appeared to have a monogenic, Mendelian pattern of inheritance (either autosomal dominant, autosomal recessive or X-linked) [28, 106]. However, research studies that have analyzed PD families with classical linkage methods have given rise to data which allowed the subsequent nomination of 13 regions of the human genome, where pathogenic mutations since been identified in five genes (α-*synuclein*, *parkin*, *DJ-1, PINK1 and LRRK2*), thus confirming the role of genetics in PD.

The identification of *LRRK2* pathogenic mutations as a cause of autosomal dominant parkinsonism which is clinically indistinguishable from sporadic PD has once again revolutionized this research field. The *LRRK2* c.6055G>A (Gly2019Ser) mutation has become renowned for its high frequency in specific racial groups (e.g., ~40% of PD patients of Berber Arab ethnicity) and appears to be present in most Caucasian populations. The *LRRK2* variant c.7153G>A (Gly2385Arg) may be the most frequent genetic risk factor the development of PD to date, but it appears to be restricted to those individuals of Chinese descent [107]. The reduced penetrance observed for *LRRK2* mutations accounts for the presence of these variants in healthy control subjects and is reflected in the diversity of the age at symptomatic onset of disease in patients. Likewise, even individuals within the same family carrying the same *LRRK2* mutation can present with symptoms decades apart with regards to age. These observations suggest that *LRRK2*-associated disease is regulated by important environmental and/or genetic modifiers [103].

3.2 PD and Cytokines

Evidence has also been accumulating over the last decade to indicate that chronic inflammation of the brain may be one of these possible disease modifiers and play a crucial role in the pathognomic dopaminergic neuronal death of PD [1, 71]. In support of this theory, proinflammatory cytokines, such as TNF-α, IL-2 and IL-6, are shown to be markedly up-regulated in the brain or the cerebrospinal fluid in PD patients [6, 24,

74, 75, 77]. Despite the potentially important role the inflammatory response, directed by cytokines, may play in the pathogenesis of PD, only a limited number of studies have been performed to assess if there is an underlying genetic influence (Table 4).

In 2000, Kruger and colleagues performed one of the first studies investigating the possible role of cytokine polymorphisms regarding susceptibility to and the pathogenesis of PD [55]. This study identified significant associations between two genes in the *TNF* pathway (*TNF*-α and *TNFR1*). These findings implicated the proinflammatory pathway in promoting the dopaminergic neuronal cell death that typifies PD. Between 2000 and 2003 further studies were performed in the Japanese and Finnish PD populations [70, 79–81]. Nishimura and colleagues investigated the frequency of variants in *TNF*-α, *IL-1*ß, chemokine monocyte chemoattractant protein

Table 4 Positive studies on cytokine gene polymorphisms in Parkinson's disease

Study	Population	Gene polymorphism	Patients	Controls	Results
Kruger et al. 2000	German	TNF-α -308 G/A	264 (114F 148M)	198	↑GA

↑ and ↓ represent a statistically significant ($p < 0.05$) increase or decrease of alleles or genotypes respect to PD patients.

M =male; F =female. 1^o =allele 1; 2^o=allele 2. AAO= affects age-at-onset of symptoms.

This table highlights the inconsistency in results (*is inversely associted compared to other studies) and nomenclature that is used to describe each cytokine polymorphism.

(*MCP-1*), and chemokine receptor-2 (*CCR-2*) in the Japanese population. Mattila et al. investigated the *IL-1* gene cluster, including *IL-1*α, -ß and *IL-1RN* along with a SNP in the intercellular adhesion molecule 1 (*ICAM1*). The results of both studies supported the hypothesis that genetic variation of proinflammatory cytokine genes may influence PD with SNPs in the *TNF*-α and *IL-1ß* genes associated (Fig. 2). However, a number of the SNPs examined showed no association with PD susceptibility.

A study in the German population also found no evidence of association with the *IL-1*α (-889 C/T) SNP with risk of PD [76]. Ross and colleagues (2004) investigated a cross-section of promoter variants in proinflammatory cytokine genes *IL-2* (-330 T/G), *IL-6* (-174 C/G), *IL-8* (-251 A/T) and *TNF*-α (-308 G/A) [108]. Although no association was observed for the variants of *IL-2*, *IL-6* and *TNF*-α, a significant decrease in the number of TT homozygous carriers for the *IL-8* gene was observed in the PD patients. Interestingly, IL-8 is also known as CXCL8 and belongs to the specific group of cytokines known as chemokines.

The cells of the brain, particularly neurons, are believed to possess a wide range of chemokine receptors [73]. Neurological injury and PD are often associated with the increase of nitric oxide and free radicals from glial cells in the brain [64, 113]. At sites of inflammation, brain cells are exposed to high concentrations of reactive oxygen species and reactive nitrogen intermediates (produced by activated neutrophils, macrophages and T-cells) as a normal part of the immune response. A potential variation in IL-8 expression in PD subjects may facilitate the influx of neutrophils, immune and activated glial cells to sites of damage and inflammation, resulting in increased oxidative damage and cell death. However when Huerta and colleagues (2004) examined the frequency of polymorphic variants in four chemokine genes, *RANTES*, *MCP-1*, *CCR2* and *CCR5*, no significant associations with PD were observed in the Spanish population studied [49]. These results support earlier results for *MCP-1* and *CCR2* observed by Nishimura et al. in the Japanese population.

In two Swedish studies by Hakansson and colleagues the frequency of several cytokine polymorphisms were studied [42]. No association with PD was observed for variants in the *IFN*-γ, *IFN*-γ*R2*, platelet-activating factor acetylhydrolase and

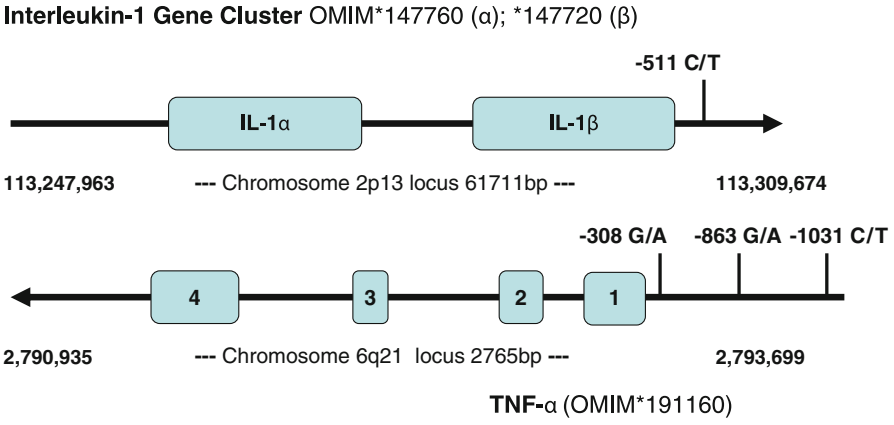

Fig. 2 Genomic structures of IL-1cluster and TNF-α

ICAM1 genes. Likewise, a promoter SNP in the *IL-10* gene did not demonstrate any association with susceptibility to PD, however it did appear to affect the age-at-onset with a significantly higher frequency of the A-allele in early-onset PD patients. Interestingly, the *IL-6* (-174 G/C) promoter SNP did show association with PD with an increased number of -174 GG carriers in the PD patients. The authors further suggest this association is stronger when interactions with a SNP in the *estrogen receptor*-β gene were considered [41].

The latest two papers on this topic have looked at the primary genes that were implicated in PD pathogenesis, *TNF*-α and *IL-1*β [118, 122]. Wu et al. (2007) investigated 4 -promoter SNPs of the *TNF*-α gene (-308, -857, -863 and -1031) in their Taiwanese samples and identified a significant association for the -863 and -1031 SNPs, which were found to be in high linkage disequilibrium in the study. The strongest association was observed with an increased frequency of the -1031 CC genotype in PD patients, and these results concur with the earlier Japanese study by Nishimura et al. (2001) where an increase in this allele with early-onset PD was observed. Wahner et al. (2007) examined the *TNF*-α (-308 G/A) and the *IL-1*β (-511 C/T) SNPs in a US PD patient-control series and observed a significant association with both SNPs, suggesting each SNP individually increased the risk of PD by two-fold and when combined three-fold (Fig. 2).

3.3 Age-Related Disorders Conclusions

It is possible that cytokine polymorphism and genetic variants influence susceptibility to the development of parkinsonism symptoms. Given this hypothesis, it is then even more likely that these variants will influence pathogenesis of the disease affecting age-at-onset, progression and severity of symptoms. The complex nature of this devastating disease is indicative of a multifactorial disorder that is influenced by environmental agents (e.g., infection) acting on a genomic background of susceptibility. The hypothesis that neuroinflammation enhances the degenerative processes involved in PD implies that anti-inflammatory therapeutics may slow disease progression. The use of nonsteriodal antiinflammatory drugs (NSAIDs) has shown some promise in both PD and Alzheimer's disease [3, 54]. At present the only symptomatic relief comes from dopamine replacement (levodopa) and dopamine agonists, as research into the genetics of PD is still a relatively young field. In conclusion, further studies of cytokine polymorphism and genetic variants within genes of the proinflammatory network in PD are certainly warranted.

4 Perspectives

The first century of this new millennium will bear witness to a new era in both ageing research and clinical practice. We are moving into the postgenomic era and the beginning of individualized medicine and treatment. This holds great promise

for the study of complex disorders such as ageing. The field of longevity genetics ("Longevics") will mature, and the identification of mutations that affect the immune system and prolong life will once again revolutionize our views of the ageing process [102]. A strong immune response is clearly important for survival, however this double-edged sword can also increase morbidity. The studies described in this chapter on cytokine gene polymorphisms and ageing certainly suggest that further work is warranted in order to achieve a greater understanding of the complex mechanism(s) underlying longevity.

The intricate nature of the cytokine cascade suggests that any imbalance may be detrimental to the individual. This possible imbalance may be due to an aberrant genomic background of the cytokine network and may be exaggerated by external forces such as infection, stress, smoking and/or diet. Many researchers support the pleiotrophic effect hypothesis as to why immunosenescence occurs by the immune system/response. To elaborate on this concept, it is thought that a proinflammatory genome-genotype ("genomotype") is beneficial in early-childhood and development when the individual is prone to infection. However as we survive past our optimal age and generalized degeneration begins, the proinflammatory genomotype becomes detrimental thus causing damage and promoting autoimmune disorders. Therefore what this phenomenon suggests is that each individual's inflammatory genomotype may behave either as a positive or negative influence on lifespan and this outcome is ultimately determined by the individual's specific environment.

