

Maternal, Neonatal, and Women's Health Nursing

*Lynna Y. Littleton, RNC, PhD
and*

*Joan C. Engebretson, RN,
DrPH, HNC*

Delmar / Thompson Learning

BRIEF CONTENTS

UNIT I: FOUNDATIONS OF NURSING CARE

CHAPTER 1: NURSING IN THE CONTEMPORARY HEALTH CARE SYSTEM 1 3

CHAPTER 2: ISSUES IN MATERNAL, NEONATAL, AND WOMEN'S HEALTH 29

CHAPTER 3: THEORETICAL PERSPECTIVES ON THE FAMILY 49

CHAPTER 4: COMPLEMENTARY AND ALTERNATIVE THERAPIES 77

CHAPTER 5: ETHICS, LAWS, AND STANDARDS OF CARE 113

CHAPTER 6: HOME VISITING PROGRAMS AND PERINATAL NURSING 139

UNIT II: HEALTH CARE OF WOMEN 163

CHAPTER 7: DEVELOPMENT OF WOMEN ACROSS THE LIFE SPAN 165

CHAPTER 8: NUTRITION FOR WOMEN ACROSS THE LIFE SPAN 185

CHAPTER 9: HEALTH CARE ISSUES FOR WOMEN ACROSS THE LIFE SPAN 221

CHAPTER 10: COMMON CONDITIONS OF THE REPRODUCTIVE SYSTEM 257

CHAPTER 11: VIOLENCE AND ABUSE 297

UNIT III: HUMAN SEXUALITY ACROSS THE LIFE SPAN 327

CHAPTER 12: SEXUAL AND REPRODUCTIVE FUNCTION 329

CHAPTER 13: GENETICS AND GENETIC COUNSELING 355

CHAPTER 14: FAMILY PLANNING 383

UNIT IV: PREGNANCY 411

CHAPTER 15: NORMAL PREGNANCY 413

CHAPTER 16: MANAGEMENT AND NURSING CARE OF THE PREGNANT WOMAN 453

CHAPTER 17: CHILDBIRTH PREPARATION AND PERINATAL EDUCATION 477

CHAPTER 18: MANAGEMENT AND NURSING CARE OF THE HIGH-RISK CLIENT 507

CHAPTER 19: PREGNANCY IN SPECIAL POPULATIONS 541

UNIT V: ASSESSMENT OF FETAL WELL-BEING 581

CHAPTER 20: FETAL DEVELOPMENT 583

CHAPTER 21: ENVIRONMENTAL RISKS AFFECTING FETAL WELL-BEING 605

CHAPTER 22: EVALUATION OF FETAL WELL-BEING 643

UNIT VI: CHILDBIRTH 675

CHAPTER 23: PROCESSES OF LABOR AND DELIVERY 677

CHAPTER 24: ANALGESIA AND ANESTHESIA IN LABOR AND DELIVERY 709

CHAPTER 25: INTRAPARTUM NURSING CARE 739

CHAPTER 26: HIGH-RISK BIRTHS AND OBSTETRIC EMERGENCIES 811

CHAPTER 27: BIRTH AND THE FAMILY 851

UNIT VII: POSTPARTUM HEALTH AND NURSING CARE 875

CHAPTER 28: NORMAL POSTPARTUM NURSING CARE 877

CHAPTER 29: POSTPARTUM FAMILY ADJUSTMENT 929

CHAPTER 30: LACTATION AND NURSING SUPPORT 955

UNIT VIII: NEWBORN DEVELOPMENT AND NURSING CARE 1009

CHAPTER 31: PHYSIOLOGIC AND BEHAVIORAL TRANSITION TO EXTRAUTERINE LIFE 1011

CHAPTER 32: ASSESSMENT AND CARE OF THE NORMAL NEWBORN 1039

CHAPTER 33: NEWBORN NUTRITION 1099

CHAPTER 34: NEWBORNS AT RISK RELATED TO BIRTH WEIGHT AND PREMATURE DELIVERY 1121

CHAPTER 35: NEWBORNS AT RISK RELATED TO CONGENITAL AND ACQUIRED CONDITIONS 1167

CHAPTER 36: DEVELOPMENTAL CARE OF THE INFANT AT RISK 1197

UNIT IX: SPECIAL CONSIDERATIONS 1237

CHAPTER 37: GRIEF AND THE FAMILY IN THE PERINATAL EXPERIENCE 1239

CHAPTER 38: COMMUNITY AND HOME HEALTH CARE NURSING FOR THE HIGH-RISK INFANT 1269

APPENDIX A: STANDARDS OF HOLISTIC NURSING PRACTICE 1291

APPENDIX B: ABBREVIATIONS, ACRONYMS, AND SYMBOLS 1296

GLOSSARY 1301

INDEX 1313

Maternal, Neonatal, and Women's Health Nursing

Maternal, Neonatal, and Women's Health Nursing

Lynna Y. Littleton, RNC, PhD

Director of the Women's Health Care Nurse Practitioner Program
Women's Health Nurse Practitioner
Associate Professor of Clinical Nursing
University of Texas Health Science Center at Houston
Houston, Texas

and

Joan C. Engebretson, RN, DrPH, HNC

Associate Professor
Nursing for Target Populations/Head of Division of Women and Childbearing Families
University of Texas Health Science Center at Houston
Houston, Texas

CHAPTER 3: THEORETICAL PERSPECTIVES ON THE FAMILY**Family System of Structure and Function**

Traditional or Nuclear Family	51
Childless Dyads	52
Extended Family	52
Communal Family	53
Unmarried Heterosexual (Cohabitation) Family	53
Homosexual Family	53
Single-Parent Family	54

Theoretical Frameworks

Developmental Theories	61
Interactional or Structural-Functional Theory	62
Role Theory	63
Systems Theory	63

Cultural Issues that Influence Families

Lower Birth Rate and Longer Life Span	64
Economics	64
Cultural Diversity	66
Choice of Marriage Partner	66
Changing Role of Women	67

Provider Models

Family Dynamics	68
Biopsychosocial Model	68
Resiliency Model of Family Stress, Adjustment, and Adaptation	70
Proactive Model for Enabling and Empowering Families	71

Nursing Implications**CHAPTER 4: COMPLEMENTARY AND ALTERNATIVE THERAPIES****Contemporary Use of Complementary Therapies Differentiating Alternative from Complementary Therapies****Background and Classification of Modalities**

Systems of Healing	82
Healing Approaches Congruent with Self-Healing	85

Complementary Modalities

Physical Manipulation	86

Implications for Research	103
Implications for Practice	103
Nursing Process	105
Assessment	105
Nursing Diagnoses	105
Outcome Identification	105
Planning	105
Nursing Intervention	105
Evaluation	107

CHAPTER 5: ETHICS, LAWS, AND STANDARDS OF CARE

Ethical Issues	113
Basic Ethical Perspectives	115
Ethical Principles	119
Code for Nurses	120
Ethical Decision-Making Model	121
Selected Dilemmas in Maternal-Child Practice	123
Legal Issues	130
Basic Legal Concepts	130
Standards of Care	131
Practicing Safely in Perinatal Settings	131
Legal Issues in Maternal-Child Practice	134
Practice Implications for Maternal-Child Nursing	135

CHAPTER 6: HOME VISITING PROGRAMS AND PERINATAL NURSING

Historical Background	140
Community Health Concepts	141
Defining Home Visitation	142
Site of Service Delivery	142
Relationship Building	142
Indications for Home Visitation	143
Provision of Acute Care	143
Health Promotion	144
Principles of Home Visitation	144
Efficacy of Home Visitation	147
Essential Skills for Home Visiting	148
Nursing Process	150
Assessment	150
Nursing Diagnoses	150
Outcome Identification	150
Planning	150
Nursing Interventions	151
Evaluation	151
Case Management	152
Making the Home Visit	152

Previsit Preparation	152	Obesity	211
Visiting the Home	155	Heart Disease	211
Postvisit Activities	157	Osteoporosis	213
Challenges of Home Visitation	158	Cancer	213
Meeting Multiple Needs	158	Nursing Implications	214
Fostering Self-sufficiency	158		
Physical and Emotional Overload	158		
Responding to Client Diversity	159	CHAPTER 9: HEALTH CARE ISSUES	
Cost and Reimbursement	159	FOR WOMEN ACROSS THE LIFE SPAN	221
Terminating the Home Visiting Relationship	159	Historical Perspective of Women's Health	222
		History of Reproductive Health Care in the U.S.	222
		Current View of Women's Health Care	223
		Sociocultural Influences	224
		Women's Health as a National Priority	225
		National Response to Women's Health Issues	225

211

Benign Pelvic Conditions	283	CHAPTER 13: GENETICS AND GENETIC COUNSELING	355
Malignant Pelvic Conditions	284	Chromosomal Basis of Inheritance	357
Nursing Implications	286	Chromosome Number and Structure	357
Menopause	288	Patterns of Chromosome Anomalies	358
Vasomotor Instability	288	Distribution of Chromosomes During Cell Division	359
Urogenital Atrophy	289	Gene Structure and Function	361
Psychologic Conditions	289	Single Gene (Mendelian) Inheritance	362
Long-Term Considerations	289	Dominant Gene Inheritance Pattern	363
Nursing Implications	290	Recessive Gene Inheritance Pattern	364
CHAPTER 11: VIOLENCE AND ABUSE	297	Polygenic and Multifactorial Inheritance	366
Intimate Partner Violence	298	Single-Gene Disorders	367
Sexual Assault	298	Autosomal Dominant Disorders	367
Violence During Pregnancy	300	Autosomal Recessive Disorders	369
Emergency Department Visits	302	X-Linked Disorders	371
Primary Care of Abused Women	303	Chromosome Abnormalities	372
Post-Traumatic Stress Disorder	305	Numerical Abnormalities of the Autosomes	372
Cultural Influences	306	Numerical Abnormalities of the Sex Chromosomes	373
Stalking	306	Structural Chromosomal Abnormalities	374
Impact in the Workplace	307	Genetic Screening	374
Portrait of an Abuser	308	Genetic Counseling	375
Nursing Implications	310	Prenatal Diagnosis	376
The Cycle of Violence	311	Nursing Implications	378
Violence Against Children	312	CHAPTER 14: FAMILY PLANNING	383
Child Abuse	313	Reproductive Decision-Making	384
Child Sexual Abuse	314	Factors Affecting Reproductive Choices	385
Children Witnessing Violence	314	Readiness for Decision-Making	386
Nursing Responsibilities	315	Contraceptive Methods	388
Violence Against Older Persons	317	Reversible Methods	388
Characteristics	317	Permanent Methods	407
Signs	317	Nursing Implications	408
Nursing Responsibilities	318	UNIT III: HUMAN SEXUALITY ACROSS THE LIFE SPAN	327
Special Case: Female Circumcision	318	CHAPTER 12: SEXUAL AND REPRODUCTIVE FUNCTION	329
		Normal Sexual Differentiation	330
		Female Reproductive Function	331
		Male Reproductive Function	334
		Sexuality	335
		Human Sexual Response	336
		American Sexual Practices	337
		Sexual Dysfunction	339
		Female Sexual Dysfunction	340
		Male Sexual Dysfunction	341
		Evaluation of Sexual Dysfunction	341
		Infertility	343
		Factors Affecting Fertility	343
		Assessment of the Infertile Couple	345
		Nursing Implications	352
		UNIT IV: PREGNANCY	411
		CHAPTER 15: NORMAL PREGNANCY	413
		Signs of Pregnancy	414
		Presumptive Signs	414
		Probable Signs	415
		Positive Signs	416
		Expected Date of Delivery	416
		Physiologic Adaptation to Pregnancy	417
		Reproductive System	417
		Breasts	419
		Hematologic System	419
		Cardiovascular System	421
		Respiratory System	422
		Gastrointestinal System	424
		Endocrine System	425
		Changes in Metabolism	427
		Urinary System	428

Integumentary System	430	Nursing Diagnoses	472
Musculoskeletal System	431	Outcome Identification	473
Eyes	431	Planning	473
Discomforts of Pregnancy	431	Nursing Intervention	473
Nausea and Vomiting of Pregnancy	433	Evaluation	473
Heartburn	433		
Constipation	434	CHAPTER 17: CHILDBIRTH PREPARATION	
Fatigue	434	AND PERINATAL EDUCATION	477
Frequent Urination	434	From Childbirth Education to Perinatal	
Epistaxis and Nasal Congestion	434	Education	479
Varicosities	435	History of Childbirth Education	479
Hemorrhoids	435	Methods of Childbirth Preparation	479
Back Pain	436	Lamaze Method of Psychoprophylaxis	480
Leg Cramps	436	Dick-Read Method	480
Health Promotion	436	Bradley Method	481
Psychosocial Adaptations to Pregnancy	438	Kitzinger's Psychosexual Method	482
Psychologic Responses to Pregnancy	438	Water Immersion	482
Becoming a Mother	439	Theoretical Basis for Childbirth Preparation	483
Becoming a Father	441	Relaxation Theories	483
The Family	442	Pain Management Theories	483
Siblings	443	Research Related to Childbirth Preparation	484
Grandparents	443	Strategies for Labor Management	484
Cultural Caring	444	Relaxation Techniques	484
Complementary Therapies	445	Acupressure	489
Nursing Process	445	Support during Labor	489
Assessment	445	Parenting, Role Transition, and Family	
Nursing Diagnosis	446	Adaptation	491
Outcome Identification	446	Additional Classes Offered to Childbearing	
Planning	446	Families	491
Nursing Intervention	446	First Trimester–Early Pregnancy Class	492
Evaluation	446	Pregnancy Exercise Classes	492
		Breast-Feeding Classes	492
CHAPTER 16: MANAGEMENT AND NURSING		Sibling Classes	494
CARE OF THE PREGNANT WOMAN	453	Grandparent Classes	495
Benefits of Early Care	454	Vaginal Birth after Cesarean Preparation	495
Preconception Care	455	Infant Care Classes	495
Preconception Assessment	455	Preparation for the Educator Role	495
Early Interventions	456	Organizations that Support and Certify Childbirth	
Prenatal Care	456	Educators	497
Availability and Accessibility of Care	456	Principles of Adult Learning	498
Facilitation of Client Access to Care	456	Group Process	498
Components of Prenatal Care	457	Cultural Considerations in Childbirth	
The Initial Prenatal Visit	457	Preparation	499
Subsequent Visits	462	Variables Influencing the Need for Childbirth	
Discomforts of Pregnancy	468	Preparation	500
Urinary Frequency	469	Choice of Provider	501
Nausea and Vomiting	469	Choice of Delivery Setting	501
Indigestion	469	Home Birth	501
Constipation and Hemorrhoids	469	Free-Standing Birth Center	502
Edema of Lower Extremities	469	Birth Center in a Hospital	502
Danger Signs to be Reported	470	Labor, Delivery, and Recovery Unit	502
Nursing Process	472	Labor, Delivery, Recovery, and Postpartum Unit	502
Assessment	472	Nursing Implications	502

CHAPTER 18: MANAGEMENT AND NURSING CARE OF THE HIGH-RISK CLIENT	507
Hemorrhagic Disorders	508
Abortion	508
Ectopic Pregnancy	510
Placental Abnormalities	510
Placenta Previa	510
Abruptio Placentae	512
Labor Disorders	514
Incompetent Cervix	514
Preterm Labor and Premature Rupture of Membranes	514
Postterm Pregnancy	517
Disorders of Amniotic Fluid Volume	517
Polyhydramnios	517
Oligohydramnios	518
High-Risk Fetal Conditions	518
Multiple Gestation	518
Rh Isoimmunization and ABO Incompatibility	519
Nonimmune Hydrops Fetalis	521
Hypertension	521
Endocrine Disorders	524
Diabetes	524
Hypothyroidism	526
Hyperthyroidism	527
Cardiovascular Disorders	527
Clinical Presentation	527
Management	528
Nursing Care	529
Pulmonary Disorders	529
Asthma	529
Tuberculosis	530
Autoimmune Disease	531
Systemic Lupus Erythematosus	531
Hematologic Disorders	532
Immunological Idiopathic Thrombocytopenic Purpura	532
Sickle-Cell Disease	533
Neurologic Disorders	534
Seizure Disorders	534
Nursing Implications	535

CHAPTER 19: PREGNANCY IN SPECIAL POPULATIONS	541
Pregnancy in Adolescence	542
Incidence and Significance	543
Adolescent Psychosocial Development	546
Issues Related to Adolescent Sexuality, Pregnancy, and Parenting	550
Nursing Implications	557
Pregnancy in HIV-Infected Women	562
Incidence and Significance	562
Screening, Testing, and Diagnosis	563

Pregnancy in Women over Age 35	571
Incidence and Significance	571
The Effects of Age on Reproduction	572
Nursing Implications	574

UNIT V: ASSESSMENT OF FETAL WELL-BEING 581

CHAPTER 20: FETAL DEVELOPMENT	583
Cell Division	584
Implantation and Fertilization	584
Placenta	587
Functions of the Placenta	587
Placental Circulation	588
Fetal Circulation	589
Newborn Circulation	591
Umbilical Cord	592
Membranes and Amniotic Fluid	592
Embryonic and Fetal Development	592
Embryonic Stage	592
Fetal Stage	598

CHAPTER 21: ENVIRONMENTAL RISKS AFFECTING FETAL WELL-BEING	605
Risks Related to Geographic Location	606
Nuclear and Chemical Accidents	607
Pesticides	607
Industrial Contaminants	608
Rural or Urban Residence	609
Warfare and Political Violence	610
Risks Related to Employment	611
Heat and Radiation	611
Chemical Exposure	612
Fatigue and Physical Risks	613
Stress	614
Risks Related to Home Environment and Lifestyle	615
Food Additives and Contaminants	615
Medications	616
Alcohol Use	621
Tobacco Smoking and Passive Smoke	622
Illicit Drug Use	624
Infections	625
Nursing Process	632
Assessment	633
Nursing Diagnoses and Outcome Identification	633
Planning	634
Nursing Intervention	634
Evaluation	634
Future Directions: Improving Public Awareness and Policies for Pregnancy Safety	634

CHAPTER 22: EVALUATION OF FETAL WELL-BEING

Evaluation of Fetal Well-Being

- Purpose
- Process
- Consequences

Genetic and Biochemical Evaluation

- Invasive Fetal Diagnostic Studies
- Maternal Serum Studies

Physical and Physiological Surveillance

- Fetal Imaging
- Fetal Heart Rate Monitoring
- Fetal Behavior Studies

Nursing Process

- Assessment
- Nursing Diagnoses
- Outcome Identification
- Planning
- Nursing Intervention
- Evaluation

Future Directions

UNIT VI: CHILDBIRTH

CHAPTER 23: PROCESSES OF LABOR AND DELIVERY

Physiology of Labor

- Theories for the Onset of Labor
- Mechanisms of Labor

Signs and Symptoms of Impending Labor

- Lightening
- Cervical Changes
- Braxton Hicks Contractions
- Bloody Show
- Energy Spurt
- Gastrointestinal Disturbances

Stages of Labor

- First Stage
- Second Stage
- Third Stage
- Fourth Stage

Interventions of Labor

- Labor Induction
- Cervical Ripening Methods
- Amniotomy
- Augmentation of Labor
- Forceps-Assisted Birth
- Vacuum-Assisted Birth
- Cesarean Section

Maternal Adaptations to Labor

- Hematologic System
- Cardiovascular System

- Respiratory System
- Renal System
- Gastrointestinal System
- Endocrine System
- Fetal Adaptations to Labor**
- Fetal Heart Rate
- Fetal Respiratory System
- Fetal Circulation

CHAPTER 24: ANALGESIA AND ANESTHESIA IN LABOR AND DELIVERY

Theories of Pain and Pain Management

Analgesia and Anesthesia

- Types of Anesthesia
- Types of Anesthesia Providers

Pain in Labor and Delivery

- Types of Pain
- Considerations in Medication for Pain

Analgesia in Labor

- Nonpharmacologic Methods
- Parenteral Analgesia
- Regional Analgesia

Anesthesia for Delivery

- Local Infiltration
- Regional Anesthesia
- General Anesthesia
- Special Considerations for Cesarean Section

Postdelivery Care for the Client Receiving

Anesthesia

- Local Anesthesia
- Regional Anesthesia
- General Anesthesia

CHAPTER 25: INTRAPARTUM NURSING CARE

Assessment of the Physiologic Processes of Labor

- Maternal Status
- Fetal Status
- Labor Status
- General Systems Assessment
- Setting Priorities and Making Decisions
- Maternal-Family Support and Interactions
- Psychologic Considerations During the Latent Phase of Labor
- Documentation and Communication
- Laboratory Tests
- Nursing Responsibilities During Labor**
- First Stage
- Second Stage
- Third Stage
- Fourth Stage (Recovery)

Precipitous Delivery

Delivery in a Nonhospital Setting

CHAPTER 26: HIGH-RISK BIRTHS AND OBSTETRIC EMERGENCIES	811	CHAPTER 28: NORMAL POSTPARTUM NURSING CARE	877
Dysfunctional Labor Pattern	813	Postpartum Care	878
Hypertonic Labor	814	Mother-Baby Nursing	878
Hypotonic Labor	818	Infant Security	879
Precipitate Labor	818	Hospital Length of Stay	879
Fetal Malpresentation and Malposition	820	Clinical Assessment	880
Breech Presentation	820	Nursing Approach to Cultural Sensitivity	881
Shoulder Presentation	823	Vital Signs	881
Face Presentation	824	Physical Assessment	883
Malpositions	825	Other Assessments	895
Maternal and Fetal Structural Abnormalities	828	Hemodynamic Status	896
Cephalopelvic Disproportion	828	Integumentary System	896

PREFACE

Maternal, Neonatal, and Women's Health Nursing was created from an understanding that effective nurse-client interaction is a foundation of proper care. Both nurse and client enter the relationship with knowledge bases of values and experiences, which inevitably shape the views and goals of each. While experience includes formal and theoretical knowledge for the nurse, each client brings a belief system that can vary by culture, religion, and education, which affects behavior and understanding about health. Acknowledging these differences and learning how to achieve a partnership of nurse and client is a goal of this text.

The framework of this book utilizes a holistic model of health care delivery that acknowledges traditional medical care, nursing roles at various levels of practice, and alternative health care modalities as complementary components of the individual's health care resources. Special attention is paid to changes in the health care system and the role of nursing as the site of delivery expands from the hospital into the community. Ultimately, the focus is on nursing care as it is delivered to women, neonates, and their families in the context of culture and the communities in which they live.

Maternal, Neonatal, and Women's Health Nursing will provide the instruction and application skills for the undergraduate nursing student to learn about maternity nursing in preparation for the NCLEX-RN™ exam. More importantly, the information and tools within will foster the development of a caring and professional nurse who is technically and ethically responsible. This text will also serve as an excellent reference for the practitioner, who can consult its pages as a clinical resource.

ORGANIZATION

The text consists of 38 chapters, organized into 9 units:

Unit I, Foundations of Nursing Care, analyzes the expectations, challenges, and rewards of contemporary practice in a number of ways. The unit begins with a discussion of modern issues pertinent to maternal, neonatal, and

women's health nursing, including theoretical perspectives on the family. It then progresses to complementary and alternative therapies with regard to women's health, followed by a study in ethics, laws, and standards of care. Finally, home visiting programs and perinatal nursing are covered in a separate chapter.

Unit II, Health Care of Women, addresses the development of women and emphasizes wellness across the life span. Maintenance of health through proper nutrition and a balanced lifestyle are discussed, followed by specific factors that jeopardize women's health, such as chronic conditions and violence and abuse.

Unit III, Human Sexuality Across the Life Span, provides discussion on sexual and reproductive function with a focus on planning to affirm health. The role of genetics and genetic counseling and family planning is also explored in this context.

Unit IV, Pregnancy, describes how to manage care of the pregnant woman and her family in various settings, within special populations, and under normal and high-risk conditions. With close attention to the nurse-client relationship, education is stressed for both childbirth preparation and perinatal health.

Unit V, Assessment of Fetal Well-Being, presents normal fetal development and the environmental risks that can play a role in preventing normal growth. Tools are provided to monitor and evaluate fetal maturation.

Unit VI, Childbirth, focuses on the expected and unexpected aspects of labor and delivery. The unit moves from the process of normal childbirth to high-risk births and obstetric emergencies. Anesthesia, intrapartum nursing care, and the role of the family are discussed in-depth.

Unit VII, Postpartum Health and Nursing Care, explores the true spirit of nursing during this emotional period of adjustment for the woman and her family. Professional care is delivered within the framework of encouragement and assistance in addition to an entire chapter on lactation and nursing support.

Unit VIII, Newborn Development and Nursing Care, explains the physiologic and biological changes manifested

in the transition to extrauterine life. Tools are offered to assess and care for the newborn, including the importance of good nutrition to maintain newborn health. In addition, nursing care of newborns at risk is explored in detail, with special attention to premature delivery, congenital and acquired conditions, and developmental care of the infant at risk.

Unit IX, Special Considerations, analyzes grief and the family as it relates to the perinatal experience and explores the unique challenges associated with caring for a high-risk infant in community and home care settings.

FEATURES

You will find a variety of special features in *Maternal, Neonatal, and Women's Health Nursing* designed to encourage self-reflection, caring, and application of knowledge. These complements to the text material support the developmental transition of student to practitioner:

- ✱ **Competencies** are included at the beginning of each chapter to present an outline of the material to follow. They call attention to the knowledge that will be expected upon reading of the content.
- ✱ **Key Terms** bolded in the chapters denote significant terminology in the subject matter. These terms are defined in the Glossary for easy reference.
- ✱ **Research Highlights** provide details of research findings in maternal, neonatal, and women's health nursing. These great resources also provide the necessary guidelines to formulate a research proposal.
- ✱ **Nursing Tips** are pearls of wisdom from experienced nurses that may prove useful for making decisions and taking action in a clinical setting.
- ✱ **Nursing Alerts** advise the reader to be aware of situations that may be dangerous to the client or nurse.
- ✱ **Client Education** boxes demonstrate how to equip clients with necessary health promotion information so they can take charge of their own well-being.
- ✱ **Reflections From Nurses And Families** are anecdotes from the experiences of nurses, clients, and their families. They are intended to stress the importance of caring at all times.
- ✱ **Critical Thinking** boxes challenge the reader to analyze the subject matter beyond rote memory and apply it to practice.
- ✱ **Case Study/Care Plans** present descriptions of potential clients and their conditions, reflecting a variety of cultural, religious, and sociological variables.

Care Plans demonstrate the appropriate nursing process approach for each case.

- ✱ **Photo Stories** furnish the reader with a full-color visual supplement to text material by demonstrating step-by-step techniques and events. These can be found in chapters 23, 24, 25, and 32.
- ✱ **Web Activities** direct the reader to additional sources of information that may prove useful in writing research papers or in clinical practice.
- ✱ **Key Concepts** direct attention toward information of considerable consequence in the text.
- ✱ **Review Questions and Activities** can be found in each chapter in intentionally varied formats that tap into different learning styles and strengths. Multiple choice, short answer, and critical thinking formats will be found.

STUDENT RESOURCES

Student Activity Software, a highly-interactive and enjoyable learning tool, is a free addition to *Maternal, Neonatal, and Women's Health Nursing*. Found on the inside back cover of the textbook, this exciting resource features 750 challenging questions delivered in a variety of formats and in a chapter-by-chapter outline. Games that test knowledge and comprehension of textbook material are included along with the capability of additional "players" for joint study.

Student Study Guide (order # 0-7668-0122-5), a print guide for self-directed learning, is available for purchase. Organized by chapter, it consists of Learning Objectives, Reading Assignments, Activities, Key Terms, and a Self-Assessment Quiz. All answers are in the back of the manual to encourage a programmed approach to learning.

INSTRUCTOR RESOURCES (ORDER # 0-7668-0123-3)

The Electronic Classroom Manager (ECM) was designed as a complete teaching tool for *Maternal, Neonatal, and Women's Health Nursing*. It assists instructors in the transition of class notes, preparing readings, creating lectures, constructing quizzes and tests, and developing presentations. This complementary item for adopters of the textbook is a two CD-ROM resource housed in a DVD package. The ECM consists of:

- ✱ **Instructor's Guide**, which provides suggestions for the direction of classroom lecture. Chapter Objectives, Student Learning Activities, Instructional Ap-

proaches, and Web Activities are presented in one format for viewing and another for personalized editing.

- **Computerized Testbank**, which consists of 1000 multiple choice and true-false questions relating to the content in the text to aid in the development of quizzes and tests.
- **PowerPoint** slides designed as a visually-appealing way to draw from key points of the textbook to en-

hance classroom lecture. This consists of approximately 450 slides developed for the Electronic Classroom Manager.

- **Image Library**, which is an extensive collection of over 600 pieces of art and photographs from the text; it is located on separate CD-ROM of the ECM. The electronic format allows the instructor to use these images to customize lectures.

ACKNOWLEDGMENTS

The following individuals should be acknowledged because without their support and skill this book would not have been possible. We are eternally grateful to these people and many more.

Earl Littleton, my husband of 35 years, who supported, encouraged, and provided unconditional love. My sisters, Carla Funderburg, Dorris Petrey, and Melva Fizeseri and my brother, John Petrey, who have been patient with my work and kind in my absence. Wentworth Eaton MD, long-time friend and mentor.

—L.L.

David Cohen, my husband, who has patiently dealt with very late dinners and frenzied weekends, and still provided support for this project. My three sons, Andrew, Adam, and Ethan, and daughter-in-law, Sarah, who being involved with their own higher education, appreciate the time and energy that has been diverted to this project. To my colleagues at UTHS School of Nursing who have heard the frustrations and elations, and steadily kept us afloat during the deadlines.

—J.E.

The many contributors to this text from all over the country. Harriett Linenberger for approving incredible photographic access. Carol Kanusky for making things happen at the hospital. Matt Kane for his organizational ability. Tom Stock for his photographic skill. Jay Purcell for his artistic design. Shelley Esposito for her attention to detail. Joe Chovan for his incredible artistic talent. Jim Zayicek for his production skill. Maureen Grealish for her editorial skill. Silvia Freeburg for her editorial skill and patience. The many students and faculty that provided input into the development of the book. And, finally, to Beth Williams, our developmental editor, who has nursed this project from beginning to end. She has demonstrated great patience and attentiveness to detail, and developed the vision of the completed product that was, at times, nebulous to us through the process.

—L.L. & J.E.

ABOUT THE AUTHORS

Lynna Y. Littleton

Lynna Y. Littleton has a diploma from City of Memphis Hospitals School of Nursing, with a BS, MS, and PhD in nursing from Texas Woman's University. She has worked in numerous women's health care settings, including labor and delivery, postpartum, and antepartum units in hospitals. She has also worked in ambulatory care settings. She is a women's health care nurse practitioner, an Associate Professor of Clinical Nursing, and Program Director of the Women's Healthcare Nurse Practitioner program at University of Texas Health Science Center at Houston. She has taught both undergraduate and graduate courses related to maternal and child health as well as women's health. She maintains a clinical practice as a nurse practitioner. She has won numerous teaching and clinical awards.

Joan C. Engebretson

Joan Engebretson received a BSN from St. Olaf College in Northfield, Minnesota, an MS from Texas Women's University, and a PhD at University of Texas Health Science Center at Houston School of Public Health. She is Associate Professor at University of Texas Health Science Center at Houston School of Nursing with an adjunct position at the School of Public Health. She has a clinical background in community health nursing, with a focus on maternal-child health. She has taught graduate and undergraduate courses in maternal-infant and women's health. She has conducted research on complementary therapies, touch therapies, and menopause. She also collaborated in the development of the Wee Thumbie, a pacifier for low-birth-weight infants. She is active in the Council of Nurse Anthropologists, the American Holistic Nurses Association, and The Holistic Nursing Credentialing board and other professional organizations.

HOW TO USE THIS TEXT

The presentation of the subject matter was designed to foster an understanding of maternal, neonatal, and women's health nursing from a variety of levels and perspectives. The following suggests how each engaging and confidence-building feature can be used to develop competency and professionalism.

CHAPTER OPENING BOX

Unique to other products within the discipline, each chapter of *Maternal, Neonatal, and Women's Health Nursing* begins on a personal note. In preparation of the content to come, the reader is challenged to examine his/her own thoughts, feelings, and experiences that might help him/her relate to the client before care is delivered. This feature serves as an introduction towards developing a solid nurse-client relationship.

COMPETENCIES

Answering the question "What am I about to learn?" best describes the purpose behind the chapter-opening competencies. By the completion of the chapter, the reader should have a working knowledge of the material presented and be able to apply it to practice. These should be used as a structure for targeting and extracting the most significant points for study.

Competencies

Upon completion of this chapter, the reader should be able to:

1. Discuss the advantages of preconception care and counseling for a woman and her partner who are planning a pregnancy.
2. Discuss factors related to accessing prenatal care.
3. Describe areas of physical and psychosocial assessment that are covered in an initial prenatal visit and in subsequent visits.
4. Summarize normal physiologic changes encountered during each of the three trimesters of pregnancy.
5. Explain nursing interventions and teaching points used to assist clients in dealing with the commonly occurring discomforts of pregnancy.
6. Describe risk-assessment measures recommended for routine prenatal visits in uncomplicated pregnancies.
7. List eight danger signs for which clients should be taught to seek immediate medical attention.
8. Discuss the teaching materials and aids available to nurses and clients.

KEY TERMS

Calling attention to new terminology before first usage within the book, these chapter-opening elements are initially listed, then provided with a definition in context, and repeated with a definition in the glossary. Terms are bolded within the chapters at first usage for easy identification. Familiarize yourself with these words, as they must be understood to assimilate the chapter material.

Key Terms

Biischial diameter	Health maintenance	Multipara	Pelvic outlet
EDB	Health promotion	Nägele's rule	Pregnancy-induced hypertension (PIH)
EDC	Interspinous diameter	Obstetrical conjugate	Preconception care
EDD	LMP	Para	Primipara
F.P.A.L.	Midpelvis	Pelvic inlet	
Gravida			

RESEARCH HIGHLIGHTS

These sections emphasize the importance of clinical research by linking theory to practice. Offering details of purpose, methods, findings, and nursing implications, the format also serves as a guide in constructing focused and accurate research proposal abstracts. Use the information

Research Highlight

Effects of Symmetric and Asymmetric Fetal Growth on Pregnancy Outcome

Purpose
Obstetrical ultrasonography was used in a study to assess the prevalence of head-abdomen circumference (HC/AC) asymmetry among small for gestational age (SGA) infants and to determine adverse fetal outcomes among symmetric versus asymmetric SGA infants when compared with their average gestational age (AGA) counterparts.

Methods
A retrospective cohort study was undertaken in which antepartum sonography was completed on women within 4 weeks of delivery. Data were collected between January 1, 1989, and September 30, 1996, on 33,740 women who delivered live singleton infants without anomalies. A HC/AC nomogram was derived from this database. Fetuses were considered to have HC/AC asymmetry if the nomogram value was greater than or equal to the 95th percentile for gestational age. Neonatal morbidity and outcome data were based on diagnosis by neonatal intensive care facility.

Findings
Of infants in the study, 16% (1,364) were at or below the 10th percentile (SGA). Among those, 80% (1,090) were symmetric and 20% (274) were asymmetric. Major anomalies were detected among asymmetric SGA infants. The mean birth weight was significantly lower in SGA infants. Preterm induction of labor was more common among asymmetric SGA fetuses. Intrapartum hypertension requiring delivery at or before 32 weeks' gestation was significantly more common in the asymmetric SGA group. Finally, cesarean delivery owing to nonreassuring fetal heart rate tracings was significantly more common in SGA than in AGA fetuses and was nearly twice as frequent among pregnancies complicated by asymmetric versus symmetric growth restriction.

Nursing Implications
A third trimester ultrasound can be a valuable diagnostic tool in identifying infants at risk for adverse outcomes related to birth weight and growth symmetry of HC/AC. Identifying those clients at risk for delivering SGA infants with asymmetrical growth patterns will afford the nurse the opportunity to educate the clients about their likelihood of delivering an infant with an anomaly. The nurse can also help prepare the clients mentally and emotionally for a change in birth plan, which might include the need for preterm induction of labor, an early delivery to control intrapartum hypertension, or a c-section delivery in the event of nonreassuring fetal heart rate tracings.

Dashe, J. S., McIntire, D. D., Lucas, M. J., & Leveno, K. J. (2000). Effects of symmetric and asymmetric fetal growth on pregnancy outcomes. *Obstetrics and Gynecology*, 96, 321-327.

contained in these boxes to learn the systematic research process and apply it to the field of nursing.

NURSING TIPS

In any profession, there are benefits to learning from more experienced professionals. You can be better prepared and more efficient when receptive to the helpful tips, hints, and strategies presented here from skilled nurses. Study, share, and discuss them with your colleagues.

Nursing Tip

QUESTIONS TO ASK ABOUT STALKING

- Are you being followed or spied on by your intimate partner (or previous partner)?
- Does your intimate partner wait outside or show up unexpectedly at your home, school, or work place?
- Do you receive unwanted phone calls from your intimate partner, or are you receiving many hang-up calls?
- Has your intimate partner sent or left you unwanted notes, letters, or other items of communication that frighten you?
- Has your intimate partner threatened to harm you, the children, or family members?
- Has your intimate partner caused damage to your personal property, for example, cut up your clothing, torn up photographs, slashed your car tires, tried to break down your door, or killed a pet?

NURSING ALERTS

As a nurse, it is important to react quickly in some cases to ensure the safety and health of your clients. This is a reminder that pitfalls exist and will train you to effectively identify and respond to critical situations on your own. Remember these important pieces of information so you can draw from them in practice.

Nursing Alert

SAFETY PLANNING
Help a client plan for safety or escape by considering the following:

- Is it safe for the woman and her children to go home?
- Are there weapons in the home?
- Has there been an increase in the frequency or severity of the violence?
- Has the woman been hospitalized in the past as a result of the intimate partner violence?
- Has the abuser threatened to kill the woman or himself?
- Has the woman thought of committing or tried to commit suicide?
- Does the abuser hurt the children?
- Has the woman attempted or is she planning to leave the relationship?

CLIENT EDUCATION

Health promotion and prevention serve as a cornerstone to a healthy society. Clients will count on you to offer your

knowledge of self-care so they can maintain their own health. Client Education boxes demonstrate how to equip clients with the proper information to take charge of their own well-being or to prepare for certain procedures or outcomes. Use these boxes to think of additional ways clients can assume responsibility for their own health and self-care.

Client Education

Fatigue in Pregnancy

Find a comfortable and reasonably quiet place and try meditation. Close your mind to external sensation and outside stimulation. Pick one of the following five methods to achieve a single focus:

1. Meditative repetition: repeat a rhythmic chant, most commonly called a mantra, that is chanted over and over
2. Visual concentration: stare at an image, such as a candle, flower, or fruit
3. Repetitive sounds: listen to a sound, such as a drum, chimes, or a waterfall
4. Physical repetitive motion: perform motions such as rhythmic breathing or a rhythmic aerobic exercise
5. Repeated tactile motion: hold or manipulate a small object, such as a rosary or tumble stone

REFLECTIONS FROM NURSES AND FAMILIES

An historic strength of the nursing profession is the manner of compassion with which nurses have undertaken their responsibilities. Reflections boxes have been added as a forum for families and other nurses to share personal experiences, encouraging respect for individual uniqueness and promoting self-awareness and introspection. Try to identify with the thoughts and emotions expressed in these stories as they serve as positive reminders that nursing is not just about treating conditions, but rather caring for people.

REFLECTIONS FROM A LABORING MOTHER

"When I got to the hospital I was 4 cm dilated. Although I had managed pretty well so far, I knew what was coming. With my first baby, once I got to be 6 cm the contractions started to hurt a lot worse and that's when I got the epidural. Talk about the difference between day and night! I felt the contractions as pressure, but they were not as painful as they had been before the epidural. With my second baby, I asked for the epidural as soon as I just got into the labor-delivery room. I didn't want to miss getting one because my labor was moving too fast."

CRITICAL THINKING

Making sound clinical decisions is imperative as a nurse. These real-world scenarios with accompanying thought-provoking questions will encourage refined judgment and reinforce the elements that play a role in learning and sharpening this skill. They serve as a reminder that application of knowledge is more significant than its acquisition.

Critical Thinking

Successful Role Adaptation
Rosie is a teen who is pregnant with her first baby, and she is approaching her eighth month. She is in the office for her prenatal visit and has brought her girlfriend; they are going to a party at a friend's house later that night.

1. How can you determine if Rosie has accepted her pregnancy?
2. What behaviors would you expect Rosie to report to indicate that she is successfully adapting to her impending role as mother?
3. What questions will you ask to determine if Rosie understands the changes that she will have to make in her lifestyle to care for her infant?

CASE STUDY/CARE PLAN

To practically apply presented material into the nursing process framework, Case Studies have been included with appropriate Care Plans. The real-world scenarios exem-

Case Study/Care Plan

ADOLESCENT PREGNANCY

Rhonda is a 16-year-old female at 26 weeks' gestation. Her vital signs are within normal limits and her weight gain is at 17 pounds. She states she is still smoking because she is concerned about gaining too much weight. She presents to the clinic for only the second time, complaining of difficulty having a bowel movement. Rhonda has stopped taking her prenatal vitamins because one of her friends told her they could make her constipated. She is living with the father of her baby. She continues to wear the clothes she wore before she was pregnant, although they appear tight and uncomfortable.

Assessment

- Age 16 at 26 weeks' gestation
- Vital signs normal
- Risk for fetal injury results from maternal smoking and lack of prenatal care
- Constipation
- Body image disturbance

Nursing Diagnosis

Risk for fetal injury related to cigarette smoking and limited prenatal care

Expected Outcomes

The client will:

- Verbalize understanding of the risk to the fetus from cigarette smoking
- Verbalize importance of prenatal visits to maintain a healthy pregnancy
- Demonstrate lifestyle changes that reduce the risk to the fetus

Planning

Collaborating with client, determine desired means of delivering necessary information, based on client's learning style and preferences.

Nursing Interventions

1. Stress the importance of ongoing prenatal care to monitor the growth of the newborn and to prevent maternal complications.
2. Explain the hazards to the fetus from maternal cigarette smoking.
3. Help client to identify her motivation to smoke and her motivation to stop smoking.
4. Refer her to a support group or find another teen who has successfully stopped smoking to discuss options with her.

Rationales

1. Many teens feel well and do not understand the necessity of prenatal visits.
2. Smoking can cause growth retardation and an increased incidence of SIDS.
3. Teen mothers are more receptive to changing health habits if the reasons are outlined in a nonjudgmental manner. Offering the option of cutting down and then quitting may soften the request.
4. Engaging Rhonda in group or peer support sessions may help her to feel less socially isolated.

Evaluation

At Rhonda's next visit, she was able to verbalize the necessity to stop or at least curtail her smoking. She had cut her smoking down to three cigarettes a day and was working to completely stop smoking. She still appeared doubtful that the prenatal visits were necessary. Refer Rhonda to the clinic's teen childbirth classes.

Review Questions and Activities

1. Why is it important for the home visitor to be culturally sensitive?
2. List two important principles of home visiting and give examples of how these might be put into operation by the nurse during the home visit.
3. List three tasks the nurse should perform before making a home visit.
4. Identify three strategies to promote communication during a home visit.
5. You are visiting a pregnant woman at home. Identify three nursing observations that might be made to assess the following: living necessities, coping and stress tolerance, and nutritional status.
6. List three strategies for ensuring personal safety during a home visit.
7. You have just completed a home visit where you provided extensive breast-feeding education and support to a new mother. How can the outcomes of this visit be evaluated?
8. Identify important areas for documentation after the home visit.
9. Discuss two limitations of home visits.
10. Discuss the challenges involved in terminating the home visiting relationship.

WEB ACTIVITIES

To offer additional helpful resources of information, Web Activities provide direction to sites that will aid in the writing of research papers and assignments. Related questions promote analysis of findings. Take advantage of the suggestions to continue your own education in maternal, neonatal, and women's health nursing.

Web Activities

- Locate your state's Visiting Nurse Association (VNA). Does it have a web site? What type of professional information is offered regarding regulations for home visits in your state? Compare these regulations with those listed for a neighboring state.
- Visit a local hospital's web site for information on its home visiting program.

plify the holistic approach of cultural, spiritual, and psychosocial aspects of nursing care and incorporate collaborative efforts in multiple settings. Take note of the care plan construction process for maternal, neonatal, and women's health and the number of variables that can play a role in its design.

KEY CONCEPTS

Key Concepts summarize the main points presented in each chapter and provide a framework to recall the material. Use these tools as a review guide or a checklist to structure your studying.

Key Concepts

- Home visitation is a means to providing direct health care services, health education, and psychosocial support to clients and families.
- The growth of social reforms and the expansion of the field of social work contributed to the rise of home care programs in the early 20th century.
- The home as the site of delivery provides the nurse with a unique opportunity to assess the client and family in their own environment.
- Home care can be provided by home health care agencies, hospitals, public health departments, schools, and other institutions.
- Cost savings in the form of reduced inpatient hospital stays is one of the many benefits of home care.
- The home visit consists of three phases: previsit preparation, the visit, and postvisit activities.

REVIEW QUESTIONS AND ACTIVITIES

At the end of each chapter, exercises encourage your application and synthesis of presented material to test your understanding and assimilation of the content. Answer the questions and follow the instructions to promote further discussion of key points from each chapter.

Administration of Spinal Anesthesia

This 29-year-old female is a gravida 4, para 3 who is being prepared for a repeat C-section. She will sit on the operating table with the nurse's assistance and support while the anesthesiologist assesses physical landmarks.

Upon identification of landmarks, preparations are made to cleanse the injection site.

The nurse has the responsibility to promote client comfort and limit motion during the procedure.

Once the area surrounding the injection site is cleansed, a sterile sponge is used to remove Betadine from the injection site.

HOW TO USE THE STUDENT ACTIVITY SOFTWARE

The Student Activity Software was designed as an exciting enhancement to *Maternal, Neonatal, and Women's Health Nursing* to help you learn difficult terms and concepts. As you study each chapter in the text, be sure to explore the corresponding unit on the CD-ROM.

Each chapter is divided into two major sections: exercises, and fun and games. Exercises can be used for additional practice, review, or self-testing. Fun and games provide an opportunity to play and practice through a variety of activities.

Getting started is easy. Follow the simple directions on the CD label to install the program on your computer. Then take advantage of the following features:

MAIN MENU

The main menu follows the chapter organization of the text exactly, which makes it easy for you to find your way around.

Just click on the button for the chapter you want, and you'll come to the chapter opening screen.

TOOLBAR

The Back button at the top left of every screen allows you to retrace your steps, while the Exit button gets you out of the program quickly and easily. As you navigate through the software, check the toolbar for other features that help you use individual exercises or games.

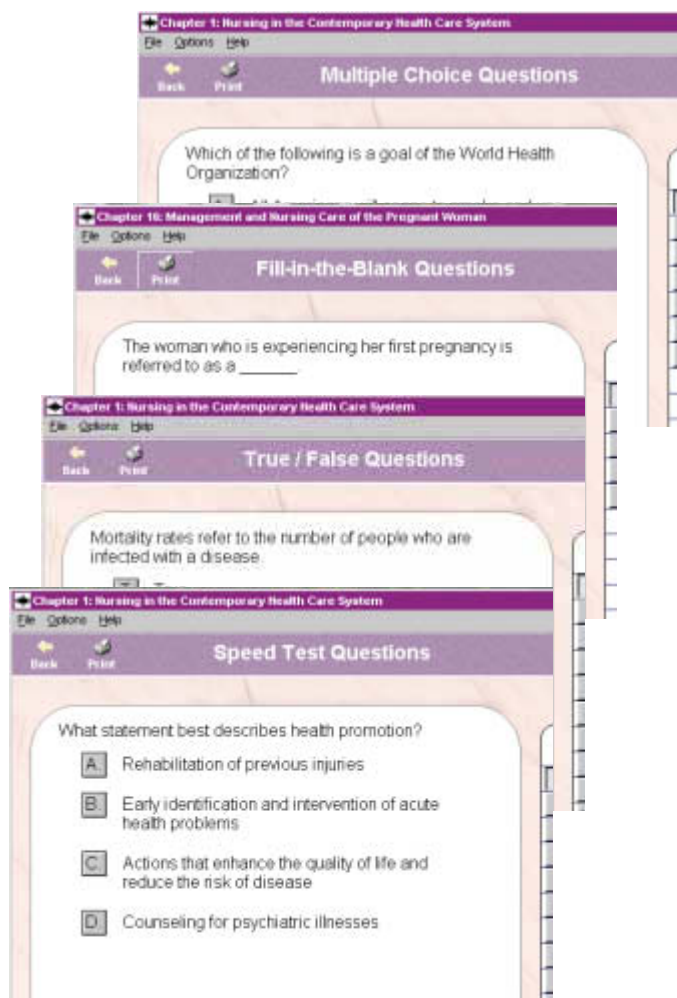

ONLINE HELP

If you get stuck, just press F1 to get help. The online help includes instructions for all parts of the Student Activity Software.

THE CHAPTER SCREEN

Here you have the opportunity to choose how you want to learn. Select one of the exercises for additional practice, review, or self-testing. Or click on a game to practice the concepts for that chapter in a fun format.

EXERCISES

The Student Activity Software acts as your own private tutor. For each exercise, it chooses from a bank of questions covering all 38 chapters. Putting these exercises to work for you is simple:

- Choose a true/false, multiple choice, or fill-in-the-blank exercise, whichever one appeals to you.
- You'll encounter a series of questions for each exercise format; each question gives you two chances to answer correctly.
- Instant feedback tells you whether you're right or wrong—and helps you learn more quickly by explaining why an answer was correct.
- The Student Activity Software displays the percentage of correct answers on the chapter screen. An on-screen score sheet (which you can print) lets you track correct and incorrect answers.
- Review your previous questions and answers in an exercise for more in-depth understanding. Or start an exercise over with a new, random set of questions that gives you a realistic study environment.
- When you're ready for an additional challenge, try the timed Speed Test. Once you've finished, it displays your score and the time you took to complete the test, so you can see how much you've learned.

FUN AND GAMES

To have fun while reinforcing your knowledge, enjoy the simple games on this disk. You can play alone, with a partner, or on teams.

- Tic-Tac-Toe:** you or your team must correctly answer a question before placing an X or an O.
- Championship Game:** challenge your classmates and increase your knowledge by playing this Jeopardy-style, question-and-answer game.

UNIT I

Foundations of Nursing Care

Nursing in the Contemporary Health Care System

Understanding the contemporary health care system is vital to providing effective and appropriate nursing care. Understanding how your personal beliefs and values may influence your interpretation of the system is also important. Consider the following:

- *Have I ever wondered what health means?*
- *How does the health care system help keep clients healthy?*
- *If I am sick and see a clinician in Idaho, would I receive the same quality of care as I would in Connecticut?*
- *What are the things that affect my health?*
- *Who pays for expensive methods of diagnoses and treatments?*
- *How do people in other cultures think about health, illness, and disease?*

Key Terms

Behavioral medicine

Objectives
Risk assessment
Social assets

Competencies

Upon completion of this chapter, the reader should be able to:

1. Describe the shift in health care delivery to encompass health outcomes.
2. Identify national goals and guidelines that direct the health care industry.
3. Discuss measures that have been undertaken to contain health care costs.
4. Apply evidence-based practice and best practice to clinical situations.
5. Discuss seven discoveries that are changing our understanding of health, illness, and disease.
6. Describe some contemporary challenges facing all health care providers.
7. Apply skills necessary for nurses to participate fully on health care teams.

Health care is affected by many factors both within the health care industry and external to it. Health care has expanded the focus beyond disease treatment to disease prevention and health promotion. A dual emphasis of cost containment and prevention has moved much of health care delivery into the community and even into client's homes. Nurses are now functioning on multidisciplinary teams.

In response to health care disparities, national objectives have been established and outcomes are being tracked. Guidelines are available to assist the clinician in providing the best care. A number of discoveries are changing our understanding of health, illness, disease, and treatment. These discoveries also have raised ethical issues and stirred controversy as they challenge some of the previous ideas about health. Nurses need specific skills to practice in the current health care system.

CURRENT STATE OF HEALTH CARE DELIVERY

Throughout history, most models of health care have been focused on diagnosis and treatment of diseases and disorders. In the late 20th century the delivery of health care, especially in the United States, underwent changes related to scientific and technologic advances. In addition to more sophisticated methods of diagnosing and treating disease,

these advances expanded the focus of health beyond disease and treatment of the person to the broader concepts of health maintenance and the health of populations. The delivery of health care also was becoming very expensive, and therefore, economics was a major factor in the changes made in health care.

Technologic Advancement for Diagnosis and Treatment

For most of the 20th century medical advances were related to the ability to diagnose and treat diseases. Biomedicine is strongly rooted in scientific discovery and therefore is profoundly influenced by the development of technology. Technologic development is constantly progressing and has transformed the way diseases are diagnosed and treated; however, medical advances often increase the costs of health care. Computerized technologies and microtechnology have allowed for more accurate monitoring and for management of intricate dynamic physiologic systems. For example, diagnostic tests and surgery can be performed on a fetus in utero to determine and limit future health problems. Complex physiologic systems can be managed and regulated by the use of pumps and other such means. As computers are developed further, more computerized technologies and microtechnology will be applied to health care.

The impact of technology on communications through the electronic means of the World Wide Web and Internet has allowed providers to access information and communicate with each other at great speeds. Clients can be diagnosed and treated over great distances through interactive television or other media. “Telehealth” has allowed clients and providers in rural areas to optimize expertise from large medical centers. The health-related information available to the public also has expanded.

Health Care Expansion

Since the late 1970s, advances in statistical analysis and epidemiology in public health have allowed for better analysis of the health of populations on international, national, and local levels. At the Alma Alta Conference (Russia) in 1978, the World Health Organization (WHO), put forth a **goal** (a broad statement of a desired outcome) that all the citizens of the world would attain a level of health that will permit them to lead a socially and economically productive life by the year 2000 (WHO, 1981). This emphasis broadened the focus of health care beyond specific diseases of individuals or public health concerns of containing or preventing epidemics. This broadened focus took three forms: early detection and treatment of disease, disease prevention, and health promotion.

Early Detection and Treatment

More sensitive and specific screening techniques became available to identify the early stages of a disease, when early treatment may reduce its development. Blood pressure and cholesterol screenings are good examples, in which disease can be detected in the early stages and thus lifestyle changes, medications, or a combination can be initiated to prevent or control development of the disease (Figure 1-1).

Disease Prevention

Disease prevention consists of measures taken to prevent the onset of a disease or disorder. Immunization is a good example of a successful effort in preventing disease. A number of public health measures have been enacted to protect public health by preventing epidemics and the spread of disease.

Health Promotion

Health promotion is a broad concept and includes actions that enhance the quality of life and reduce the risk of disease such as developing good stress management skills. Health promotion was defined by the WHO (WHO, 1986) to include not only individual well-being but also partnerships between lay and professional participants, professional and community groups, and other multilevel institutions and formal and informal groups.

Figure 1-1 Routine blood pressure measurements are useful for early detection of some health problems.

The emphasis on disease prevention and health promotion has permeated most of health care. Government agencies and private foundations have been developing recommendations to move the health care system toward promoting better health for the entire population. Health indicators have been identified that allow more accurate evaluation of the health of the U.S. population and identify risk factors that may be targeted for better health outcomes. Awareness of disparities in the health of different groups of people has been the impetus for developing programs to improve the availability and quality of health care for all (Figure 1-2). With the emphasis on health, health care services and programs are increasingly being provided in community settings, with individuals and communities engaged as partners in the pursuit of health.

Risk Assessment and Management

Through epidemiologic studies, associations were made between diseases and certain conditions, exposures, or behaviors. Thus, factors were identified that could predict with some degree of probability that a person might

Figure 1-2 Health promotion activities may include exercises appropriate to the client's age and ability.

develop a disease in the future. **Risk assessment** is the process of examining the risk factors that place a person at risk for disease. For example, epidemiologic studies demonstrated an association between cigarette smoking

and a number of diseases. This association is for populations and cannot predict whether a certain person will develop a disease. These studies, however, do show that someone who smokes cigarettes is statistically more likely to develop a disease such as lung cancer compared with someone who does not smoke cigarettes. In many cases, biomedical research has strengthened the association by revealing physiologic links between risk factors and disease such as those between cigarette smoking and cardiovascular disease. Risk assessment and management are now part of basic clinical care.

Some of these risk factors can be altered, thereby decreasing the probability of acquiring a disease. Changing dietary and exercise behaviors are examples of initiating change to lower cholesterol levels, thereby reducing the risks of coronary artery disease. Other lifestyle changes, such as taking vitamins, avoiding smoking, and maintaining a healthy weight, may be undertaken to promote health rather than prevent a specific disease. With improved general health, the probability of getting a disease also may be reduced. Preventive and health-promoting efforts are relatively inexpensive. Health screenings, immunizations, and health education and counseling are low in cost when compared with the cost of complex acute care. Chronic debilitating diseases are costly, especially when the client needs long-term personal care. Many diseases, such as osteoporosis, can be very debilitating and require extensive nursing and medical care.

Movement of Health Care to the Community

Consistent with the shift in emphasis toward health, interventions have also shifted from large hospitals into the community in which the holistic approach has come to be recognized as increasingly important. New types of care delivery are emerging, such as day hospitals, day surgery, and transitional care, to move clients from the hospital to the home or other community setting. Nurses are finding positions in facilities for short-stay convalescence. Many centers that serve the chronically ill and geriatric populations are employing nurses for client education and other facets of nursing care. Home health care agencies employ nurses to provide care in the home to clients across the life span. Nurses are frequently providing both high-risk perinatal and neonatal care in the home as well as in hospitals and clinics. Nurses have had to incorporate interdisciplinary knowledge and cognitive skills to respond to this change in focus. As risk factors become better understood, psychologic, social, and environmental factors frequently are being implicated as contributors to health.

Primary care has been a growing area for health care and has expanded opportunities for nurses in all areas of practice. *Primary care* is the provision of integrated acces-

Nursing Tip

ANA POSITION STATEMENT

The American Nurses Association (ANA) issued a position statement supporting the promotion of health and prevention of disease and illness and disability. This position advocates comprehensive primary, secondary, and tertiary levels of prevention and engaging client participation. Prevention has long been within the scope of nursing as nurses work toward wellness with clients, families, and communities (ANA, 1995).

sible health care by clinicians who address a large majority of personal health care needs, developing a sustained partnership with clients in the context of family and community (Institute of Medicine, 1996).

In addition to providing services to promote health and provide early detection and treatment of health problems, many nurses are beginning to work with local groups to promote the health of the community. Nurses often work with schools, churches, senior citizen centers, and other community organizations (such as the United Way and March of Dimes) to improve community health. Some of these collaborative efforts have resulted in building new clinics or health centers that may be run primarily by advanced practice nurses (APNs) and nurses at other levels. Other nurses may be involved in developing safe recreational areas for children and adults to exercise. Nurses' roles in the community have expanded and are predicted to expand even more as communities build their capacity for health environments.

Change in Philosophy

A substantially different relationship between client and clinician is required when dealing with health issues. In the traditional medical model, the clinician generally plays the active role and the client is the passive recipient of care. The need for a modification in that relationship has been addressed by two major advisory groups on health care change in the United States, the Robert Wood Johnson Foundation (1992) and the Pew Charitable Trust Commission on Health Professions (1995). In keeping with the goals for the nation, both groups have recommended restructuring of the relationship between the health care provider and client to one that emphasizes partnership rather than one of physician's orders and client compliance. These recommendations specify that the accomplishment of these goals requires a shared responsibility among individuals, families, communities, health professionals, media, and the government (Public Health Service, 1990). The Pew report also recommends that health care providers collaborate with clients and work together for health goals. These guidelines are based on the tenet that relationships among people constitute the foundation of all therapeutic activities (Pew, 1995).

An emphasis on health promotion and disease prevention relies on client participation and engagement in the therapeutic process, as does management of chronic illness. These modifications in the therapeutic relationship are congruent with nursing philosophy. Nursing interventions often have been health related such as instruction on a healthy diet, proper exercise, and other health-enhancing behaviors involving self-care. The current health care climate encourages the nurse-client relationship to be one of a partnership of mutual respect and setting of goals.

The American Holistic Nurses Association (AHNA) has described this relationship through the nursing process (Dossey, Keegan, & Guzzetta, 2000). In the Standards of Practice for Holistic Nurses, the nurse collaborates with the client and other health care team members. The nurse partners with the client in a mutual decision-making process to create a plan and engages the client in problem-solving. The nurse supports the client's participation in the plan, thus facilitating the client's efforts in health-seeking behaviors.

Cost Containment

As a social institution, the health care industry has a mission to develop the science and art of medicine and make health care services accessible to the public. The mission of healing has a long history and is the foundation for health care ethics. The mission of service recognizes the vulnerability of the client and thus is different from the motive of profit. The friction between these two coexisting missions is beneficial because they act as checks and balances within the system.

The costs of health care have continued to increase. Much of the increase is related to the high cost of technology and the expense of educating and training personnel to operate and interpret this technology. The health care sector constitutes more than 14% of the Gross National Product (GNP), and this percentage is projected to increase (Institute of Medicine, 2001). In 1970, the National Academies of Sciences (NAS) established the Institute of Medicine (IOM) to advance and disseminate scientific knowledge to improve human health. The IOM examines policy matters pertinent to the health of the public and acts as advisor to the federal government to identify issues of medical care, research, and education (IOM, 2001). The IOM issues reports to direct health policy and was asked by the U.S. Congress to address increasing health care costs.

Nurses must have some understanding of the economic forces that are now driving much of the organization of health care delivery such as managed care, cost containment, privatization, and the focus on prevention and efficiency. Emphasis now is on health care as a business and thus on the need to balance cost containment with competitive client satisfaction. The emphasis has increased the need to streamline health care delivery services to be more cost-effective and to compete for market shares, which has affected nursing roles. It was the streamlining of health care, for example, that led to the development of advanced practice roles. More often today, nurses are being asked to consider the cost-benefit ratio of their actions.

Cost-benefit analysis is the process of comparing the monetary cost (input) of doing something with the cost of the outcomes. The goal is to see if the benefits are

greater than the costs. One of the most important concepts in the economics of health care is a cost-effectiveness analysis. **Cost-effectiveness analysis** compares the cost of doing something and measures the outcomes in non-monetary terms such as diseases or risks found, lives saved, or extra years lived (Gorin & Arnold, 1998). Effectiveness approaches allow the inclusion of issues such as quality of life, patient satisfaction, and comfort. This expanded definition allows for the inclusion of many nursing interventions. Nurses, however, must always be concerned about cost-benefit analyses because they often are used by administrators.

ACTIVITIES TO IMPROVE HEALTH

With the expanded focus and the shifts in emphasis discussed previously, the health care industry has established indicators to track the health of the U.S. population and has published goals and prevention guidelines for clinicians. Efforts are under way to address and better understand disparities in health. A number of adjustments in the organization of health care have addressed the economic issues of spiraling costs.

Identify Health Indicators

With the focus shifting to health, it has been necessary to identify determinants of health. Health indicators often have relied on **mortality rates**, the ratio of the number of deaths in various categories to a given population. These numbers often are written as rates; for example, the infant mortality rate (IMR) is the number of infants who die over the number of live births. The IMR often has been used to determine the quality of health in a country or population. For example, in the United States the IMR had decreased from 10/1,000 births to nearly 7/1,000 births in 1997, indicating that the target objective for the year 2000 would be met (National Center for Health Statistics, 1999). Specific signs and symptoms generally define disease. Thus, statistics can be collected on the number of people who have a disease, or the **morbidity rate**.

Whereas mortality and morbidity rates can be said to measure the absence of health, other indicators of health have been more difficult to measure. Health indicators have been established and evaluated by the U.S. Department of Health and Human Services (DHHS) in collaboration with the Centers for Disease Control and Prevention (CDC) and the National Center for Health Statistics (NCHS). These indicators are specifically stated in the published **objectives** (specific short-term achievements expected to result in the accomplishment of a goal) and are used to measure and evaluate progress toward the goals.

Establish Health Goals

The emphasis on health was reflected in the 1979 publication of “Healthy People: The Surgeon General’s Report on Health Promotion and Disease Prevention” (DHHS, 1979). This document outlined goals and strategies to improve the health of the nation. These goals have been evaluated and new goals and specific objectives toward are established each decade. The first “Healthy People” document outlined three broad strategies: **disease prevention** (activities that prevent a disease or disorder), health promotion, and health protection (DHSS Department of Health & Human Services, 1979). These categories were subdivided into areas of concern with subsequent objectives.

“Healthy People 2000” established three main goals: Increase the span of healthy life, reduce health disparities, and achieve access to preventive services for everyone. Priority areas were established and over 300 measurable objectives identified (Public Health Service, 1990).

The U.S. Public Health Service (PHS) is responsible for coordinating activities directed toward attainment of the objectives. A midcourse review was put in place to provide an ongoing evaluation. These reviews generally are published shortly after the midpoint of the decade, for example, 1985, 1995, and so on, and these reports are available on the Internet at <http://odphp.osophs.dhhs.gov/pubs/hp/2000/prog.htm>. Currently, the progress toward meeting the goals is tracked and may be found through the NCHS (NCHS, 2001).

The current overall goals for “Healthy People 2010” are to increase quality and years of healthy life and to eliminate health disparities that are associated with race, ethnicity, and socioeconomic status. Community partnerships with persons, organizations, health care systems, and other partners are required to achieve these goals. The current objectives are listed under 28 focus areas (NCHS, 1999). Health indicators have been identified, objectives can be linked to these indicators, and data will be collected to determine the extent to which the objectives have been met. The leading health indicators for “Healthy People 2010” are given in Box 1-1. In addition to the goals for the nation described previously, state and local health departments have established goals, many of which are modeled after the “Healthy People” goals.

Address Health Disparities

Some U.S. populations had greater morbidity and mortality than did others. On multiple health indicators, ethnic, racial, and socioeconomic disparities exist (Moss, 2000; Lillie-Blanton et al., 2000). Research is being conducted to better understand issues related to the populations with poorer health such as access to care, social issues, and the

Box 1-1 Leading Indicators for “Healthy People 2010”

- Access to health care

effects of poverty. Currently, the large number of uninsured is an area of great concern. Disparities among population groups exist even when racial and ethnic disparities in income and health insurance coverage are eliminated (Weinick, Zuvekas, & Cohen, 2000).

A second aspect of disparities in health is the variation in practice patterns and the gap between what is known scientifically about medical treatment and what is practiced. The disparities in health led to an evaluation of access to health care services and redirecting resources to expand access. The Agency for Health Care Policy and Research (AHCPR) was created in 1989 to respond to concerns about the health care system (AHCPR, 1998). Its mission is to support, conduct, and disseminate research that improves access to care and the outcomes, quality, cost, and utilization of health care services (AHCPR, 1998). Decision makers at all levels are targeted by this agency: clinicians, clients, and policymakers. The agency has been renamed and is now the Agency for Healthcare Research and Quality (AHQR). The AHQR supports a rigorous research program that focuses on health care quality and the outcomes of health care services. The IOM also has issued a report that lays out a strategy to reduce medical errors that is directed toward government, industry, consumers, and health providers. The strategy was initiated because of reports of death and injury as a result of medical errors. The goal is to reduce medical errors by 50% in the next 5 years (Richardson, Kohn, Corrigan, Donaldson, 2000).

Institute Evidence-Based Practice or Best Practice

Evidence-based practice is a systematic approach that uses existing research for clinical decision processes (Westhoff, 2000). Reports are developed through epidemi-

ologic studies or rigorous syntheses and analyses of relevant scientific literature. Many of these reports use meta-analysis and cost analysis (AHQR, 2001). *Meta-analysis* is a process in which the published research studies on a particular topic are analyzed and results compiled when possible. Often, more than one research study or a very large study is required to warrant a recommendation for practice. This process allows for analyses of a group of small studies, and the findings can then represent a larger number of participants. Many times, however, published studies may not include all the necessary information for inclusion and therefore do not meet the criteria for inclusion in the meta-analysis. These reports are available to clinicians and are helpful in bringing the most well-informed up-to-date knowledge to clinical practice. With the use of the World Wide Web and Internet and connections to large information centers and databases, clinicians can access these reports and apply them to practice. Many of the guidelines now available have been generated from these systematic analyses. To initiate the process, a clinical question must be formulated and a search conducted. Two sources for published reviews are the Cochrane Database of Systematic Reviews and MEDLINE. Knowledge of research is necessary to critically appraise these studies. These reviews quickly give clinicians an idea about the current state of research so they can apply that knowledge to clinical practice. Good clinical practice in any discipline combines a knowledge of the latest clinical evidence to complement clinical assessment, clinical skills, and experience and clinical judgment (Westhoff, 2000). *Best practice* has been described in the nursing literature as a combination of evidence-based practice, clinician's judgment, and client preference (Hickey, Ouimette, & Venegoni, 2000).

Organizations are striving to provide cost-effective care based on the best evidence. Health care administrators are increasingly monitoring the outcomes of delivery of care in their organizations. This process involves gathering data on the status of client outcomes. For example, an organization may want to look at outcomes of deliveries and then compare them (e.g., the rate of cesarean sections or postpartum infections) with other institutions that are of similar size and have similar clientele. This process is called benchmarking. The organizations would evaluate their practice with guidelines, standards, and the literature on evidence-based practice. The organizations would then attempt to implement these guidelines, standards, and recommended practices and may alter the way care is delivered to meet those standards and improve outcomes. Many hospitals hire nurses for positions of outcomes managers. These nurses gather and analyze data from outcomes and may be involved in problem-solving techniques, such as continuous quality improvement, to achieve or improve on the benchmark standards.

Research Highlight

Caregiver Support for Women during Childbirth

Purpose

To systematically assess the effects of continuous support during labor on mothers and babies.

Method

Systematic search of the Cochrane Pregnancy and Childbirth Group Trials Register and the Cochrane Controlled Trials Register through April 2000. The review included 14 trials involving more than 5,000 women. Accompanied and unaccompanied women were compared. Persons accompanying the woman varied—nurses, midwives, family members, or lay persons. Varying designs of the included studies were discussed.

Findings

Continuous support reduced the likelihood of administration of pain medications (odds ratio, 0.59; 95% confidence interval; 0.52, 0.68), operative vaginal delivery (odds ratio, 0.77; 95% confidence interval, 0.65, 0.90), cesarean delivery (odds ratio 0.77, 95% confidence interval; 0.64, 0.91) and a 5-minute Apgar score less than 7 (odds ratio, 0.50; 95% confidence interval; 0.28, 0.87).