By necessity, both the immune response and the ageing process are determined by genetic, environmental and stochastic factors. Each component is thought to produce a different size effect on a single biological pathway and therefore comparisons are extremely difficult to make. Therefore, the identification of genetic and environmental factors involved in regulating the cytokine response will help highlight other biological pathways that are important in maintaining a healthy immune system. A further confounding effect is gender, as a consistent increased number of females are becoming centenarians than males. The reason(s) for this difference remain unresolved, although studies suggest that gender may effect a differential immune responsiveness which then leads to an inflammatory phenotype. This observation of a gender-bias is supported by similar findings in age-related diseases such as PD, which is more prevalent in males.

Given the complexity previously described, how can one objectively measure the contribution of cytokine genetics to immunosenescence? This question is of course applicable to every pathway postulated to have an effect on the ageing process. Likewise, the underlying answer may also be the same being that one must measure the genetic influence(s) of the overall pathways. To date, as reviewed in this chapter, most studies have examined a small number of variants in one or two cytokine genes and observed inconsistent associations. This has in part been due to small sample sizes and financial restraints. However, the advances that are being made in molecular genetic techniques (including large-scale, rapid genotyping and direct DNA sequencing) will allow objective measurements of cytokine genetics with respect to immunosenescence to be ascertained. This means there is an unprecedented opportunity now available to help unravel the mechanism(s) of the immune system regarding ageing and age-related disorders.

Genome-wide association studies provide an objective measure of genetic variations and are an extension of the classical patient-control studies. These studies are now common-place in leading scientific journals (Nature, Science and the New England Journal of Medicine). Recent genome-wide association studies have identified polymorphisms of cytokine genes as being involved in numerous age-related disorders, like multiple sclerosis [5, 25, 26, 39, 40, 43, 65, 84, 116]. It remains to be seen if these types of association studies will lead to the identification of those genetic factors which influence ageing. These studies will likely require a large collaborative effort to obtain the necessary numbers of aged individuals that will provide the statistical power needed to observe moderate "effect sizes". The Genetics of Healthy Ageing (GEHA) is a current European study of nonagenarian sibling pairs which should have the statistical power to elucidate whether the earlier suggestive changes in cytokine polymorphisms in relation to age and perhaps gender have any coherence, across heterogeneous populations of nonagenarian siblings [31].

Ageing research is becoming of greater interest and importance. The average human lifespan continues to be increased, which has resulted in an expanding proportion of elderly people in society. The developments in molecular, gerontological research have created the potential for survival beyond that of centenarians. The development of stem cell research alone could allow for the generation of completely new cells and organs. In the case of PD, mouse embryonic stem (ES) cells have been used for cell replacement therapy in an animal model of PD [50, 87]. From cultured ES cells, Kim and colleagues (2002) were able to generate a supply of neurons that produce dopamine. The neurons functioned normally and gave clear behavioural responses when grafted into the brains of rats that model PD. The potential benefits of revolutionary experiments like this regarding the treatment and possible prevention of age-related pathologies and perhaps even the rate of ageing itself mean that the deteriorative processes of ageing may no longer be the scourge of mankind.

Acknowledgments OAR is funded by an APDA research grant and a Rapid Response Award from the Michael J. Fox Foundation. We are grateful to our Research Nurse Anne Murphy and to Department of Health and Social Services Northern Ireland and the Wellcome Trust for funding towards the Belfast Elderly Longitudinal Free-living Ageing Study (BELFAST). This chapter is dedicated to the memory of Donna J. Hinkle (1948–2007).

Role of TLR Polymorphisms in Immunosenescence

Carmela Rita Balistreri, Giuseppina Candore, Giuseppina Colonna-Romano, Maria Paola Grimaldi, Domenico Lio, Florinda Listì, Sonya Vasto, Letizia Scola and Calogero Caruso

Contents

Abstract: Innate immunity provides a first line of host defense against infection through microbial recognition and killing while simultaneously activating a clonotypic immune response. Toll-like receptors (TLRs) are principal mediators of rapid microbial recognition and function mainly by detection of pathogen-associated molecular patterns (PAMPs) that do not exist in the host. The different members of TLRs recognize several PAMPs, such as peptidoglycan for TLR2, lipopolysaccharide (LPS) for TLR4, flagellin for TLR5, and CpGDNA-repeats for TLR9. Several endogenous ligands of various TLRs have been also identified in the host. In this chapter, we describe the involvement of TLR-4 polymorphisms in immunosenescence, and in particular in age-related diseases, suggesting the crucial role of molecules of innate immunity on these diseases pathophysiology. Hence, we observed that proinflammatory alleles may be related to unsuccessful aging as atherosclerosis and Alzheimer's disease; reciprocally, controlling inflammatory status by antiinflammatory alleles may allow to better attain successful aging.

1 Introduction

Ageing and longevity are due to a complex interaction of genetic, epigenetic and environmental factors [1]. The genetic component seems to have a relevant role in the attainment of longevity, because it is involved in cell maintenance systems, including immune system. An optimal performance of the both innate and clonotypic branches of immune system has been correlated with survival to extreme ages [2]. The ageing of immune system, known as immunosenescence, is the consequence of changes of clonotypic and innate immune cells caused by lymphoid tissue involution and chronic antigenic overload. The antigenic stress affects the immune system thorough out life with a progressive activation and generation of inflammatory responses involved in the pathophysiology of age-related diseases. Most of the parameters influencing immunosenescence appear to be under genetic control, and immunosenescence fits with the basic assumptions of evolutionary theories of aging, such as antagonistic pleiotropy. Accordingly, the innate immune system, by neutralizing infectious agents, plays a beneficial role until the time of reproduction and parental care, but, by determining a chronic inflammation, can play a detrimental one late in life, in a period largely not foreseen by evolution. In contrast, the clonotypic immune system, with advancing age, shows an exhaustion, due to accumulation of memory cells, which fill the immunological space [2]. As already mentioned, the genetic background seems to modulate the functionality of innate/inflammatory and clonotypic responses and consequently the inflammatory state occurring with advancing age [1, 2]. So, genes encoding molecules involved in innate/clonotypic immunity might influence the susceptibility to age-related diseases and the survival to extreme ages. In other words, the presence of pro/antiinflammatory genotypes might determine a negative or positive control of inflammation, influencing the susceptibility to age-related diseases and/or promoting longevity [2].

In this chapter, we describe the involvement of Toll-like receptor (TLR) 4 polymorphisms in immunosenescence, and in particular in age-related diseases, suggesting the crucial role of molecules of innate immunity on these diseases pathophysiology. Hence, we observed that proinflammatory alleles may be related to unsuccessful aging as atherosclerosis and Alzheimer's disease (AD); reciprocally, controlling inflammatory status by anti-inflammatory alleles may allow to better attain successful aging.

2 TLR4

The innate immune system is the first line of the defensive mechanisms that protect host from invading microbial pathogens. Host cells express various pattern recognition receptors (PRRs) that sense diverse pathogen-associated molecular patterns (PAMPs), ranging from lipids, lipoproteins, proteins and nucleic acids [3, 4].

Recognition of PAMPs by PRRs activates intracellular signaling pathways that culminate in the induction of inflammatory cytokines, chemokines, interferons (IFNs) and upregulation of co-stimulatory molecules. To date, it has been identified three families of PRRs, usually defined as "the trinity of pathogen sensors": Toll-like receptors (TLRs), NOD-like receptors and RIG-like receptors (RLR). NLRs with known functions detect bacteria, and RLRs are antiviral [3, 4].

TLRs family include, in human beings, 10 members that trigger innate immune responses through nuclear factor-κB (NF-κB)- dependent and IFN-regulatory factor (IRF)-dependent signaling pathways [4, 5]. TLRs are evolutionarily conserved molecules and were originally identified in vertebrates on the basis of their homology with Toll, a molecule that stimulates the production of antimicrobial proteins in *Drosophila melanogaster* [6, 7].

Some molecules of this family are expressed at the cell surface, whereas others are expressed on the membrane of endocytic vesicles or other intracellular organelles (Fig. 1). The structure of these receptors is quaternary and they are composed of an ectodomain of leucine-rich repeats n (LRRs), which are involved directly or through accessory molecules in ligand binding, and a cytoplasmic Toll/interleukin(IL)-1 receptor (TIR) domain that interacts with TIR-domain-containing adaptor molecules (Fig. 2) [8]. The different members of TLRs recognize several PAMPs, such as peptidoglycan for TLR2, lipopolysaccharide (LPS) for TLR4, flagellin for TLR5, and CpGDNA-repeats for TLR9 (Fig. 1) [9–12]. Several endogenous ligands of various TLRs have been also identified in the host [13].

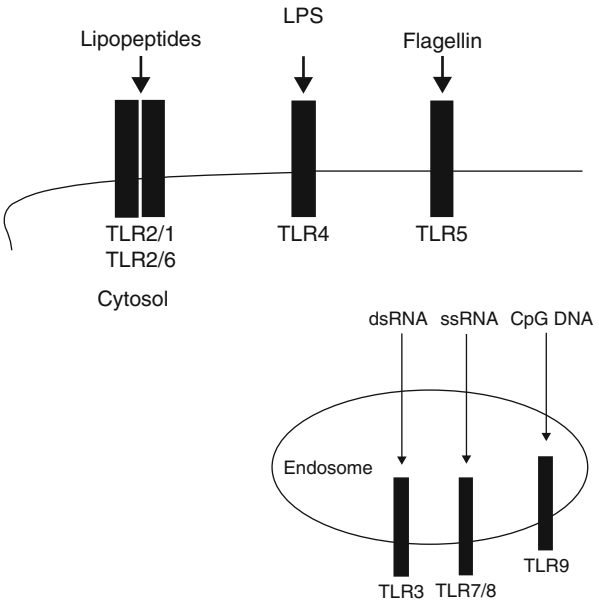

Fig. 1 The members of TLR family are expressed at the cell surface and on the membrane of endocytic vesicles or other intracellular organelles. They recognize several microbial molecules, as shown in the figure.