Nursing Implications

Intrapartum support has clear benefits and no known risks. Providers should encourage the provision of continuous presence, hands-on support, and encouragement to women in labor, which may come from a nurse, midwife, or lay person. Nurses could be involved in the education of labor support persons.

Develop and Publish Guidelines

The PHS convened the U.S. Preventive Services Task Force (PSTF) in 1984 to make recommendations over a range of clinical preventive services (Hickey, Ouimette & Venegoni, 2000). National guidelines to help health care providers implement preventive care were established and published in the *Guide to Clinical Preventive Services* (PSTF, 1996). These guidelines suggest age- and gender-specific screening tests, immunizations, and health advice. The second edition (PSTF, 1998) presents practical instructions for incorporating prevention into office and clinic routines. Guidelines are updated, and many are available on the AHQR website. Many of these updated topics relate to maternal, infant, and women's health.

Other guidelines have been established by consensus panels through the National Institutes of Health (NIH) to examine the research and current knowledge about a specific problem or treatment and make recommendations for practice. The National Guideline Clearinghouse is a pub-

licly available database of evidence-based clinical practice guidelines, updated weekly, that is available over the Internet (www.guideline.gov). AHQR also publishes guidelines for practice.

Other guidelines are established for specific populations or specific medical conditions. These often are disseminated and published through professional organizations such as the American College of Obstetricians and Gynecologists (ACOG). This group has issued a number of guidelines in their technical bulletins and committee reports.

Nursing organizations also have published guidelines for practice. The Association of Women's Health, Obstetrics, and Neonatal Nurses (AWHONN) has guidelines for nurses on several issues related to maternity care, perinatal education, neonatal care, and women's health. Other professional groups, such as the National Association of Neonatal Nurses (NANN) and the AHNA, have standards of practice; the ANA has guidelines and position papers to guide practice. Other groups such as the March of Dimes and American Cancer Society publish guidelines for pro-

professionals and the public related to health promotion and disease prevention.

Work Toward Cost Containment

In an effort to provide the most cost-effective care, a number of changes in the organization of health care delivery and payment structures have been instituted. Best practice takes into account the most cost-effective way of delivering services and ways to make best care accessible to all persons.

Appropriate Technology

The most appropriate technology is often the most cost-effective kind. The most appropriate technology should be used to diagnose and treat illness. For example, critics have cited that using expensive technology, such as screening clients with magnetic resonance imaging for potential health problems, incurs excessive costs. Conversely, not using technology when it could prevent further health problems also is costly. For example, not monitoring fetal heart sounds during labor could result in prolonged hypoxia that, in turn, would result in chronic problems for that child (Figure 1-3). These illnesses often are very costly. Consensus reports and specialty guidelines have been developed to guide practice in the most cost-effective manner.

Another area of appropriate technology is using a variety of providers. In many cases a generalist is more appropriate and hence more cost-effective than is a specialist. Nurses prepared as APNs have been used in many cases to provide cost-effective management of patients.

Figure 1-3 Fetal monitoring during labor is a good example of the appropriate use of technology.

Many of these APNs first provided primary care to low-risk clients. The role has expanded to providing specialized care in acute-care settings. Many managed care facilities have used APNs as the most effective technology, which has impacted the nursing profession by defining differentiated levels of practice to ensure that nurses are prepared to practice within the scope of their license. These certifications document the nurse's experience and mastery of a specialized body of knowledge. The effort to differentiate practice has impacted nurses at all levels. In many cases, roles between ADNs and nurses with a Bachelor of Science in Nursing (BSN) degree also are beginning to be differentiated. Baccalaureate-prepared nurses also are being certified to practice in specialties. One certification available to BSNs is Holistic Nurse Certification. This certification documents that the nurse has demonstrated mastery of a body of knowledge based on holistic autonomous care to clients which is based on research and nursing theory.

Managed Care

The advent of managed care has had a major impact on the U.S. health care delivery system in the last decade of the 20th century. **Managed care** refers to health care plans with a selective list of providers and institutions from which the recipient is entitled to receive health care that is reimbursed by the insurer (Committee on the Future of Primary Care, 1996). Typically, managed care plans also control the nature, amount, and site of services provided. Access to specialists may be restricted through the use of primary care providers as gatekeepers to the system (Mezey & McGivern, 1999).

Managed care in the United States has evolved over time and continues in its evolution. Growth of managed care plans varies according to region but predominates in large- to medium-sized markets (Committee on the Future of Primary Care, 1996). Evolution of managed care plans includes numbers of persons served, types of plans, and investment of providers.

In the 1960s and 1970s, health care costs became a major focus of attention in this country because they were becoming an ever-increasing portion of the national budget. There also were indicators suggesting that, without intervention, the escalation of health care costs would continue. Clearly, some measures needed to be implemented to control costs. By 1994, 180 million people were insured by private insurance plans and 115 million people were enrolled in some type of managed care plan (Bailit, 1995).

Three types of managed care plans currently exist: preferred provider organizations (PPOs), health maintenance organizations (HMOs), and point-of-service plans (POS). PPOs allow the consumer to see any provider or use any health care institution. The rate of reimbursement,

however, is better when a provider or institution within the network is used.

Health maintenance organizations offer the consumer fewer options. Consumers must identify a primary care provider from a list of providers. When specialist care is sought, there must be a referral from the primary care provider or the expenses will not be reimbursed. The incentives for consumers to use this type of care usually are that the plan requires only a small copayment (\$10 to \$25) and all other expenses are covered by the plan. In HMO plans, hospitalization is usually covered by insurance, with a small copayment (\$10 to \$25).

Point-of-service plans are more flexible but more expensive for the consumer than are the other plans. PPOs allow the insured to be a member of an HMO but also seek health care outside the HMO at increased cost.

All three types of managed care plans offer advantages and disadvantages for the client, physician, and health care agency. The client is the primary concern for nurses. Managed care has changed the focus from institutional care to community care, with prevention and early detection as goals. Thus interest has moved toward primary care in the community. Many clients see this as an advantage; however, the result has been that when clients are admitted to the hospital they generally are sicker and have shorter stays.

Health maintenance organizations operate on the philosophy of providing preventive and early treatment. The care plans usually are set on capitated rates. The implications for physicians are that they must see more clients in a given period of time to break even. In general, this increase in flow rate has increased waiting time for appointments and time in the waiting room. The increased flow rate also has meant that physicians can no longer spend time with clients to answer questions or give explanations, which has led to disgruntled physicians and clients.

The major disadvantages clients see in managed care plans include relinquishment of choice of and limited access to health care providers. Many times it is the employer who initiates the managed care contract. Consumers provide little or no input. It may be necessary to relinquish excellent health care providers that have been clients' physicians or nurse practitioners for years because the managed care plan will not pay for their care. The private health care provider also seemingly had more time and was more available to the client.

Managed care has produced major effects on hospitals. Because the managed care plan makes contracts with hospitals and providers, these companies are very powerful. A managed care company contracting with a hospital for 500 deliveries per month results in a huge financial resource for the hospital. Losing the contract may be devastating to the economics of that hospital. It is especially stressful for the institution when the managed care com-

pany then awards the contract to the competition. The results on hospitals have been closings, mergers, and cost-containment measures.

Initially, cost-containment measures focused on early discharge. Later, care maps, critical pathways, guidelines, and protocols were developed to streamline patient care and make it cost-effective. Because nursing salaries are one of the major costs, many times hospital administrators have chosen to reduce staff or substitute licensed vocational nurses or technicians as a means of cost reduction. Later, administrators realized the lack of wisdom in this decision and are looking at the necessity of having more highly prepared nurses on staff.

Develop Collaboration with Multidisciplinary Teams

With the broader focus on health and the simultaneous concerns of improving effective care for all while containing costs, collaborative efforts from a variety of disciplines are necessary (Figure 1-4). *Multidisciplinary care* has been described as sequential provision of discipline-specific health care by various persons, whereas *interdisciplinary care* includes coordination, joint decision-making, communication, shared responsibility, and shared authority (Dossey, Keegan, & Guzzetta, 2000).

Three national foundations have addressed the health care system and made recommendations for health care delivery and provider education. The Pew Health Commission, Rockefeller Foundation, and Robert Wood Johnson Foundation have made recommendations and sponsored programs that foster interdisciplinary approaches to health (Hickey, Ouimette, & Venegoni, 2000). These organizations also have supported efforts in curricular reform to educate providers to an orientation to population health, primary care, and community health. Projects were spon-

Figure 1-4 Multidisciplinary care involves coordination and joint decision-making with members of other health disciplines.

sored in which nurses, physicians, social workers, and nutritionists collaborated to provide comprehensive family-oriented care in a community setting. Before disbanding in 1999, the Pew Health Professions Commission proposed a

Box 1-2 Twenty-one Competencies for the 21st Century

1. Embrace a personal ethic of social responsibility and service.
2. Exhibit ethical behavior in all professional activities.
3. Provide evidence-based, clinically competent care.
4. Incorporate the multiple determinants of health in clinical care.
5. Apply knowledge of the new sciences.
6. Demonstrate critical thinking, reflection, and problem-solving skills.
7. Understand the role of primary care.
8. Rigorously practice preventive health care.
9. Integrate population-based care and services into practice.
10. Improve access to health care for those with unmet health needs.
11. Practice relationship-centered care with individuals and families.
12. Provide culturally sensitive care to a diverse society.
13. Partner with communities in health care decisions.
14. Use communication and information technology effectively and appropriately.
15. Work in interdisciplinary teams.
16. Ensure care that balances individual, professional, system, and societal needs.
17. Practice leadership.
18. Take responsibility for quality of care and health outcomes at all levels.
19. Contribute to continuous improvement of the health care system.
20. Advocate for public policy that promotes and protects the health of the public.
21. Continue to learn and help others learn.

Adapted from the Pew Health Professions Commission. (1998). *Recreating Health professional practice for a new century. The Fourth Report of the Pew Health Professions Commission*. San Francisco, CA: Pew Health Professions Commission.

set of 21 competencies for all health professionals (Pew 1998); these are found in Box 1-2. These 21 competencies were further differentiated for various practice levels of nursing: Licensed Practical Nurse, ADN, BSN, and those with a Master of Science in Nursing (MSN) degree (Brady et al., 1999).

Working closely on **interdisciplinary teams** (health care delivered by persons from various disciplines who share responsibility, authority, and decision-making) has allowed professionals from different disciplines to understand other disciplines and appreciate their contributions to client care as well as better understand different perspectives. Ideally, this approach offers the most comprehensive care to clients; however, it also requires good communication skills. Most disciplines have developed their own language, perspectives, and unique body of knowledge. It may not be easy to understand the perspective of persons in another discipline or their contribution to care. Conversely, nurses sometimes find it challenging to articulate the perspective and contribution of nursing.

The Pew Commission also made a number of recommendations on scope of practice and regulation of professions that would inform and protect the public against the actions of health care professionals outside of their scope of practice (Pew, 1995). Nurses often find that they are collaborating with other nurses and with nurses at other levels of practice. For example, a Baccalaureate-prepared nurse may be working with an APN. It is important to be clear on the unique professional perspective of nursing and the scope of practice at each level to effectively collaborate.

CHANGING VIEWS IN UNDERSTANDING HEALTH, ILLNESS, AND DISEASE

Recent discoveries and advances in knowledge from many disciplines have enhanced our understanding of health, illness, and disease. Some of the older approaches to health care are being challenged by advances in biologic research, behavioral medicine, and environmental medicine combined with advances in the social sciences related to the social and cultural aspects of health. Clients also have sought out complementary and alternative therapies to augment their health. Many of these therapies have been incorporated into health care delivery.

Biologic Science

Advances in the biologic sciences, such as breakthroughs in genetics and the mechanisms that connect the mind and body, are changing the understanding of many diseases and risk factors.

Genetics

The Human Genome Project, a collaborative coordinated research effort through the NIH and Department of Energy, was funded by the U.S. Congress in 1988 (Jenkins, 2000). A second private organization, Celera Genomics, concurrently worked on decoding the human genome. This scientific breakthrough has made headlines and is predicted to radically change the diagnosis, risk assessment, and treatment of many diseases. These discoveries raise ethical, economic, and clinical issues at all levels of client care. Implications exist for medical management of predicted disease risks based on genetic profiles. Nurses will need to understand genetics to interpret information for and communicate it to clients. Professional nursing organizations (such as the International Society of Nurses in Genetics) exist that are dedicated to the scientific, professional, and personal development of nurses in the management of genetic information (Jenkins, 2000).

Ethical issues include protection of client confidentiality, which is among one of the foremost issues for providers and consumers (Jenkins, 2001). The impact that genetic screening may have on family relationships is another ethical impact. The potential uses of genetic information, fetal stem cells, and cloning are current topics of ethical discussion. Nurses in maternity and women's health need to be aware of the difficult ethical issues in making decisions related to fetal outcomes based on genetic knowledge available through prenatal screenings (Grant, 2000).

The National Coalition for Health Professional Education in Genetics (NCHPEG) has proposed a set of core competencies in genetics for all health care professionals (NCHPEG, 2001). Need exists for health professional curricula to incorporate genetic information so that professionals will be able to provide appropriate and accurate information for their clients.

Neuropsychology

Understanding of the physiologic mechanisms of thoughts and emotions has radically changed our understanding of many diseases. Selye's (1956) general adaptation syndrome described the systemic response of humans to stressors. Up until that time it was thought that specific diseases had specific causes. Selye's work generated a shift in thinking to the possibility of a person's resistance to disease being altered by the generalized effects produced by a variety of stressors. Continued research identified the neurologic and endocrine pathways by which humans respond to emotions such as fear, anger, and appreciation (Copstead, 1995). These pathways were further illuminated with the discovery of neuropeptides and neurotransmitters that connect a thought or emotion to physiologic changes (Pert, 1997). The pathways involved in anger and hostility and the way in which these emotions can result in

Critical Thinking

Competencies in Genetics

The National Coalition for Health Professional Education in Genetics (NCHPEG, 2001) has put forth a set of core competencies in genetics essential for all health care professionals. All health care professionals should, at minimum, be able to:

- Appreciate the limitations of their expertise in genetics.
- Understand the social and psychologic implications of genetic services.
- Know how and when to make a referral to a professional in genetics.

What do you think the role of a professional nurse is related to the criteria above?

How would you prepare yourself to function responsibly in the area of genetics?

How would you keep current in this area?

cardiovascular disease are fairly well understood (Rundell and Wise, 1996). This knowledge has been translated into stress management interventions in many areas of health care such as cardiac rehabilitation programs. Depression also has been associated with many diseases and has clear associations with heart disease (Rundell & Wise, 1996). Theoretical mechanisms related to emotions and the immune system are being developed as is a body of research on psychoneuroimmunology. This area has particular implications for nurses because they are in a position to facilitate coping and stress management in clients.

Environmental Medicine

With the excitement of the Human Genome Project, it is crucial to recognize that genes are only a part of complex disease processes. Very few diseases are the consequence of only genes or a single environmental event. Generally, diseases result from a combination of individual differences in susceptibility to diseases and dysfunctions that are linked to environmental exposure (Environmental Health Perspectives, 1997). Figure 1-5 illustrates the interaction of genetic predisposition, environment, and human behavior.

The DHHS, in collaboration with several private agencies including the Pew Charitable Trusts, has published guidelines to promote the development of a stronger public health system to protect citizens from environmental

Figure 1-5 The interaction of genetics, behavior, and the environment.

threats to health (PEHC, 2000). The effects of environmental toxins are of particular interest in the area of maternity nursing because prenatal exposure to some toxins has been linked with birth defects.

Behavioral Medicine

Behavioral medicine is a branch of medicine that focuses on behavior and the cognitive, emotional, motivational, and biobehavioral interactions that result in behavior. A growing awareness exists regarding the behavioral underpinnings of disease. Many risk factors are involved in human behavior, and these behaviors interact with biologic factors to influence health outcomes. Human behavior is a critical avenue for prevention and treatment. The NIH has defined the term *behavioral* in various ways: overt actions; underlying psychologic processes such as cognition, emotion, temperament, and motivation; and biobehavioral interactions (Kirschstein, 2000). All these factors are part of our understanding of human behavior. Human behavior and its relationship to health outcomes have implications for nurses counseling clients about health promotion.

Research in the neurosciences has advanced the treatment of many brain and neurologic disorders from sleep disorders to dementia. Understanding of the connections between anger, hostility, and other emotions has been incorporated into cardiac rehabilitation programs. Progress in understanding the mind and immune system promise to have implications in many diseases.

A large area of research is ongoing in the area of better understanding of motivation and behavior change. This type of research is crucial if one is to modify behaviors to improve health. Some of the major areas of behavior with implications for health outcomes include nutrition, exer-

cise, stress management, violence, smoking, the use of other harmful or addictive substances, and sexual behavior resulting in sexually transmitted diseases and unwanted pregnancies.

Social Aspects of Health

All societies have social structures, referring to the organized patterns of relationships between persons and groups in society. One social structure is the family. The roles that family members play and the effects of family dynamics on health are beginning to be addressed in health care (Figure 1-6). The effects of single-parent families on children, domestic violence, and isolation of older persons from family members are some of the social issues with medical consequences. Socioeconomic status and gender issues also are important social factors in health care, and their relationships to disparities in health outcomes are being examined.

Socioeconomic Status

Recent research is uncovering the impact that social inequities have on health. Risks of morbidity and mortality are increased with lower socioeconomic status (Wilkinson, 1996; Evans, Barer, & Marmor, 1994). This discovery has opened the frontier of medicine that examines health determinants embedded in the social structure of society. Social status generally is measured by income, education, employment, or housing. Research suggests that one's position in the social hierarchy affects one's health, with those at the lower end having poorer health. Although the mechanisms are unclear, much interest exists in the concept of social capital or one's **social assets** (benefits to health related to social position and socioeconomic status) and its relationship to health outcomes (Hawe & Shiell, 2000). Social networks and social relationships are increasingly

Figure 1-6 Family dynamics may have a significant impact on health.

being documented as being important in all aspects of health. Healthy egalitarian societies are more socially cohesive, have stronger community lives, and generally have better health indicators of lower mortality and morbidity than do societies with broad social disparity (Wilkinson, 1996).

Gender Issues

Women and men have gendered social roles and expected behavior in society. Gendered stereotypes also exist in the health care system. Most of medical research and approaches are based on knowledge about men. Women are biologically different from men and exist in a different social position in society. Women have higher incidences of certain diseases, such as depression, than do men. Women have different patterns of health care use than do men (Loustanaunau & Sobo, 1997). A series of workshops known as the Hunt Valley workshops, in 1991, recommended an agenda to advance research in women's health (NIH, 1999). That same year, the NIH established the Office of Research on Women's Health (ORWH). Researchers and clinicians are now beginning to understand how differences in gender culture and socioeconomic backgrounds influence the causes, diagnosis, progression, and treatment of disease. The ORWH ensured that clinical trials addressed issues regarding women's health and that there was appropriate participation of women in clinical trials. An additional goal of ORWH was to increase opportunities for women in biomedical research careers. The research agenda has been evaluated and updated in 1996–1997. The new agenda targeted specific areas of medical research and addressed the following overarching issues (NIH, 1999):

1. Women are important sources of new information that will correct essentially male models of normal functions and pathophysiology.
2. Research into women's health must include physical, mental, and emotional changes that occur over the full biologic life cycle.
3. Multidisciplinary research is essential.
4. Social research and behavioral research are necessary and need to be integrated into mainstream medical disciplines.
5. Collection of research data on women to better understand female function and pathophysiology should continue.

Cultural Issues and Health

Systems of health care exist in all cultures. All cultures have developed ways of explaining health and illness and have given names to particular disorders called diseases. These schema are called explanatory models and contain a

name for a condition or disorder, an understanding of what that disorder is, how one acquired it, what the course of the disorder would be, and suggestions for treatments (Kleinman, 1980). Biomedicine is one system of health care with a specific explanatory model and a scientific method of uncovering knowledge. Other systems may have different names and understandings of the disorder and may ascribe very different treatments. If the client and provider are based in discordant explanatory models, communication is impeded and the client is less likely to adhere to the recommendations given by the biomedical provider.

Kleinman (1980), a medical anthropologist, described three classic sectors of health care that are present in all cultures: professional, popular, and folk. Science-based biomedicine is the foundation of the professional sector that, in the United States and Canada, is synonymous with the health care system. This sector includes all the associated professions that work in collaboration with medicine such as nursing, physical therapy, occupational therapy, nutrition, psychology, and social work. These professions are greatly influenced by the biomedical approach to health and treatment of disease based on empirical science and sophisticated technology.

The second sector, the popular sector, is the largest. This sector incorporates the health care and health information provided by family, friends, and other social networks. Most health decisions are made and most health-related behaviors occur in this sector. That is, it is within the family and social networks that orientations toward health and lifestyle practices, such as eating, exercising, and simple remedies, take place. This sector also is the one in which the decision to seek help from other sectors occurs, as well as decisions regarding when, for which purposes, and from whom to seek additional care. This sector also determines if and how the person adheres to recommended treatments or advice.

The third sector, folk or traditional medicine, includes all the sacred and secular healers practicing outside the professional sector. This sector has recently gained great popularity in countries in which biomedicine has been well established. Sacred and secular healers have emerged in North America and Europe having a variety of complementary and alternative therapies. Many of these therapies have gained popularity outside of their original ethnic group, and many health care plans are moving to integrate some of these therapies into the mainstream health care system. For example, acupuncture is being researched and incorporated into some health care plans.

Recognition of these three sectors and the interaction among them is necessary for the nurse to facilitate clients from culturally diverse backgrounds to negotiate the health care system. **Cultural competency** describes a process of integrating cultural awareness in the delivery of

culturally appropriate clinical care. Cultural competency is becoming a more recognized skill for all health care providers.

Complementary and Alternative Therapies

Increasingly, the public has been employing various strategies to enhance health and in some cases treat disease. Some of these strategies are massage and other forms of body work, use of food supplements and herbal remedies, and various forms of psychologic and spiritual techniques. Providers of these treatments comprise one of the more rapidly growing sectors of the work force. Many of these treatments are being researched, and the NIH has a center for studying them. Most of these treatments are used as adjuncts to biomedical health care, and many are being integrated into health care systems. The popularity of these treatments, and in some cases their proven effectiveness, has opened new approaches to promoting the health of clients. This popularity is of particular interest to those in the nursing profession because many of these strategies have been reported on in the nursing literature and have been practiced as autonomous nursing interventions. These strategies are facilitating health care providers to broaden their view of disease processes to the illness experience. In doing so, providers can begin to better understand and provide help and support to clients in their experience with illness or their attempts to stay healthy.

CONTEMPORARY CHALLENGES IN HEALTH CARE DELIVERY

A number of issues and challenges exist for clients and for anyone working in health care. Many of these concerns are associated with the recent trends and advancements in health care. Technologic advances bring not only increased ability to extend care and access information but raise new challenges. Changing U.S. demographics raise issues of meeting cultural competence and dealing with issues of age and gender. Cost containment remains an issue. One of the strategies in cost containment is differentiated practice on multidisciplinary teams, which is of particular interest to nurses because we have several levels of practice.

Rapidly Changing Technology

Technology is increasing in all areas. Technology in diagnosing, monitoring, and treating clients is changing almost daily. The most radical changes in our culture have been the technologic developments in how we attain, process,

and communicate information. The term for these developments is informatics and specifically **health care informatics** (integration of computer science, information science, and health care professionals involved in collecting, processing, and managing data). The ANA defined nursing informatics as a specialty that integrates nursing science, computer science, and information science in identifying, collecting, processing, and managing data and information to support nursing practice, administration, education, research, and the expansion of nursing knowledge (ANA, 1994).

Technology in Diagnosis and Treatment of Disease

Technologic breakthroughs in health care are coming from scientific research at many levels: the systems, molecular, and genetic levels. Technologic devices (such as miniaturized surgical instruments that allow intricate surgeries to be done with minimal trauma to clients) have reduced hospital stays. Understanding how to use and interpret these new technologies is a continuing challenge for nurses. Keeping abreast of new advances in areas of medicine such as genetics calls for continuing study on the part of every professional.

“Telemedicine” allows for assessment, monitoring, and treatment of clients at a distance. For example, while the mother is at home the heart rate of her fetus can be monitored and conveyed electronically to the hospital or clinic for interpretation. These technologic advances require that nurses be adept in using the latest technology.

Technology in Communication and Health Informatics

The nursing profession has been engaged in developing a common language for nursing practice and in defining a nursing minimum data set (NMDS) to reflect the common core of data that describes nursing practice. The four classification systems generally used for nursing and supported by the ANA are North American Nursing Diagnosis Association (NANDA) Nursing Diagnosis Taxonomy, the Omaha System, Home Health Care Classification (HHCC), and Nursing Intervention Classification (NIC) (Romano, 2000). The ANA has issued a position statement in support of the development of national nursing databases and establishment of a uniform language for nursing practice (ANA, 1994). The ANA has recognized NANDA as a body to be used for development, review, and approval of nursing diagnoses.

One of the major ethical issues concerning the use of computers in health care and electronic medical records is that of client privacy and confidentiality. Nurses are frequent processors of client information and must be

accountable for the accuracy of data and maintenance of security to protect client confidentiality. The ANA position paper on privacy and confidentiality (ANA 1999) addresses these issues and states that nurses should contribute to the development of standards, policies, and laws that protect patient privacy and the confidentiality of health records and information. New legislation is slated to take effect in 2001 to protect the privacy of client's medical records. Many in the health care field are concerned that putting systems in place to comply with these regulations will be difficult and costly.

Client Access to Health-Related Information

Clients can now access much of the same health-related information as can health care providers. Many government websites with clinical guidelines and medical information are open to the public. Web browsers can access medical journals and scientific information. Nurses and other health care professionals are familiar with peer-reviewed journals and the research process to help evaluate health information. Clients may not have the appropriate background to interpret this information and may become needlessly worried or misinterpret appropriate actions.

Client Education

Using the Internet

The following are some questions that can guide clients in evaluating information on the Internet:

- Does the information seem logical?
- Is the information consistent with information from their health care provider?
- Is the website trying to sell a product or service?
- Are unrealistic or unsubstantiated claims being made?
- Is the information extremely biased against biomedicine or a different complementary therapy?
- Is the information documented and researched?
- Are there links to reputable sites?
- Do the creators of the site have credentials, institutional affiliations, or sponsorship?

Clients also are exposed to many helpful organizations that may have chat rooms that serve as self-help groups. Clients may find many valuable resources for health problems by searching the Internet. Much misinformation also is available on the Internet, and nurses may be in the position to help clients interpret the information they receive and sort out accurate information from useless or potentially harmful information. Without help, clients may be subject to fraudulent claims and inaccurate information.

Changing Demographics

The U.S. demographics are changing. Trends in ethnic distribution and the projected increases in the population of older persons have implications for health care provision.

Ethnic Pluralism

A dramatic increase has occurred in U.S. ethnic and minority populations. The U.S. census has classified people according to race as African American, Caucasian, other races, and people of Hispanic origin (Census gov, 2001). According to census projections, European Americans are the majority; however, African Americans, Hispanics, and other ethnic groups are increasing at a faster rate. Projections of the increase in population between 1995 and 2050 are as follows: Caucasians are expected to increase by 35.1%, African Americans by 82.8%, other races by 233.9%, and Hispanics by 258.3% (Administration on Aging, 2001). As a result, health care providers are providing care to clients who often do not speak the same language and have beliefs, values, and traditions that differ from their own. Cultural competence and linguistic competence are needed to respond effectively to health care encounters with these clients.

The Office of Minority Health (OMH) has published recommendations for national standards and an outcomes-focused research agenda regarding ensuring cultural competence in health (OMH, 2001). These recommendations are clustered into those pertaining to linguistic competence and the provision of appropriate interpreters and translation of written materials and those that relate to cultural competence. Several recommendations were made for organizations to promote competencies of the staff, engage the communities, and promote accountability. Formal certification for interpreters now exists in a few states (Cross Cultural Health Care Program, 2001).

It is important to recognize not only how to communicate with clients but how cultural differences may affect their health. Some biologic differences exist among cultures that affect certain diseases, such as Tay-Sachs disease in Ashkenazi Jews or the way some groups react to medications. Cultural beliefs, values, and traditions are the bases for most human behavior such as diet and exercise

habits. *Culture* refers to integrated patterns of human behavior that include language, thought, communication, actions, customs, beliefs, values, and institutions of racial, ethnic, religious, or social groups.

Aging of the Population

In addition to changes in ethnic and racial makeup of the country, the population of older persons is projected to increase by 17% in 2010, 75% from 2010 to 2030, and 14% from 2030 to 2050 (AOA, 2001). This population will increase to about 79 million. From 2010 to 2030, the rate of growth will exceed that of the population under the age of 65 years; therefore, the proportion increases to 20%. This increase is related to low fertility rates, maturing of the baby boomers, and a decrease in mortality rates of adults in older age groups. Older women generally outnumber older men. The health concerns related to the aging population are the dependency burden of this large number of elderly if they are in poor health. Thus, it is an important public health concern and a humane objective to help the aging population maintain good health (Figure 1-7).

Balancing Cost with Best Practice

Contemporary health care continually balances the best practice and best use of technology with the attempt to keep costs from escalating. In addition to other technologic factors that increase costs, litigation adds to the costs of delivering health care. Differentiated practice has been discussed as a means to streamline care.

Figure 1-7 Good health, a positive attitude, and healthy behaviors are important at all ages.

Litigation

Litigation in health care has increased. With the increase in technology, providers often feel they need to use expensive tests, even if not medically necessary, to avoid being sued. As clients become more knowledgeable about health issues, they are demanding more tests and sometimes treatments. Providers feel they must practice defensively to avoid lawsuits, which often adds to the costs of health care.

Differentiated Practice and Regulatory Issues

Differentiated practice focuses on the structuring of roles and functions of nurses according to education, experience, and competence. Several models have been used to redesign nursing practice in institutions to use nurses most efficiently and effectively (Koerner et al., 1995). Many of these models also used clinical pathways. These pathways were designed as interdisciplinary plans of care to manage client populations by diagnosis or medical procedure. For example, a normal delivery with no complications might follow a clinical pathway. In one example (Koerner et al., 1995), a clinical specialist with an MSN would serve as case manager to coordinate the care based on holistic knowledge and familiarity with research and theory. The nurse, generally with an associate degree, would provide care for specified periods of time in structured settings with well-established policies and procedures and for clients who do not deviate from the clinical pathway. The primary nurse, generally with a BSN, would provide integrated health care from admission to discharge in both structured and unstructured settings. Many hospitals have instituted some form of differentiated practice and the use of clinical pathways.

NURSING IMPLICATIONS

Nurses must understand the environment of the health care system to function as a member of the health care team and adapt the environment to benefit the client. The holistic approach corresponds well with the changing orientation of health care delivery. Holistic nursing care is based on the view that an integrated whole has a reality independent of and greater than the sum of its parts (Dossey, Keegan, & Guzzetta, 2000). Holistic nursing involves understanding the interrelationships of the biologic, psychologic, sociocultural, and spiritual dimensions of the person who is interacting with the internal and external environments. This philosophic approach is consistent with most nursing theories (Stevens-Barnum, 1994; Mariner-Tomey, 1994) and has been used to differentiate autonomous nursing practice from that of other disciplines such

as medicine, nutrition, and psychology. The holistic approach is the foundation of contemporary nursing practice and provides for delivery of the most comprehensive nursing care. This philosophy also enables nurses to assume a proactive role and become leaders in the new health care system.

NURSING SKILLS FOR PROFESSIONAL PRACTICE

In the current health care system, it is not sufficient for the practicing nurse to simply follow physician's orders. As an important member of the health care team, the contemporary nurse is required to participate in planning and implementing effective, cost-efficient health care. This role requires a nurse who has good cognitive abilities and who is able to reason and apply sound clinical judgment. As health care and information technology continue to advance, the nurse must have adept technical skills, which include the efficient use of technology. Nurses also need excellent communication skills for counseling and educating clients and communicating professionally with the interdisciplinary team. Self-reflection also is an important skill for the nurse to advance professional and personal development. These skills are learned throughout the nurse's career; however, the foundation must be laid during basic nursing education. Obtaining refined and sophisticated nursing skills requires practice; however, theoretical concepts must be socialized into the basic nursing curriculum.

Cognitive Skills

Cognitive skills, frequently referred to as critical thinking skills, include attainment of knowledge, ability to reason, analytic processing, clinical judgment, problem-solving, and critiquing. Attainment of knowledge is the focus of preparatory formal education and professional continuing education. The ability to reason is the foundation of any professional role. *Reasoning* is the act of discovering, formulating, or concluding by the use of reason or thought. Reasoning is an essential skill for practicing nurses and is the basis for proficiency in clinical judgment. Although reasoning is considered to be an ability all humans have to some degree (often called common sense), a more formal type of reasoning is required for the practice of nursing, which has been labeled critical thinking. Critical thinking skills can be very difficult to teach and more difficult to learn because they involve using abstract thought, judgment, and logic. **Critical thinking** is a formal and structured type of reasoning used in nursing as the foundation for sound clinical judgment. It involves reasoning, processing data, analyzing, and evaluating. The first step in the

learning process is to define and describe these concepts involved with reasoning.

All reasoning has a purpose, and usually it is to try to understand a phenomenon, settle a question, or solve a problem. The holistic nurse uses reasoning to understand the client, analyze and interpret information about the client, and engage in problem-solving.

Reasoning can be very complex because it is based on assumptions and reflects a certain point of view. Reasoning involves organization of data, information, and evidence shaped into concepts or ideas. Analytical processing must take place. Conclusions are drawn when the process is complete and some meaning is placed on the conclusions. All reasoning therefore leads to outcomes that have implications or consequences, which may be positive, negative, or unexpected. It is therefore important for the nurse to practice self-reflection and develop critiquing skills.

Critical thinking uses a structured type of reasoning. When used properly, critical thinking goes beyond stating personal preferences and opinions. This type of thinking allows the nurse to think independently of cultural and experiential knowledge and, at the same time, critique and integrate these sources of knowledge. Critical thinking involves more than simply restating facts; it involves an active use of formal knowledge.

Critical thinking allows one to distinguish among three different types of questions, that is, those with:

1. One right answer (factual questions)
2. Better or worse answers (well-reasoned or poorly reasoned answers)
3. As many answers as there are human preferences (opinion answers)

Only the second category of questions is amenable to reasoned judgment following critical thought. Unless nurses can distinguish between these three types of questions, it is possible that they will make decisions based on personal views rather than sound reason and intellectual thought (Elder & Paul, 1996). Successfully using this process is fundamental to sound clinical judgment.

Vickers (1997) clarified the need for critical thinking by asserting that there are a very large number of beliefs about health, some of which are contradictory. It is very unlikely that all commonly held health beliefs are both valid and useful. For example, when a woman becomes pregnant, it is a widely held belief that she needs to increase her dietary intake sufficiently to maintain the health of two entities, the mother and unborn child. The reality is that if a woman adopts this attitude and does not manage her diet conservatively, her risks for obesity, pregnancy-induced hypertension, and gestational diabetes are increased. It is through the process of logical reasoning and critical thinking that these conflicts are resolved.

Several components are necessary to begin to successfully use critical thinking. A specific formal knowledge base and experience are required to develop competencies in this area (Kataoka-Yahiro & Saylor, 1994). The knowledge base is begun during prenursing courses and is built on throughout the nursing career. Technical skills also are established during basic education but need to be refined with experience. As technology advances, the focus on clinical decision making, client-focused data, and client-appropriate solutions will radically alter the way concepts are defined and decisions in nursing are made (Turley, 1996). The ability to adapt to unforeseen elements of change requires flexibility.