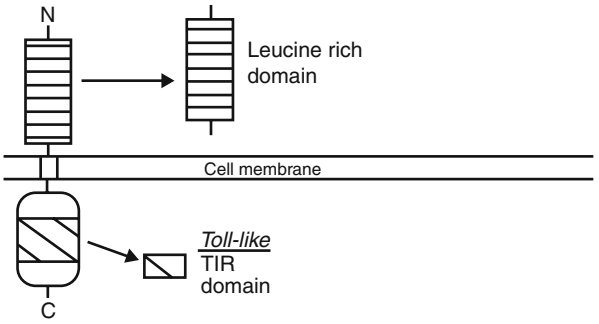

Fig. 2 The TLR structure is composed of an ectodomain of LRRs, which are involved directly or through accessory molecules in ligand binding, and a cytoplasmic Toll/interleukin-1 (IL-1) receptor (TIR) domain that interacts with TIR-domain-containing adaptor molecules.

Taking into account their ability to link several molecules, it has been postulated that the genes encoding TLRs receptors would be subject to diversifying selection [14] This is because the proteins are in direct contact with molecules of microbial origin, which might change in structure to evade immune detection. In fact, weak purifying selection seems to apply in the case of the TLRs [14, 15]. Furthermore, the need for detection of various signature molecules seems to come and go in evolution. For example, while some invertebrates are highly sensitive to LPS, most invertebrates are not [16–19]. Drosophila exhibits no response to pure LPS or lipid A at all. Similarly, most vertebrates (fish, amphibians, reptiles, and birds) are at least relatively insensitive to LPS, if not entirely unresponsive [14]. In the case to Danio rerio and Gallus gallus, it is clear that TLR4 encoding genes are represented in the genome. However, in fish and in birds, these TLR4 homologs evidently to not trigger the same set of events as witnessed in mammals. Besides, among mammals, sensitivity to LPS is quite variable, depending upon which endpoint is examined. Humans, anthropoid apes, ungulates, and rabbits are highly sensitive to LPS; mice, rats, and baboons are comparatively resistant [14].

To date, it is possible to suggest that TLRs receptors are the key molecules of natural responses and they also provide a link between innate and clonotypic immunity [20–22]. These evidences have also opened inquiries into previously unknown disease mechanisms [23–25]. Their ability to detect different PAMPs gives a link between infection and various human diseases [23–25]. In fact, members of TLR family have been involved in the pathogenesis of several diseases by studies of people analyzing the incidence of diseases having different polymorphisms in genes encoding TLRs. So, it has been evidenced the crucial role of well-known component of TLR family, the TLR4, in some diseases, as atherosclerosis and AD [24–26].

TLR4 has been identified as the first human homologue of the Drosophila Toll [6, 7]. The extracellular domain of TLR4 that contain over 600 amino acids is highly polymorphic compared with the transmembrane and intracellular domain of the protein [5, 18]. This TLR4 polymorphism contributes to species-specific differences in recognition of LPS, the prototypic TLR4 ligand [5, 19]. The intracellular TIR domain, which is composed of three highly conserved regions, contains

150 amino acids [5, 20]. The TIR domain modulates protein–protein interactions between the TLRs and signal transduction elements [5, 20]. As already mentioned, TLR4 has been shown to be involved in the recognition of LPS, a major cell wall component of Gram negative bacteria [14]. In addition to LPS, TLR4 recognizes several endogenous ligands, such as oxidized-LDL (ox-LDL), lipoteichoic acid, heat-shock proteins (HSP), fibronectin and Aβ amyloid peptide of AD. Its activation by induction of NF-kB and mitogen dependent protein kinase pathways determines the production of cytokines, chemokines, other inflammatory mediators (Fig. 3) [13]. Therefore, it has been suggested that activated TLR4 triggers not only innate immunity but also clonotypic immunity. TLR4 activation on dendritic cells induces the expression of costimulatory molecules and production of inflammatory cytokines [22]. Then, activated dendritic cells present microorganism derived peptide antigens expressed on the cell surface with Major Histocompatibility Complex class II antigen to naive T-cells, thereby initiating an antigen-specific clonotypic immune response [20–22].

TLR4 activity and function may be modulated by genetic polymorphisms (for the most part, single nucleotide polymorphisms, SNPs), prevalently presented in extracellular domain. It has been identified a functional SNP in the human TLR4 gene, an A-G base transition at position +896 base pairs from the transcriptional start site, resulting in an aspartic acid to glycine exchange at position 299 in the amino-acid sequence (referred to as Asp299Gly or +896A/G) [27, 28]. This SNP

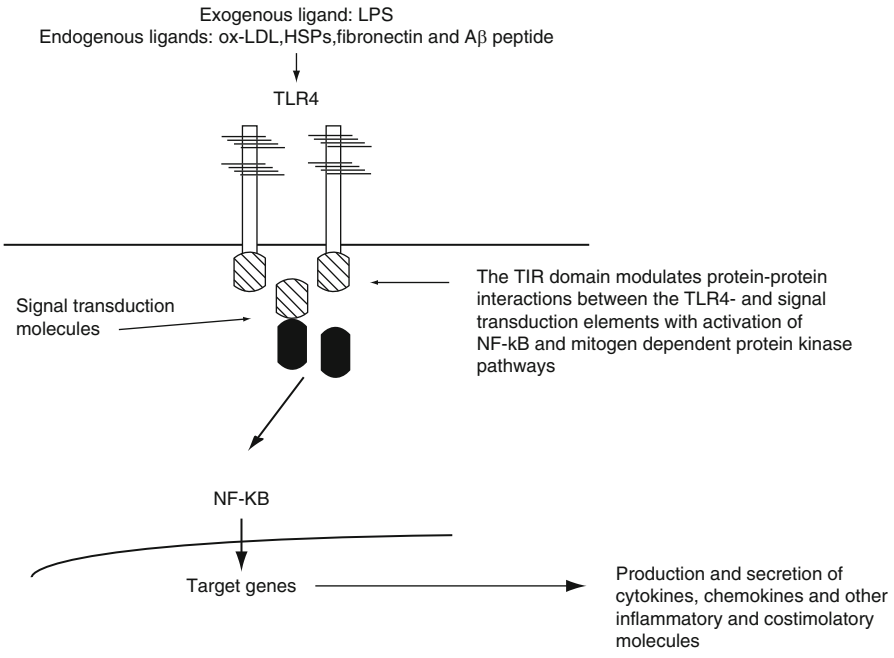

Fig. 3 Activation of TLR4 receptor by LPS (or other agents, as endogenous molecules-as shown in the figure) induces transmembrane signals that activate NF-kB and mitogen dependent protein kinase pathways, determining the expression of a wide number of genes encoding proteins, such as cytokines, with regulatory functions upon leukocyte activation and tissue inflammation.

causes hyporesponsiveness to LPS as well as an increased risk and susceptibility to Gram-negative infections both in human and experimental animals. Recently, it has been suggested that this SNP plays a role in a variety of human diseases, ranging from infectious and inflammatory diseases to cancer [23–26]. So, TLR4 plays a key role in both innate and clonotypic immunity to Gram-negative bacteria and to other agents and it seems to be the hub of inflammatory pathophysiology of age-related diseases, as atherosclerosis and AD [23–26].

3 Involvement of TLR4 in Age-Related Diseases: Its Role in Atherosclerosis, AD, and Cancer

By now, evidence is accumulating that TLR4 could affect atherosclerosis in multiple ways [24, 25, 28–35]. The association between TLR4 and atherosclerosis is consistent with findings showing that TLR4 mRNA and protein are more abundant in atherosclerosis lesions than in unaffected vessels [24, 25, 30]. Furthermore, cultured human vascular endothelial cells express little TLR4 under baseline conditions, and they express high levels of TLR4 on stimulation with proinflammatory cytokines [29]. Among cellular components presented in atherosclerotic plaques are several TLR4-expressing cells, including macrophages, endothelial cells, smooth muscle cells, T-cells and dendritic cells [24, 25, 28–35]. It is largely accepted that ox-LDL as well as other endogeneous ligands, that are expressed during arterial injury, as HSP are responsible for TLR4 ligation and activation. However, taking into account the role of life-long pathogen load on the development of elderly inflammatory status and atherosclerosis, PAMPs should also be involved in TLR4 activation (Fig. 4) [2, 28–37].

To date, there is a large body of genetic data pointing the involvement of Asp299Gly SNP in atherosclerosis development. Ultrasound analysis of carotid arteries in a large Italian population showed that the Asp299Gly was found less frequently in people with progressive lesions representing carotid atherosclerosis, compared with a control group. These results were confirmed by other studies that found a protective effect of the TLR4 variants on acute coronary events. However, other studies investigating a potential association of this SNP with cardiovascular diseases (CVD), as myocardial infarction (MI), did not yield significant results (Table 1) [28, 36–46]. On the other hand, association studies are influenced by a number of possible confounding factors, like the total number of patients and controls and the homogeneity of the population in term of geographical origin among others. Artefacts might occur if the controls are not ethnically matched with the patients.

Literature data have also recently demonstrated the involvement of TLR4 receptor in neurodegeneration. It is now known the role of innate immunity, and precisely of microglial cells, in the inflammatory pathogenesis of AD, as stated by the amyloid cascade/neuroinflammation hypothesis. The former is responsible for the production of the neurotoxic substances, such as reactive oxygen and nitrogen

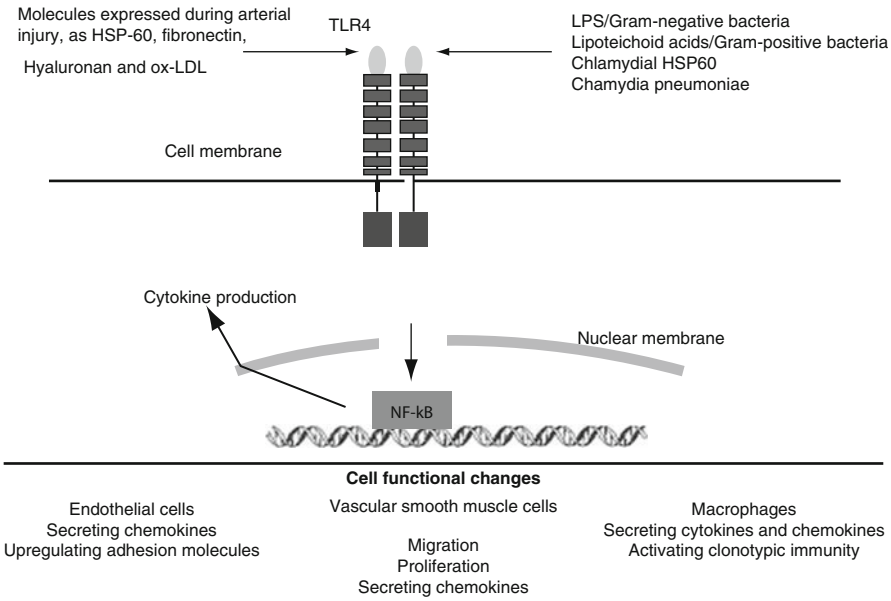

Fig. 4 TLR4 signaling pathway and its relation with atherosclerosis. Both endogenous and exogenous ligands can activate TLR4 on cells, such as endothelial cells, vascular smooth muscle cells, adventitial fibroblasts, dendritic cells and macrophages. Activated TLR4 lead to activation of the NF-KB. This activated transcription factor mediates the expression of several genes and the secretion of proinflammatory cytokines and chemokines, and it also induces expression of adhesion molecules. Ultimately, these processes might initiate or promote atherosclerotic lesions.

species, proinflammatory cytokines, complement proteins and other inflammatory mediators that bring important neurodegenerative changes. Some studies have suggested that activation of microglial cells may be induced throughout the binding of Aβ peptides. Several membrane proteins expressed on microglial cells seem to be implicated in Aβ peptides binding. It has been demonstrated that TLR4 receptor binds highly hydrophobic Aβ peptides aggregates suggesting the production of neurotoxic substances. A further, not mutually, alternative explanation on the key role of microglial activation may be related to the role of TLR4 as LPS receptor. In fact, also in AD life-long pathogen burden has been linked to the pathophysiology of the disease. So it should to be biologically plausible that functional variation in the TLR4 gene might influence the susceptibility to sporadic AD [47–56].

This might be the case for the allelic variants of TLR4 gene, as Asp299Gly SNP, associated, as above described, with an attenuated receptor signaling and a blunted inflammatory response. Association between this polymorphism and AD has been described by Minoretti et al. [57] in an Italian population sample. Our preliminary results of a recent study have confirmed that Asp299Gly polymorphism of TLR4 gene is associated with AD [56].

It has been also suggested the involvement of TLR4 receptor in cancer [23]. It is known the involvement of inflammation, as an etiological factor in several human cancer. Growing evidence suggests that the chronic inflammation induced

Table 1 Summary of studies investigating the potential association of Asp299Gly **TLR4SNP** with cardiovascular diseases

References	Association studies	Results	P-value
Kiechl et al[28]	Carotid stenosis	Participants with SNP have lower incidence of carotid stenosis	0.05
Ameziane et al[38]	Acute coronary events	Participants with SNP have lower incidence of coronary events	0.037
Balistreri et al[39]	MI	Patients (men) with SNP have lower incidence of MI	0.002
Edfeldt et al[40]	MI	Men with SNP have increased incidence of MI	0.004
Zee et al[41]	MI and stroke	Not significant	0.25
Yang et al[42]	Coronary artery stenosis	Participants with SNP have not lower risk of stenosis	0.9
Labrum et al[43]	Carotid events	There was no association between SNP and baseline intima-media thickness (IMT) or progression of IMT over the 3-year follow up	Not significant
O'Halloran et al[44]	Coronary artery disease	There was no evidence overall that the resistance alleles cumulatively influenced the risk of CVD compared to controls or stable angina patients	0.12, and 0.40, respectively
Vainas et al[45]	Peripherical arterial disease	Among patients affected by peripheral arterial disease, TLR4 +896 G allele carriership was univariantly associated with extensive (more than two vascular territories affected) atherosclerotic disease	0.02
Nebel et al[46]	MI	Patients (men) with SNP have not lower incidence of MI	0.36

by different pathogens may also play a role in pathophysiology of some cancer, as gastric cancer [23, 58–62]. Considering that genetic susceptibility is a major risk factor for this disease, it has been hypothesized that sequence variants in genes that regulate inflammatory response may modify individual susceptibility to cancer. So, some studies have analyzed the relationship between the associations of several functional polymorphisms in genes involved in LPS signaling variants and risk of cancer. Garza-Gonzales et al. [59] have investigated the association of Asp299Gly TLR4 SNP and distal gastric cancer in a Mexican population. The results obtained have not demonstrated any association between this SNP and distal gastric cancer, suggesting that it do not contribute to the development to disease. The same data have been obtained in a study performed in a Venezuelan population [60]. In an other study, it has been investigated the role of different SNPs of some inflammatory genes, as Asp299Gly of TLR4 gene, in 377 patients affected by colorectal cancer

and 326 controls from Spain [61]. There was no statistically significant association between this SNP and colorectal cancer risk. However, different results have been found in a study performed in 710 patients affected by lymphoma [62]. In fact, the TLR4 Asp299Gly variant was positively associated with the risk of mucosa-associated lymphoid tissue lymphoma (OR=2.76, 95% CI=1.12–6.81) and Hodgkin's lymphoma (OR=1.80, 95% CI=0.99–3.26). Hence, this study suggests an effect of this SNP in factors of the innate immune response in the etiology of some lymphoma subtypes.

4 Conclusions

Genetic factors play an important role in the ability to achieve exceptional old age, theoretically two class of genes can be considered to be at play [1]. On the one hand, individuals with a genetic make-up useful to achieve extreme old age most likely present with mutations that significantly increase the risk of premature death by lethal, age, and nonage-associated diseases. On the other hand, it has been suggested that genetic variants conferring protection against basic mechanisms of aging and/or age-related illnesses also might exist [1, 2].

To discover the gene factors that let an organism to survive beyond its reproductive age, it is necessary to use an extreme phenotype. From this perspective, the centenarians are the good choice as they represent the survived tail of a very special segment of population. They comprise a cohort of living people who celebrate today the 100th birthday and escaped neonatal mortality, preantibiotic era, fatal outcomes of age-related complex diseases. A small number of centenarians is in quite good heath (in "*good robustness*"), defined as ''group A'' by Franceschi et al., ''escapers'' by Evert et al., and ''exceptionals'' by Gondo et al. [63–65]. The centenarians also represent that segment of population who better adapted and readapted from both biological and non-biological point of view. Centenarians, as representative of longevity, consent to understand the role played by genetic structure of population on the onset of phenotype and the historical dynamism of the longevity trait from a demographic point of view. So, they are the best model for studying the genetics of longevity, and for identifying the genetic factors involved in age-related diseases, since the centenarians represent selected survivors who have clearly delayed or in some cases even escaped age-related diseases, that affect old people and are responsible their morbidity and mortality [66]. Hence, centenarians are a human model of disease-free [67]. In addition, centenarian offspring have increased likelihood of surviving to 100 years and show a reduced prevalence of age-associated diseases, as CVD and less prevalence of cardiovascular risk factors [68, 69]. So, genes involved in CVD may play an opposite role in human longevity, as Asp299Gly SNP. In particular, we have postulated that alleles associated to CVD susceptibility should not be included in the genetic background favoring longevity. So, the genetic background promoting pro-inflammatory responses may play an opposite roles in CVD and in longevity [37, 70–72].

Following a novel approach to study genes involved in CVD and reciprocally in longevity, we have recently demonstrated that antiinflammtory allele of Asp299Gly SNP of TLR4 gene, +896G, is overrepresented in male Sicilian centenarians and underrepresented in men affected by MI, with intermediate values in control population [37]. Thus, our results suggest a role of the innate immune defense system and particularly TLR4 in CVD, and our comparison with the oldest old may help elucidate the role of genetics in age-associated diseases characterized by a multifactorial etiology [39]. Accordingly, TLR4 polymorphisms, which attenuate receptor signaling, enhance the risk of infections, but decrease that of atherogenesis, presumably by limiting inflammatory responses [27, 28]. Hence, the mutation might result in an increased chance of longevity in a modern environment with reduced pathogen load and improved control of severe infections by antibiotics.

However, a recent study has excluded a noteworthy influence of Asp299Gly SNP upon human longevity or MI in German men [46]. The causes of the discrepancies seem be not clear, but the inclusion criteria, the studied populations, and the measured endpoint differed substantially among the studies. Further, it is claimed that results obtained on human populations should always be replicated. Indeed, association with particular genetic polymorphisms and longevity is reported for some population but not for others. However, this is not strange because, as underlined by Capri et al. [73] human populations are characterized by specific gene pools that arise from the particular group's history in terms of chance (genetic drift) and environment (natural selection). Hence, replication cannot reasonably be expected for longevity in light of the considerations discussed in that study.

The suggestion that enhanced male life expectancy is associated with antiinflammatory TLR4 SNP is interesting in view of the role of TLR-4 proinflammatory allele in the control of infectious diseases [25]. In order to rationalize these two seemingly conflicting situations, it might be argued that males carriers of the antiinflammatory allele who are lucky enough not to contact serious bacterial infection earlier in life may have an increased chance of long life survival (trade-off). However the same appears not to be true for female life expectancy [74].

Signal Transduction Changes in T-cells with Aging

Tamas Fulop, Gilles Dupuis, Carl Fortin and Anis Larbi

Contents

Abstract: There are several functions of T-lymphocytes which are altered with aging. The cause is not exactly known. However the changes in T-lymphocyte activation could be caused by the altered T-cell receptor (TCR) signaling after ligation. The recently described membrane lipid rafts (MR) are critical to the assembly of the TCR, the CD28 coreceptor and the IL-2 receptor signaling machinery. The defect in IL-2 production by $CD4^+$ T-cells with aging is not due to lower levels of expres-

sion of the TCR, CD28 or intracellular signaling molecules. However, there is a direct correlation between the activation of $p56^{Lck}$ and LAT at the cellular level and their association/recruitment with the lipid raft fractions of $CD4^+$ and $CD8^+$ T-cells. $p56^{Lck}$, LAT and Akt/PKB are weakly phosphorylated in MR of stimulated $CD4^+$ T-cells of elderly as compared to young donors. Moreover, MR undergo changes in their lipid composition (ganglioside M1, cholesterol) with aging. There exists a differential role for lipid rafts in $CD4^+$ and $CD8^+$ T-cell activation with aging and consequently a differential localization of CD28 which may explain disparities in response to stimulation in human aging, mainly affecting the $CD4^+$ T-lymphocyte population.