Kataoka-Yahiro and Saylor (1994) described attitudes of nurses that are considered essential for the development of critical thinking skills: self-confidence, independence, fairness, responsibility, risk-taking ability, discipline, perseverance, creativity, curiosity, integrity, and humility. Critical thinking and intellectual thought are expressed through professional and personal communication. Certain standards are used to judge intellectual thought; these are clarity, precision, accuracy, relevance, depth, breadth, and logic (Paul & Elder, 1996). The degree to which these standards are met determines how logical the thought is and how valid the conclusions are that are based on that thought. These standards apply equally to critical thinking.

Clarity refers to having purpose of thought. Clarity involves differentiating the nurse's purpose from related purposes, and it requires periodic evaluation to ensure that thinking stays on target. To act on thought that lacks clarity exposes clients to unnecessary health risks and the clinician to unnecessary medical and legal risks.

Precision involves understanding the scope and meaning of the issue at hand. When issues are complex, they may need to be broken down into components to identify which type of question is to be resolved. To lack precision of thought increases the risk of unneeded therapy for the client.

Accuracy is ensured by identifying assumptions to determine if they are justifiable. Another factor involved in accuracy of reasoning is self-evaluation by the reasoner of personal beliefs and values that may influence reasoning outcome. Seeking the opinions of others is a method that promotes accuracy through an overt attempt to consider all points of view related to the issue before making decisions.

Many times problems are very complex, and whether all data surrounding the issue are relevant may be unclear. A determination must be made as to which data are sufficient and necessary to use in finding a solution. Analysis of the information until it is reduced to component parts may be useful. Sufficient depth and breadth must be considered to avoid missing important details or related issues. Caution must be advised to avoid reduction to oversimplification. When oversimplification occurs, important con-

textual factors may be eliminated from the decision-making formula, leading to unacceptable outcomes for the client or health care provider.

Cognitive skills necessary for critical thinking include interpretation, analysis, evaluation, inference, explanation, and self-regulation (Pless & Clayton, 1993). To interpret data necessitates the ability to categorize, recognize the significance of, and clarify the meaning of concepts. Through the process of analysis the reasoner is able to examine ideas, identify arguments, and determine the components of those arguments. Evaluation skills are required to assess claims and determine the validity of arguments. It is only through analysis, synthesis, and evaluation that inferences can be made to develop hypotheses and draw conclusions. The ability to articulate is required of the skilled reasoner to explain the findings, share the results, and justify the procedures, and then to present arguments that are reasonable. Self-awareness is required by the reasoner to evaluate the logical process.

Optimal nursing care depends on the nurse's ability to use logical reasoning and critical thinking skills throughout the nursing process. Reasoning is used to identify and conceptualize problems in terms of the nursing process through analysis of the problem, synthesis of this information into a plan of intervention, and identification of outcomes to facilitate modification of the plan of care to meet client needs (Table 1-1).

Technical Skills

As health care becomes more efficient and with continual technical changes in medical equipment, nurses must keep their technical skills current. Basic technical skills related to the operation of technology generally are part of the nurse's foundational education; however, these skills must be developed and expanded in practice. Nurses need to know how to operate, appropriately use, understand, and maintain technical equipment. Technologic proficiency

Table 1-1 Critical Thinking Skills Applied to the Nursing Process

Critical Thinking Skill	Nursing Process Element
Attainment of knowledge	Assessment
Integration of knowledge	Nursing diagnosis
Ability to reason through	Outcome identification
Analytic processing	Planning
Clinical judgment and problem-solving	Nursing intervention
Critiquing	Evaluation

goes beyond knowing how to operate a particular machine or execute a procedure. Nurses must be adept in interpretation of technology. It is not sufficient to record technologic data; nurses must understand and interpret that data and integrate that understanding into the nursing process. Nurses' participation in the health care arena and their close relationship with clients' experiences place nurses in a position to develop devices to facilitate their work and for client use.

Information technology is changing rapidly, and electronic communication is the technology of the future. Nurses must be adept at using this technology both to keep their own information up to date and to ensure that appropriate nursing data are part of clients' records. Opportunities also exist for nurses to use this media creatively to educate clients.

TECHNICAL SKILLS FOR THE CONTEMPORARY NURSE

1. Use of Technology
 - Operation of equipment and supplies
 - Maintenance of equipment and supplies
2. Interpretation of technology
3. Application of technologic expertise

Communication Skills

Communication skills are vital to the entire nursing process, and they are important to the nurse's ability to engage in interrelationships. All communication involves a sender and receiver. The nurse must be clear and accurate in both roles. Thus, nurses need to be astute in various types of communication: verbal, nonverbal, written, and virtual. Nurses also are senders of nonverbal communication; through self-awareness, nurses develop insight into subtle forms of communication.

A strategy of communication often used in client care includes client teaching and counseling. Client teaching follows the nursing process and must be anchored in a mutually derived diagnosis of lack of knowledge. Teaching is done with individual clients, families, and groups. Nurses are expected to develop client education programs and teach groups of clients (Figure 1-8). Skills in sequencing material and presentation of information appropriately to the selected audience are useful, and expert knowledge of the topic is essential.

COMMUNICATION SKILLS

1. Mastery of various types of communication
 - Verbal
 - Nonverbal
 - Written
 - Virtual
2. Application of specific methods of communication
 - Teaching
 - Counseling
 - Formal presentations
3. Domains for communication
 - Inter- and intraprofessional communication
 - Nurse-client communication

A nurse may conclude the problem or nursing diagnosis is lack of knowledge when, in fact, it may be that the recommended intervention is in conflict with the client's value system or the client does not have access to resources to adhere to the recommendations. In these cases, client counseling may be the more appropriate intervention. This skill includes working with the client in mutual problem-solving and developing creative solutions that are uniquely suited to the needs of the client and situation.

Nurses communicate in a number of domains that include different audiences and various media. In addition to communicating with clients, nurses must communicate effectively with professionals from multiple disciplines. To do so, nurses must be familiar with the scientific process and the perspectives of other members of the health care team.

Figure 1-8 Client teaching often takes place in a group setting such as in this seminar on family planning.

Writing skills are the hallmark of intellectual and professional credibility. Nurses are increasingly writing in charts, correspondence, and client education. Many also are writing books and journal articles for professional and lay audiences. The written word allows for precision and inclusiveness that are not available through oral communication. Writing and formal speaking are venues by which nurses' intellectual and critical thinking skills are evaluated by others within and outside of the profession. The aforementioned criteria are the standards by which professional work often is judged.

Electronic or virtual types of communication are the media that nurses need to master in the future. It is vital for the viability of the profession that nurses develop the skills to communicate through this media. This media allows for avenues of expression that go beyond words and the two-dimensional printed page. This technology allows three-dimensional and animation effects that afford enormous potential for new types of communication. Nurses can communicate through mass media such as television, radio, local periodicals, and presentations using multimedia. Competence in the use of various media therefore is valuable.

Collaborative Skills

The nurse of the 21st century must develop collaborative skills. These skills are necessary to function as a member of the health care team required to meet the needs of the client, family, and community. It has been suggested that personal objectives are suppressed to meet the objectives of the team (Eddy, 1996). The need for collaborative skills is best illustrated through application of the concept of continuity of care for clients across settings. Although health care providers may be specialists, communication and evaluation must occur across disciplines. The nurse is in an excellent position to communicate client needs across disciplines (Hunt, 1998). The nurse must collaborate with physicians, families, third-party payers, attorneys, and members of other disciplines to meet the health care needs of the consumer (Carnevali & Thomas, 1993). As technology advances, collaboration among disciplines is likely to become increasingly important (Lasker et al., 1997). In fact, Roger J. Bulger, president of the Association of Academic Health Centers, suggested that no covenant among health care providers would be complete without acknowledgment of the need for collaboration among all the members of the team (Bulger, 1998).

Cultural Competency

Cultural competency is a skill that is developed through continual exposure, reflection, and awareness of cultural differences. This process begins with a recognition of the

importance that cultural heritage plays in any human interaction. An understanding of one's personal heritage provides a platform from which to understand the culture of others. Cultural heritage refers to those beliefs and values that guide and orient our behavior, many of which are so integrated into daily life that one is generally unaware of one's own cultural perspective. Nurses may focus on the culture of the patient when it is different from their own but are unaware of the cultural heritage of their own beliefs. This lack of awareness then takes the form of prejudices, assumptions, and expectations. Decisions may be made from this cultural basis and may therefore create ethical conflicts. Thus, it is important for nurses to be aware of their own beliefs to avoid imposing them on others. Value clarification is a strategy to increase personal awareness and make some of the beliefs explicit.

Because cultural competency is a dynamic process, a defined level at which the nurse is competent does not exist. Rather, the competent nurse is one who continually engages in the process of increasing competency. Barry (1996) and Kavanaugh and Kennedy (1992) describe the following five steps in developing cultural competency:

1. Awareness and acceptance of cultural differences, which requires an open mind about other views of the world.
2. Awareness of one's own biases and attitudes, which can become barriers in interacting with others.
3. Recognition of dynamic differences among cultures without promoting the superiority of one culture over another.
4. Developing basic knowledge about other cultures through literature, observation, participation, interaction, and communication with people from diverse cultures.
5. Adaptation of clinical practice by being receptive to different cultures, actively seeking consultation from persons from that culture, and incorporating those ideas into one's practice. Skills also include articulating an issue from another's perspective, recognizing and reducing resistance to different ideas, and admitting mistakes and learning from them.

Economic Expertise

As the nursing profession advances and individual nurses work on interdisciplinary teams, nurses will need to understand the importance of economic issues in the delivery of health care. Nurses need to be able to justify their own participation in health care. They also are held accountable for keeping unnecessary costs under control. Nurses acting as case managers must understand the health care payment system to be able to direct client interventions

Critical Thinking

Values Clarification to Develop Cultural Awareness

Recognition of personal values includes assessing, exploring, and determining the ideals, principles, and behaviors that give meaning to our lives. Effective value clarification allows the nurse to be aware of personal values before being confronted with different values in the clinical setting. The purpose is not to change personal values but to become aware of personal beliefs and values. The following are three strategies for this exploration. Select a number of positional statements and identify if you strongly agree, agree, do not care, disagree, or strongly disagree. (There are no right or wrong answers.)

Women should have the right to abortion on demand.

Mentally retarded people should be sterilized.

Women should not use anesthesia during labor.

Teenagers should not be taught about birth control measures in public schools.

Menopausal women should not take hormonal replacement therapy because it is against nature.

Complete the following sentences:

If I were pregnant and unmarried, I would . . .

Sexually active teenagers should . . .

If I were a parent of a teenager, I would . . .

If I were having a baby, I would want . . .

Rank these priorities. With limited resources, which clients should be given care?

Preterm infants weighing less than 2 pounds at birth.

Infants born with the human immunodeficiency virus.

Antepartal clients with complications of pregnancy.

Family planning agencies.

Web Activities

- Use a search engine to look up a particular health-related topic.
- Search a medical library site for evidence-based practice.
- Visit the website of the American Nurses Association, and examine some of the position statements.
- Visit the website of the Office of Women's Health at the National Institutes of Health, and explore the research agenda concerning women.
- Visit the websites of the Centers for Disease Control and the Agency for Healthcare Research and Quality, and search for guidelines for practice.

Self-Awareness and Reflective Practice

One of the most overlooked skills is that of self-awareness. This skill is important in the development of one's intuitive ability and the integration of personal knowledge. The skills used to develop this ability are self-reflection, value clarification, intuition, and cultural competency. Self-reflection is a practice that is useful in the nurse's ability to reflect on actions, thoughts, and beliefs and critique these for further development. This activity develops awareness and integration of personal and professional experience. Value clarification is important in understanding one's personal belief system as it pertains to professional ethics. Reflective practice is a deliberate process of discussing, reflecting, and even keeping a journal about one's practice. These activities are a systematic way to gain new insight, understanding, and compassion about one's clinical practice.

Development of Intuition

Historically, nurses have worked in a biomedical environment that has been greatly influenced by scientific reasoning. The traditional nursing process has focused on this type of analytic thinking. In practice, however, as the nurse moves from a beginner to an expert practitioner, other types of skills are integrated. In a study of the development of clinical excellence in nursing, Benner (1984) linked the expert's ability to move beyond simple application of rules and analytic processes to the development of an intuitive grasp of complex situations. Intuition, according to Rew (1996) has three attributes: the knowledge is

that are economically feasible. Many nurses have moved into administrative roles that rely on a good knowledge of business operations. Some advanced degree programs combine an MSN with a master's degree in business administration. Other programs have a strong economic component in the curriculum.

immediate, it is received as a whole and goes beyond the obvious, and it can occur in the absence of the conscious analytic process.

Beginners often choose to focus on technical skills and analytic reasoning until they develop proficiency. These skills often are emphasized in the beginning of formal education programs for nurses. In some cases, practicing nurses do not continue to develop the more holistic skills. The full range of these skills can be integrated into the nursing process so that the beginner may progress to expert through the integration of knowledge, experience, and intuition.

Rew (1996) discussed the need for the holistic nurse to develop not only the empirical or scientific skill, but also aesthetics, ethics, and a personal way of knowing that engages the development of intuitive thinking. A nurse with developed aesthetics skills attends to feelings and things that are pleasing to the senses (Rew, 1996). This nurse is very aware of sounds, sights, smells, taste, and touch and intervenes by creatively altering these elements in the environment. The professional expert nurse also is aware of values and employs this awareness in ethical practice.

Key Concepts

- An understanding of population health and the need to cut costs have shifted the emphasis of the health care delivery system from treatment of disease to prevention and health promotion. The concepts of risk assessment and management have pervaded all of health care.
- This shift has moved much of health care to the community setting and engaged multidisciplinary teams of providers, with both individuals and communities as active partners in the pursuit of health.
- Concerns for cost-effectiveness have affected the organization of health care delivery and required differentiated practice on the part of nurses.
- Health care providers are being more accountable for evidenced-based practice and for use of various guidelines to ensure the best quality health care practice.
- The ways of understanding health and illness are changing related to the following: advances in biologic science, environmental medicine, and behavioral medicine; the social aspects of health; cultural understanding; and complementary and alternative therapies.
- Contemporary issues include dealing with technology and informatics, changing demographics, and economic issues.
- The nursing profession historically has valued and described a holistic approach that is congruent with the changes in health care delivery.
- The nurse needs not only to develop content knowledge but also cognitive skills, technical skills, communication skills, cultural competence, collaborative skills, and a practice of self-reflection to fully enact the professional role.

Review Questions and Activities

1. One of the most fundamental shifts in health care delivery in the United States in the late 1900s has been:
 - a. Lowering of costs of providing care
 - b. Expansion to a focus on health
 - c. Emergence of nurses to positions of power in health care delivery
 - d. Advancement of isolated specialtiesThe correct answer is b.
2. The United States has been tracking health goals since:
 - a. 1949
 - b. 1959
 - c. 1970
 - d. 1979The correct answer is d.
3. Which governmental agency was established to reduce disparities in the delivery of health care?
 - a. National Institutes of Health
 - b. Food and Drug Administration
 - c. Health Care Financing Agency
 - d. Agency for Healthcare Research and QualityThe correct answer is d.
4. The Office of Research on Women's Health was established to:
 - a. Reduce medical costs
 - b. Standardize care to minorities
 - c. Promote research on women's health
 - d. Gain political equity for womenThe correct answer is c.

5. Which of the following is a true statement regarding cultural competency?

- One can be certified by taking a short course
- One must go to foreign countries to learn this
- One must understand one's own culture
- One must learn this from certified experts

The correct answer is c.

6. Holistic theories in nursing are most congruent with which of the following issues in contemporary health care?

- Managed care
- A focus on health promotion
- Multidisciplinary teams
- Alternative systems of health care

The correct answer is b.

Issues in Maternal, Neonatal, and Women's Health

The practice of maternal, neonatal, and women's health care nursing is very complex. Many of the issues related to this nursing practice can be associated with strong emotional reactions.

- *As a nurse, which issues would I place as most important to be resolved related to women's health?*
- *Do I ascribe to the philosophy that a pregnant woman is one client or two clients?*
- *Do I think additional services are needed to meet the nation's needs and resolve issues related to maternal, neonatal, and women's health?*

Key Terms

Cost containment

Evidence-based practice

Position statement

Risk-benefit analysis

Competencies

Upon completion of this chapter, the reader should be able to:

1. Discuss pertinent issues related to maternal, neonatal, and women's health.
2. Describe how these issues have developed in recent history.
3. Detail technologic advances in the field of maternal, neonatal, and women's health.
4. Analyze the importance of goals and guidelines for the practicing nurse.
5. Describe how health policy affects the practice of maternal, neonatal, and women's health.

Nursing in maternal, neonatal, and women's health care is very challenging and very rewarding. Some of the complexities of today's practice are discussed along with the social, economic, medical, and legal challenges facing nurses who practice in this field.

CHANGES IN MATERNAL, NEONATAL, AND WOMEN'S HEALTH CARE

Many factors have affected the course and practice of women's health care over the past few years and decades. Some of the most important influences are discussed.

Advances in Diagnosis and Treatment

Many advances in diagnosis and treatment have been made in the 20th century. These advances have included use of new technology, better methods of prenatal screening, better methods for management, and recognition of new entities affecting health. Examples of advances in women's health are the routine use of Pap tests, mammography, and the advent of laser technology for treatment of gynecologic conditions.

In the 1960s Rh₀(D) immune globulin (RhoGAM) made an important contribution to maternal and newborn health by greatly reducing the number of cases of Rh isoimmunization. Before the introduction of RhoGAM, women who were Rh-negative and pregnant with an Rh-positive fetus were at risk for having an infant with hy-

drops, and that risk increased with each succeeding pregnancy. Since the routine administration of RhoGAM the incidence of this condition has decreased sharply, with the exception of women who have had an early spontaneous

REFLECTIONS FROM A NURSE

"I have been in nursing for almost 40 years and in maternal, neonatal, and women's health for most of that time. Expectations of nurses have changed radically during my career to the extent that the practice of nursing today requires much more responsibility and accountability for tasks that were not in the nursing domain when I went into practice. I wish I could predict how maternal, neonatal, and women's health nursing will change over the next 40 years. As I near retirement, if I were asked what advice I would give new graduates into the profession, I would say to never be afraid of taking risks or accepting change. In taking risks, however, be sure that you practice within your scope of practice, within the law, and within your personal ethics—and always consider the best interests of your clients."

abortion and are unaware of the need for antibody testing and immunization.

Fetal monitoring first became available in the 1970s for general use. When fetal monitoring was first developed, it promised to drastically reduce or eliminate the incidence of fetal intrauterine hypoxic ischemic events that occurred during labor. As a result, the number of children born with brain damage and the incidence of unnecessary cesarean sections would be decreased. Although the technology has flaws, it is still widely used. The American College of Obstetricians and Gynecologist (ACOG) and the American Academy of Pediatrics (1997) suggest that there is no difference between use of the electronic fetal monitoring and auscultation for assessment of fetal heart tones, if the equipment is used and documented properly. Much of the accuracy of fetal monitoring relates to the ability of the health care provider to interpret the monitor readings. In 1996, a consensus panel of experts met to begin to standardize the terminology related to fetal monitoring to clarify some of the ambiguity in interpretation (National Institute of Child Health and Human Development Research Planning Workshop, 1997). This panel of experts decided that the major weakness of the use of fetal monitoring was the lack of standardization of definitions and terminology among users. This panel made recommendations that should increase the reliability and validity of fetal monitoring results in practice and research.

In the 1970s, ultrasonography became an important tool in the diagnosis of maternal, neonatal, and women's health conditions (Callen, 1994). This technology has been important in identifying ectopic pregnancy before rupture. Ultrasonography has been instrumental in performing other tests such as amniocentesis and chorionic villus sampling. This technology has been widely accepted and performed in pregnancy to establish gestational age, fetal anomalies, and multiple gestation. In the neonatal arena, ultrasonography has become an important tool in assessing the infant for intraventricular hemorrhage. In the women's health arena, ultrasonography has been used to screen for ovarian cancer, uterine fibroids, and endometrial cancer. This technology has advanced to the degree that three-dimensional ultrasonography is now available. An expert nurse with special training may be the provider that conducts the ultrasound evaluation (Huffman & Sandelowski, 1997).

The biophysical profile (BPP) was developed to provide additional information about fetal well-being. The BPP uses ultrasonography in combination with fetal monitoring technology to increase the reliability of prediction of negative fetal outcome. The BPP has increased the likelihood that the health care provider will identify the fetus at risk. The incidence of negative fetal outcome, however, has still not been reduced to zero.

Endoscopy has been a major advance in the diagnosis and treatment of women's health problems and has elimi-

nated the need for major surgery in many cases. The laparoscope has been used for salpingectomy, myomectomy, and oophorectomy (Schenk & Coddington, 1999). The hysteroscope has been used for menstrual ablation to treat intractable uterine bleeding, with few risks and side effects. Most recently the endoscope has been used in a transcervical, transvaginal approach to visualize the fallopian tube from the uterotubal junction to the fimbria (Surrey, 1999).

Advancement in diagnosis and treatment has been made with the Human Genome Project. The advancement has significant implications for diagnosis and treatment. Two examples of application of knowledge obtained by the Human Genome Project follow. Research has been done on the Y chromosome. Until recently, scientists had great difficulty determining its role. It was thought that the Y chromosome played a limited role in fertility (Jegalian & Lahn, 2001). New findings demonstrate that the history of this sex chromosome has been strikingly dynamic. These findings have assisted in the explanation of some infertility problems in males. If deletions occur in any of three significant areas on the Y chromosome, infertility results. This type of azoospermia may be successfully treated with intracytoplasmic sperm injection.

Another example of application of knowledge discovered from the Human Genome Project is the technology in which gene and stem cell transplantations are used to treat disease. The earliest use of this technology was to treat genetic disorders such as cystic fibrosis and Duchenne muscular dystrophy (Kaji & Leiden, 2001). Geneticists have identified human genes involved in many disorders involving single genes and some cancers.

Health Indicators

In 2000, a national state-by-state survey was completed and a report card developed (National Women's Law Center, FOCUS/University of Pennsylvania & The Lewin Group [FOCUS/Lewin], 2000). The report card provides indicators that measure women's access to health care services; the degree to which women receive preventive health care and engage in health-promoting activities (Figure 2-1); the occurrences of key health conditions in women; and the extent to which the communities in which women live enhance their health and well-being. The indicators are displayed in Box 2-1.

This survey further identified 27 benchmarks related to the indicators that should be met. The results indicate that performance by the nation is unsatisfactory because some of the states or the District of Columbia have only met five of the benchmarks. The single benchmark met by all states and the District of Columbia is women aged 50 years and older receiving mammograms. The benchmarks missed are shown in Box 2-2.

Figure 2-1 This woman is managing her diabetes successfully during pregnancy by following her insulin injection schedule and keeping all regular prenatal health appointments.

Findings of this study further indicate that women's access to health care is seriously compromised by inadequate health care coverage. Approximately 14% of women are uninsured. The percentage of uninsured women varies by state. Hawaii provides the best coverage, with 7.5% of women uninsured. Texas provides the worst, with 28% of women aged 18 to 24 years uninsured (FOCUS/Lewin, 2000).

Neither the nation nor the states have met the challenge of helping women secure better access to key health care services and increasing the availability of health care providers. No state met the national goal of 90% for women receiving first trimester prenatal care. The degree to which each state met the goal varied. Maine was closest with 89.9% of pregnant women receiving first trimester prenatal care, New Mexico had a 69.7% rate, and the rate in the District of Columbia was even lower at 64.6%.

The key indicators of health and causes of death vary by state. Thirty states met the national goal for reduction of the number of women who died from heart disease. Dis-

Box 2-1 National Indicators of Women's Health

- Women without health insurance
- First trimester prenatal care
- Women in a county without an abortion provider
- Pap smears
- Mammograms
- Colorectal screening
- Eating five fruits and vegetables per day
- No physical activity during leisure time
- Overweight
- Smoking
- Binge drinking
- Heart disease death rate
- Lung cancer death rate
- Breast cancer death rate
- High blood pressure
- Diabetes
- Rate of acquired immunodeficiency syndrome
- Rate of chlamydia
- Maternal mortality rate
- Poverty
- Wage gap
- High-school completion

Adapted from National Women's Law Center, FOCUS/University of Pennsylvania & The Lewin Group. (2000). *Making the grade on women's health: A national state-by-state report card*. Washington DC: National Women's Law Center.

Box 2-2 National Benchmarks Missed by All States and the District of Columbia

- Women without health insurance
- First trimester prenatal care
- No physical activity during leisure time
- Overweight
- Eating five fruits and vegetables per day
- High blood pressure
- Diabetes
- Life expectancy
- Poverty
- Wage gap

Adapted from National Women's Law Center, FOCUS/University of Pennsylvania & The Lewin Group. (2000). *Making the grade on women's health: A national state-by-state report card*. Washington DC: National Women's Law Center.

parities exist among states. Minnesota has the best record, with 65.4 per 100,000 deaths from coronary heart disease; Mississippi has the worst record, with 141.2 per 100,000 deaths.

Infant mortality rates reflect the health of society. Eighteen states met the national goal for the infant mortality rate. Disparity exists between states. Massachusetts had the lowest rate, with 5.2 deaths per 1,000 live births. The District of Columbia had 15.9 deaths per 1,000 live births (FOCUS/Lewin, 2000).

This study further found that income levels and educational attainment are major factors associated with disparity in occurrences of illness and death. A wage gap still exists between men and women. On national average, women are paid 72.3% of what men are paid. This disparity also varies by state.

Risk Assessment and Management

Risk assessment, early identification, and prevention of complications apply to maternal, neonatal, and women's health. In the case of pregnant women, risk assessment is used to identify those women who have factors that contribute to having negative maternal or fetal outcomes. The risk can be biologic, behavioral, environmental, psychologic, or social. Assessments of maternal and fetal risks are completed and documented at the first visit and each additional client interaction with the health care system.

Providing neonatal care risk assessment is essential because the infant is unable to discuss signs and symptoms. Risk assessment may be the only tool available to the health care provider to predict adverse reactions and conditions. As we obtain more information about genetic makeup, risk assessment will become even more important as a tool.

Women's health care risk assessment is used to screen for cancer, domestic violence, eating disorders, and chronic diseases. Early identification and treatment can prevent illness, facilitate recovery, and prolong life.

Cost

Health care costs have escalated. New technology usually is very expensive, which adds to the costs of health care. In 1900, a woman's life expectancy was 48.3 years. In 1997, a woman's life expectancy had increased to 79.4 years (Office of Women's Health, 2000). The attempt to make this life extension of good quality has increased costs. Perinatal costs have escalated as a result of increasingly expensive intensive care as neonatal techniques have improved and resulted in fetal viability at decreasing gestational ages.

In women's health care, the number of women having hysterectomies has increased so much that hysterectomy is now the second most common major operative procedure performed in the United States. Of these procedures, 90% are performed for benign conditions (Summitt, 2000). Each year in the United States 590,000 hysterectomies are performed. The only operative procedure performed more commonly is cesarean section (Rosenfeld, 1997).

In the past decade much attention has been focused on the costs of health care. This focus has led to questions such as should a hysterectomy in the woman over 35 years of age include oophorectomy because of the risk for subsequent ovarian cancer? These kinds of questions increasingly are being asked, and the term risk-benefit analysis is being seen more frequently in the medical literature (Podszaski, Mortel, & Ory, 2001). **Risk-benefit analysis** is the determination of whether the risks of a certain procedure outweigh the benefits to the client of performing that procedure. One of the risk factors now being considered more commonly is cost.

Goals and Guidelines

Cost containment refers to the reduction of expenses by working more efficiently. Cost containment has come to the forefront as a factor in delivery of health care. Thus, it has become very apparent that it is no longer acceptable for individual health care providers to act without considering health care costs. Practice must become standardized, and a number of goals and guidelines have been established to guide health care providers.

The Agency for Healthcare Research and Quality (AHRQ), formerly known as the Agency for Health Care Policy and Research (AHCPR), is a federal agency that focuses on health care quality and outcomes of health care services. The AHRQ supports research on all aspects of health care provided to women, including quality, access, cost, and outcomes. The AHRQ has a number of ongoing studies investigating heart disease, stroke, breast cancer, and the health care practices of women. The findings of these studies will be used to determine and set federal policy. These studies also will assist in identifying strategies to improve health care provided to women.

The Centers for Disease Control and Prevention (CDC) set forth health goals in "Healthy People 2010" (CDC, 2000) that provide health care providers with benchmarks to attain in health promotion and disease prevention. These goals assist health care providers in conceptualizing health at a population rather than an individual level. Each individual outcome, however, contributes to the population statistics.

Each profession sets forth guidelines for members of that profession. The American Nurses Association (ANA) sets forth policies and position statements to help guide

nurses. For example, the ANA has set forth a **position statement** (formalized statement by a professional organization to express the opinion of its membership) on home care for the mother, infant, and family following birth (ANA, 1995). This position statement strongly supports individualized postpartum care provided to the family in the home environment.

In a 1991 position statement, the ANA crafted a statement concerning physical violence against women (ANA, 1991). This statement formalized support for the education of nurses, health care providers, and women in the skills necessary to prevent violence against women.

Agencies have issued guidelines for care in maternal, neonatal, and women's health, including the American Academy of Pediatrics (AAP); American College of Obstetricians and Gynecologists (ACOG); Association of Women's Health, Obstetric, and Neonatal Nurses (AWHONN); and National Association of Neonatal Nurses (NANN). It is important that nurses gain familiarity with these guidelines because a national standard of care is being developed based on them. This means that the individual nurse is expected to provide the same services with the same degree of skill as is any other nurse. Standardization of care is a way of protecting against negative outcomes and reducing costs.

TRENDS IN MATERNAL, NEONATAL, AND WOMEN'S HEALTH CARE

The nurse in maternal, neonatal, and women's health nursing must be aware of trends that affect practice. Whereas many trends are affecting today's health care system, some of the major factors are described in this chapter.

Medicalization and Demedicalization

During the 19th century and early part of the 20th century, most persons received health care in their homes or community settings (Hawkins & Bellig, 2000). Public health nurses provided much of this community care. These nurses provided well-child care, prenatal care, and postpartum care in a number of settings, including schools and homes. It was not unusual at the turn of the 20th century for a pregnant woman to deliver her child at home under the care of a lay midwife or a nurse, especially in rural areas.

As medicine evolved as a profession in the 20th century, physicians decided it was more appropriate for their clients to deliver in hospitals (Rinker, 2000) (Figure 2-2). It was thought that advances in technology, equipment, anesthesia, and medication would reduce maternal and infant morbidity and mortality.

Figure 2-2 Most births in the United States today occur in a hospital setting.

The incubator was developed in the late 1800s, which provided warmth and protection for preterm infants. As this technology has advanced, it has enabled the survival of preterm infants at earlier gestational ages. This technology provided another argument that delivery in the hospital was safer than it was at home.

As medical specialties developed in the 19th and 20th centuries, specialty hospitals were built to provide the skilled care required for women to birth their children. Medication use became common in obstetric care delivery. Some women received so much sedation that they did not remember delivering their infants. Visitors were not allowed in the labor or delivery rooms because it was thought they posed the threat of infection for the mother and infant. Fathers were considered visitors.

Other practices related to childbirth were equally as rigid. When delivery was imminent, women were moved from their labor bed to a stretcher and transferred to the delivery room. Once there, they were moved again to the delivery table. Here, women's hands were often restrained with leather straps so they would not put their hands in the sterile field during delivery.

Anesthesia is another area in which advances were made. Home delivery usually was without anesthesia. In the hospital, however, women were given general or spinal anesthesia. When general anesthesia was given, women had no memory of the birth. Particular care had to be taken in administering anesthesia to avoid sedation of the neonate. If the neonate was sedated, resuscitation was

required. Ether as an anesthetic agent posed additional dangers of explosion; inhalation of fumes by health care providers; and maternal hemorrhage, which frequently occurred because of uterine atony. The dangers of general anesthesia led to the popularity of spinal anesthesia.

The saddle block was the most frequently used type of spinal anesthesia. It was administered when delivery was imminent, as determined by the crowning of the baby's head. After the woman was transferred to the delivery room, she was required to sit up for administration of the saddle block. She also was required to be very still so the anesthesiologist would have a stable and sterile field for insertion of the needle. This process sometimes required 15 to 20 minutes, and the client continued to have contractions throughout the procedure as well as feeling the urge to push. Because saddle block anesthesia did not impair the woman's memory or produce uterine atony, it was preferred over general anesthesia. Still, no visitors were allowed in the delivery room, including the husband (Zwelling, 2000).

In the 1960s women became more empowered and began to insist that childbirth was a natural process and many of the medical interventions that had become customary were not necessary. Women began taking childbirth education classes in an effort to understand the processes of labor and strategies for pain relief that did not involve anesthesia or sedation. Childbirth education classes flourished, and many of these classes were taught by nurses (Figure 2-3). It was because of childbirth classes that women began to ask their physicians why husbands and other family members could not be present for labor and delivery. As client requests mounted, physicians became advocates for loosening hospital policies.

Nurses continue to support, teach, and value childbirth education classes even when clients plan to receive an

epidural. Epidural anesthesia became very popular in the 1970s and 1980s. It offered the advantage of pain relief that could be administered early in the labor process. It allowed the woman to be awake and participate in her delivery and did not have some of the adverse effects of general and spinal anesthesia. Continuous epidurals became popular because the tube could be inserted and anesthetic agent injected when the client was approximately 4 to 5 cm dilated. Thus, when the pain returned, the agent could be injected again through the tubing that remained in place.

In summary, the past century of maternity care has been one of medicalization as physicians increasingly made decisions for women, and demedicalization as women decided they wanted control of this natural process. Today, more births outside of hospitals are occurring, and more women are choosing midwifery care as opposed to physician care for their childbirth experience.

Decreased Hospital Stay

Decreased hospital stays have been a major source of cost reduction in the past 10 years. In the 1980s, a 3-day hospital stay was standard for a normal delivery and a 5-day hospital stay was standard for major operative procedures such as a hysterectomy or cesarean section. In the 1990s, however, the 24-hour discharge of mother and newborn became common. After many complaints from health care professionals and clients and some tragic outcomes, Congress stepped in and federally mandated that insurance companies must cover a 48-hour hospitalization after delivery. Women may return home sooner if they request. If complications occur, the hospital stay may be extended past 48 hours. Clients having hysterectomy or cesarean section typically return home 3 to 4 days after surgery.

Reduction in Intervention

In the practice of maternal and child health care, reduction in intervention has been a major issue in the past decades. Many women consider birth a natural process. Yet when they were admitted to the hospital, they had to experience childbirth under the control of physicians. Induction of labor was widespread, use of Lamaze was discouraged in many facilities, and forceps deliveries and cesarean sections were commonplace. Some of these interventions were undertaken as first choices under the advice of physicians. As women have become more verbal and cost-containment more of an issue, some interventions have been reduced.

Family-Centered Care

In 1994, Celeste Phillips, a maternity nurse, and Dr. Loel Fenwick worked together to develop the concept of family-centered maternity care. Family-centered maternity care is

Figure 2-3 Childbirth education classes are a means for women and their partners to learn about pain management and the birth process.

Research Highlight

Evidence-based Protocol

Purpose

To develop an evidence-based protocol for initial evaluation and treatment of urinary incontinence and to design procedures to facilitate implementation of the protocol in clinical practice.