Keywords: T-cells • CD4+ T-cells • CD8+ T-cells • Lipid rafts • Signal transduction • Aging Cholesterol • CD28 Coreceptor

1 Introduction

Most of the cell functions occur through specific receptors triggered by various ligands. T-cells possess several receptors which lead to their activation and to the maintenance of their activation status. Antigenic recognition by the T-cell receptor (TCR) triggers a series of biochemical events that result in the expression of a range of genes that are essential to T-cell responses, expansion and effector functions [1]. In addition, ligation of costimulatory CD28, that is required for interleukin-2 production and commitment to proliferation [2], enhances lipid raft polarization [3, 4]. Thus, CD28 triggering is essential for sustained T-cell activation [2]. Once IL-2 is secreted it will act in a paracrine manner on T-cells to trigger their clonal expansion via the IL-2 receptors. Membrane lipid rafts (MR) are dynamic structures and the time-dependent recruitment or exclusion of signaling proteins in these MR control T-cell activation and immune responses [5]. Moreover, lipid rafts are dynamic structures whose composition and function may vary according to cell types and cell subsets, especially in the case of T-lymphocytes [6]. Heterogeneity in MR composition and function may explain disparities in lymphocyte subset functions [7].

2 Signaling via TCR, CD28 and IL-2 Receptors and Their Changes with Aging

2.1 Receptors Involved in T-Lymphocyte Activation

The encounter of pathogens with lymphocytes will initiate their activation resulting in clonal expansion. The cascade of signaling molecules initiated by the stimulation of specific surface receptors results in the activation of several transcription factors. The most important receptors implicated in the clonal expansion of T-cells are the

TCR, the coreceptors including CD28 and the IL-2 cytokine receptor (IL-2R). These receptors function via an intracellular signaling cascade assuring the specificity and the fidelity of the expected response. T-cells need a first signal (signal 1) priming them to the possibility to respond by a clonal expansion to a specific antigen presented in the frame of a major histocompatibility complex (MHC) by an antigen-presenting cell (APC). This will assure that the whole membrane and the early signaling machinery is readily assembled to proceed toward the next stage, that is, the progression toward the full, sustained response. This is ensured by various coreceptors among which the most important is CD28, which represents signal 2. Signals transmitted by this receptor assure that the clonal expansion occurs via a sustained activation by the creation of the immune synapse (IS). Finally, as the concerted CD28 activation leads to the production of IL-2, it should also efficiently stimulate T-cells, representing signal 3. Altogether these receptors act for a complete response of T-cells assuring an adequate response to a specific antigen. With aging several studies have shown that the number of TCR is not changed. The CD28 number, claimed as a biomarker of aging, seems to decrease mainly in the case of a specific T-cell subpopulation, the memory CD8+ T-cells. These cells seem to represent a very late differentiated population characterizing immunosenescence [8]. These cells are the result of continuous chronic stimulations by antigens probably of viral origin including cytomegalovirus (CMV) and other herpes viruses, as similar changes were observed during CMV infection [9]. They are also the result of the low-grade chronic inflammation, however, the inflam-aging theory could not be validated in SENIEUR donors. One naturally arising question is whether this is a normal process related to aging, whether related to age-related disease processes or to the progressing frailty syndrome occurring in certain groups of elderly subjects. Our works suggest that in case of CD4+ T-cells the number of CD28 co-receptor is not decreasing, while it is decreasing in the CD8+ T-cell subpopulation [10]. Whether, the expression of IL-2R change during aging is still controversial, however, our work suggests a maintained expression in healthy elderly individuals. The TCR and CD28 are signaling via two specific cascades, however, there are more and more data suggesting that a cross-talk could exist between these two major pathways. We will describe these signaling pathways individually and in their cross-talk with a special emphasis on changes occurring with aging. However, first we will discuss MR and their role in signaling with special emphasis on the age-related changes.

2.2 Membrane Lipid Raft Function and Composition

One of the most important advances in membrane biology and consequently in the signaling field was the discovery of the existence of lipid rafts in the cell membrane that are now called membrane rafts (MR) [11]. These microdomains are composed mainly of satured lipids, cholesterol, glycosphyngolipids, GPI-anchored proteins, and posttranslationally modified proteins. These high-melting sphingolipids packed with cholesterol generate a liquid-ordered phase (lo) arrangement. This composition forms an efficient signaling platform necessary for an adequate signaling and cell response.

TCR ligation induces a redistribution of phosphorylated proteins into MR, which are highly compact relatively small domains (20–200 nM). The saturation of the lipids as well as the enrichment in cholesterol both allow the rafts to move through the membrane as discrete units. Their movement will be differentially segregated to the various poles of the cell depending on their main specific component, such as ganglioside M1 (GM1), GM3, or flotillin. The consequence of cell polarity is the asymmetric localization of membrane receptors and signaling molecules between the leading edge (at the cell front) and the uropod at the rear edge [12] This cell polarity will also influence the protein composition and the protein–protein interactions into the rafts. Data support the role of MR in the asymmetric distribution of membrane proteins during cell polarization. There is still a debate on which interactions direct and determine the MR movements and functions, and whether they involve cholesterol, membrane proteins, or both [13]. Experimental data seem to indicate that there could be several types of rafts playing different roles [14]. Furthermore, the role of MR is not limited to signal transduction, but also to lipid transport, virus entry, cell movement, as well as cell–cell communication. The accumulation or clusters of signaling molecules via MR initiate the formation of a signaling platform, which increases the efficiency of signaling. T-cell activation is the consequence of the interaction between the TCR and specific antigen presented by the APC. Signal 1 is occurring over a time frame of a few seconds but the interaction between T-cells and APC can be sustained for many hours. This prolonged interaction leads to the formation of the supramolecular activation cluster (SMAC) at the immunological synapse (IS). Thus, the sustained T-cell activation via organized MR signaling ultimately leads to the formation of a mature IS needed to achieve full T-cell activation through the contribution of CD28. The organization and composition of the membrane will directly modulate the formation of such a signaling platform, which ultimately influences cellular activation and functions. Thus, MR play a very important role in signaling by the formation of the signalosome, which are multicomponent transduction complexes. The correlation between the capacity of a molecule to be recruited into the IS and its preference for being linked to membrane rafts is still debated. However, very recent experimental evidence suggest that dynamic rafts reorganization at the IS favor T-cell activation by generating an environment where signal transduction is protected and essentially amplified [12]. Thus, the recruitment and clustering of MR within the IS segregate negative and positive actors of T-cell activation and protect TCR signaling.

Furthermore, the localization of molecules throughout the membrane is dependent on posttranslational modifications including acylation, farnesylation, and palmitoylation. Recently, it was demonstrated that LAT phosphorylation was not optimal in antigen-primed anergic CD4+ T-cells after TCR ligation [15]. It is of interest that LAT association with membrane rafts was defective in these CD4+ T-cells and this was partly explained by the impaired palmitoylation of LAT. It can be supposed that the posttranslational lipidation of the signaling molecules targeting them to MR under stimulation is altered with aging. In T-cells some of the signaling machinery is constitutively included in MR, such as the TCR, Lck, while other molecules are recruited during activation, such as CD28, IL-2R, LAT, PI3K. It is of note that we presented evidence that CD4+ and CD8+ T-cells require differential activation [10].

The signaling machinery in CD4+ T-cells relies on MR for its assembly, while in CD8+ T-cells a certain preassembly of the signalosome decreases the necessity of MR for adequate signaling. This could be perhaps explained by the differential fate of these two T-cell subpopulations. There are still numerous questions to answer on the role of MR in T-cell activation and IS formation, nevertheless, a consensus exists, which states that in a way or another MR participate in T-cell activation.

2.3 The Contribution of Membrane Lipid Rafts to the Altered-T-Lymphocyte Functions with Aging

We have reported an alteration in the function of MR with aging. MR poorly coalesce in $CD4^+$ T-cells of elderly subjects [10] although the alterations are less pronounced in the case of $CD8^+$ T-cells. We have also reported alterations in the recruitment and activation of Lck and LAT into MR of T-cells from aged humans [16]. One important finding was that CD28 and IL-2R were weakly recruited to MR in $CD4^+$T-cells of elderly subjects. In contrast, these proteins were already located to MR in $CD8^+$ T-cells from elderly subjects prior to stimulation. These observations suggested that the assembly of the signaling machinery in $CD4^+$ T-cells relies largely on MR, whereas in $CD8^+$ T-cells a preassembly of the signalosome has been suggested by us [10] and by others [6, 7].

Moreover, MR of $CD4^+$ and $CD8^+$ T-cells behave differently in polarization experiments induced by anti-TCR/CD28-coated beads. While the beads induced MR polarization to the region of contact in $CD4^+$ T-cells of young and elderly individuals, the beads failed to induce coalescence in $CD8^+$ T-cells of both groups of donors. Recently, it was supposed that the expression of CD8 gives to the cell a "dominant-negative" phenotype towards MR polarization [6] as it occurred in immature $CD4^+CD8^+$ T-cells [18]. Thus, MR functions may be settled on during T-cell selection by an unknown mechanism. Altogether these data suggest that $CD4^+$ T-cells heavily rely on MR to reach a full state of activation, while $CD8^+$ T-cells due to their pre-existing signalosome could circumvent "lipid rafting." This raised the possibility that similar age-related changes in MR cholesterol composition may affect differentially $CD4^+$ and $CD8^+$ T-cells, the former being much more affected.

To further support the hypothesis that the properties of the signalosome in $CD8^+$ T-cells differ from that of $CD4^+$ T-cells we assessed the effect of MR disruption on T-cell proliferation. Data revealed that $CD8^+$ T-cells were less sensitive to a low concentration (0.5 mM) of β-methyl cyclodextrin, a MR disrupting agent, as compared to $CD4^+$ T-cells. Whereas the proliferative response of $CD4^+$ T-cells of young and elderly donors was completely abolished, there still remained a partial response of $CD8^+$ T-cells to TCR/CD28 stimulation. These observations suggested differential intrinsic properties of MR in $CD4^+$ T-cells as compared to $CD8^+$ T-cells which may result in a differential mode of signaling. These data may also explain the differential kinetic of IL-2 production by $CD4^+$ and $CD8^+$ T-cells.

One key component of MR is cholesterol which serves to stabilize their structure and to modulate their fluidity [19]. The concentration of cholesterol was 1.6-fold higher in MR fractions from $CD4^+$ and $CD8^+$ T-cells of elderly subjects as compared to young individuals. The anisotropy of $CD4^+$ and $CD8^+$ T-cells and MR fractions prepared from these cells was increased by approximately 10% in the case of elderly donors, suggesting an inverse correlation between MR cholesterol content and plasma membrane fluidity. The cause of the increase in the concentration of cholesterol in resting T-cells with aging is not known but may be the result of an imbalance in cellular cholesterol metabolism. Preliminary data from our laboratories indicate that significant changes occur with aging in the HDL-mediated reverse cholesterol transport. This mechanism is membrane raft-dependent [20] and suggests that its deregulation may contribute to the elevated plasma membrane cholesterol content in T-lymphocytes from normolipemic elderly humans. Altogether the increased cholesterol content and decreased fluidity of the membrane found here in both T-cells subsets reinforce our previous data in T-cells [21], contributing to functional decrease, however can not give an explanation for the differential functional behavior between these T-cells subsets. In this context another question arises concerning the properties of the lipids ordering the lipid rafts. We showed a quantitative increase in rafts cholesterol with aging but changes in oxidative status should alter MR properties and functioning as well. Since $CD8^+$ T-cells possess a cytotoxic activity via their granules, they may be gifted with a higher potency towards oxidation and other aggressions than $CD4^+$ T-cells also explaining why they were less affected by immune senescence. Moreover, unsatured fatty acids were shown to inhibit T-cells activation and functions by selectively displacing signaling molecules from MR. Thus, changes in fatty acids composition may also explain discrepancies between young and elderly donors as well as between $CD4^+$ and $CD8^+$ T-cells from the same donor. We are currently addressing these questions.

In view of the alterations in plasma membrane cholesterol concentration in MR, we also analyzed the distribution of the GM1. The GM1 fluorescence intensity in $CD4^+$ and $CD8^+$ T-cells of elderly individuals was more than two-fold than that measured in the corresponding T-cells of young donors. The increase in GM1 may have critical effects on T-cell functions that depend on MR, namely the recruitment of proteins involved in the early events of signaling. In this connection, it has been reported that over-expression of membrane microdomains constituent such as GM1 in PC12 cells can suppress nerve growth factor signals by modulating signal-transducing molecules localization and plasma membrane fluidity [22]. As a corollary, high levels of GM1 in MR of resting $CD4^+$ T-cells of elderly individuals may interfere with GM1 turnover [23] resulting in defects in early T-cell signaling as well as in IL-2 production.

The end-point of MR function is to induce the formation of the IS via SMAC [24, 25]. The data of O'Keefe et al. [26] showed that the formation of SMAC is not required for activation of naïve $CD8^+$ T-cells, giving support to the differential sensitivity of activation between $CD4^+$ and $CD8^+$ T-lymphocytes. This reinforces our hypothesis that $CD4^+$ T-cells did not behave in the same manner as $CD8^+$ T-cells in aging due do their differential mode of signalling. The triggering of CD28 is a critical step for MR polarization which results in SMAC formation leading ultimately to IL-2 production [27]. Differential alterations in the CD28 signaling between $CD4^+$ and $CD8^+$ T-cells

subsets may clearly explain the functional alterations of MR with aging leading to altered signaling and function mainly in $CD4^+$ T-cells, as will be described below.

2.4 T-cell Receptor Signalling and its Changes with Aging

T-lymphocyte activation culminates in cell proliferation and differentiation into effector and memory cells. The engagement of the receptors by duly presented antigens leads to a specific response driven by the signaling cascade. At the very early step of T-cell activation there are several key events that determine the specificity and the intensity of T-cell response. The first step in TCR-mediated signaling is the activation of different tyrosine kinases, leading to the tyrosine phosphorylation of several downstream molecules. The first signal through the TCR induces the phosphorylation of Lck, via recruitment of ZAP-70 leading to LAT phosphorylation (see Figure 1) which becomes a scaffold for the recruitment of multiple partners including other adaptor proteins and enzymes involved in phospholipid metabolism such as phosphatidylinositol-3-kinase (PI3K) and phospholipase-Cγ1 (PLC-γ1). A host of experimental data support the view that many proteins involved in T-cell signaling such as $p56^{Lck}$, LAT, SLP-76, protein kinase-Cθ and Gads are recruited in MR, whereas others such as CD45 are excluded [28] or transiently associated as in the case of CD4 [29].

The activation of Lck is a very tightly controlled process, which involves phosphatases, such as CD45 and the tyrosine kinases Csk, as well as regulatory molecules, such as Cbp/PAG and FynT. The control of Lck activation involves the tyrosine phosphatase CD45 and the PTK Csk which is regulated by the MR-resident Cbp/PAG and FynT, as well as the CaMKII substrate, cytosolic resident C3BP [30–32]. Csk is a ubiquitously expressed cytosolic PTK; it plays a negative regulatory role in cells by inhibiting intracellular processes induced by Src tyrosine kinases. The Csk SH2 domain interacts specifically with several tyrosine phosphorylated molecules and among them with the recently identified adaptor-Csk-binding protein/phosphoprotein associated with glycosphyngolipid-enriched microdomains (Cbp/PAG). Cbp/PAG has been shown to be palmitoylated and targeted to rafts. In resting human T-cells Cbp/PAG is constitutively phosphorylated and this results in recruitment of Csk to the rafts. This interaction increases the catalytic activity of Csk on its substrate, thereby inhibiting Src tyrosine kinases activity. However, this interaction is reversible. The dephosphorylation of Cbp/PAG releases Csk and promotes the activation of Src kinases upon TCR stimulation. This represents a sort of threshold regulator in T-cell activation. So far, no data exist concerning the activity of these factors with aging. However, it can be hypothesized that the interaction between Cbp/PAG and Csk is altered, therefore affecting the release of Csk.

With aging there is a well-known deregulation of the immune response. This deregulation is mainly the reflection of alterations in the cellular immune response mediated by T-lymphocytes. The main alterations are the decreased proliferation due to reduced IL-2 production leading to altered clonal expansion. The causes of this decline are not well understood, however, many explanations have been proposed.

One hypothesis to explain this observation suggests alterations in TCR-dependent signaling. During the past few years our laboratory has greatly contributed to the elucidation of the multiple changes in TCR signal transduction [16]. We and others have shown that several steps of the signaling cascade following TCR ligation are altered with aging [33]. However, much effort has focused on downstream events of T-cell signaling and less attention has been given to possible alterations in upstream events [34, 35], including the assembly of signaling molecules in MR. Recently, we have presented evidence that the age-related alterations in T-cell activation are linked to changes in MR composition and function [16]. It is now well documented that other early events related to protein tyrosine phosphorylation following TCR activation are altered in T-cells with aging, such as the generation of myoinositol 1, 4, 5-trisphosphate, intracellular free calcium mobilization, and PKC translocation to the membrane. It was also shown that defects in translocation of PKC following TCR stimulation are present in T-cells of old humans [15] and mice. Recently, our work showed that the activation, that is, tyrosine phosphorylation of the upstream molecules, such as Lck and LAT was also altered with aging. Thus, with aging we observe an alteration in all activation phases of T-cell signaling. This activation via the intermediate signaling events finally should lead to the activation of NFAT and NF-kB for the production of IL-2, which is consequently also altered with aging (Fig.1).

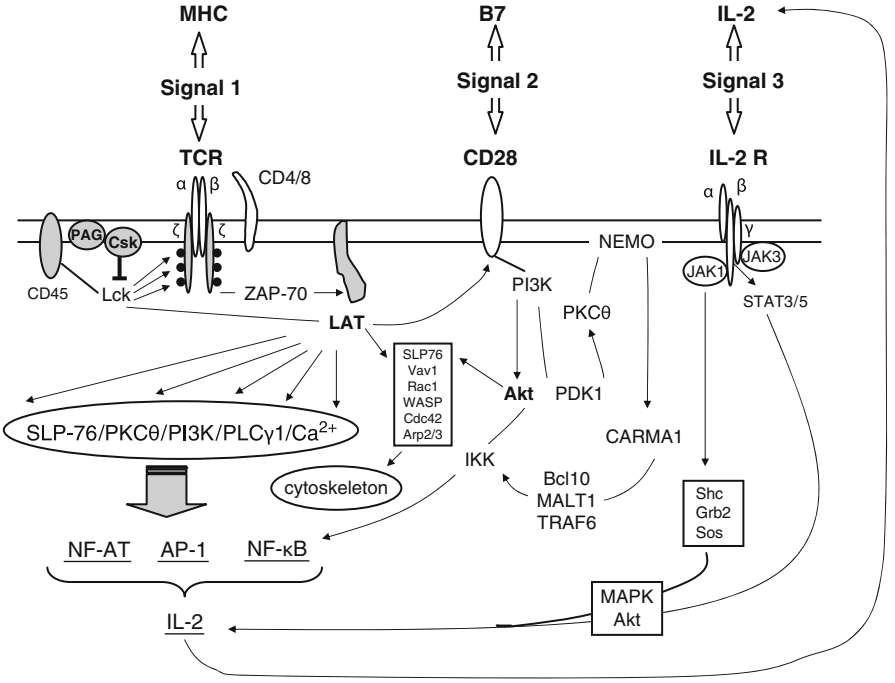

Fig. 1 Signalling pathways involved in signal 1, 2, and 3. TCR, CD28 and IL-2 receptor signalling is shown. The signalling events shown here are described and quoted throughout this review

Recently, data clearly showed that changes in MR machinery also occur in autoimmune diseases such as in systemic lupus erythematosus (SLE). Jury et al. [36, 37] demonstrated in their paper that $p56^{Lck}$ was over-associated in MR of $CD3^+$ T-cells explaining the hyperactivity of these cells in SLE patients. Based on the data presented, we suggest that the changes in MR composition and functions lead to impaired $p56^{Lck}$ activation and may be the main cause of the alterations in $CD4^+$ T-cell functions and consequently in immune senescence.