Method

A review of the literature was conducted, including a descriptive report from the Association of Women's Health, Obstetric, and Neonatal Nurses (AWHONN) Continence for Women Project. Twenty-one public, private, and other women's health sites were identified to collect data from 1,474 women. A protocol was developed, sites were selected, site co-coordinators were trained to collect the data, and the process was evaluated. The participation of a representative sample was the first outcome measure. Feedback from the site coordinators was the second outcome criterion. Feedback from the site coordinators was in the form of feedback about the orientation session and on the experience of implementing the protocol.

Findings

Of the original 36 sites, 15 participated in the study. The settings met criteria for diversity of patient population. The site coordinators provided positive feedback.

Nursing Implications

The Continence for Women Project demonstrated potential for development and testing of an evidence-based protocol for clinical practice. Nurses are in an ideal position to perform utilization research and develop protocols that can standardize treatment of many issues related to the health care of women. The nurse of the 21st century will have to develop the skills of evidence-based practice analysis and decision-making.

Sampselle, C.M., Wyman, J.F., Thomas, K.K., Newman, D.K., Gray, M., Dougherty, M., & Burns, P.A. (2000). Continence for women: Evaluation of AWHONN's third research utilization project. *Journal of Obstetric, Gynecologic, and Neonatal Nursing*, 29, (1), 9–17.

based on 10 principles that reverse many of the restrictive policies and practices and return choices about the childbirth process to families (Figure 2-4). This philosophy has been adopted across the country as women decide they want to be in control of their bodies and reproductive processes (Zwelling, 2000).

Community-Centered Care

There has been a trend to move maternity care away from major medical centers and to community-based facilities. The effect of this change has been twofold. Being in the community enables better family interaction in the birth process because of convenience. This practice also has caused the maternity facilities in major cities to gain a higher percentage of high-risk maternity clients, changing the client demographics of and increasing the costs to these facilities.

Evidence-Based Practice

Evidence-based practice is a systematic approach to finding, appraising, and judiciously using research results as a basis for clinical decision-making (Westhoff, 2000). This type of systematic approach to decision-making is becoming more popular in health care in general but specifically in maternal, neonatal, and women's health. Westhoff (2000) provides a detailed description of the processes of appraising evidence found through meta-analysis of studies based on the development of research questions related to this topic. Evidence is appraised and categorized based on the level of research available. The approach has proven so useful that in 1997 the AHRQ established 12 5-year contracts to institutions across the United States to serve as evidence-based practice centers. Several of these topics are related to women's health. Duke University, Durham, North Carolina, is studying cervical cytology and

treatment of uterine fibroids. MetaWorks, Inc., Boston, Massachusetts, is studying management of breast disease. Oregon Health Science Center is studying diagnosis and treatment of osteoporosis. The University of Texas Health Science Center at San Antonio, Texas, is studying management of chronic hypertension in pregnancy and management of chronic fatigue syndrome, a condition seen more commonly in women (AHCPR 2000).

UNDERSTANDING WOMEN'S HEALTH

The many elements that overall comprise women's health are discussed.

Biologic Health

Until the 1990s it was assumed that the biology of men and that of women were identical and therefore what worked in the treatment of men should work for women. In the 1990s, the public began to question the validity of this assumption. As a result of this questioning, the Women's Health Initiative was begun to study parameters of women's health. It became apparent that women metabolize alcohol, experience heart disease, and metabolize medications differently than do men. The Women's Health Initiative currently is studying other biologic differences between men and women. One area of investigation is the interrelationship of hormones and mental health.

Behavioral Health

Behavior is a very important component of health. It is becoming increasingly apparent that obesity is a particular problem in our society. Being overweight contributes to the development of chronic diseases such as diabetes, hypertension, and cardiovascular disease. The negative health effects of being overweight can be prevented by early identification and treatment. Overeating in pregnancy contributes to the development of gestational diabetes, increases the risks for negative fetal outcomes because of macrosomia and hypoglycemia, and increases the woman's risk of developing adult onset diabetes later in life. Because gestational diabetes is a major health problem in the United States the Centers for Disease Control and Prevention, or CDC (1986), issued guidelines for enhancing diabetes control through maternal and child health programs. Despite these guidelines the incidence of gestational diabetes has not decreased.

Environmental Health

Rural women face unique and specific health challenges regarding health care access as a result of geographic and

occupational circumstances. Many women in the United States are farmworkers. An estimated 313,000 farmworkers may suffer from pesticide-related illnesses each year and from 800 to 1,000 farmworkers die each year as a direct result of pesticide exposure (Gaston, 2001).

Women are exposed regularly to teratogens in the workplace, as are men. Manicurists are exposed to inhalants that may be toxic. Nurse anesthetists have a higher rate of spontaneous miscarriage than does the normal population. There may be numerous other examples of workplace exposure to teratogens. A detailed discussion can be found in Chapter 21.

Social Health

In the exploration of the differences between women's and men's health, a leading question is that of biology compared with sociocultural determinants to explain these patterns. An attempt to differentiate between these factors was discussed in the Agenda for Research on Women's Health for the 21st Century (U.S. Department of Health and Human Services, 1999). One suggestion was to use the terms *sex* and *gender*, respectively, to refer to biologic and sociocultural differences. This differentiation is similar to the one between race and ethnicity, which refer to biologic and sociocultural factors, respectively. These definitions are controversial and the overlap between these factors is very complex.

Two classic studies described women's thought processes as different from but not inferior to those of men. Gilligan (1982) described women's complex process of moral reasoning as being rooted in relationships rather than purely rational principles. Men generally are more concerned with individual rights, justice, autonomy, and independence; women generally are more concerned with relationships and principles of caring for and connection with others. Belenkey et al. (1986) described women's different ways of knowing, opening up a number of avenues of women's thinking and behavior that contrasted with some of the male models of knowing.

As we come to understand more about the effects of socioeconomic status on health, we find that many of the issues disproportionately affect women. Greater numbers of women live at low income or poverty levels, both in single-parent families and among older persons (Administration on Aging, 2001). Poverty affects not only access to health but also many of the resources needed to promote health such as a healthy diet and places to exercise. Lack of power and social status creates additional stressors that can be damaging to one's health over time. Women have different patterns of health care use than do men; women use health care services more than do men and, on average, live longer than men.

Women's social roles and expectations also impact their health. Women's roles as mothers may make them

more aware of health and more receptive to health education because they are eager to promote the health of their families (Loustanaunau & Sobo, 1997). In many families, however, women may play a subservient role to their male partners. If the family is prone to domestic violence, women are more likely to be the victims. Women may be reluctant to leave an abusive relationship because of the role expectations of wife and mother. Women also may relate to their doctor or nurse practitioner in a different manner than do men relevant to their social roles.

In industrialized countries as women joined the labor force, generally their fertility rates declined. In developing countries, this relationship is much more complex (Sargent & Brettell, 1995). In many cases women see clear, concrete advantages to reducing their own fertility; however, social pressures may make it impossible for them to do so. This contradiction between beliefs and reality may lead to physical and emotional overburdening of women, posing health threats to these women and their children.

Cultural Health

Women's roles are determined by culture. In many cultures, women make decisions about their health and that of their family. Culture also determines many activities of women that have health implications. Cultural beliefs and values underlie the basic assumptions about biomedicine and the delivery of health care.

Cultural Influences in Women's Health

Women often are the decision-makers regarding nutrition, daily health practices, and treatment of minor illnesses. These decisions arise from cultural heritages and the attendant beliefs, values, and practices related to health and health-seeking behaviors. For example, dietary habits, food choices, and food preparation are based on cultural practices. Pregnancy and birth are special transition times, with particular customs and beliefs that direct activities and behaviors. These beliefs direct behavior throughout a woman's life span. For example, cultural beliefs and traditions influence who gives information about menses and reproduction to a pubescent girl. These factors also influence the type of information given to the young woman and the circumstances under which this information is shared. Feminine hygiene practices, such as douching, bathing, and acceptable activities during menses, are culturally related.

Cultural beliefs also will influence a woman's social roles and her relationship with her husband and other family members. Those things that constitute appropriate activities and decision-making roles within and outside of the family generally are determined by culture.

In many cultures, women do not have social authority to access health care outside of the family (Sargent & Brettell,

Figure 2-4 Family-centered care involves family members, in addition to the pregnant woman, in decision-making processes.

1995). Other family members, generally the woman's husband, must make the decision to go to a health care provider and whether to adhere to the provider's recommendations. These cultural practices may be minor and involve the woman's husband coming with her to the clinic; in contrast, they may be extreme, and may involve a husband refusing to bring the woman or children to receive health care or not permitting the woman to use contraception.

Mattson (1993) discussed the impact of culture on childbearing women. She describes the cultural nature of beliefs regarding the antepartum period such as preparation for birth, taboos, practices to ensure a safe delivery, and who transmits knowledge about birth. During the intrapartum period cultural beliefs influence who controls the labor and delivery process, who attends the birth, the location of the birth, positions for laboring and delivery, and degree and type of interventions at birth. Cultural beliefs during the postpartum period have an impact on birth rituals, allowable maternal activities, dietary patterns, norms for maternal and child contact after birth, and who controls postnatal care.

Menopause is another example of a biologic transition, the management of which is significantly affected by cultural beliefs. Use or nonuse of hormone replacement therapy during perimenopause, for instance, is highly influenced by cultural beliefs and values.

Culturally Influenced Behaviors with Health Implications

American cultural values of what a woman should be also reflect predominantly male values. Despite women's acceptance of these values, they can lead to poor health for

women. Images of beauty and acceptable appearance often lead to poor dietary habits as increasingly younger women are attempting to lose weight in the pursuit of a cultural ideal. Many women seek out cosmetic treatments and even surgery to attain cultural standards of beauty. Breast augmentation, liposuction, and other cosmetic surgeries may carry considerable health risks. Naomi Wolf (1992) provided an in-depth description of these behaviors, noting that the images of beauty are political and cultural ideas that perpetuate the position of women as ornamental, whose value and self-worth is dependent on their physical beauty and sexual allure.

Cultural Influences on Biomedical Care

Another cultural aspect of health care of women is the cultural perspective of biomedicine. Before the emerging awareness with the establishment of the Office for Research on Women's Health (ORWH), most biomedical knowledge was based on studies and understanding of men. Women's health consisted of gynecologic and obstetric issues. Research generally was not conducted on women because the hormonal changes during the menstrual cycle were considered variables that would be difficult to control. (It has since been discovered that men also experience hormonal fluctuations.) As we begin to learn more about the biologic differences between men and women, we are discovering that all systems may be different and treatments resulting from studies in men may not always be generalized to women.

The use of language influences the way we react to the world and behave in it. Anthropologists have studied biomedical metaphors and found them to be predominantly military, economic, or other masculine models (Martin, 1987). In examination of biomedical and scientific texts, females are depicted as body and emotion, equated with nature, and considered inferior to males. Males are depicted as having culture, mind, and reason. These metaphors reflect a cultural approach to health in which women's bodies, associated with nature, are to be controlled. Another anthropologist, Davis-Floyd (1992), studied biomedical birth practices as a ritual response to contemporary society's extreme fear of natural processes and the use of technology as an expression of American cultural beliefs of the superiority of technology over nature.

Complementary and Alternative Therapies

Women often use complementary and alternative therapies. Because of their focus on health promotion, these therapies may be particularly appealing to women. Women may be more inclined to use these therapies because women traditionally are in positions to nurture the health of their family

members. More women also are taking control of their own health needs and those of their families (Olshansky, 2000). Many of these therapies are gentle and nourishing and therefore more in keeping with women's social roles. Several herbs have shown some efficacy in relieving menstrual and menopausal discomforts. Many of these therapies also facilitate relaxation and reduce stress, and they may be appealing because women and others with limited social power frequently have additional stress.

ISSUES RELATED TO MATERNAL, NEONATAL, AND WOMEN'S HEALTH CARE

As trends in maternal, neonatal, and women's health have developed, issues have evolved that have affected practice in the field. Among those issues are cost containment, access to care, medical errors, reproductive ethical issues, medical-legal issues, and issues related to the philosophy of care provision.

Cost Containment

Cost containment involves reduction of cost through efficiency. One of the common procedures in discussing cost is cost-effectiveness. In fact, there are individuals whose sole purpose in employment is determining the cost-effectiveness of certain procedures. This process is a very sophisticated one by which models are developed to determine whether outcomes for two procedures are equivalent and whether the cost is more or less, depending on the procedure chosen. The cost-effectiveness model looks at many factors related to choosing the procedure that has the best outcome at the lowest price. Nurses have taken the lead in conducting some of these cost-effectiveness studies.

For example, Heaman et al. (2001) studied preterm birth. Five categories of health determinants were identified related to preterm birth: social and economic factors, physical environment, personal health practices, individual capacity and coping skills, and health services. These categories were used in design of a program to provide health strategies for women to help prevent preterm labor.

Fleschler et al. (2001) studied severity and risk adjustment related to obstetric outcomes, diagnosis-related group (DRG) assignments, and reimbursement. The impetus for this study was that risk and variation in condition were not adequately considered when determining reimbursement. These nurses assisted in determining correct benchmarks for high-risk obstetric clients, especially those experiencing preterm labor. The results were that cost-appropriate, quality care was being provided.

Roberts and Sward (2001) studied birth outcomes reported through automated technology. This study

examined whether birth center clinical outcomes could be efficiently reported using an automated birth log. It was determined that the automated birth log was a good communication tool that provided an excellent means of data storage.

As long as costs remain an issue in health care, there will be a need for nurses to perform studies such as those mentioned. Numerous benchmarks exist in this field that have yet to be established and measured.

Access to Care

Access to care remains a very important issue related to maternal, neonatal, and women's health. An estimated 48 million Americans lack access to health care, and 44 million have no health care insurance (Gaston, 2001). Many of the uninsured are women. When a person does not have insurance, access to health care may be delayed and treatment may be less effective or ineffective. In addition, access to care involves the availability of appropriate health care services in the community, transportation, and childcare—and many other factors. Ensuring affordability of health care continues to be a major issue in the United States as is evidenced by public attention, congressional rhetoric, and the impairment present when some women finally do receive the needed care.

Reduction of Medical Errors

Increasingly, medical errors have gained attention as being major causes of morbidity and mortality. The Institute of Medicine, or IOM (2000), indicates that errors usually represent plans in which the system failed and the breakdown resulted in harm. Further, the IOM suggests that errors depend on two kinds of failure: actions do not go as intended, or the intended action is not the correct one. These two types of errors are commonly referred to as error of execution or error of planning, respectively. Contrary to popular belief, errors usually are not caused by incompetence (Dickenson-Hazard, 2001). In many instances, downsizing and re-engineering, which are facts of life in contemporary health care organizations, are found to be at the root of the problem (Knox et al., 1999). In some instances, organizational changes undertaken to increase productivity or cut operational costs result in systems that break down, and often, client safety is not a primary consideration.

Nurses have been an easy target on which to place blame for medical errors. In reality, nurses are doing their jobs in a health care system that is in turmoil. Individual nurses and nursing organizations across the country are committed to improving health care by developing practice standards, developing system improvements, and recruiting additional workers to the profession (Dickenson-Hazard, 2001).

Figure 2-5 Charting is a responsibility of the entire interdisciplinary care team.

Reducing the occurrences of medical errors must be a collaborative effort on the part of doctors, nurses, administrators, and all other health care workers (Underwood, 2001). Nurses are an important part of the solution (Figure 2-5). Client outcomes are better in hospitals with higher staffing levels and higher ratios of registered nurses in the staffing mix than in hospitals with lower levels and ratios. Nurses are fiercely committed to quality client care (Kincaide, 2001).

The AHRQ recommends that clients become involved in their health care as a means to reduce medical errors. The AHRQ provides 20 tips in a client education fact sheet, an adaptation of which is included in the Client Education box.

Ethical Issues

Many potential ethical issues are related to maternal, neonatal, and women's health. Chapter 5 discusses these issues in some detail. Gene and stem cell therapies are just two areas representative of these concerns. Several ethical concerns have been raised about gene and stem cell therapies. Many members of the public are troubled by perceived and actual problems associated with altering the genetic composition of humans. Specific concerns have been raised about the appropriate traits to be selected for genetic modification. Concern also exists about the potential for inadvertently altering the genetic composition of germ cells. Finally, there has been concern about the use of fetal tissue in the treatment of disease (Kaji & Leiden, 2001).

Medical-Legal Issues

The major medical-legal issue in nursing today is malpractice. *Malpractice* is a specific kind of negligence that

Client Education

Preventing Medical Errors

The AHRQ (2000b) recommends these 20 tips for clients to help prevent medical errors:

1. The single most important way you can prevent errors is to be an active member of the health care team.
2. Make sure all doctors know about everything you are taking, including prescription medications, over-the-counter medications, vitamins, and herbs.
3. Make sure your doctor knows about allergies and adverse reactions you may have had to medications.
4. When your doctor writes a prescription, make sure you can read it.
5. Ask about your medications in terms you can understand at the time of prescription and the time of administration.
6. When you pick up your medications from the pharmacy, ask: Is this the medicine that my doctor prescribed?
7. If you have any questions about the directions on your medication label, be sure to ask them.
8. Ask your pharmacist for the best device to measure your liquid medicine.
9. Ask for written information about the side effects your medicine could cause.
10. If you have a choice, choose a hospital at which many patients have the procedure or surgery you need.
11. If you are in a hospital, consider asking all health care workers who have direct contact with you whether they have washed their hands.
12. When you are being discharged from the hospital, ask the doctor to explain the treatment plan you will use at home.
13. If you have surgery, make sure you, your doctor, and the surgeon agree and are clear on exactly what will be done.
14. Speak up when you have questions or concerns.
15. Make sure that someone, such as your personal doctor, is in charge of your care.
16. Make sure that all health professionals involved in your care have important health information about you.
17. Ask a family member or friend to be there with you and to be your advocate.
18. Know that "more" is not always better.
19. If you have had a test, do not assume that no news is good news.
20. Learn about your conditions and treatments by asking your doctor and nurse and by using other reliable resources.

Following these AHRQ recommendations does not guarantee clients will avoid experiencing medical errors. By participating in their own care, however, clients can reduce this possibility.

occurs when the standard of care that reasonably can be expected is not performed (Aiken & Catalano, 1994). Four elements are required to prove liability for malpractice:

1. Duty
2. Breach of the standard of care
3. Proximate cause
4. Harm to the client

Further discussion of the concepts involved with proving malpractice will help clarify the meaning of these elements and make them more easily understood. All four components must be present for malpractice to occur.

The concept of duty is a legal term that means that the nurse has or should have undertaken the care of the client in the capacity of a nurse. Duty may be independent of payment for services (Hall, 1996). For example, a nurse comes to the labor and delivery unit to deliver a message to another nurse. As she enters the unit, it is very apparent there is a crisis situation because the nurses are engaged in preparing for an emergency cesarean section. As the nurse passes a client's room, the client calls out: "Nurse. Can you help me?" The nurse is from the neonatal unit and has no experience in dealing with laboring women. She has no duty to assist this client. If the nurse enters the room, the care provided must meet the same standard of what a

reasonable prudent nurse would do under the same or similar circumstances. If this standard is not met and harm to the client results as a result of the nurse's action or inaction, then malpractice can be proven.

If the nursery nurse, rather than entering the room, explained to the client that she was not a labor and delivery nurse and therefore was not qualified to deliver nursing care to the laboring client, she has not taken on the duty to provide such care. The ethical nurse, however, should find the appropriate nurse to assist the client.

Many of the malpractice cases in maternal, neonatal, and women's health nursing involve poor pregnancy outcomes. Some examples of negative outcomes are infants born with low Apgar scores in the face of nonreassuring fetal heart monitoring patterns and shoulder dystocia. Shoulder dystocia is an emergency condition in which the fetal shoulders become entrapped in the maternal bony pelvis after the head has been delivered. Immediate action is required to prevent permanent damage to the infant or death. Many times these infants experience nerve damage if there is too much traction placed on the neck in an attempt at vaginal delivery. The nerve damage can cause a paralysis of the affected upper extremity.

In the past, physicians were primarily the target of malpractice suits. As the status of nursing has involved, however, professional responsibility has increased and so has legal accountability (Aiken & Catalano, 1994). Currently, when a malpractice action is taken, the nurse is usually involved as an employee of the hospital. The involvement may be as simple as not maintaining adequate documentation or as complex as failing to intervene on the client's behalf when the physician does not perform a timely cesarean section.

Hagedorn & Gardner (1997) suggest there are several ways nurses can reduce their risks of being a defendant in a lawsuit. Nurses must develop caring relationships with clients, because a failed relationship between a health care provider and the client and family is a major source of malpractice claims. The key to good relationships is good communication.

Nurses must maintain clinical competence (Hagedorn & Gardner, 1997). It is not acceptable to practice based on yesterday's knowledge. In this age of change, nursing is not the same profession it was 10 or even 5 years ago. The only way to remain clinically competent is to continue to practice and continue to learn.

Nurses must know their legal responsibility (Hagedorn & Gardner, 1997). It is no longer safe to assume the nurse will not be sued because the physician and hospital have more financial resources. Knowing responsibility also refers to being familiar with standards, guidelines, and institutional policies and procedures.

The nurse must define appropriate assignments (Hagedorn & Gardner, 1997). As costs are being reduced,

nurses are being asked to take on more responsibility with the aid of assistive personnel. The nurse is accountable for assignments given to assistive personnel and the outcome of that care. The nurse also should be cognizant of the fact that unsafe assignments can be declined.

Nurses must take action when the client's condition deteriorates (Hagedorn & Gardner, 1997). In the physician's absence, the nurse is responsible and accountable for attempting to provide the health care the client requires. If the client decompensates, it is the nurse's responsibility to call another physician if the client's physician is not available to provide the needed intervention or is unable to provide the needed intervention because of policy or condition. For example, if the hospital has a policy that a family physician may perform a delivery in a low-risk pregnancy, when the client's condition changes the nurse has a duty to discuss making a referral with the family physician. If the physician refuses to make the referral, the nurse has a duty to advocate for the client and institute action by what is called the chain of command. The chain of command is a method of providing care when the physician is not following policy or is placing the client in danger. The staff nurse usually notifies her immediate supervisor, who notifies the chief of obstetrics. The chief of obstetrics ordinarily will resolve the issue. In case of nonresolution, however, the chain of command further involves hospital administration and the chief of the medical staff. Any such intervention should be documented.

Nurses should defensively document client care, treatment, and intervention (Hagedorn & Gardner, 1997). Accuracy is of paramount importance. Additionally, all legally relevant material should be documented (Figure 2-6). In nursing documentation, several important considerations should be made (Box 2-3).

Moore (1997) indicates that proactive risk management begins with the nurse at the bedside. The nurse should feel empowered to be proactive. Organizations that want to reduce their risks of being sued will empower nurses to work in a proactive manner to advocate for the client and prevent client dissatisfaction and harm.

Philosophy of Care

Philosophy of care refers to the values the nurse places on certain interventions regarding client care. For example, much discussion is occurring about whether it is more important for the nurse to ensure the technology is working correctly and the documentation is flawless or whether it is more important for the nurse to concentrate on those aspects of practice that are related to touch. Touch in this context means communicating with the client, ensuring comfort, and ensuring the client's individual needs are met. Traditionally, nursing has been a high-touch disci-

Figure 2-6 Accurate and timely documentation is a strong defense against legal action.

pline. There are those who insist that the concept of caring is what makes nursing different from other professions and why nurses are held in high esteem by the public. In maternal, neonatal, and women's health, the high touch philosophy is very much required to meet the client's needs. The nurse in this specialty must be very skilled to manage the high-tech versus high-touch dilemma.

Box 2-3 Considerations in Nursing Documentation

- Accuracy
- Thoroughness
- Compliance with standards
- Individualized nursing care based on client need
- Appropriate goals and interventions that are timely in completion
- Discharge planning

NURSING IMPLICATIONS

Changing trends in maternal, neonatal, and women's health nursing have implications for nursing practice, education, and research. These implications will be discussed in some detail.

Nursing Practice

Nursing practice is affected by trends in the health care industry. These trends help determine which skills will be required of practicing professional nurses. The acquisition of these skills will determine successful licensure and credentialing.

Skills Required for Practice

As the profession continues to develop, the skills required to practice maternal, neonatal, and women's health care nursing will change. Nurses must know the parameters within which they can practice so as not to exceed that which is legal. To practice beyond one's scope of practice is illegal. Currently, the skills required are those discussed in Chapter 1 and some competencies specific to the specialty. The nurse in maternal, neonatal, and women's health nursing is required to have strong assessment skills. In this field, in particular, nurses are asked to care for the fetus in utero and the newborn in the nursery. Neither of these clients can communicate verbally to let their needs be known. Technologic skills are required to use fetal monitoring equipment, ultrasonography, and fetal pulse oximetry. Other technologic advances also are certain to occur.

Credentialing and Licensure

Licensure is a requirement of state law to perform the services of a registered nurse and to call oneself a registered nurse. To become licensed, the person must graduate from a school that is approved by the Board of Nursing in the state in which the school is located. Licensure has been classified as defining the minimal acceptable standard for the practice of professional nursing.

Credentialing is a process that the individual nurse undertakes beyond basic education and licensure. Credentialing is sought to illustrate expertise in an area of practice. At this time in the United States, credentialing is required for advanced practice in nursing. There has been overtone, however, to make certification more broadly applicable to the general practice of nursing. Certification is the process by which a nurse becomes credentialed as an expert. In maternal, neonatal, and women's health nursing there are a number of advanced practice specialties that require certification, including nurse midwife, women's health care nurse practitioner, and neonatal nurse practitioner. Each of these specialties requires a certification

Research Highlight

Improving Outcomes for Newborn Twins

Purpose

To compare newborn outcomes and costs of hospital stays for twins.

Methods

A prenatal clinic in central Texas. A retrospective historical cohort study was completed of women pregnant with twins—one group of 30 women received care in a specialized twin clinic with a research-based care protocol and one consistent caregiver; the other group of 41 women received standard prenatal care.

An advanced practice nurse provided prenatal care, including weekly clinic visits, home visits, and 24-hour availability for telephone support.

Data on gestational age at birth, birth weight, length of stay in the neonatal intensive care unit (NICU), and hospital charges for newborn care were obtained.

Findings

No newborns of less than 30 weeks' gestation were born and the mean birth weight was 249 g higher in the specialized care group. Days in the NICU were reduced from a mean of 17 days in the standard group to 7 days in the group receiving specialized care. Charges were \$30,000 less per infant in the specialized care group.

Nursing Implications

Neonatal outcomes were improved, and costs and hospital stays were reduced significantly in the group receiving specialized care.

Ruiz, R.J., Brown, C.E.L., Peters, M.T., & Johnson, A.B. (2001). Specialized care for twin gestations: Improving newborn outcomes and reducing cost. *Journal of Obstetric, Gynecologic, and Neonatal Nursing*, 30, (1), 52–60.

examination and specific criteria, which are designed to provide information about continued competency.

Nursing Education

Nursing education must continually change and develop as does the practice of nursing. There has been a push from licensure agencies to include jurisprudence in the undergraduate nursing curriculum. Core competencies have been developed to integrate the study of genetics into the curriculum of nursing schools. Technologic advances, such as fetal monitoring and ultrasonography, have mandated that nurses develop skills in maternal, neonatal, and women's health nursing that were beyond the scope of nursing practice a decade ago.

Nurse educators must remain competent practitioners, which may mean that the faculty member must find opportunities to practice in addition to teaching responsibilities. Competency also requires that faculty update their

knowledge through continuous learning, reading, and formal and informal educational programs.

Nursing Research

Nursing research related to maternal and child health has developed over the last decade. Research utilization projects sponsored by AWHONN have studied the use of upright versus recumbent position for the second stage of labor to reduce fetal compromise and maternal pain; and the use of exhalatory versus sustained bearing down during the second stage of labor to reduce abnormal fetal heart rate patterns and low Apgar scores. Other research utilization projects have included "Transition of the Preterm Infant to the Open Crib" (Medoff-Cooper, 1994) and "Second Stage Labor Management" (Niesen & Quirk, 1997). The scope and diversity of research related to mothers, fathers, infants, and families over the past 25 years is vast (Moore, 2000). Much more research is still to be done.

Collaboration within the Profession

Collaboration within nursing will become a necessity for nursing research. Many research questions require large samples to provide meaningful results. This type of research requires multiple investigators and multiple sites. Evidence exists that some of this type of research is ongoing. An example of this type of research is Lund et al. (2001) who undertook a study to develop and evaluate an evidence-based protocol for assessment and routine neonatal skin care to educate nurses about the protocol and design procedures for implementation of the project in 51 hospitals across the United States.

Interdisciplinary Collaboration

Collaboration with other professions for research is equally important for nursing. This type of collaboration opens up possibilities for answering research questions in settings and in populations that otherwise would be unavailable. The nurse brings very important skills to the research team as a team member and as a principal investigator.

Web Activities

- Using the Internet, which sites can you find that are related to maternal, neonatal, and women's health?
- Determine what the agenda is for the Women's Health Initiative.
- What is the average cost per day in a neonatal intensive care unit?
- Which resources are available to the pregnant woman who is homeless?
- Which resources are available to the woman who cannot afford the expense of milk and dairy products during her pregnancy?

Key Concepts

- Maternal, neonatal, and women's health care nursing is very complex and poses unique challenges to nurses who practice in this field.
- Nursing in maternal, neonatal, and women's health care is influenced by societal trends.
- Cultural and societal trends must be acknowledged and understood by nurses who practice in the field.
- A number of professional organizations guide nurses in determining the most cost-effective and beneficial interventions for the best practices in a given situation.
- Evidence-based practice results in less liability for malpractice.
- Many ethical considerations arise when trends in practice change. As members of a collaborative interdisciplinary team, nurses are in a unique situation to have input into practice changes.
- Nurses must develop an open attitude toward politics because politics are involved in all institutions and practices.

Review Questions and Activities

1. Name 5 factors that are instrumental in determining whether a woman has access to health care.
2. What is the origin of practice standards and guidelines? What is the purpose of standards and guidelines?
3. Why has great emphasis been placed on prenatal care for women?
4. Why is neonatal ICU care so expensive?
5. What are the risks and benefits of managed care?

Theoretical Perspectives on the Family

Nurses who work with families or clients who have families often respond as if these families were similar to or should be like their own. These responses make it difficult to understand and respect the diverse cultural and personal values and needs of clients' family units or family members. Use the following questions to examine your personal feelings:

- ❖ *How do families change over time? For example, how is a family with an adolescent different from that same family when the child was a newborn?*
- ❖ *How do you feel about families that are structurally different from your own?*
- ❖ *Have you spent time with a communal family or a couple who is homosexual who have children?*
- ❖ *How do you think nurses can incorporate families into their care of clients?*
- ❖ *Which strengths do you appreciate about your family?*
- ❖ *Which concerns do you have about your family?*

Competencies

Upon completion of this chapter, the reader should be able to:

1. Identify various family structures.
2. Discuss some of the common issues related to specific family structures.
3. Discuss theoretical frameworks of families that are relevant to the nursing profession.
4. Discuss the developmental theories of family as they pertain to the childbearing family.
5. Discuss how systems theories apply to family dynamics.
6. Identify contemporary social and cultural issues that impact families.
7. Apply the Resiliency Model of Family Stress, Adjustment and Adaptation to the childbearing family.
8. Describe how a nurse might incorporate the Proactive Model for Enabling and Empowering Families into professional care.

Nurses provide care to clients who are members of families, to aggregates of clients who form families, or to families as units. A common definition in nursing identifies the **family** unit as a group consisting of an adult or adults, and living and unborn children linked by kinship or social bonds whose function is to provide for the physical, psychological, and cultural needs of its members. Family units are estimated to provide 75% of all the health care received by family members, including health promotion, disease prevention, early intervention, and rehabilitation (Duffy, 1988). In cross-cultural studies of health care, Kleimann (1980), an anthropologist, found that the family was consistently the key in determining health-related behaviors. Nurses provide care to the family unit to maintain or enhance the family's ability to provide for the needs of its members.

Nurses, beginning with Florence Nightingale, have explicitly or implicitly accepted responsibility for caring for the family unit. Nightingale (1858, 1863) called for improved living conditions and health care for soldiers' children and wives. In 1904, Wald established general principles for home nursing. These included assessing the family's ability to care for an ill member, evaluating the family support system, including neighbors and community agencies, and making referrals to community agen-

cies. These principles are in the American Nursing Association standards of community health practice (Whall, 1993).

The family, as a unit, has been the domain of community health. Community or public health nurses have considered the family—not the individual—the unit of service in the context of their larger goal, facilitating the health of the community. Maternal-child nursing has focused on family-oriented care beginning with the need to care for mother and infant together. Maternal-child nurses later expanded their sphere to care for the entire family unit as it prepared for and then incorporated a new member. Throughout nursing, nurses now include in their sphere of responsibility the care of the family.

Nurses' understanding of family as a concept varies with the patient care situation and also over time. At one time, nurses viewed the family as an aggregate of persons of different ages. Using that frame of reference, nurses assessed the family because it was the context for providing care to the client. Nurses now understand the concept of family to mean a unit, which may be their client. To care for the family unit the nurse is concerned with family development, dynamics, interaction, and the health of the family as a whole. An understanding of family development, dynamics, and interaction enables the nurse to work effectively with the family in crisis and to facilitate the

Critical Thinking

Definition of Family

Think of the families you know. Describe them to yourself.

- What do you think a typical family is?
- Do you know any typical families?

health of the family in various health situations. A developmental approach and an understanding of parental role attainment also allow the nurse to provide anticipatory guidance to the childbearing family.

This chapter includes descriptions of the structure and function of the family system, treatment frameworks for caring for the family unit, current issues affecting families, provider models, nursing implications, and a care plan.

FAMILY SYSTEM OF STRUCTURE AND FUNCTION

For the purposes of this section **family structure** refers to family form (e.g., single- or two-parent) and marital patterns (e.g., communal or homosexual). In North America in the 1950s and 1960s, a family generally consisted of heterosexual parents in a long-term marriage raising their biologic offspring. In the intervening years, divorce, remarriage, same-sex relationships, and different kinds of adoption have become more common. Our ideas of what makes a family unit encompass much more than the traditional family with the homemaker mother, working father, and their biologic children (Okun, 1996).

Traditional or Nuclear Family

The traditional family is a **nuclear family** composed of two generations, parents and their children. Their **extended family** includes members of other generations, such as grandparents, great grandparents, aunts, uncles, nieces, and nephews, or perhaps even a second nuclear family. In the classic family, the father provided for the economic needs of the family and the mother was a homemaker. In 1998, in the United States, only 25% of all households were composed of married couples with their children under 18. This is compared to 27% of families that are maintained by one parent (U.S. Census, 1998).

Myths of Idealization, Harmony, and Effortlessness

Family members may experience unnecessary anxiety if they hold idealized expectations of so-called normal family life or family traditions that are in conflict with their actual experience (Walsh, 1993). Families are in a continual state of change. The members are aging, and experiencing the need to accomplish different developmental tasks and move on to new stages. Emotional, physical, and economic resources of a family are limited to a greater or lesser extent, and always to some extent. At times, family members have competing not complementary needs. For example, a husband may desire to spend time alone reading after a busy day at work. However, his wife, excited by changes at her workplace, wants to tell him about her day. At the same time, the two toddlers demand attention because one is tired and the other is hungry. Each family member may feel some anger and resentment toward the others. Some angry words may be exchanged: "You never listen to me anymore." "You don't show any consideration for me." Do you think this family is in trouble? The answer probably is no, that is, if the family members know that families are not perfect and that it is almost impossible to get through daily life without some stress. If all goes well the toddlers will be asleep in a couple of hours, the wife will have told her news, and the husband will have some time to read.