2.5 CD28 Dependent Signaling and Their Changes with Aging

For an efficient T-lymphocyte activation, the T-cell co-receptors (e.g., CD28, ICOS) should also be activated by their ligands (e.g., CD80/CD86) expressed on antigen presenting cells (APC) [38–41]. Certain pathways seem to be privileged and among them the phophatidylinositol 3-kinase (PI-3K; *See* Fig. 1). The main components of the PI-3K pathway include the following molecules PI-3K→Akt→IKK→NF-κB and PI-3K→PDK-1→PKCθ→IKK→NF-κB from which certain are recruited to MR. Interestingly, the CD28 pathway also activates the Lck, LAT, SLP-76, Grb2/GADS, Vav and the protein phosphatase PP2A [42–45]. Ultimately this co-stimulatory pathway regulate the translocation of NF-AT and NF-κB [46, 47]. The cytoplasmic tail of CD28 is phosphorylated by Lck which in turn initiate the recruitment and activation of PI-3K [48]. PI-3K initiates the translocation of Akt (PKB) in MR following its phosphorylation by PDK1. PDK1 is inserted in MR and phosphorylates PKCθ which leads to the activation of the latter molecule. The activated PKCθ recruit NEMO to MR and activates, via CARMA1 (CARD11), the complex Bcl10/MALT1/TRAF6 [43–45]. This complex induces the ubiquitination of IKK, its degradation by the proteasome and, finally the activation of NF-kB and the translocation of the Rel proteins to the nucleus. Thus, PI-3K and Akt are the essential early components for the induction of T-lymphocytes functions by the concurrent and/or individual activation of TCR et CD28 [45, 49]. All these events assure that IL-2 will be produced and secreted. As the level of CD28 expression is decreasing with aging this could contribute to the diminished production of IL-2 via an altered T-lymphocyte signaling, leading ultimately to a decreased T-lymphocyte clonal expansion.

Our recent work indicates that CD28 signaling leading to the phosphorylation of Akt is decreased mainly in $CD4^+$ T-cells from aged individuals. Akt was weakly activated in $CD4^+$ T-cells of elderly subjects but not in the case of $CD8^+$ T-cells. These data indicate a critical alteration in CD28 signaling in $CD4^+$ T-cells of elderly subjects, which can not be explained by the slight change in CD28 expression. Paradoxically, the marked increase in $CD28^{low}$ $CD8^+$ T-cells did not affect Akt activation. This further contributes to the decrease of NF-κB activation in mice and in humans already shown to be due to a decreased inactivation of IκB by the proteasome. Moreover, in view of the pleiotropic effects of Akt, its decreased activation also suggested that in $CD4^+$ T-cells, downstream signaling events including the up-regulation of the transcription factors, NF-kB and NF-AT, would be impaired and that would result in defects in

cytoskeletal rearrangements, cell cycling and ultimately in a decreased production of IL-2 in T-cells. We have also demonstrated that the CD28 number only partly explains the inability to activate adequately T-cells as Akt activation was more efficient in $CD8^+$ T-cells, having reduced CD28 co-receptors, compared to $CD4^+$ T-cells, having relatively conserved CD28 co-receptor number with aging. Our most recent results seemed to suggest that this is not the decreased number of CD28 co-receptors which plays the crucial role but the altered CD28 localization as a determinant factor of the immunosenescence [10]. Thus, changes in the CD28 co-receptor signaling might have far reaching consequences on T-cell functions in aging.

These findings explain one very important finding in immunosenescence which is the differential sensitivity of $CD4^+$ and $CD8^+$ T-cells towards activation induced cell death (AICD). $CD4^+$ T-cells are more susceptible to AICD than $CD8^+$ T-cells [50]. This can be explained by the differential signaling of CD28 towards Akt activation as this pathway mediates the survival/apoptosis of T-cells. Moreover, we already published data showing that the level of expression of a special receptor is not the best marker for cellular function but its differential membrane localization, such as for Toll-like receptors [51] and/or signaling molecules will ultimately influence cell fate and this immune function.

2.6 Convergence of TCR/CD28 Signaling Pathways in T-cells Activation and Their Changes with Aging

The signaling pathways elicited by TCR and CD28 converge for inducing the translocation of NF-κB and initiate the transcription of the IL-2 gene. It was suggested that the amplification of the signaling cascade initiated by the TCR is mainly dependent on CD28 for the polarization of MR [47]. Indeed, the engagement of CD28 induces the redistribution of MR enriched in GM1 at the site of TCR contact with APC. CD28 generates a favorable environment where the signals are protected, segregated and amplified. This prolonged physical stability between the T-lymphocyte and APC is fundamental to the production of IL-2 and to the clonal expansion of T-lymphocytes [40]. The IS formation is occurring after the MR polarization. The IS is a special spatial region highly organized containing signaling proteins, adhesion and cytoskeleton molecules [3, 24, 52, 53]. In this context, it is of note that the activation of $CD4^+$ and $CD8^+$ lymphocytes differ in their dynamics. The $CD4^+$ necessitate a prolonged activation to be able to proliferate, while a hour contact is enough in case of $CD8^+$ lymphocytes [54]. Three different studies including our suggest a differential role for MR in the activation of $CD4^+$ and $CD8^+$ cells [6, 10, 17] as described above.

In summary, with aging, there is an alteration of T-cell signaling either in signal 1 or signal 2 or both. As already described there are many alterations in the signaling cascade of T-cells, including calcium metabolism, tyrosine kinases phosphorylation, and PKC translocation to the membrane. Moreover, it is now well accepted that there are alterations in the very early stages of the signaling cascade, that is, in the composition and function of MR. There is an increase in cholesterol and sphingolipid content,

while a decrease in Lck and LAT tyrosine phosphorylation was observed. Not only was the composition of membrane raft found altered but also their functions. With aging MR polarize much less than do those of young subjects. These changes, taking into account what was described above concerning the role of MR in IS formation, underline the functional changes observed in T-cells with aging. It is of note that various subpopulations of T-cells are differently affected. $CD4^+$ cells are most affected by these signal transduction changes with aging, whereas although $CD8^+$ T-cells are also affected, their reactivity is better maintained than that of $CD4^+$ T-cells. Nevertheless, one should also consider the changes within CD8 and CD4 susbets, i.e., naïve versus memory cells. This will need further investigations to identify whether the loss of cellular functions and signaling are only due to loss of CD28 expression (in the memory cells) or has another origin.

2.7 IL-2 Signalling and its Changes with Aging

IL-2 is one of the most important cytokine for T-cells representing the "signal 3" for the efficient clonal expansion of T-cells under antigenic stimulation [55]. IL-2 receptor is composed of several subunits having specific role, however only the β subunit is involved in the signaling initiation [56, 57]. Whether this subunit is associated with MR for effective signaling is still controversial. Nevertheless, the signaling cascade is well known. The ligand attachment to the IL-2 receptor is initiating the activation by tyrosine phosphorylation of Janus kinases 3 (JAK3), which in turn activates the signal transducer and activator of transcription 3 and 5 (STAT3 and STAT5) [58, 59]. This results in the translocation to the nucleus of these transcription factors which initiates the cellular response of proliferation [60]. The Jak/STAT pathway is a rapid intracellular communication system used by many cytokines and growth factors to mediate signals from the plasma membrane to the nucleus in order to regulate proliferation and differentiation of most tissue types (*See* Fig. 1). These pathways play a crucial role in the induction of the T-cell response to these cytokines namely clonal expansion [60, 61]. Many factors are controlling the Jak/STAT pathways which are also zinc dependent [62]. Furthermore, the Jak/STAT is one of the signaling pathway which is sensitive to redox conditions [63, 64].

In T-cells from elderly individuals we reported recently an alteration in IL-2 receptor signal transduction resulting in decreased JAK3 and STAT3/5 activation [65]. Thus, aging is accompanied with a signaling defect of the cytokine receptors IL-2 independently of the receptor number, as was already demonstrated [21] except for the very elderly aged over 90 years. This latter phenomenon seems to be in accordance with studies demonstrating less immune dysfunction in old old compared to young old individuals suggesting a contribution of an intact immune system to longevity. It is of note that zinc supplemented at physiological doses could not modulate the altered IL-2 signaling of individuals aged up to 90 years old. This suggests that either the normal zinc levels in T-cells are not sensitive to a supplementation or that the zinc mediated processes including anti-oxidant, anti-inflammatory, membrane physiology

maintenance are not major players in the altered signaling. Indeed, as we have shown, one of the basic age-related alterations affects the membrane composition [10]. In contrast, over 90 years old, the zinc could reverse the negative signaling effect of IL-2 indicating that the physiological behavior of T-cells of old–old individuals is fundamentally different. This needs further studies to determine the mechanism by which zinc is acting but it can be hypothesized that the inhibitory molecules like Protein inhibitor of activated STATs (PIAS) can be more efficiently modulated at this age [66]. This indicates that in T-lymphocyte activation one should always take into account the negative regulatory factors too.

3 Membrane Lipid Rafts and Cytoskeleton

T-cell activation involves F-actin rearrangements. Several molecules which are associated with DRM participate in tethering DRM to the actin cytoskeleton. Actin polymerization is regulated by the RhoGTPase Rac1 which activates WASP and Cdc42 which upreglulates the activity of Scar/WAVE. Activation of WASP and WAVE stimulates F-actin branching by upregulating the activity of the Arp2/3 complex [67]. The interaction between DRM and the actin cytoskeleton works in two directions: DRM-associated proteins regulate F-actin rearrangements whereas the actin cytoskeleton serves to induce and sustain DRM polarization in activated cells. During the formation of IS, CD28 is responsible for actin rearrangement and the coalescence of DRM. In addition, the adaptors Vav1 and Slp76 are key regulators of actin rearrangements required for the accumulation of signaling molecules/DRM at the T-cell/APC interface. The upregulation of Vav1 activity by CD28 is achieved through Lck. Thus, Lck is involved in CD28-related actin remodeling, MR coalescence and T-cell activation. A decade ago, it was found that F-actin polymerization was altered in T-cells of elderly under stimulation. No data in relation to MR exist, however, considering the alterations found in their composition and function in T-cells with aging we can suggest that the F-actin rearrangements could also be deficient in aging. Taken together, it can be concluded that with aging there is an alteration in T-cell activation due to a deregulation of the intracellular signaling pathways via an alteration of the T-cell membrane composition leading to altered functions, such as proliferation and IL-2 production. Although F-actin polymerization has been reported to be altered in lymphocytes of aged mice [68], there are no data in T-cells with respect to actin reorganization in young or elderly subjects and the relationship to MR.