If the couple has unrealistic expectations of what marriage and family should be like, the family may be in trouble. Does the wife still have expectations about romantic love that are not always met in the context of a busy family life? Does the husband resent the interest his wife takes in her work? Perhaps the wife believes that a good mother is never angry, tired, or crabby and becomes overwhelmed

Critical Thinking

Nostalgia for Family Traditions that Never Existed

"Nostalgia for a lost family tradition that never existed has distorted our perceptions and fueled the myth that any deviation from the idealized normal family is inherently pathological" (Walsh, 1993).

- What do you think of the preceding statement?
- What do you think Walsh meant by the words "idealized normal family"?
- Why are families important?

by the demands this idealized notion of motherhood places on her.

Myths of Egalitarianism and Fairness

Perhaps in an ideal world men and women (parents, marital partners) would receive equal pay for equal work and would contribute time, energy, and ability equally in caring for the family. The world is changing but is not ideal. Many persons still view the family as the woman's domain, and often, the woman has primary responsibility for children and the elderly. The roles of men and women in the family often lag behind the roles they have in the work world. For example, although women participate in the work force they continue to do most of the housework (Walsh, 1993).

Myths of Rigid Gender Roles

In the narrow definition of the classic family, the father worked outside the home to provide economically for the family and the mother was responsible for home making, including childcare. The classic family was the norm for only a few unusually prosperous years in the 1950s, when three fifths of families conformed to the classic model. In pre-industrial times "families functioned as a workshop, school, church, and asylum. Most work took place in the household, with children considered economic assets and members of the work force" (Walsh, 1993). Women had limited time for child rearing because of the work they did to meet their obligations to the family economy. Fathers, older siblings, and extended family participated in child rearing (Walsh, 1993).

Myth of Treating All Children Equally

Imagine a family in which one child has congenital heart problems, another lacks coordination but loves music, and another has natural athletic abilities. What would you think of parents who did not differentiate among these three children? You would probably think that they were bad parents. This is an extreme example of treating all children equally because one of the children has heart problems. What would your reaction be if only the second and third children were in the family? Should not their individual interests and abilities be honored and supported? Parents who ignore their children's individual differences decrease opportunities to highlight the unique qualities each child brings to the family. Nevertheless, parents often say, "I treat all my children equally," the implication being that doing so is a good thing. Children are not the same, however, and each child has individual needs. Responding to each child as an individual may make the already com-

Critical Thinking

Each Child is Unique

"Each child, then, presents an opportunity to his parents for a unique adventure as he unfolds and develops" (Satir, 1972, psychologist).

Think of children you know.

- How are they alike?
- How are they different?
- In what ways should they be treated the same?
- In what ways should they be treated differently?

plicated job of parenting even more complicated but certainly more rewarding.

Childless Dyads

Couples, also called **dyads**, may be childless by choice, because of infertility, or because of spontaneous abortions. Nurses should not assume they know why a couple is childless or what being childless means to a couple. Childless couples are sensitive to the intrusion by others into their personal lives and possibly painful issues. Bradt (1989) states that a couple's decision not to have children is influenced by many cultural changes. A woman may choose not to become a mother for many reasons. Women today have greater educational and professional opportunities. A woman may need to work for financial reasons or may not want to bear the responsibilities of parenthood. A woman may take into account the high divorce rate when deciding whether to have a child. Moreover, women today have access to birth control and abortion. About 5% of women who have been married are childless by choice (Friedman, 1992).

Nurses who successfully counsel childless couples are aware of the many avenues that couples may take in resolving issues related to being childless. Couples who are not childless by choice may be struggling with whether to accept being childless, pursue fertility treatments, or adopt.

Extended Family

Extended families are of two main types. Three, four, or even five generations may live in one household or two or more nuclear families may live in households located near each other (Figure 3-1). Even when members of the extended family do not live together, they may give and

REFLECTIONS FROM CLIENTS

Tom and Jill pursued fertility treatments. When the treatments were unsuccessful, they decided to remain childless and now say, "We like having time for each other and feel very close. We also enjoy relationships with our nieces and nephews."

Philip and Sue pursued fertility treatments unsuccessfully and now are the proud parents of two adopted children. They say, "We wish we had decided to adopt right away because we love being parents."

Steve and Mary thought about having children but have successful careers that bring them into daily contact with young adults whom they mentor. They say, "We are happy with our lives the way they are. We don't want to change a thing."

receive social support and exchange goods and services. Even in families separated by great distances the availability of transportation and communication permit extended kinship ties (mainly to parents and siblings) that provide support to nuclear families (Friedman, 1992). Families may have an extensive support network or extended family that includes kin and nonkin, for example, godparents, neighbors, and fellow church members.

Figure 3-1 Grandparents often assume some childcare responsibilities in extended families.

Relationships Within the Extended Family and Parenting

Various dyads form within all families. These dyads may lead to weakening of the bonds of the extended family. For example, the couple may focus on each other to the exclusion of children and parents, leading to neglect of their children and elderly parents. Parents may focus on their relationships with their children or with their own parents, leading to a decline in the marital bonds. Ideally, extended family members will provide additional resources of time, energy, and psychosocial connections to all the members. Grandparents, aunts, and uncles may be involved in nurturing children and supporting their parents (Bradt, 1989).

Communal Family

A **communal family** forms when individuals, couples, or families live together and jointly carry out family functions. Couples may or may not be monogamous. Child rearing responsibilities may be shared or parents, perhaps particularly mothers, may retain responsibility for rearing their biologic children. Polygamous families, in which one husband has several wives, are a variant of communal families.

Unmarried Heterosexual (Cohabitation) Family

Increasingly, couples are living together without entering into marriage. They may have children that they bring to the relationship or they may have children together. Recently, there has been an increase in older couples choosing to cohabit. Couples may enter into these relationships to meet needs for love and belonging. They may view **cohabitation** as a temporary stage, a trial period before entering a legal marriage. Older couples may choose cohabitation to avoid disturbing existing inheritance plans for children from other relationships or to avoid reduction in social security or pension benefits.

Homosexual Family

Homosexual families are diverse, as are all families. The household may be headed by a single parent or a couple. In either case the parent or parents may be gay or lesbian. The children may be adopted, biologic, foster, or some combination.

Persons who are gay or lesbian and know they want to become parents may select mates partly on that basis. They may achieve parenthood by adoption, artificial insemination, or heterosexual activity. Gay persons may use a surrogate mother. Adoption remains difficult for homosexual couples, although it does occur. These families face

Critical Thinking

Couples who are Homosexual Becoming Parents

Describe the financial, societal, and cultural hurdles faced by same-sex parents. Ask yourself how you feel about couples who are gay or lesbian becoming parents. Will your personal feelings influence the care you provide?

some challenges. For example, how will they ensure that the nonlegal or nonbiologic parent has an ongoing parenting role if the couple separates, or if the legal or biologic parent dies? Parents who are gay may experience the bias against men being the primary caregivers. Parents who are gay or lesbian who have children from heterosexual marriages may remain single to avoid custody disputes with their former spouses (Okum, 1996).

Single-Parent Family

The single-parent family has only one parent, mother or father. Single-parent families are formed in numerous ways: when adults without marital partners choose to have a child, when teenagers become pregnant, when parents in traditional families divorce or separate, and when a spouse dies. Single-parent families are most likely to be headed by mothers. In the United States, only 3% of children live in father-only families, whereas 22% of children live in mother-only families (Levy, 1995). In the early 1990s, almost 3 of every 10 births were to single mothers, many of them teenagers (Farley, 1995; Friedman, 1992). Poverty and teenage motherhood increase the potential for problems in single-parent families; however, when these factors are not present, single-parent families are as successful as are two-parent families (Seibt, 1996).

Single-Parent Families and Poverty

Single-parent families are more likely to be financially disadvantaged than are two-parent families. A higher incidence of poverty exists in families headed by women. The gap between the earnings of men and women has narrowed in recent decades; nevertheless, in 1990, for those working full-time, the average woman earned only 16 cents for every dollar earned by the average man (Levy, 1995). Children in single-parent families are at higher risk

for dropping out of school, premarital teen birth, and being out of school and unemployed than are children in two-parent families (Levy, 1995). There is some indication that these risks are related to poverty rather than to having a single parent. Children of mothers who have high-school diplomas are more than twice as likely to complete requirements for high-school diplomas compared with children of mothers who do not have high-school diplomas (Mare, 1995).

REFLECTIONS FROM A CLIENT

"As a single mother, I often felt ambivalent about leaving household chores undone to spend time with my children or to take time for myself. As a solution, I decided to ask myself if the chore would matter in 50 years. When the answer was no, the chore could wait—and almost always did."

Role Overload: Flexibility and Social Support

Single parents are responsible for the economic, physical, spiritual, and emotional care of the family. Single parents may be overwhelmed if they try to perform all family functions well. They may find it particularly difficult to neglect household chores to provide physical and emotional care for their children. Single parents may benefit from help in setting priorities. Single parents also may worry about having enough time to spend with their children and may need help balancing work and family responsibilities (Seibt, 1996).

Single parents may feel cut off from social activities that meet their needs for affection and companionship.

Nursing Tip

SINGLE PARENT SUPPORT

Nurses may refer single parents to support groups, such as Parents Without Partners, that provide help with parenting and also act as a source of social support for single parents.

Research Highlight

Maternal Employment and Parent-Child Relationships in Single-Parent Families of Low-Birth-Weight Preschoolers

Purpose

This study explores the differences in parent-child and family relationships of single mothers of low-birth-weight and full-term preschool children. Family environmental factors, such as employment of the mother, employment history, and employment attitude-behavior consistency were studied in relation to family relationships.

Methods

Data regarding employment, the Parenting Stress Index, Feetham Family Functioning Survey, and Home Observation for Measurement of the Environment were gathered on single mothers with low-birth-weight and full-term preschool children, 60 and 61 mothers, respectively.

Findings

Employed mothers provided more stimulating home environments and had more positive perceptions of their children. These results could be related to other related effects such as education, income, and number of children. Mother-child relationships and family functioning were similar for families of preterm and full-term children.

Nursing Implications

Employment and gestational status had little effect on mother-child relationships. It is unclear whether the early intervention often provided by nurses and other health care professionals to families having preterm infants may have prevented family dysfunction.

Youngblut, J. M., Singer, L. T., Madigan, E. A., Swegart, L. A., & Rodgers, W. L. (1998). Maternal employment and parent-child relationships in single-parent families of low-birth-weight preschoolers. *Nursing Research*, 47, (2), 114–121.

Parents with well-established sources of support outside the family will be less likely to deprive their children of parenting by turning to their children for emotional support (Seibt, 1996). Social support provides family members with emotional support, a communication network, feedback, and good will from others; social support also enhances self-esteem (Danielson, Hamel-Bissell, & Winstead-Fry, 1993).

Emotional Climate for Resolution of Losses

Members of single-parent families are likely to experience a sense of loss, even in families in which a single person chose to be a parent. Children will fantasize about how their lives would be different if they had a second parent. Parents will find themselves wishing for help or support from a partner. In families in which children express these

feelings and are listened to, the children are likely to realize that some of these fantasies are unrealistic. They will also, with the help of the parent and the social support system, be able to identify solutions to meet their needs. If there is no father to coach the little league team, perhaps a grandfather, uncle, or family friend will step in. Single parents who have open communication with other adults similarly will be able to voice and resolve their sense of loss.

In single-parent families formed after divorce, the feelings of loss may be more intense. The family will experience a period of destabilization. Divorce is a crisis for the nuclear family and also for the extended family. The effect of divorce on the family varies with the ages of the children and length of the marriage. Families at greatest risk for divorce are those with preschool and school-aged children. Children in these groups may respond to divorce by regressing developmentally, adding to their parents' stress. When divorce occurs while the children are adolescents

Critical Thinking

Children in Single-Parent Families

"The children raised by single parents can be just as healthy and normal as those raised in the traditional two-parent family. In fact, despite the obstacles, children in most single-parent families are provided with the love and nurturing that all children need and deserve" (Seibt, 1996).

- What do you think Seibt means by the term normal?
- Which needs are met when a child is loved and nurtured?
- Can you think of ways to evaluate whether a child's needs for love and nurturing are being met?

the problems of completing the developmental tasks of adolescence are compounded and frequently the process is prolonged. After divorce the family may take from 1 to 3 years to stabilize (Friedman, 1992). The process of family stabilization is aided when the parents meet their financial responsibilities, continue to talk with each other about parenting issues, and support the other parent's relationship with the children. Parents also need to find ways to rebuild or maintain their separate financial resources and social networks (Carter & McGoldrick, 1989).

In all families, good communication helps the members resolve their sense of loss. Good communication is characterized by the ability of the family members to listen attentively, share feelings about themselves and their relationships, state clearly what they think and feel, stay on topic, speak for themselves and not for others, and have respect and regard for the feelings of others (Olson, 1993).

Nursing Tip

SINGLE-PARENT FAMILY

"After a death or divorce, the reorganized, single-parent family often bonds itself into a very close unit emotionally." (Seibt, 1996).

Reconstituted Family

A **reconstituted family** differs from a traditional family. These differences are described subsequently. Authors use various terms to label the reconstituted family, including remarriage family, stepfamily, and **blended** family. These terms are used interchangeably herein.

Born of Losses

The reconstituted family forms because the earlier marriage or partnership of one or both of the parents ended. Usually the marriage ended in divorce or, less frequently, a spouse died. When members of the reconstituted family have recovered emotionally from the loss of the earlier marriage and have accepted their own and the other's fears about forming a new family, they can begin imagining and planning for the new family. Ideally, they will accept that it will take time and patience for all the family members to take on new roles in the reconstituted family. There will be a period of confusion as they decide where to spend holidays and what their relation is to people to whom other members of the reconstituted are biologically related (e.g., their stepfather's sister). They will have to work through the issues of who belongs where, who has authority for what, and how space and time will be apportioned to various members. They will need to deal with emotional issues, including guilt, loyalty conflicts, a desire

Nursing Tip

RECONSTITUTED FAMILIES: THE MOST TYPICAL

"Following divorce about 75% of men and 65% of women go on to remarry. By the year 2000, remarried families were predicted to become the predominant family form—the most normal, in the sense of typical" (Walsh, 1993).

- One out of every 3 Americans is a member of a stepfamily.
- 52%–62% of all first marriages end in divorce and 75% of all divorced persons remarry.
- 43% of all marriages are remarriages for one of the adults.
- 60% of all remarriages eventually end in divorce. This makes stepfamilies one of the more typical family structures. (Stepfamily Association of America, 2001) <http://www.stepfam.org>

for mutuality, and the fact that some past hurts may never be resolved. The family that successfully negotiates these tasks will develop a family that permits children to move from the household of one biologic parent to another and engages in the ongoing work to keep lines of communication open between the parents, grandparents, and children (Carter & McGoldrick, 1989). The family members also will have twice as many sources of support, four sets of aunts and uncles and grandparents.

Family Members' Histories

Members of the remarried family join the family at different points of their individual, marital, and family life cycles. Adults and children may have experienced differing parenting and housekeeping styles and differing traditions in previous families. As a result they may vary in their developmental stages, values, and convictions. For example, a man who has never been married or has never been a parent may marry a woman who has two children, an adolescent daughter and a preschool-aged son, from an earlier marriage. The teenager is developmentally at the stage of moving away from close family ties to peer relationships. Her mother may be dealing with issues related to letting her begin to separate from the family while her stepfather is trying to establish a relationship with her (Visher & Visher, 1993).

Parent-Child Relationship

The reconstituted family may have a very different meaning for children and adults. Adults may view the new family as an opportunity for happiness. In contrast, the children are likely to experience the new family as a threat to their relationship with their biologic parent. In the reconstituted family, children are likely to act out because their sense of security is threatened. When biologic parents and stepparents understand that their relationship threatens the child's feeling of security, the stepparent can avoid taking on a parental role until the child shows readiness. The stepparent can act as a caring adult friend to the child and as a support person to the biologic parent (Seibt, 1996).

The bond between the couple and the bond between the stepchild and stepparent to a large extent are formed independently of each other. The couple's bond, however, usually precedes and provides a foundation for satisfying the child-stepparent bond. Both are needed to establish a successful family (Papernow, 1993).

Influential Biologic Parents

Noncustodial parents, that is, biologic parents who do not live with the children, may have a great impact on the reconstituted family. Children may continue to fantasize

about their biologic parents getting back together long after the marriage has ended. The children may see their parent's marriage to a new partner as a betrayal of the former spouse, especially if the former spouse died. Children struggle with divided loyalties when choosing who to invite to important events and with whom to spend time. When parents are hostile and living in separate houses, children are more likely to be successful at causing rifts. They gain power from threats, such as "I'll go live with my dad if you don't let me go out," or from comparing their mother and stepmother, "My real mother lets me go out." These problems are minimized when the adults are able to maintain cordial relationships and open communication around parenting issues (Visher & Visher, 1993).

Members of Two Households

Although the marriage ends when parents with children divorce, the family does not end. Parents continue to have a parenting relationship with each other and with their children. The family takes on new forms, often with children moving back and forth between two homes, with different customs, foods, and ways of doing things. Family members are likely to experience tension when the children prepare to leave one home and when they arrive at the other home. At each transition the children may struggle with feeling left out of one home and needing to become an insider in the other home. Children may not have an identifiable space or may find their space intruded on by stepsiblings. Finding ways to deal with the ongoing transitions is difficult but important. When families do not find ways to manage the transitions, children who experience repeated feelings of being excluded, intruded on, or rejected may develop strong feelings of anger and depression (Visher & Visher, 1993).

Legal and Social Relationships

Stepparents may have an ongoing parenting role that is not recognized legally or socially in their community. Stepparents may not be able to sign for medical care, may not receive invitations to graduation ceremonies, and may be forgotten when biologic parents are asked to join the parent-teacher association at school or other child-centered volunteer activities.

Financial Issues

Finances are likely to take on meanings beyond the intrinsic value of money. To a child, knowing that child-support payments are arriving intermittently or late may add to feelings of vulnerability ("Will I lose my home and end up homeless?"), abandonment ("If she cared, she would send the money on time"), and guilt ("Having to send money to support me is hurting her"). The anger

and resentment of former spouses toward each other also are likely to influence their financial dealings. The spouse paying child support may wonder if the money is being spent to meet the needs of the child. The custodial parent may feel anger that the noncustodial parent's living standard has not been affected by the divorce, whereas the custodial parent and the children have a lower standard of living. Stepsiblings may receive differing levels of support from the non-custodial parent, which adds more tension to their relationship. In contrast, having child-support payments arrive routinely may enhance the child's sense of security and decrease tension between the former spouses. The noncustodial parent who routinely pays child support may feel satisfaction and be more likely to remain involved with the children in other ways, maintaining the parenting role.

Additional Relatives

If each of the marital partners has been married before and brings children to the family, they will each have experienced at least three previous family systems: the family of origin, the first marital family, and the single-parent family. The children will have experienced at least two previous family systems (Visher & Visher, 1993). The re-constituted family may have a total of four sets of grandparents and step-grandparents. There will likely be aunts, uncles, and cousins from all the previous families. All these persons may add to the support system available to the family.

Myth of the Wicked Stepmother

Stepmothers and families in which the woman is the step-parent (stepmother families) are likely to experience more stress than are stepfathers or families in which the father is the stepparent. This extra stress on these families may be partly related to the fact that women are still expected to set the emotional tone for the family. More probably, the additional stress in stepmother families is related to the father having custody of the children. Mothers generally are expected to retain custody of their children. These social expectations may add to the mother's and the children's stress. Tension between the mother and stepmother also may add to the stress (Visher & Visher, 1993). Children may wonder what is wrong with them, thinking that their own mother does not want them, no matter what the circumstances of the custody agreement. The mother also may experience anger, frustration, and guilt. Her feelings may exacerbate the children's difficulties dealing with a sense of divided loyalties between mother and stepmother (Engelbreton, 1982). A number of children's stories describe stepmothers as evil and wicked. These stereotypes may create additional tension for the stepmother.

Myth of Instant Love

In stepfamilies there are many relationships and not all persons entering the family do so by choice. Remarried parents and stepparents, however, may cling to the myth of "instant love" in the hope that the new family will end the pain that they and their children feel as a result of past losses. The implicit demands that everyone be friendly and feel good can lead to anger, guilt, and tension. Not all stepfamilies are the same; families with a stepfather and a mother and her children tend to experience less stress than do other stepfamilies. Families with a stepmother and father with his children experience more stress, as described previously. Families with the greatest likelihood of divorce are families to which both parents bring children. The larger the family the more difficult the task of forming emotional bonds between all members. Families in which the members can give up the myth of instant love and let relationships develop slowly and naturally will be the most successful (Visher & Visher, 1993).

Papernow (1993) has described emotional and developmental stages that families go through in the process of developing an integrated stepfamily household. Members fantasize about what the family will be like, immerse themselves in the family, become aware of differences, and ally along biologic lines during times of tension. Adults become aware that changes need to be made, lead-

Critical Thinking

Establishing a Family Unit

"Slowly, former alliances and ways of doing things become transformed, as stepfamily members move from having little or no emotional connections between them to the establishment of bonds that give them a sense of belonging together as a family unit" (Visher & Visher, 1993).

As a nurse you understand that it may take time for members in a stepfamily to establish a strong sense of bonds. How would you respond to a mother who is holding a newborn and looking somewhat sad when she says, "I've never had these feelings for my stepdaughter. I love this baby so much"? Would the following statements support the mother's bonds with both children? "This baby is so precious. Having a new baby can be an exciting time in a family. What is your stepdaughter's name? Will she see her baby sister soon?" What else could you say?

ing to mobilization and then action. During these stages the family may find the tension intolerable and may divorce because they cannot work as a team. It may take the adults 5 or 6 years to bond as a team to meet family stressors. In successful families, contact and resolution are the stages of deepening stepparent-stepchild relationships and recognition that the family has achieved stability as a unit.

Myth of the Re-Creation of Another Nuclear Family

Although the family members may fantasize that they are creating a nuclear family with two parents and their children, the stepfamily or remarried family is a more complicated unit. To function successfully, family members must negotiate the complicated issues related to helping children move between two households. When successful the family will have semipermeable boundaries, allowing the adults to communicate about parenting issues and the children to establish a sense of belonging in both households while, at the same time, maintaining a sense of separateness, cohesion, and unity within the household (Engelbreton, 1982; Visser & Visser, 1993).

Conflicts

Conflicts may occur between the stepparent and parent of same sex, the spouse and former spouse, biologic groups, stepparents and stepchildren, and parents and biologic children. Of course, conflict may occur between any and all members of the extended family. Sources of conflict include discipline, finances, and sexuality.

Discipline

Discipline issues can be a source of much conflict in all families, but stepfamilies have some unique concerns. It is unlikely that any two people agree completely on discipline. In a family where both parents care for the child from birth, they have an opportunity to develop their discipline styles from infancy. While this does not mean that both parents will agree on discipline styles, they do have an opportunity to work out some of the conflicts while the child is very young. In stepfamilies, one of the parents has an established discipline style and relationship with the child. The new partner must establish a relationship as well as a discipline style with that child. Often the child will resent and challenge the discipline from the stepparent. In some cases, the custodial parent also resents the stepparent's discipline and emerging relationship with the child. This can be a source of much distress in the family. The best advice is for the parents to agree on some disciplinary rules and then present a united front to the child. This avoids overt conflict between the parents and provides more security for the child.

REFLECTIONS FROM A STEPMOTHER

Seth was 6 years old and had lived with his stepmother since he was 4 years old, when his biologic mother had died. He had known his stepmother since he was a toddler. He saw little of his biologic mother's mother. He called his stepmother's parents grandma and grandpa. His grandpa thought he was wonderful, and he and Seth loved being together. However, when his grandpa learned that his daughter, Seth's stepmother, was pregnant, he said, "Finally a real grandchild." His wife quickly turned to him and said, "Don't ever say that again." Fortunately, Seth was not present, and his bond with his grandpa was not harmed. Years later, when Seth and his younger half-brothers were adults, his stepmother recounted that scene, saying, "There were so many feelings of guilt and anger, but we were enriched. It didn't just happen. Our lives have been so much richer than if we were just a nuclear family."

How could you respond if your client spoke of having "real" grandchildren? What makes a family relationship real?

Finances

Parents who are providing financial support to both their stepfamily and their biologic children may feel like "walking wallets," who have had their personal control and power taken from them. Women who have learned to survive as the head of a single family may resent losing their sense of control or power in a new relationship. Both adults are likely to equate money with power and may keep financial matters secret from each other. Finances may serve as the focus for both parents when the family is dealing with power issues and may exacerbate other power issues in the relationship (Visser & Visser, 1993).

Sexuality

Sexuality is likely to be a source of tension in a stepfamily. The newly married couple may exhibit overt sexual behavior that is stimulating to their children. The new family may include teenagers who find themselves attracted and stimulated by their proximity to each other more overtly than siblings who have grown up together and who repressed similar feelings at a young age. Stepfathers and stepdaughters may be attracted to each other. Incest taboos that apply to biologic relatives may be weakened. Daughters generally compete with the mother for the attention of the father. Sons generally resent the father who they view as competing for attention from the mother. These issues are heightened in stepfamilies (Visher & Visher, 1993).

Nursing Implications

The goals of counseling are based in the numerous issues that stepfamilies are likely to be coping with, discussed previously. Helping the couple establish a strong primary bond, which will determine the stability of the family, is the primary task of counseling. The couple will need to establish and support their individual roles in issues related to discipline. Family members will need to establish new alliances that go beyond biologic ties. They will need to resolve issues of loss, anger, grief, and guilt so that they

can be assertive in meeting their own needs and defining limits within the new family. Children will need to have a sense of personal space as they come and go between two households. Communications about parenting relationships need to be established and maintained between ex-spouses and stepparents. All members need to be flexible in adapting and readapting to the multiple and complex relationships within the family (Visher & Visher, 1993).

Visher and Visher (1993) give specific guidelines for working with stepfamilies or members of stepfamilies.

- ✱ Avoid holding to an ideal family model. The stepfamily does not and will not fit the nuclear family model.
- ✱ Stepfamilies may experience extreme stress related to culture and to their structural complexities. They therefore may exhibit more emotional distress than do members of traditional families. This may not indicate a need for in-depth therapy but rather a need for support and validation of their experiences. As they gain in confidence and experience a sense of

Client Education

Working with Reconstituted Families

The following tips might be useful in working with a reconstituted family:

- All members of the family need to realize that establishing family rituals, traditions, and relationships will take time.
- Parents must take the time and energy to nurture their own relationship because it is pivotal for the health and stability of the family.
- All members of the family need to establish dyadic relationships and learn to function as a family unit.
- Parents need to work together to establish mutual rules related to discipline.
- Parents should help make noncustodial children feel they are a permanent part of the family. When they visit, make sure they have their own space to keep personal items.
- Parents should take extra time for holiday planning because there are additional relatives to consider.
- All members of the family must be flexible.

Critical Thinking

How Family Members Are Connected

When Seth was 8 years old and his brothers were 2 and 3 years old, his aunt (his biologic mother's sister), came to stay with the family for a week. His stepmother recalled her thoughts and feelings as she anticipated the visit. "This person is only related to one of my children. How will she treat the younger children who don't have biologic aunts?" She wondered: "What is my relation to her? I don't have a name for how we are connected. She is family but she is an alien element." The visit started with the two women treating each other politely but formally. Their relation began to change when the aunt bought presents for each of the boys. The visitor was becoming an aunt to all of the boys. Then the women could talk about their anxiety and find common ground.

How can a nurse support the transformation of awkward relationships into supportive relationships?

mastering the tasks of their unique family, the chaos will probably decrease.

- ✱ The most beneficial interventions for counseling stepfamilies include validating experiences, educating family members about the issues related to integrating the stepfamily, reducing family members' sense of helplessness, and strengthening the couple's bond.
- ✱ There may be times when family counseling meetings should include other significant adults, for example, adult friends, grandparents, or ex-spouses. The purpose of such meetings should be clearly defined before they occur and limited to issues involving the children to avoid undermining the couple's bond.
- ✱ Nurses who counsel the family may have strong feelings (countertransference) both positive and negative, about stepfamily situations. It is therefore important to consult with others while counseling families.

THEORETICAL FRAMEWORKS

Several theories related to family are found in the disciplines of psychology and sociology. Four theoretical frameworks applicable to the nursing professions, particularly nursing with childbearing and child rearing families, are the developmental, interaction (or structural-functional), role, and systems frameworks. The first three allow the nurse to assess the family as a unit; an understanding of role theory is necessary to evaluate individual roles within the family.

Developmental Theories

Developmental theories look at families as they develop over time. Common to developmental theories, each stage has specific tasks. The tasks are represented by the development of the family. For example, the birth of a child presents the tasks of caring for an infant. Successful mastery of the tasks at each stage prepares the family to master the tasks of subsequent stages and maximize the health of the family. Many developmental frameworks exist with various numbers of stages. One of the classic developmental frameworks describes eight stages through which a family progresses from marriage of the couple to death of both (Duvall & Miller, 1985). Duvall orients the stages around the development of the traditional family structure. It is important to note that each stage has tasks for the couple-family unit and for the development of the children. Often, families in traditional structures fail to acknowledge the need to nourish the spousal relationship. Other family

development theorists, such as Carter & McGoldrick (1989), have identified stages that are not limited to traditional family structure. The family progresses through these stages led by the oldest child. Duvall identifies the source of developmental tasks as biologic and physical maturation, cultural and social expectation, and individual aspirations and values.

Family Tasks

The tasks that society expects of the family at different stages and the focus on childbearing-rearing families is most relevant to nurses who care for women and families perinatally. According to Duvall (1977), certain tasks are incumbent on all families:

- ✱ Providing physical maintenance: food, shelter, and health care.
- ✱ Allocating resources: physical, time, and space.
- ✱ Dividing labor to support the home and family.
- ✱ Socializing family members.
- ✱ Communicating and appropriately expressing feelings.
- ✱ Bearing and rearing children.
- ✱ Relating to the community.
- ✱ Maintaining morals, values, and cultural beliefs.

Eight Stages of Family Development with Tasks

1. *Beginning Family*: This stage spans the start of the marriage to the birth of the first child, including establishment of a new household and the beginning of the nuclear family. The following tasks are important for the new couple to perform:
 - ✱ Establishing a mutually satisfying marriage.
 - ✱ Planning for the possibility of having children.
 - ✱ Relating harmoniously to kin.
2. *Childbearing Family*: This stage begins with the birth of the first child and lasts until the child is 30 months of age. The tasks are the following:
 - ✱ Having, adjusting to, and encouraging development of the infant.
 - ✱ Establishing a satisfying home for parents and infant.
 - ✱ Expanding kinship roles to include the grandparents of the child.
3. *Family with Preschool Children*: This period covers the years from the time the oldest child is 2.5 years old until the youngest child is 5 years old (Figure 3-2). The tasks are the following:
 - ✱ Adapting to critical needs and interests of preschool children.

Figure 3-2 Families go through predictable growth stages as members are challenged to adapt to developmental transitions of the family unit combined with changing needs of individual members.

- Meeting the needs of additional children while continuing to meet those of the firstborn.
 - Coping with energy depletion and lack of privacy.
4. *Family with School-Aged Children:* The time from when the oldest child is 6 years of age until the child turns 13 years of age is considered the school-aged stage. The tasks are the following:
 - Constructively fitting into the community of families with school-aged children.
 - Encouraging the child's educational achievement.
 - Meeting the physical health needs of all family members.
 - Maintaining a satisfying marital relationship.
 5. *Family with Teenagers:* This time period begins when the oldest child is 13 years of age and ends when the youngest child is 20 years of age or leaves home. The tasks are the following:
 - Balancing teenagers' freedom with responsibility as they mature and emancipate from the family.
 - Establishing postparenting interests and careers.
 6. *Launching Center Family:* This period covers the years between the time the first child leaves home and the last child leaves home. The tasks are the following:
 - Releasing young adults into lives of their own with appropriate rituals and assistance.
 - Maintaining a supportive home base.
 - Building a new life together as a couple.
 - Assisting with aging or ill parents.
 7. *Middle-Aged Family:* This phase refers to the years from the time the last child leaves home to the retirement or death of one of the spouses. The tasks are the following:

Nursing Alert

FAMILY DEVELOPMENTAL TASKS

Family members engage in individual developmental tasks simultaneously with family developmental tasks. Sometimes these tasks may create conflict. For example, meeting the family task of adapting to needs and interests of a preschool child may create tension with the needs of the young adults to establish intimacy.

- Rebuilding the marriage relationship.
 - Maintaining ties with older and younger generations.
8. *Aging Family:* This period lasts from the retirement of one or both members of the couple through the death of one of the spouses, ending with the death of the remaining spouse. The tasks are the following:
 - Adjusting to retirement.
 - Closing the family home, or adapting it for the physical limitations associated with aging.
 - Coping with bereavement and living alone.

Interactional or Structural-Functional Theory

The structural-functional approach to family theory generally understands the family as a subsystem of society. This approach is important to nursing because it allows the nurse to evaluate the family system as a whole, the parts of the family system, and the family system as it interacts with other systems. Friedman (1992) uses the structural-functional theory along with the general systems and developmental theories to provide a “comprehensive and holistic perspective” for assessing family dynamics and the internal and external forces that influence families. When assessing the family using the structural-functional approach the nurse considers the family's structure or organization and how it allows the family to carry out its goals or functions.

Structure

The structure of the family is the way the family is organized. Is the family traditional, a single-parent family, a family resulting from remarriage, and so on? Where is the power in the family? What are the subsystems of the family group? What is the family lifestyle (values, communication, roles, and power)? (Friedman, 1992). If the family structure or organization is functioning well, then the family will carry out its functions.

Function

Functions are those things the family does to meet the needs of its members and of society. Friedman (1992) lists five family functions that are important in assessing and intervening with families:

1. **Affective Function:** Promotes the stability of family members by meeting their psychologic needs.
2. **Socialization and Social Placement Function:** Socializes children to become contributing members of society and gives social status to family members.
3. **Reproductive Function:** Allows the family to continue over generations and allows society to survive.
4. **Economic Function:** Allows the family to acquire and allocate adequate financial resources to meet their needs.
5. **Health Care Function:** Allows the family's physical needs to be met.

Role Theory

Role theory is based on the understanding that certain behaviors and responsibilities are identified with certain positions. Every person has numerous positions. For example, a man may be a father, husband, son, bricklayer, gardener, neighbor, and so on. Each of these positions has related roles or behaviors associated with it. One of the man's roles as father is to provide childcare. He is likely to share this role with the child's mother and, perhaps, with extended family members and childcare workers. Friedman (1992) stresses that understanding role theory is essential for all nurses who care for families to allow nurses to support healthy role behaviors and determine role problems. This is particularly relevant for childbearing families as they learn parenting roles. Some of the issues surrounding role theory are discussed next.

Conflicting, difficult, or impossible demands may place strain on family members. Examples include a single mother who is expected to provide childcare, work full-time, cook three meals a day, and keep a clean, tidy home. The successful single parent will modify these expectations to manage her role. A mother whose job is vital to her family's economic well-being may find herself having to choose between the needs of a sick child and the requirements of work. Having the support of others may be vital to her in meeting the conflicting demands on her time. Some mothers will have others who can take over her role when needed. For example, the mother and father in a family are likely to share in nurturing children. Extended family members, teachers, members of the religious congregation, and others also may participate in caring for the children.