4 Negative Regulation of T-Lymphocyte Activation and its Changes with Aging

Lymphocytes are not only positively activated by kinases but also negatively. This can be at the level of various molecules of the signaling cascade or the termination of the activation process. One way to negatively regulate T-lymphocyte activation is

through protein phosphatases (PPases). In addition to the kinase component of T-cell activation, it exists other enzymes which intervene in the negative regulation of the signaling cascade such as the PPases and the phosphatidylinositol (PtdIns) phosphatases [69, 70]. The most important targets of PPAses are the activation pathways of Lck and PI-3K. SHP-1 dephosphorylates and inhibits PI-3K [47, 71]. The PPase SHIP and the PtdIns phosphatase PTEN converge for the negative regulation of PI-3K. While SHIP hydrolyses the phosphate groups on phosphotyrosine residues of PI-3K, the PTEN cut the phosphate groups in position 3 of PtdIns-3, 4, 5 trisphosphates, destroying recognition site by the PH domain of PI-3K [71–73]. The activity of PPases, which is as finely regulated as that of protein kinases, ultimately also depends on their interaction with MR. This is clearly demonstrated for the modulation of CD45 activity [74–76] and as we have demonstrated for the PPase SHP-1 [77]. CD45, when located in MR has a positive effect on Lck activation, while when CD45 is displaced, such as in the quiescent state, Lck is inactivated. We have recently shown a similar phenomenon for SHP-1 in neutrophils [77]. There is more and more experimental evidence that the balance between tyrosine kinases and phosphatases is essential for the maintenance of the resting status and for activation, which can predict alterations with aging. Only a few data exist concerning phosphatase activity in T-cells with aging. CD45 is a receptor-like phosphatase expressed on all nucleated hematopoietic cells. One key function of CD45 is to serve as a positive regulator of Src tyrosine kinases, by opposing Csk function, and dephosphorylating the negative regulatory C terminal tyrosine of Src tyrosine kinases. CD45-protein tyrosine phosphatase activity in old T-cells was found to be decreased compared to young cells [78]. However, it may be necessary to reassess the behavior of CD45 under activation in terms of its involvement in the IS, from which it is usually excluded upon T-cell activation. Our own studies using cholesterol repletion of T-cells from young subjects, being a partial aging model of T-cells, suggest alterations in phosphatase activities (our unpublished data). Furthermore, because in neutrophils which are very short-lived cells important alterations were found for SHP-1 activity, it can be suggested that phosphatase activities might also be altered with aging in long-lived cells such as T-cells. Our very recent data indicate that there is much more SHP-1 content in the membrane of T-cells from elderly compared to young subjects [79]. The activity of SHP-1 is also increased in T-cells of elderly as determined by tyrosine phosphorylation following anti-CD3 and anti-CD28 stimulations compared to identical conditions in T-cells of young subjects. The exact significance of this increased activity is not well understood, but could have a negative effect on Lck activation [80]. Altogether, there are interestingly very few data concerning the phosphatase activity in relation to TCR activation. Certainly, no data exist concerning their association/recruitment to MR. This should be further explored in the future.

The other way to negatively regulate T-lymphocyte activation is by scaffold Homer proteins. The Homer proteins are composed of three members. These proteins expressed in several tissues were found in MR of glial cells. These Homer proteins were, until very recently, associated to Ca^{2+} mobilization, following their interaction with TRP canonics (TRPC) [81]. However a recent publication of Huang and al [82] clearly demonstrate that Homer2 and Homer3 are negative regulators of lymphocyte activation. These proteins compete with calcineurin for NF-AT. This

competition stops the calcineurin-dependent dephosphorylation of NF-AT and its subsequent translocation to the nucleus. These results raise the possibility that Homer (1, 2 ou 3) could be differentially recruited in MR of lymphocytes in elderly subjects. A preferential and sustained recruitment of Homer in MR could contribute to the diminution of the immune response of elderly subjects.

Thus, most of the early signaling events were shown to be altered with aging in human T-cells especially in $CD4^+$ T-cells. Thus, it would be very difficult to assign the alteration in T-cell activation to any of the participating signaling molecules. Then, what can be the cause of these signaling alterations in T-cells occurring during immunosenescence? Could a common change explain this signaling alteration in T-cells upon activation? Investigations in the late 1980s already suggested that biochemical and biophysical alterations of the cell membrane could be responsible for the altered immune response with aging. Alterations in the lipid composition and fluidity of the cell membrane were found [83]. One explanation that is naturally emerging is the changes at the membrane level either qualitatively or quantitatively.

5 Membrane Composition Changes with Aging: Role of Cholesterol

It was suggested several decades ago that the T-cell membrane from elderly subjects is more rigid than that of young subjects [83]. We recently presented evidence that an increase in free cholesterol could explain these physicochemical changes observed about 20 years ago [19]. There is a twofold increase in the T-cell membrane cholesterol content with aging. Cholesterol is an essential component of the membrane as it maintains a certain order in the plasma membrane structure, as it is now well recognized, through the MR (*See* Fig. 2). This increase in cholesterol content leads to the contention that if we can extract the overcharge we would be able to restore T-cell functions. Unfortunately, until now only partial restoration of the functions was obtained. Methyl-β-cyclodextrin (MBCD) used in small quantities has so many other membrane disturbing effects that no functional improvement was observed in T-cells of elderly [21, 84]. Statin (which inhibits cholesterol synthesis via the inhibition of the HMG-CoA reductase) used at high concentrations necessary to see a reduction in cellular cholesterol levels in Jurkat cells resulted in apoptotic death [51]. The only known physiological cholesterol extracting agent is high-density lipoprotein (HDL). HDL via the reverse transport of cholesterol is able to decrease the membrane cholesterol content very rapidly, but it was much less efficient in case of T-cells of elderly (our unpublished data). Nevertheless, the proliferation and IL-2 production of T-cells of elderly were slightly improved.

The other way to assess the role of cholesterol is to replenish the membrane of T-cells of young subjects with cholesterol to the level observed in T-cells of elderly subjects. Our results with the replenishment with free cholesterol have shown a decrease in proliferation and IL-2 secretion, such as observed in immunosenescence. Thus, increased cholesterol in the membrane of T-cells from young subjects

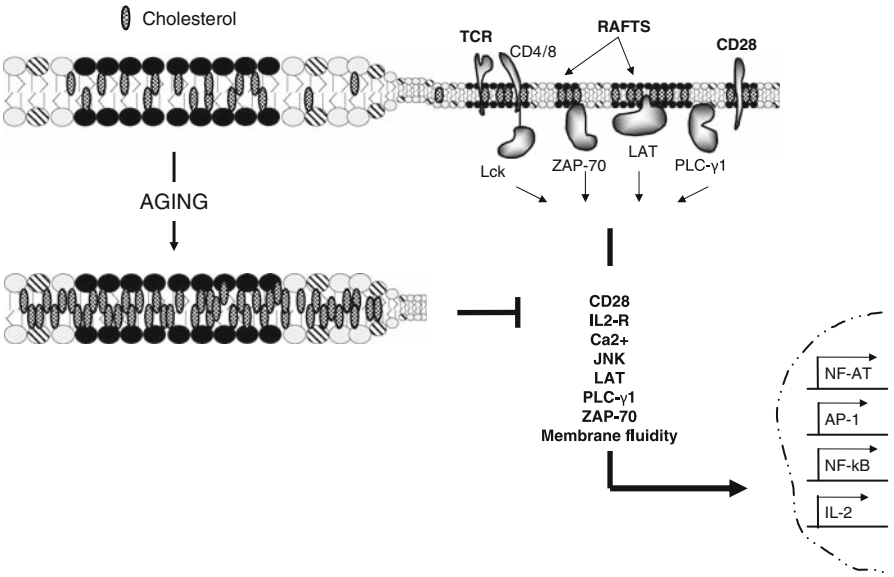

Fig. 2 Age-associated alterations in TCR signaling. TCR signaling events which are altered with aging are depicted here. Non-cited molecules or pathways are not changing with age. The relevant reference can be find throughout this review

rendered them functionally aged. In the mean time the GM-1 content in the membrane is increased. There is no explanation why the cholesterol is increasing as the serum cholesterol content is remaining unchanged in elderly subjects. It could be that the cholesterol uptake is dysregulated, the intracellular cholesterol production via the HMG-CoA reductase can be increased, or that the reverse cholesterol transport assured by HDL is deficient. Our recent experimental data seem to indicate that the reverse transport of cholesterol by HDL is indeed altered in T-cells with aging.

6 Do Membrane Rafts Properties Contribute to Human Immunosenescence?

Considering all the changes described above the question naturally arises what is the role of MR and could changes in their composition and in their function contribute to the altered T-cell activation observed during immunosenescence? The experimental data presented so far seem to support a positive answer to this question. With aging, as described above, we demonstrated an alteration in the function of the MR as they are almost unable to coalesce in $CD4^+$ T-cells with aging. The alterations are less dramatic for $CD8^+$ T-cells. We have demonstrated an alteration in the recruitment and activation of Lck and LAT into MR. In this context one of the most important findings is that the CD28 as well as the IL-2R cannot be recruited to the membrane rafts in $CD4^+$ T-cells of elderly subjects explaining

the alteration of the signaling of these receptors with aging. In contrast, in $CD8^+$ T-cells these receptors are already recruited to the MR. Thus, the age-associated alterations in their properties include the increase in cholesterol content, impaired coalescence, and selective differences in the recruitment of key proteins involved in TCR signaling. It can be thus hypothesized taking into account these experimental data that the increased rigidity of the membrane following the increase in cholesterol content limits MR functionality. This loss of function leads to the inability to recruit to the IS the necessary machinery or alternatively to exclude the nonparticipating molecules to reach an adequate activation, which is a hallmark of immunosenescence.

7 Conclusion

With aging we observe an alteration of the immune response collectively designated as immunosenescence. One of its most striking aspects is the altered T-cell activation for clonal expansion by specific antigens. The causes of this decreased activation are not completely known. Recent studies shed light on the role of signaling alterations following TCR and CD28 ligation. The final outcome of protein rafting is the formation of the IS, which is needed to sustain the activation, which will result in a proper immune response. We can document changes in molecular events with aging, but we are not yet able to explain these changes. The ultimate defect in signaling can be explained by the newly discovered membrane rafts alterations in composition, function, and size with aging. These functional and physicochemical properties are influenced by intrinsic as well as extrinsic factors. Understanding the events that lead to changes in the TCR signaling cascade would be of great benefit considering the large number of diseases in which MR dysfunction is thought to play a role. Altogether these data suggest that MR alterations in T-cells do contribute to immunosenescence.

Acknowledgments This work was partly supported by a grant-in aid from the Canadian Institute of Health Research (No 63149), Research Center on Aging, the Faculty of Medicine of the University of Sherbrooke, ZINCAGE project (EU contract n. FOOD-CT-2003-506850), T-cells and Aging "T-CIA" (QLK6-CT-2002 02283), the Deutsche Forschungsgemeinschaft (DFG PA 361/11-1 and SFB 685-B4), the Fortune Program (of Tübingen University Medical School). We thank the Clinical Research Center for assistance and access to microscopes.