Individuals never have roles in isolation. Roles are reciprocal, and the role partners influence and adapt to each other constantly. For example, the parent and child roles are continually being modified as the child makes developmental gains and the parent responds. In families, roles are allocated by someone in a leadership role. That person is assigned the role by culture and social class. Roles may be assigned by what the family needs done, by individuals and may also seek satisfactory roles within the family. Families use regulatory mechanisms to maintain equilibrium. The regulatory mechanisms are adaptations of roles to meet the family's needs for outside resources and internal cohesiveness. When family members do not meet their expected roles, both formal and informal, the family may experience difficulty or loss of homeostasis. For example, if the mother's formal role is to provide income the family may experience stress if she becomes ill and unable to work until or unless another family member, perhaps a grandparent, comes to their aid. If the mother's informal role was as peacekeeper between her husband and son and her illness prevents her from carrying out this role, the father and son may have difficulty resolving disputes.

In families in which roles are complementary, compatible with family and social norms, meeting the psychologic needs of family members, flexible in responding to change, and not overloading one or more members, then all family functions probably are being carried out. The family is said to be coping adequately to meet its needs (Friedman, 1992).

Systems Theory

Systems theory has its roots in the physical sciences. Sociologists adapted the understanding that systems can be explained in terms of how they interact with their environment and with their subsystems to evaluate social systems. Friedman (1992) described systems theory as inclusive and powerful. Understanding the family as a system allows the nurse to view the family as a client to be assessed and treated as a whole rather than as an aggregation of individual clients.

Family as a System

A nurse who takes the family systems approach to evaluating a family thinks of the family as a goal-directed unit made up of interdependent and interacting parts that endure over a period of time (Figure 3-3). The family is a relatively open or closed system; that is, the family interacts, to a greater or lesser extent, with other systems. **Family boundaries** establish the family's separateness from the environment and regulate input and output. Families with rigid boundaries are relatively closed and limit family members' interaction with others, who may be potential

Figure 3-3 The nurse must understand a family's system and structure to provide appropriate care and guidance.

sources of support. Families with few boundaries may have members who are so focused outside the family that they neglect the needs of other family members. An overly closed family system (self-contained) gives little output (energy, material, and information) to the environment and receives little input (energy, material, and information) from the environment. An overly open family system gives so much output and receives so much input from the environment that it is in danger of losing its sense of being a unique, intact entity.

Family subsystems include individuals, such as the husband, who interacts with another individual subsystem, the wife. Subsystems may include more than one individual. One subsystem, the marital couple, may interact with another subsystem, the children in the family. The focal system is the system or subsystem that is of particular interest. For example, the mother-infant pair is the focal system when the nurse is teaching the mother to bathe her newborn child. The nurse also may be interested in the family suprasystem, that is, the extended family or the community to which the family belongs. The nurse may be evaluating the relationship of the mother to others in her extended family or to the community to determine the level of support available to the new mother.

Family systems experience adaptation when they adjust to changing demands and resources from the environment or to internal needs and changes. Self-regulation is the process of adaptation that occurs when the system adjusts internally by modifying subsystems, or externally by controlling its boundaries. It can accept or reject input, and it can modify its structure to accommodate changes.

Family Systems Concepts that Guide Nursing Interventions

Nurses who assess and intervene in family systems are guided by understanding the following:

- The members of a family system are interdependent. The interrelationships are so intrinsically bound that if one member changes, changes will occur in the entire system.
- The family system is greater than and different from the sum of its parts. This is called nonsummativity. One aspect of the family cannot be understood apart from the rest of the family system, and the family as a whole cannot be understood from one of the members.
- The assessment of a family's interactional patterns may be approached from various vantage points. The process is more relevant than is the content. This is known as equifinality.
- Understanding family structure, organization, and transactional patterns aids in understanding the behavior of family members. A major strength of family systems theory is that it naturally allows for incorporation of developmental, interaction, and role theories.

CULTURAL ISSUES THAT INFLUENCE FAMILIES

Many forces affect families. These forces include better health care and public health systems that lead to longer life spans and lower infant mortality rates. The economy of the community in which the family lives influences the family's economic status. Families in the United States and Canada belong to diverse cultures. The role of women in the workplace has changed a great deal since the 1950s and 1960s. These issues are discussed in the subsequent sections.

Lower Birth Rate and Longer Life Span

Fewer children are being born into most American families, and older family members are living longer. The U.S. Census Bureau (2000) estimates that the birth rate per 1,000 persons decreased from 16.7 in 1990 to 14.6 in 1998 (NCHS, 2001). By 2030, 21% of Americans will be 65 years of age or older. Middle-aged adults may find themselves responsible for aging parents, with few siblings to share the caregiving responsibilities. In contrast, the family generations may offer mutual support. The older generation may provide financial support and other services to the younger generations, and the older generation may receive support during times of illness.

Economics

Financial status influences the type of housing, food, health care, and education families can provide for their members. In late adolescence and early adulthood, decisions are made about education, career, marriage, and

childbearing that may determine long-term economic well-being. Individuals make these decisions in the context of family expectations, family economic status, as job availability, and social norms (Farley, 1995).

Numerous factors influence the financial status of families. Elderly families (with members over 65 years of age) were half as likely to have income levels below the poverty rate in 1989 (12%) as they were in 1969 (25%) because Social Security benefits were indexed to the rate of inflation in 1971, ensuring that Social Security income kept pace with inflation. The increase in home prices and the expansion of the system of private pension funds also contributed to the decrease in impoverished elderly families. Older persons could sell their increasingly valuable homes and purchase smaller homes or rent and have a substantial amount of money left over to augment their income. Older persons also were more likely to have contributed to pension plans and thus were more likely to have income available in the form of a pension.

In contrast with older persons, children are more likely to live in families with incomes below the poverty level. In 1997, 19% of children lived in families with incomes below the poverty level compared with 17% in 1975. During those years the poverty level increased from 12% to 15% for Caucasian children and decreased from 41% to 37% for African American children. Hispanic children also experienced an increase in the likelihood that they would live in families with incomes below the poverty level. In 1990, 14% lived in poverty compared with 16% in 1997. From 1985 to 1993, the percentage of children living in poverty increased. In 1994, as the economic conditions in the country improved and more jobs became available, paying higher wages, the percentage of children living in poverty decreased.

The growing numbers of families that are headed by women are likely to be among the 20% of American families with the lowest income, because women often have low incomes. Families with dual incomes are more likely to be among the 20% of Americans with the highest income (Levy, 1995). From 1975 through 1997, the median income of mother-only families was never more than 35% of the median income of two-parent families (U.S. Department of Health and Human Services, 1999). In 1997, 32.4% of all births in the United States were to unmarried women, up from 5.3% in 1960 and 28% in 1990 (U.S. Department of Health and Human Services, 2000).

Although an increasing percentage of children are born into single-parent families with low incomes many families with children benefited from social changes, including generally better-educated parents and smaller family size. In 1970, 70% of all children lived with two or more siblings (at least three children). In 1990, more than 50% of children lived with one or no siblings (no more than two children). Parents were more likely to have a higher education and therefore a higher income. From 1969 to 1989,

the proportion of children living in families with incomes above \$50,000 (in 1989 dollars) increased (Levy, 1995). On average, family incomes increased from 1979 to 1996, primarily because women were in the work force.

Most families, however, are not average. (Remember when you add $10 + 3 + 2$ and divide by 3 the average is 5 but none of the numbers you started with is 5.) The economic status of families often is discussed using income distribution. To determine income distribution all families are ranked by income, then divided into five groups, with 20% of all the families in each group. Economists can then determine how much of the total annual income of a country each group receives. The groups are called quintiles, or simply fifths, for example, the top or bottom fifth. In the United States, the distribution of income has changed over the past twenty years. The lowest quintile accounted for less of the aggregate income: 5.3% in 1980 down to 4.3% in 1999 (U.S. Census, 2001). The top quintile

Critical Thinking

Cultural Practices

At a recent social gathering a group composed of two Muslim couples from Egypt, a Coptic Christian from Africa, a nonreligious couple from China, a nonreligious couple from South America, and two nonreligious North American couples discussed how their mates were chosen. The parents of the couples from Egypt, Africa, and China had arranged marriages. All the couples whose parents had arranged marriages expressed satisfaction with this process of finding a mate. The North and South American couples expressed opposition to arranged marriages and emphasized the importance of finding their own mate. All the couples expressed satisfaction with their mate and the process they had experienced.

- What do you think about how a marital partner is chosen?
- Can you imagine getting to know and love someone before you marry?
- Can you imagine getting to know and love someone only after you marry?
- Which values do you have that make it easier to imagine one situation over the other?
- Do you value individual autonomy more than family, or do you value family more than individual autonomy?
- How might your values get in the way of working with people who have different values?

accounted for 41.1% of the income in 1980 and up to 47.2% in 1999. As a matter of fact, the top 5% of the population accounts for more than two times the income of the bottom two quintiles. Thus, only 20% of the population account for nearly ½ of the total income. The rest is distributed over 80% of the population.

Cultural Diversity

Culture is used here to mean the customs, ideas, beliefs, values, social structure, and language that a family transmits to successive generations. A given family's cultural behaviors and beliefs are based on membership in larger groups, often ethnic or national. Shared language, nationality, or ethnic group, however, does not necessarily indicate shared culture. Cultures often include subcultures. For instance, the European-American cultural group includes German, Italian, Scandinavian, and many other subgroups. Subculture membership may be based on religious practices, educational level, and socioeconomic status. Different cultural groups continually interact, resulting in changes when members of the interacting cultural groups respond to different ideas or behavior patterns. Therefore cultures are dynamic, changing constantly (Cuellar & Glazer, 1996).

In most cultures the family has three social functions. Society expects the family to provide food, shelter, clothing, and medical care to meet the physical needs of its members. The family also is the primary source of communication and emotional support, providing the individual with both preparation for and respite from the demands of society. Finally, the family transmits its cultural values, beliefs, and traditions from the older to the younger generations, thereby providing for continuity of the society.

Immigration increases the diversity of cultures in the United States. Before the mid-1920s there was little restriction on immigration to the United States. From that time until 1965, however, immigration was greatly limited from all regions except Northwestern Europe. This restriction was removed beginning in 1965. From 1965 to 1999, an estimated 27 million persons immigrated to the United States. In the 1950s, immigrants were primarily from

Nursing Tip

ACCULTURATION

When families immigrate to a new culture, a process of acculturation occurs. This process may progress faster with younger generation than older generations. For example, a Chinese family immigrating to the United States may have some internal conflict because adolescents begin to acculturate to popular American youth-oriented culture and fail to offer respect to their aging relatives, which is a traditional Chinese value.

Europe. Late in the 20th century, immigrants were primarily from Asia and Latin America (Doyle, 1999).

Cultural variations can be seen in families. Organizational structure and role flexibility within families varies from culture to culture. In some cultures, the males make all instrumental decisions. For example, in Hispanic families, often the male must be included in any decision regarding birth control. In other cultures, women make that decision independently.

Cultures modulate the nuclear (parents and children only) family's relationships with extended (nuclear family and grandparents, aunts, uncles, and cousins) family and the family's relationships to society. For example, a Mexican family may expect unmarried adult children to live in the family home until marriage. In contrast, a middle-class family in the United States likely expects adult children to move out on their own after their formal education is completed. It is not a universal family norm for young adults to live apart from their nuclear family for long periods.

Choice of Marriage Partner

People choose marital partners to meet their needs for love and belonging, companionship, emotional and economic stability, and procreation, among other reasons. Mate selection is greatly influenced by place of birth, current residence, and the social control exerted in one's culture (Okum, 1996). In the dominant North American culture, persons are expected to choose their own mates. In other cultures, parents or matchmakers may select mates.

Generally, first-generation immigrants (those born elsewhere who immigrate) retain the patterns of mate selection dominant in their original culture. The second generation (children born to first-generation immigrants), however, often takes on the values of the dominant culture. When the second generation reaches dating and marital age, conflicts between the two generations may arise.

Nursing Tip

CULTURAL SENSITIVITY

Many sources are available regarding cultural diversity. Nurses must remember not to stereotype clients. Great diversity exists within a culture as well as between cultures.

People may choose mates of differing races, cultures, and religions. These differences sometimes increase difficulties within the marriage. Their difficulties may include knowing less about each other's cultures than people who are in same race, culture, and religion marriages do. These persons also may have to deal with racism and prejudice within their families and communities. There may be a disparity in their level of knowledge about the other's culture. For example, because the dominant culture is more likely to be depicted in popular media, a partner who is African American will probably know more about the culture of a partner who is Caucasian than the other way around (Okum, 1996). When these difficulties can be resolved, the couple may have a satisfying and emotionally rich marriage.

Same-Sex Partners

With a few exceptions, marriages of same-sex couples are not culturally or legally established. Thus, long-term same-sex couples face unique challenges. In many places throughout the world, same-sex couples and their supporters have been working to change existing laws to ensure that their relationships are afforded the same rights and obligations available to married couples under the law. Economic benefits that generally have not been available to same-sex couples include health care insurance for dependents and rights of inheritance. The dependent partner in a same-sex relationship does not have the right to alimony, an obligation on the part of the supporting partner in a heterosexual common-law or married relationship. In a heterosexual marriage if one of the marriage partners becomes extremely ill and is unable to make health care decisions, the other partner is able to do so legally. This has not been true for same-sex couples and is one of the rights they desire.

At present only one country, Cambodia, extends equal marriage rights to homosexuals. The Netherlands passed a bill authorizing same-sex marriage in 2000 that is expected to take effect in 2001. Once the bill is in effect, same-sex partners who marry will have all the same rights as do heterosexual married couples except for the right to adopt. In Brazil, a bill passed in 1996 gives same-sex partners rights, including inheritance, joint-income declaration, and joint income consideration in purchasing a house. In Canada, the Human Rights Act was changed in 1996 to eliminate discrimination based on sexual orientation. In the Canadian province of British Columbia, in 1997, legislators passed laws giving same-sex couples the same rights as common-law heterosexual couples. In Denmark, since 1984, same-sex couples have had equality with heterosexual couples under laws governing inheritance and taxation. Beginning in 1999, Danish same-sex couples could adopt their partner's children but could not adopt outside

the partnership. Norway, Sweden, and Spain have laws similar to those of Denmark. In France, in 1998, unmarried same-sex and heterosexual couples were given many of the tax breaks and legal benefits married couples have. Although adoption became easier for unmarried heterosexual couples, this option was not extended to same-sex couples. In Hungary, in 1996, registered same-sex couples gained the same rights as common-law couples, except the right to adopt. In Iceland, same-sex couples have had the same rights and responsibilities as other couples since 1996, except that they cannot adopt, practice artificial insemination, or have church weddings. However, doing so has little, if any, legal impact. In Hawaii, same-sex marriages were permitted for a few hours in early 1996. A stay of the court ruling was granted to the state; subsequently, voters in Hawaii passed a constitutional amendment prohibiting same-sex marriages. However, same-sex couples can register in Hawaii as reciprocal beneficiaries. Recently, in Vermont, the house has passed a bill that will create a system that gives same-sex couples the same rights, obligations, and benefits as heterosexual couples. A similar bill is currently in the U.S. Senate (Robinson, 2000).

Changing Role of Women

In 1970, 42% of women marrying for the first time were teenagers. By 1990, that figure was 17%. In 1970, 46% of women marrying for the first time were 20 to 24 years of age. By 1990, that number was 41%. In 1970, 8% of women marrying for the first time were 25 to 29 years of age. By 1990, that number was 27%. A similar shift was seen in the age of first-time marriage for men (Clark, 1995). Several social changes are related to the delay in marrying. Young adults spend more years in school, women participate in the labor force, and sexual experiences outside of marriage are more likely to be considered permissible.

Women Working Outside the Home

Men and women work to meet economic needs and goals. They may also work to meet needs for belonging, interesting activities, and a sense of purpose. Although significant differences remain between gender experiences regarding participation in the work force, educational level, and occupation, these differences have been lessening since the beginning of the industrial economy early in the 19th Century. In recent decades, delays in marrying and childbearing and laws making discrimination on the basis of gender and marital status illegal have contributed to increased participation in the work force by women. Because many women can meet their financial needs adequately, women are now more likely never to marry, or if they marry, to divorce and never remarry. A woman who marries and

remains married is likely to outlive her spouse and, therefore is likely to depend greatly on her earnings and pension entitlements during widowhood. The real wages of semi-skilled men in the work force have decreased. Therefore, to have adequate income to support a family, the spouses of semi-skilled men need to be employed (Wetzel, 1995).

Any participation in the work force by married mothers with children under 18 years of age increased from 51% in 1970 to 73% in 1990, and full-time participation increased from 16% to 34%. For the same years, any participation in the work force by married mothers with children aged 6 to 17 years increased from 58% to 78%, and full-time participation increased from 23% to 40%. For married mothers with children under 6 years of age any participation increased from 44% to 68%, and full-time participation increased from 10% to 28% (Wetzel, 1995).

Divorce

From 40% to 50% of first marriages by women (the woman's first marriage may be the man's second or third marriage) are likely to end in divorce. Women of African American descent are more likely to divorce than are Caucasian women. Women of Hispanic descent are less likely to divorce than are women in the other two groups. Several additional factors are associated with divorce. Women who marry before 20 years of age, persons who have begun but not completed an educational degree or diploma, and women whose firstborn child was conceived before her first marriage are more likely to divorce (U.S. Bureau of the Census, 1992).

Children and Childcare

The increase in mothers working outside the home has led to a need for accessible, affordable, and high-quality childcare. Parents desire childcare that protects their children's health and safety and provides developmental stimulation. Finding childcare may be difficult, time-consuming, and frustrating for all families. Poor families have a particularly hard time finding high-quality childcare because of the expense involved. Some parents work opposite shifts to care for their children. Grandparents, siblings, and other relatives may care for children. Children are cared for by unrelated adults in the child's or the adult's home, in schools, and in organized childcare facilities. Families may combine various sources of care to meet their childcare needs (Hayes, Palmer, & Zaslow, 1990).

PROVIDER MODELS

Family-focused nurses may focus on an individual within the context of the family or on the family system. When the nurse provides care to an individual client in the context of the family, the individual is understood to be a sub-

system of the complete family system. The complete family system is the individual's environment, shared with the other individual family members. Others in the family system support the identified client. The nurse teaches subsets of the family to care for the family member if indicated or to provide support to the client (Friedemann, 1993).

Nurses who care for the family as a unit (the master system) promote changes in the family system. To accomplish for change goals, nursing interventions may extend to the community or environment of the family. Nurses use provider models based in psychoanalytic, general systems, and stress and family coping theories. Nurses also incorporate their understanding of family development, family function, education, learning, and social support to formulate and carry out family-system nursing interventions (Friedemann, 1993).

To carry out interventions in the family system, nurses first assess the system to determine which if any changes are needed. The assessment includes evaluation of family-system processes, individual factors, interaction between family members, and interaction of family and interpersonal systems with the environment. Goals for changes in the family system are established based on analysis and synthesis of the assessment data. Nurses are more likely to be effective when they set goals that are congruent with family needs and values. After goals are established, interventions are planned and implemented to meet the goals. Throughout the entire process the nurse evaluates the family changes and modifies goals and interventions as indicated by the family response (Friedemann, 1993).

In this section concepts or models for caring for families are introduced. These include the concept of family dynamics based in psychoanalytic therapeutic models, the biopsychosocial model based in general systems theory, and the resiliency model based in earlier models of stress and coping. The proactive model for enabling and empowering families is described. A case study that uses the nursing process in accordance with the proactive model follows.

Family Dynamics

The concept of family dynamics is rooted in psychoanalytic therapeutic models. Psychoanalysts originally focused on the impact a mother's role during early childhood has on determining an individual's future development. **Family dynamics** means the ongoing emotional processes within the family (a social unit) over time, as the individuals and the family unit develop (Walsh, 1993). Friedman (1992) emphasizes the importance of evaluating family power to understand the relationships between family members and between the family and its environment. Answers to questions such as those that follow give the nurse information about family dynamics:

Critical Thinking

Care of Families as Individuals or as a Unit

In *First, Do No Harm*, Lisa Belkin (1993) described 15-year-old Patrick, his family, and the hospital community where he had spent much of his life. Patrick was born with Hirschsprung disease. The severity of the disease and the more than 20 surgeries that gradually removed his intestine had left Patrick dependent on intravenous (IV) nutrients dripped directly into his heart. His veins were too damaged by numerous previous IV lines to be useful for the IV feedings. Patrick had survived longer than most children with this disease but was entirely dependent on this type of feeding. Patrick was on a ventilator and had a feeding tube. The feeding tube was intermittently clogged as a result of chronic infections.

Patrick's biologic family consisted of his mother, Oria, and his grandmother. His father had left his mother before he was born. When not at the hospital, Patrick slept at his grandmother's home, which was next door to his mother's home. His mother often worked three poorly paying jobs. To encourage her to spend more time with her son, social workers found her a job in the hospital cafeteria. They included her in meetings about his care, although often she was late or simply did not come. The nurses were angry with her because she often slept or sat silently during her short and infrequent visits to her son. The grandmother who provided most of Patrick's care at home did not visit the hospital.

In the hospital the play therapist, a primary nurse, and many others constituted Patrick's surrogate family. When the primary nurse who cared for him for the first 10 years of his life left the hospital to take another job, she "gave" Patrick to the primary nurse, Kay. Kay remained involved in Patrick's care until his death. Both Kay and the play therapist, Richard, took Patrick on outings. Patrick called Kay at home in the middle of

the night when he was scared, anticipating surgical procedures. Celebrities visited Patrick, and he participated in hospital celebrations of major holidays.

Patrick was re-admitted to the hospital with another serious infection of his feeding tube. It was later discovered that Patrick had contaminated his line with feces and dirt to ensure that he would be admitted to the hospital. He had done this previously. Patrick admitted that he did not want to die but was fearful of being outside the hospital. After Patrick's death, his mother stated that she was "bone tired" and that she was not a bad mother, although she felt that the staff did not understand that Patrick had been seriously ill for 15 years and the whole family was tired.

Throughout Patrick's life the professionals who cared for him viewed him, not his family, as the focus of care. They did not ignore his mother but limited their assessments and interventions to attempts to change the ways she mothered. Patrick's mother had long ago decided that the doctors and nurses were better parents to Patrick than she could ever be. They were better educated, more sophisticated, wealthier, and could ease his pain better than she could.

- Did the nurse's role harm or help Patrick?
- Was it helpful for the staff to take Patrick on outings and allow him to call them at home?
- Do you think Patrick's family was addressed?
- Would viewing the family unit rather than Patrick as the focus of care have improved Patrick's life?
- How do you think the nurses viewed the mother's lack of response?
- How did it happen that the nurses gave good care to the child and wonderful attention to the mother but missed the family?

- Who made the decision?
- What was the effect of the decision on individual family members and on the family as a whole?
- Is the power to make decisions shared or does it reside with one family member?
- What does the decision-making say about the family's values?

Understanding a family's dynamics may help the nurse predict areas in which the family may experience difficulty (Figure 3-4). For instance, in families in which decision-making rests with the father and mother, and the children do not participate in decision-making, the children may experience difficulties as adolescents and young adults. Perhaps they will rebel, acting out their need for power and autonomy. Conversely, they may

Figure 3-4 Family dynamics and role responsibilities will vary from family to family.

have difficulty carrying out adult roles, demonstrating a sense of incompetency and powerlessness.

Biopsychosocial Model

The biopsychosocial model is based on general systems theory. It illustrates the interaction and boundaries between the systems in which a person exists, for example, those between a person and family subsystems and those between a person and his or her nervous system. The person is part of, yet separate from, the family. The family is part of, yet separate from, the community. The biopsychosocial model strengthens the case for evaluating and treating the family as part of providing health care (McCubbin & McCubbin, 1993).

The **medical model** or **traditional model** of health care is based on the assumption that illness can be understood in terms of the person who is ill and biologic processes. The biomedical model has been very successful at treating persons with specific diagnoses. The emphasis is on the cause and effect of the illness, as explained using medical science, and on concrete signs and symptoms. Generally, the psychological, social, and behavioral aspects of an illness have been ignored or considered beyond the professional's responsibilities in caring for a person. The health care provider whose understanding of illness is limited to the biomedical model is unlikely to perceive a need to evaluate a family as a whole or to explore emotional and psychological stressors in a person's life. The profession of nursing, however, maintains a holistic perspective compatible with the biopsychosocial model.

Resiliency Model of Family Stress, Adjustment, and Adaptation

The Resiliency model of family stress, adjustment, and adaptation was developed from earlier models of stress and family coping by McCubbin and McCubbin (1993). The resiliency model focuses on family adaptation to acute or cumulative stress. Interventions follow evaluation of family functioning and diagnosis of a problem. The goal of nursing intervention is to support the family to enhance their coping skills to facilitate family adjustment and family adaptation. The nursing interventions are most likely to be effective when nurses recognize family strengths and resiliency (McCubbin & McCubbin, 1993).

A family's response to stress is partly determined by the number and severity of the stressors. If the illness stressors are few and relatively minor the family will probably experience a process of adjustment, which is described in the model as the adjustment phase. If the illness stressors are more severe the family is likely to undergo more extensive changes, which is the adaptation phase of the model.

Adjustment Phase

McCubbin and McCubbin (1993) define a **stressor** as a demand placed on the family that produces, or has the potential of producing, changes in the family system. The more threatening the stressor is to the family as a unit, to the family resources, or to the family's coping abilities, the greater the severity of the stress. Families are more or less vulnerable to stress. The degree of vulnerability is related to the number of stressors and to the difficulties family members may be experiencing in the current life cycle stage.

Family types also influence family response to stressors. Families that are of the resilient type have bonds within the family that follow established patterns and allow for flexibility. Resilient families generally are better able to deal with adversity and to maintain or enhance family functioning than are other family types.

Family resistance resources refer to the resources that affect the family's ability to respond to a stressor, without having to make major changes to established family functioning patterns. Families with more resources are more likely to be able to avoid a major crisis when a stressor occurs. Resources may be spiritual, psychological, economic, or material.

Family appraisal of the stressor is the family's understanding of the illness. The culture and community of the family members influence their understanding of a given stressor. Family appraisal of the stressor refers to the family's expectations about the stressor. For example, a family

whose child is diagnosed with a severe visual impairment may view this as an overwhelming hardship that will lead to family breakdown or as an opportunity to develop new skills to support the child to develop fully.

Family problem-solving and coping refer to the family's ability to identify and respond effectively to manageable problems related to the stressor and to the multitude of coping behaviors that the family uses as it responds to stress. Coping behaviors have as their goal maintaining or enhancing family equilibrium.

Family response to stress and distress refers to the family's tension in response to the stressor. Reducing or managing the tension avoids stress. Family stress is experienced when the demands placed on the family exceed the family resistance resources and coping abilities.

Family bonadjustment, maladjustment, and crises refer to the extent of the hardship a family experiences in response to the stressor. Bonadjustment is responding to a stressor by making only minor changes that have a positive outcome. Maladjustment may occur in response to severe stressors and results in a state of crisis. Families in crisis are disorganized and, despite repeated attempts to adjust, are unable to restore stability to the family. A family crisis may be necessary to identify and make the major adaptive changes needed to restore stability. Therefore a family crisis may indicate a functional and not dysfunctional family system.

Adaptation Phase

The family adaptation phase occurs when adjustment has not been successful and the family is in crisis. Illnesses in family members often require changes in the family system. The family adaptation phase includes adaptation within the family and between the family and its community. The process of adaptation occurs in response to an accumulation of stressors. The more severe the stressor accumulation and the greater the family's vulnerability, the more difficult will be the task of adapting.

Family types and newly instituted patterns of functioning refer to the categorization of families based on processes they use to maintain a bonded and ongoing family unit. In the family adaptation phase, the family has realized that existing processes are not adequate for the demands placed on the family system and that new patterns of functioning are required to maintain a bonded and ongoing family unit. Families with an ill member may need to change the way they use their time, share work at home and in the work force, and develop closer relationships with health care professionals and, perhaps, with extended family.

Family resources, strengths, and capabilities refer to the family's capabilities or potential to meet the demands with which it is faced. Two important capabilities are the

family's strengths and resources. These may be personal, social, and familial. For example, family members may consistently communicate clearly with each other, a source of family strength.

Family appraisal includes the family's understanding of the stressor and assessment of the family's ability to cope with the stressor. This appraisal allows the family to determine which changes in family functioning are necessary to meet the demands imposed by the stressor. Appraisal also includes schema and meaning. Families assign meaning to an illness based on an evaluation of the family's past and future. A family's schema includes shared values, beliefs, expectations, goals, and so on.

Problem-solving and coping refer to actions taken by the family to manage the demands of a stressor. Actions may be taken to reduce the demands placed on the family by the illness, obtain needed resources, manage tension, and appraise the situation with the goal of understanding it in such a way that it is more positive and therefore more manageable.

Bonadaptation, maladaptation, and crises refer to the outcome of the adaptation process. When family stability and satisfaction are restored, bonadaptation is achieved. When stability and satisfaction do not occur, the family experiences maladaptation. A crisis situation then occurs, forcing the family to attempt to find a new way to adapt.

Proactive Model for Enabling and Empowering Families

The proactive model for enabling and empowering families is based on the assumption that a given family is competent or able to become competent (Dunst, Trivette, & Deal, 1994). If the social system had not failed to provide opportunities for the person to develop or display competencies, the person would be acting competently (Figure 3-5). Effective intervention results in family members developing and displaying competent behaviors and being empowered to acknowledge their own roles in making changes in behavior.

Those using the proactive model hold that the family is a social unit within other formal and informal social support systems and networks. Those who provide care based on the proactive model act from a proactive stance with the goal of enabling or empowering their clients. The three terms are defined below.

- 1. Proactive stance:** Belief that people are, or have the capacity to become, competent.
- 2. Enabling:** The creation of opportunities for competencies to be displayed or developed.
- 3. Empowering:** The help seeker or client acknowledges that the behavior changes he or she has made were due, at least in part, to his or her own actions.

Figure 3-5 Each family member brings a unique set of competencies to the family system.

There are four major components of the model.

1. **Family Needs and Aspirations:** Nurses who use the proactive model want to help the family members identify their own needs and aspirations, not to superimpose the nurses needs and aspirations onto the family. To meet this goal the nurse will act as a partner, not a parental figure, to the family members. The nurse will learn about the family's strengths, including sources of social support and other resources available to them.
2. **Family Functioning Style:** This includes the family's beliefs and values, interactional behaviors, and competencies. These are the characteristics that indicate the family's strengths. The family uses these to respond to crisis situations, cope with normative life events, and promote growth and development in all family members. It is most important to acknowledge family strengths and resources that can be mobilized to meet needs. Building on existing strengths facilitates family functioning.

Critical Thinking

Empowering the Family

"It is not simply a matter of whether or not family needs are met, but rather the manner in which needs are met that is likely to have empowering consequences" (Dunst, Trivette, & Deal, 1994).

Look back at the description of Patrick and the care he received. How may the manner in which his family's perceived needs were met have influenced their feelings of power or powerlessness?

- What could the nurses have done to increase the family's sense of power, that is, their sense that they could effectively make choices that were good for their family?
- Think about how you might approach a family with limited financial resources and a chronically ill member. Will your approach leave the family feeling more or less empowered?

3. **Support and Resources:** These are sources of support and resources that are outside the family but that may be called on in times of need. Support refers to emotional, physical, informational, and instrumental resources and includes the immediate family, relatives, professionals and agencies, and the larger society.
4. **Help-Giving Behaviors:** The behaviors of professionals are most effective when they are positive, non-threatening, and support and enhance the autonomy and self-esteem of the help-seeker. The relationship between the nurse and the help-seeker is a partnership.

Web Activities

- Search the websites listed in the Resources section above and explore resources and information for single parents and stepfamilies.
- Search the Internet for support groups for various family concerns, such as families with a new baby or family caretakers of a chronically ill member.
- Examine Internet sites for appropriate information based on the principles and theories discussed in this chapter.

Case Study/Care Plan

IMPLEMENTING THE NURSING PROCESS USING THE PROACTIVE MODEL

The nurse who works in labor and delivery sees Joel nervously pacing in the waiting room. Earlier, during his wife's labor with their second child, he had left the room quickly if she seemed distressed or if a procedure was being carried out. He had chosen not to be present during the delivery of the couple's first child. Now, when his child is about to be born, he says, "I don't know anything about babies. I've never even held one." The nurse says, "Lots of men have been in your shoes, and they did fine. Fathers are important people. I will help you the first time." The father quietly says, "Thank you." Later, the nurse from the newborn nursery wheels out the baby in the isolette. When the father reaches out to the baby, the nurse says, "You aren't allowed to walk with the baby. You might drop him." She then wheels the baby into the mother's room, with the father following some distance behind.

The labor and delivery nurse is in the room with the mother. As the father enters the room the mother turns to her and says, "What does he know about it? He didn't go through it." The nurse says, "No, he doesn't get to be a mother but I bet he'll be a great father. He is so concerned and anxious about the two of you." The father is standing awkwardly near the door. Turning to him the nurse says, "Sit down in that chair. Arrange your arm to make a cradle to hold your baby." She then places the baby in the father's arms, making sure the baby is well supported. Then, after making sure the baby is awake and alert, she says, "Look at him. He wants to see your face. Good. Now talk to him. Keep watching. Did you see him respond? Your baby knows you. He likes to hear your voice. He knows it." The baby had turned to the sound of his father's voice. The father then settled back more comfortably in the chair and smiled. He kept looking at the baby and started touching his face. The nurse turned to the mother and said, "You have a great family." The mother smiled.

Assessment

During her assessment of the family, the labor and delivery nurse noted the father's pacing, his comment about never having held a baby, and the mother's comment that suggested she did not think he knew much about parenting. The nurse's informal assessment was that the father was not sure how to father and the mother also was insecure and doubtful about his abilities.

Nursing Diagnosis

If she had formalized her diagnosis it might be the following: potential for family maladaptation to the baby owing to lack of experience caring for infants.

Expected Outcomes

Family members will begin to understand and accept the differing roles they play and the unique attributes each brings to the family unit.

Planning

Throughout the process, the labor and delivery nurse collaborates with the family as she plans her intervention.

Interventions

The father shares his lack of experience with a newborn, and the nurse suggests a plan. She offers to help him; he accepts. All her actions are geared to helping this family function as a unit. She acknowledges the mother's role in giving birth and her roles as wife and mother in this family. The nurse stresses the positive aspects of the father's behavior and, through teaching and encouragement, empowers him to become an active parent and partner with his wife. The family unit is strengthened. The nurse does not side with either parent at the expense of the other.

(continued)

Evaluation

The nurse needs to observe the interaction of the family unit. The manner in which the father interacts with the infant reveals a lot about his relationship with the infant, his wife, and their adaptations to the new infant. The way the couple interact with each other also is important. For example, when the father brings flowers to the wife and tells her how proud he is of her, this would be one indicator of a positive adjustment to the birth of a child.

NURSING IMPLICATIONS

When applying the nursing process to a family, the nurse follows the usual steps of the process but for the family as a whole and not for an individual client. During the assessment, information is gathered about the structure, interrelationships, and dynamics of the family. The strengths, resources, and concerns of the family also are assessed. A

diagnosis is then made based on the assessments. A plan is developed through a mutual process. For the plan to be successful, the family members must act as collaborators. Nursing interventions should follow the proactive-empowering model. The outcomes are on the level of the family and not on the level of the individual client.

Key Concepts

- Many types of family structures exist: traditional, extended, single-parent, reconstituted, unmarried heterosexual, homosexual, and communal structures. These need to be understood to adapt nursing care to an individual family.
- Many families hold family myths that often direct their relationships. These myths often are not based on facts.
- Family functions of providing for its members, child rearing, and transmitting cultural values are found

across cultures. The beliefs, values, and manner in which the functions are carried out, however, are highly dependent on culture.

- Several theoretic models related to function are used in nursing. Some of the most common are developmental, interactive structural-functional, systems, and role theory models.
- Health care providers approach the family based on provider models or orientations. Nursing uses holistic and empowerment models.

Review Questions and Activities

1. In general, health care providers tend to have expectations regarding families that are predicted on which family structure?
 - a. Traditional
 - b. Single-parent family
 - c. Reconstituted family
 - d. Communal

The correct answer is a.
2. Traditional families who believe the mother is responsible for the happiness and well-being of all family members are ascribing to which family myth?
 - a. The myth of instant love
 - b. The myth of treating all children equally

- c. The myth of rigid gender roles
- d. The myth of egalitarianism

The correct answer is c.

3. Which task do single-parent families and reconstituted families have in common?
 - a. They have significant losses to resolve
 - b. They have additional family members to incorporate into the family
 - c. They need to combine divergent family histories into a harmonious unit
 - d. Legal relationships are ambiguous

The correct answer is a.

4. Which is an example of an approach to families that uses the empowerment model?
 - a. The nurse discerns the diagnosis after a brief assessment of the problem
 - b. The nurse conducts her intervention in collaboration with other health care professionals
 - c. The nurse begins the process by having the family identify their own strengths, needs, and aspirations
 - d. The family is expected to solve their own problems independently

The correct answer is c.

5. In the resiliency model, which of the following describes the adaptation phase?
 - a. A period of rapid decline related to the inability to deal with the accumulation of stressors

- b. A response to an accumulation of or prolonged stressors
- c. Family maladjustment is an inevitable outcome
- d. Problem-solving is left to health care providers

The correct answer is b.

6. Who are the most likely to live in poverty?
 - a. Homosexual families
 - b. Communal families
 - c. Families with children
 - d. Reconstituted families

The correct answer is c.

Complementary and Alternative Therapies

Kim is a 52-year-old nurse who was diagnosed with breast cancer. She was treated surgically with a modified radical mastectomy, followed by chemotherapy for 6 months and radiation therapy for 6 weeks. Having grown up on a farm, Kim felt that proper nutrition might reduce the side effects of chemotherapy and radiation and decrease the chance of a recurrence. She consulted a nutritionist who put her on a diet of all organic foods, including a juice consisting of celery, carrots, parsley, lettuce, and beets. After her treatments, she continued to restrict her diet and incorporated yoga, exercise, writing in a journal, and meditation into her daily routine. Kim feels that the most difficult part of her experience was dealing with the fear of cancer recurrence.

Have you ever wondered how you would react to a life-threatening diagnosis? Engaging in complementary therapies (CTs) may improve one's sense of well-being and control throughout such an experience. Some CTs have been reported to decrease the side effects of standard treatments. However, CTs may be expensive in terms of time, energy, and money, and the degree to which they may interfere with standard biomedical therapy or yield toxicities of their own often is not known. Nurses can influence the decisions clients make regarding the use of CTs, which often are widely advertised and easily available.

Key Terms

Acupressure	Biomedicine	Culture	Meridian
Acupuncture	Chi	Dosha	Moxibustion
Allopathy	Chi gong	Healing	Phytotherapy
Alternative therapies	Complementary	Holism	Prana
Ayurvedic medicine	therapies	Integrated medicine	Vitalism

Competencies

Upon completion of this chapter, the reader should be able to:

1. Differentiate between complementary and alternative therapies.
2. Discuss the evolution of traditional healing systems and their influence on healing approaches in the 19th century.
3. Identify the influencing factors for the contemporary use of complementary therapies by clients and their families.
4. Describe a classification of complementary modalities of healing.
5. Evaluate research related to complementary therapies.
6. Discuss legal, regulatory, and ethical issues encountered by nurses with regard to complementary therapies.
7. Discuss the use of complementary therapies for health promotion.
8. Identify indications and contraindications for complementary therapies in women with health deviations.
9. Recognize resources for further education or certification to incorporate complementary therapies into the client's plan of care.

The popularity of complementary and alternative medicine (CAM) increased in the 1990s. The terms alternative, complementary, and unconventional medicines have been used interchangeably in the literature and in health care practice. Because the range of modalities and the purposes for using them are complex, clarification of the terms is warranted. The term **alternative therapy** implies outside of or apart from **biomedicine** (the scientific-based professional medicine taught in medical schools and generally practiced in the United States and Canada) and is best reserved for the therapies used instead of biomedical treatment. In the literature, the term alternative therapy has been used to describe many of the popular activities to enhance health, including nutrition, exercise, massage, and use of vitamin supplements. Because many of these therapies are used as a complement to biomedical treatment or for health promotion, **complementary therapy (CT)** is a more appropriate term. These modalities are used along with biomed-

ical treatment for comfort, pain reduction, and symptom relief. Many CTs also facilitate coping and promote or maintain general health.

Many health care providers, health maintenance organizations, and third-party payers are advocating **integrated medicine**, which combines biomedicine with CTs to provide holistic care. This change in health care delivery has come about largely because of consumer demand for holistic health care services. Consumers want emphasis on health promotion, self-care, and attention to the human experience of health and illness.

This consumer movement has large implications for the nursing profession, which has a conceptual basis oriented toward holism, with a focus on health. Biomedicine has had a historic focus on the diagnosis and treatment of disease, whereas nurses have focused on the experience of the person along the health-illness continuum. Many modalities currently identified as popular CTs have previously been described as independent nursing interven-

REFLECTIONS FROM A NURSE

"As an oncology nurse caring for women with breast cancer, I became interested in complementary and alternative therapies (CAMs) as I noted that more and more clients were seeking these therapies. Many of these women had metastatic disease and were coming to the major comprehensive cancer center where I worked as a clinical nurse specialist with the hope of a cure, only to be disappointed that they had exhausted all treatment options. Other women who were without evidence of active disease wanted to do all that they could to prevent cancer from recurring. Women were consuming large doses of vitamins and herbs, sometimes with evidence of toxicity. One client was admitted for severe electrolyte imbalances resulting from coffee enemas, and another with thrombocytopenia and bleeding related to the combination of chemotherapy and ginseng. Young women receiving adjuvant chemotherapy were experiencing disabling hot flashes from the toxic effect of the drugs on the ovaries. This was particularly distressing because hormone replacement therapy is contraindicated in women with breast cancer, and there were no known effective alternatives. Little was known about CAM use and its effects in clients with cancer prior to the 1970s and 1980s. It was apparent, however, that women with breast cancer were desperate for anything that might offer some degree of hope and control over this ravaging disease."

tions (Snyder & Lindquist, 1998). Nurses are in a position to provide or help the client access many of these services. Nurses also should assess client interest in and use of such services to help clients safely integrate complementary modalities into their health care.

CONTEMPORARY USE OF COMPLEMENTARY THERAPIES

As health care providers it is important to understand consumer changes in health care use. The surfacing of public interest and demand for complementary therapies is a change in the consumer culture for health care. This interest has stimulated much research on the efficacy of these treatments in the United States, Canada, Europe, and worldwide. Research also has focused on better understanding of who uses CTs, why and how they are used, and satisfaction with their use.

Surveys have indicated that CT use increased in the 1990s. Many surveys indicate that about half the U.S. population uses some form of CT. Some well-known surveys have found that the rate of use of CT increased from 33% in 1992 to 42% in 1997 (Eisenberg et al., 1993, 1998). Other surveys have found similar or higher rates of use (Landmark Report, 1998; Villaire, 1998). The rate increases in clients with chronic diseases; for example, one survey in clients with cancer found the use rate was 83% (Richardson et al., 2000). Women account for two thirds of the use of CTs, which is consistent with their more frequent use of conventional health care services (Beal, 1998). These surveys may underestimate use because they generally ask respondents to identify from checklists modalities they have used in the past year. Therefore, if the respondent has used a modality not listed on the form or not within the past year, the response does not get tabulated. Other surveys have described CT users as highly educated, relatively affluent, and often having a holistic orientation toward health (Astin, 1998; Eisenberg et al., 1998; McGuire, 1988). Most respondents paid for these services themselves, spending collectively more than \$27 billion annually in the United States. The amount spent was comparable to all U.S. physician services. In one survey of consumers, 44% used CTs in the past year, 60% of these perceived the treatments to be as effective as traditional ones, and 89% would recommend CT to others (Oldendick et al., 2000). In many cases, consumers do not tell their physicians nor are physicians aware of the use of CTs. Problems can result from treatment contraindications, interactions, and poor communication patterns between client and provider.

Because little was known regarding the efficacy of CAM, Congress mandated the National Institutes of Health (NIH) to set up an Office of Alternative Medicine (OAM), which was started in 1992. This office was later upgraded to the National Center for Complementary and Alternative Medicine (NCCAM), which was established to study non-conventional therapies for potential efficacy and to disseminate information to providers and the public. Centers have been established around the United States to study

Research Highlight

Alternative Medicine Use in Older Adults

Purpose

To determine the use of complementary and alternative medicines in Americans aged 65 years and older.

Method

Secondary analysis of data collected in a nationally representative, randomized telephone survey of adults regarding alternative medicine use in the past 12 months. The sample comprised 311 adults over the age of 65 years.

Findings

Of those surveyed, 30% reported they had used at least one alternative medicine, most commonly herbal preparations. Nearly 20% had visited an alternative medicine provider in the past year, most often a chiropractor. The older persons who had a primary care provider were more likely to use alternative therapies than were those with no such provider. Over half of all seniors who used such therapies, however, did not tell their physicians.

Nursing Implications

1. Use of alternative therapies in older adults is of particular concern because many have multiple medical problems and are likely to be taking prescription medicines as well, thus increasing the risk of adverse interactions.
2. Nurses should ask clients which medications they are taking, including all over-the-counter preparations, vitamins, minerals, and herbs.
3. Nurses should encourage clients to discuss alternative medicine use with their physicians.

Foster, D. F., Phillips, R. S., Hamel, M. B., & Eisenberg D. (2000). Alternative medicine use in older Americans. *Journal of the American Geriatrics Society*, 48, 1560–1565.

various aspects of alternative and complementary healing. CAM practices have been cataloged into seven broad categories: mind-body interventions, bioelectromagnetic applications, alternative systems of medical practice, manual healing methods, pharmacologic and biologic treatments, herbal medicine, and diet and nutrition in the prevention and treatment of chronic disease (National Institutes of Health, 1994) (Box 4-1). Some modalities have been recommended for incorporation into general health care. For example, integration of behavioral and relaxation therapies such as meditation, hypnosis, and biofeedback into medical management of chronic pain and insomnia was recommended by a NIH consensus panel of experts (Chilton, 1996).

Several peer-reviewed journals have been established to focus exclusively on CAM therapies. A number of research studies and articles related to CAM also have been published in most medical and specialty journals across

Box 4-1 Classification of Complementary and Alternative Practices

- Alternative systems of medical care: acupuncture and homeopathic medicine
- Bioelectromagnetic applications: electromagnetic fields and electrostimulation
- Diet, nutrition, and lifestyle changes: macrobiotics and nutritional supplements
- Herbal medicine: echinacea and ginseng root
- Manual healing: chiropractic and therapeutic touch
- Mind-body control: art therapy, meditation, and music therapy
- Pharmacologic and biologic treatments: antioxidanting agents and chelation therapy

Nursing Alert

CANCER RECURRENCE

For women with a personal history of breast cancer, all exogenous hormonal preparations, including hormone replacement therapy (all oral, patch, vaginal, and injectable forms) and oral contraceptive agents, are contraindicated owing to the potential for such agents to stimulate recurrence of breast cancer. Some biologics are sold that contain ground animal ovaries and other hormonal agents. Phytoestrogens also should be avoided because their influence on cancer recurrence has not been validated scientifically.

health care disciplines. According to one survey, 64% of medical schools have added courses covering CAM (Wetzel, Eisenberg, & Kaptchuk 1998).

The American Holistic Nurses Association, which focuses on incorporating select complementary modalities into nursing care, is one of the fastest growing nursing organizations. The American Holistic Medical Association is a comparable organization of physicians who advocate incorporating select CAM into holistic health care.

National commissions related to health care delivery have made recommendations related to CAM. Both the Robert Wood Johnson Foundation and the PEW Charitable Trust called for the following recommendations: cost containment, focus on health, use of innovative and diverse provisions for health care, and engaging the client as an active agent in health care (Marston & Jones, 1992; PEW, 1995). The Hastings Center for Bioethics established goals for medicine in 1996, calling for more research on alternative therapies (Callahan, 1996). The Institute for Alternative Futures (1998 <http://www.altfutures.com>) anticipates that two thirds of the population will use some form of CAM by 2010. Many of these complementary modalities are well-matched with the changing health care focus on health promotion and healthy lifestyles.

DIFFERENTIATING ALTERNATIVE FROM COMPLEMENTARY THERAPIES

It is important for nurses to distinguish between treatments used in place of biomedical care and those therapies used to complement biomedical treatment or to promote health and well-being. Cassileth (1998) differentiates between alternative treatments, which are used in place of biomedical treatments and lack scientific proof of efficacy, and

Nursing Tip

DISADVANTAGES OF COMPLEMENTARY AND ALTERNATIVE MEDICINE THERAPY

Some disadvantages associated with some complementary and alternative therapies are the following:

- May be based on anecdotal evidence and testimonials
- Lack scientific data
- Lack standardization
- May be costly
- May interfere with the effectiveness of standard therapies

CTs, which are helpful and applicable during illness and in health. These CTs are noninvasive, gentle, pleasant, often natural, and have stress-reducing effects. A number of biologic treatments for serious diseases such as cancer, acquired immunodeficiency syndrome, and heart disease would best fall into the alternative category. These therapies are primarily ones that have not undergone rigorous clinical trials for safety and efficacy; however, in many cases, research is currently under way. These alternative therapies often are invasive and may contain active biologic or chemical agents; thus, while having potential benefits, they may have inherent toxic or harmful effects. In other instances, the treatment itself may not be toxic but can be dangerous if used in place of or if its use delays effective medical treatment. Sometimes these treatments may be effective in certain circumstances, and anecdotal accounts may add to their appeal to potential users. Professional nurses should be aware of the potential dangers of unconventional therapies and follow the code of practice of their state and professional ethical codes in using or endorsing these treatments. This information generally can be found through the Board of Nurse Examiners of each state.

This chapter focuses on CTs. These generally gentle, natural, noninvasive, holistic treatments are used as supplements to biomedical treatments or to enhance health and well-being. Many CTs are used to reduce stress, enhance coping, and engage the natural healing of the body. Their use parallels the public interest in self-help, human potential movements, and consumer interest in enhancing health and wellness. Although some clients may abandon biomedical treatment to pursue these treatments, most use these therapies in conjunction with

Critical Thinking

Complementary and Alternative Medicine Literature

As a responsible health care provider, you search the literature related to alternative and complementary therapies. You find a variety of reports about a particular modality. Being a critical consumer of the literature, you ask yourself the following questions:

- Are the authors uncritically enthusiastic?
- Do they make unsubstantiated claims?
- Do they have a vested interest in promoting a service or product?
- Do they make general comments against biomedicine?
- Are the authors uncritically dismissive of the modality?
- Do they make unsubstantiated claims disapproving of the modality?
- Do they make general comments against complementary therapies?
- Do they have any knowledge about the modality?

biomedicine or to enhance their health and sense of well-being.

BACKGROUND AND CLASSIFICATION OF MODALITIES

Many of these modalities have their origins in ethnic traditional healing or the historical healing practices of Europe and America. Because many of these modalities are used to improve or maintain health and to cope with illness, they can be viewed as part of the client's or family's actions toward health and reflect cultural orientations and understandings about health. Therefore, when caring for clients from diverse cultures, it is important to understand some of their traditional health beliefs and practices. Practices of traditional cultural systems of healing, such as acupuncture, traditional Chinese medicine (TCM), yoga, or traditional Indian Ayurvedic medicine are becoming popular with clients of diverse backgrounds. As clients are exposed to health care modalities from other cultures, many are incorporating those practices into their own use. In Europe and America, before the use of anesthesia and antibiotics, a number of healing practices were used that were

intended to bolster the body's natural healing. Many of these are resurfacing now as clients search for natural means of promoting health and healing, incorporating physical, psychological, social, spiritual, and environmental health.

Systems of Healing

Systems of healing generally employ several modalities under an organizing unified framework. For example, biomedicine is the system of scientifically based professional medicine taught in medical schools. It is the system of healing with which most persons are familiar. Biomedicine uses many modalities of physical manipulation, such as surgery, ingested and applied medications, therapeutic diets, and other therapies (such as psychotherapy) within one system. **Healing** systems reflect a way to classify disease, determine causes, and provide treatment based on an understanding of health and illness. Healing systems also provide for the education and preparation of practitioners and the delivery of the practice to the public. Differing systems have existed across cultures and over time. Some of the currently popular healing modalities, such as acupuncture and yoga, are derived from healing systems that have evolved over thousands of years.

Healing systems are dynamic and culturally embedded. Many of these systems have developed over time and have incorporated techniques adapted from the environment and interaction with other cultures. (**Culture** is the knowledge, beliefs, art, morals, customs, laws, and other characteristics of persons and members of society [Andrews & Boyle, 1995]). All these systems have components of treatment, prevention, and wellness. Cultural beliefs, values, and worldviews are reflected in the way in which persons understand illness. Five traditional healing systems are discussed briefly: TCM, Ayurvedic, yoga, shamanic, and ritual healing systems.

Traditional Chinese Medicine

Traditional Chinese medicine is a complete health system that is thousands of years old. It encompasses exercise, herbal medicine, massage, nutrition, and a holistic approach to healthy living. (**Holism** is the philosophy of integration of body, mind, and spirit within a dynamic environment.) TCM also includes treatments using herbs, acupressure, and acupuncture. The TCM system is based on the interrelatedness between the whole person and nature. The philosophy of health is based on a balance of opposites. The popular symbol for the union of yin and yang in a circle reflects one aspect of this complex philosophy. The philosophies of Taoism, Confucianism, and Buddhism underlie these ancient healing arts (NIH, 1994; Kaptchuk, 1983; Micozzi, 1996). Assessment of the client

includes examination of the characteristics of the radial pulse, skin, and mucous membranes; a thorough health history also is obtained.

The concept of energy is described in Oriental healing systems as chi, ki, or qi. **Chi** is best translated as the point at which matter converts to energy or energy to matter (Kaptchuk, 1983). Chi is understood to flow through various energy channels of the body called **meridians** that have been mapped out over centuries of Oriental medical practice. Illness is a disturbance of chi within the body that may be caused by external factors (environmental influences), internal factors (mental states), and factors other than these (Ergil, 1996). Treatment modalities aim to restore balance and the unimpeded flow of chi through the meridians. Specific points along the meridians correspond with various organs or aspects of the body. **Acupuncture** and **acupressure** are applied at the meridians to facilitate the smooth flow and balance of chi. In acupuncture, fine needles are inserted into the skin and rotated; in acupressure, physical pressure is applied to specific points along the meridians. **Moxibustion** is the application of heat, herbs, or both to the energy points. Various forms of massage and touch, both contact and noncontact, also are used to manipulate and balance energy. **Chi gong** (“working the chi”), tai chi, and other Oriental movement techniques use breathing, movement, and meditation to cleanse, strengthen, and circulate the vital life energy and blood. Chinese medicine has developed a text describing the complex practices of preparing and administering herbs. The most common Oriental practices currently used in the West are acupuncture, acupressure, and forms of chi gong, including tai chi.

The efficacy of these treatments currently is being studied. A NIH consensus panel of experts (co-sponsored by the OAM and the Office of Medical Applications of Research [OMAR]) evaluated scientific and medical data on the uses, risks, and benefits of acupuncture procedures for a variety of conditions. Acupuncture was recommended as an effective treatment for nausea caused by chemotherapy drugs, surgical anesthesia, and pregnancy; for pain resulting from surgery and dental procedures; and for a variety of musculoskeletal conditions (CAM Newsletter, 1998). Most Chinese herbal preparations are individually mixed and specific for each client. The efficacy of Chinese herbal therapies has not been researched in Western scientific trials and may defy the type of clinical trial research used in biomedicine that standardizes dosages and measures disease and treatment-specific outcomes.

Many practitioners of TCM have a lengthy period of schooling and apprenticed practice and many can legally practice in the United States under a state waiver that allows ethnic groups to obtain medical services from a traditional healer. More recently, several states have enacted legislation regulating and licensing acupuncturists, ensur-

ing sterile needles are used and practitioners have met certain standards. Use of Oriental herbal medicine is not regulated, however, and caution should be used because many of the herbs are imported directly from the Orient and may contain contaminants. Because these herbs are not mass-produced, they do not need to pass U.S. standards of clean preparation for consumers. Various combinations of herbs often are used, increasing the likelihood of drug interactions.

Ayurvedic Medicine

Ayurvedic medicine originated in India and means knowledge of life or science of longevity. These ancient teachings have been passed on through the Vedas, a body of ancient Sanskrit literature. Modern Ayurvedic medicine has been revived by Maharishi Mahesh Yogi and is known as Maharishi Ayurveda (Micozzi, 1996). It is holistic and based on the concepts of balance and a vital life force. Ayurvedic medicine in India is centered on the concept of **prana**, a type of vital energy. Health is based on well-being, prevention of disease, and aligning lifestyles with one’s individual constitution and personal medical history. Harmony with the environment is sought through understanding and balancing circadian rhythms, seasons, behavior, emotions, and other sensory experiences. Diet, herbs, yoga, meditation, and internal cleansing preparations are addressed in the concept of health. Three **doshas** or metabolic types of people exist: kapha, pitta, and vata, with one being dominant. For optimal health, all doshas need to be in balance; however, the dominant dosha determines the types of foods and other lifestyle practices one should incorporate. This ancient and complex system, with its focus on prevention and holistic integration, is of interest as Western biomedicine focuses more on prevention and holistic health. Transcendental meditation, often practiced in Ayurvedic medicine, has been used by many Westerners.

Yoga

Yoga is a classic Indian practice dating back 5,000 years. It is a philosophy of ethics and personal discipline. Although Yoga is an entire system of life practice with a spiritual philosophy, many Westerners use the techniques without ascribing to the entire practice that includes a philosophy of living. Aspects of the practice of hatha yoga, which focuses on fitness, have become the most popular. Various stretches and postures are used to relieve mild aches and pains, increase flexibility and coordination, and reduce stress while promoting deep relaxation. Breathing, stretching, taking various body postures, and meditating are incorporated in yoga. The purpose of these exercises is to improve circulation, stimulate the internal organs, stretch the body and restore normal alignment, and facilitate proper

REFLECTIONS FROM A CLIENT

"When I developed a nagging pain in my left thigh and hip in 1988, I went to many physicians in search of a cause and treatment. Finally, 17 doctors and 1 year later, a neurosurgeon, who insisted on a myelogram (despite the multiple MRI films I carried with me to the consultation with him), diagnosed a meningioma impinging on my thoracic spine. After a laminectomy to resect the benign tumor, my pain was partially relieved enough so that I was able to discard my cane and gradually wean myself off opioid analgesics. The pain did not go away entirely, however, despite extensive physical therapy, rehabilitation, and nerve blocks.

My long-established faith in the medical model as a health care practitioner was seriously challenged as I slowly realized that there was no cure for the pain. Once I accepted that fact, however, I was able to mobilize other resources for dealing with the pain. Over the past decade, I have engaged in a number of complementary therapies, including acupuncture, neuromuscular massage, yoga, biofeedback, and healing touch. I find that I am best able to manage the pain with regular massage, meditation, and yoga, and with healing touch sessions as needed. Having this experience with pain has enabled me to look beyond the biomedical community for self-care and holistic approaches to enhance my sense of health and well-being, even though the pain is still present."

breathing. Yoga has been shown to reduce blood pressure, reduce heart rate, improve circulation, enhance memory, and release endorphins, the body's natural opiates.

Shamanic Healing

Shamanic healing systems refer to many traditional cultural healing systems. Many of these systems have multi-

ple components and providers such as midwives, bone-setters, herbalists, seers, massagers, and spiritual healers. Medicine and religion are fused in these systems; the medicine person also may be the religious and, in some cases, the political leader. Often, the healer is called a shaman. The shaman's healing powers are related to the ability to communicate with the spiritual world for direction in healing. The shaman enters a controlled trance or altered state of consciousness by drumming, making repetitive sounds, meditating, or using plant extracts. This state of ecstasy, in which the shaman is able to transcend the physical body and sojourn into the spirit world, is one of the most characteristic elements of shamanic systems (Kinsley, 1996). The healing practices may involve physical manipulation, ingestion or application of natural substances, and supranormal actions. A shaman learns these skills through an apprenticeship with an elder shaman. A special marking at birth, exhibition of special healing skills as a child, or overcoming a personal illness or hardship identifies future shamans. The calling is a life-long commitment to healing the members of the community (National Institutes of Health, 1994; Micozzi, 1996). Shamanic systems most familiar to American nurses are Native American healing systems, Curanderismo, Espiritismo, Santeria, and African folk healing systems such as hoodoo, voodoo, and rootwork (Gordon, Nienstedt, & Gesler, 1998). Many popular healers incorporate shamanic practices.

Ritual Healing

Spiritual or religious healing has been part of most cultures. Laying on of hands, prayer, and other religious rituals are fairly universal parts of healing practice. These types of healing practices need to be approached in the context of the religious belief and practice. Healing has been a strong emphasis in Judeo-Christian practice and beliefs. Numerous accounts of ritual or spiritual healing are recorded in the Bible and the literature about the saints (Kinsley, 1996). In some Christian denominations, such as Pentecostalism, healing is a central practice. A charismatic healing revival has been evident in the Catholic Church over the past 25 years (Csordas, 1994). One of the Sacraments of the Catholic Church has been changed from being called Last Rites to Anointing of the Sick. Healing rituals also have become more evident in Protestant and Jewish religious practices. Recently, medical and scientific investigators have begun to look at the healing power of faith and religious ritual practices (Dossey, 1993; Koenig, 1999). Levin (1994) found positive health benefits associated with participation in church activities. Some religious ritual practices include penance, forgiveness, meditation, and prayer. Some religious ritual practices also include primal religious experience, which is a physical, psychological, and spiritual experience of ecstasy.

Nursing Implications

The traditional healing practices mentioned previously reflect cultural heritages and beliefs about health, illness, and life in general. These systems also reflect the fundamental cosmologies or philosophic beliefs about the structure of the universe that are intertwined with religious heritage. Nurses should approach the use of these practices as part of culturally competent care. When the practices are not harmful and do not interfere with medical treatments, nurses should support and facilitate clients in their use and practice. Clients determine which practices are congruent with their belief system; nurses should never impose a ritual or symbolic healing system on clients.

Recently, many people in Western cultures have become very interested in varying systems of health and healing. Often the yoga teacher or the shamanic healer is a person of European-American descent who has developed an interest in this system without being from the traditional culture. Many times these healers or teachers have studied extensively with a healer or expert and have adapted the practice or part of the practice for contemporary Western use. Nurses should be cautious about making referrals because a certification process rarely exists in these healing systems and one does not usually know much about the individual practitioner. Word of mouth or other referral sources often are helpful in locating good resources. Some organizations, such as the American Holistic Nurses Association, may be useful in providing information and resources.

Healing Approaches Congruent with Self-Healing

In the 19th century, several approaches to healing were developed. While having some efficacy and continuous practice, many of these approaches were eclipsed by the technologic advances of the 20th century. Modern biomedicine changed dramatically in the 20th century with the discovery of anesthesia that made surgery possible, development of antibiotics and, most recently, understanding the human genome. Some of the 19th-century approaches have experienced a resurgence in popularity. Some of these popular approaches are discussed. The commonality is the underlying purpose of facilitating the body in healing itself or maximizing health.

Vitalism has been an underlying belief in many cultural healing practices and in many of the following self-healing approaches popular in the 19th century. Vitalism refers to a “vital energy” or spiritual force. This force or energy is necessary to explain life and health, which cannot be reduced to physical and mechanical function. This philosophy describes the ways in which many therapeutic techniques were thought to aid in healing, such as those used in Christian Science, chiropractic medicine, osteopa-

thy, naturopathy, homeopathy, hydrotherapy, acupuncture, and in hypnosis, crystals, and other types of psychic healing. The philosophy of vitalism has been integrated into health care in many approaches that use a holistic approach to healing. Some of the more popular approaches are discussed: osteopathy, chiropractic medicine, homeopathy, and naturopathy.

Osteopathic Medicine

Osteopathy, founded in America by Andrew Taylor Still in 1892, is a healing art that places emphasis on the structural integrity of the body. A comprehensive system of diagnosis and therapeutics was based on this interrelationship between anatomy and physiology. The principles are holistic and include the unity and self-regulation of the body. When it is in normal structural relationship and has favorable environmental conditions and adequate nutrition, the body is capable of making its own remedies against disease and other toxic conditions (Wagner, 1996). Currently, there are 15 schools of osteopathy in the United States. Graduates earn a doctor of osteopathy degree, or DO. Doctors of osteopathy are licensed to practice all recognized branches of clinical medicine, having much the same education as do medical doctors. Doctors of osteopathy have additional training and emphasis in diagnosis and treatment of the musculoskeletal system and osteopathic manipulative therapy. Somatic dysfunction is based on local asymmetry, restriction of motion, or fixed postural tension. Treatments include medication, surgery, physical therapy, osteopathic manipulative therapy, and education about nutrition and lifestyle. The American Osteopathic Association has a research institute that has focused on the techniques and principles behind osteopathic manipulative therapy. With the convergence of osteopathic medicine and biomedicine, today many of these techniques are used in standard medical practice (www.am-osteo-assn.org).

Chiropractic Medicine

Chiropractic medicine is a manual healing art that originated in the American Midwest in late 1895, founded by Daniel Palmer, a self-educated healer. He based the profession on two premises: vertebral subluxation (a spinal misalignment causing abnormal nerve transmission) is the cause of virtually all disease; and chiropractic adjustment or manual manipulation of the subluxated vertebra is the cure. Chiropractors treat primarily musculoskeletal conditions, principally back and neck pain and headaches. Although criticized for their one cause—one cure approach and marginalized by biomedicine, the American Medical Association (AMA) was recently found guilty of antitrust violations in banning interprofessional cooperation between medical doctors and chiropractors. The Agency for Health Care Policy and Research (AHCPR) endorsed spinal

manipulations for back pain in the 1994 Guidelines for Acute Lower Back Pain. Chiropractors are licensed throughout the English-speaking world and educated in accredited schools. They have a professional code of ethics and standards of practice. Four years of course work builds on science prerequisites in college. Several research studies have shown chiropractic treatments to be effective in low back pain and headaches. Additional trials have begun to demonstrate efficacy in a number of organ disorders, and in hypertension and infant colic (Redwood, 1996).

Homeopathy

Samuel Hahnemann, a German physician and chemist, developed homeopathy in the early 1800s (Jacobs & Moskowitz, 1996). He adhered to a belief in holism in which the totality of symptoms is interrelated, and remedies need to be individualized to the unique experience of the client. All healing was essentially self-healing. He felt that symptoms were the body's attempt to self-heal. Based on these observations, he developed a process of provings in which a substance that produced the same symptoms in a well person could be used to augment the body's efforts in combating disease. This practice of using medications producing symptoms similar to those of the disease contrasts with the standard practice of **allopathy** (traditional or established medical or surgical procedures, both invasive and noninvasive, used in the diagnosis and treatment of mental or physical illnesses), or using medicines to counteract the symptoms. Hahnemann believed that spirit was more powerful than matter; therefore, the essence (spirit) of the medicine was more important than the substance. He innovated a rigorous system of experimentation and established a *Materia Medica*, which now has over 2,000 remedies. Medications are prepared by a series of dilutions and agitations, and the end result is more essence and less matter. These preparations, some diluted beyond Avogadro's number, are so dilute that not even a molecule of the substance can be found in the solution (Jacobs & Moskowitz, 1996). This fact has been puzzling to many biomedical scientists who have difficulty accepting the possible efficacy of a medication without substance.

Homeopathy is practiced widely in Europe, India, Mexico, and other parts of the world; it flourished in the United States until the early 20th century. In 1914, the Flexner Report standardized medical education in the United States and led to a ban on homeopathic medicine by the AMA (Starr, 1984). Practitioners of homeopathic medicine currently are adding homeopathic practice to an existing legal practice license. Many medical doctors and chiropractors also practice homeopathy. Hahnemann's original research in the provings was conducted with rigor that set the stage for much medical research, including in-

oculations. Current research has demonstrated efficacy in a number of chronic conditions, such as asthma, allergies, and other conditions not involving advanced tissue damage.

Naturopathy

Naturopathy is concerned with a philosophy of life rather than a particular type of disease treatment. Naturopathy is holistic and focuses on health. It was founded in the late 1800s from the European nature cures, with roots back to the time of Hippocrates. Benedict Lust brought the concept to the United States in the late 1800s (Pizzorno, 1996). Lust integrated osteopathic medicine, chiropractic, hydrotherapy, and homeopathy as an alternative to the biomedical system. Naturopaths believe that most disease is the result of ignoring or violating the laws of nature. Naturopaths espouse natural treatment, healthy nutrition (primarily vegetarian), fresh air, and natural light as natural healing. This philosophy of healing has become popular because it combines a critique of the established pharmaceutical emphasis with a focus on nutrition, exercise, and the environment. The principles of naturopathy are holistic; the whole person is treated, with a focus on preserving health, preventing disease, avoiding harm, and using the inherent natural healing systems of harmony to correct the underlying cause of disease (Pizzorno, 1996). The practitioner is a teacher whose major focus is to educate the client toward natural health.

The establishment of three colleges of naturopathy in the United States and related research in nutrition, environmental medicine, and clinical ecology have contributed to the rise of naturopathy in contemporary health care. Naturopathic physicians are licensed in some states and practice as primary care providers. They use a variety of natural therapies and diagnostic methods. Required education is a bachelor's degree in biologic science that is similar to a premedicine program and a 4-year accredited graduate program.

COMPLEMENTARY MODALITIES

A host of complementary therapies and therapists currently is available. These are discussed in the following general categories: physical movement and manipulation, ingested and applied substances, energy-based therapies, psychologic or mind-body therapies, and spiritual healing.

Physical Manipulation

Manipulation of the physical body is a common type of modality and includes those body movements a person

performs and therapeutic manipulations performed by a therapist on the client. Physical manipulations in biomedicine include surgery, physical therapy, and other physical treatments. Complementary modalities include exercise and physical movements, and various types of body work.

Exercise and Physical Movements

Exercise and physical movements have a well-established link to health and well-being. A number of specific techniques and approaches currently is available. Exercise programs are designed to do one or a combination of the following. Flexibility exercises are planned and deliberate actions taken to enhance range of motion using a combination of stretching and relaxation techniques, such as yoga and calisthenics. Endurance exercises are used to build stamina and general conditioning. They often are aerobic and are helpful in maintaining cardiovascular health and losing weight. Aerobic exercises aim to increase cardiac endurance and include fast walking, jogging, cycling, and swimming. Strengthening exercises often use weights or machines, with repetitions to build muscle. Sports and athletics often are good methods to achieve a variety of exercise benefits.

Exercise is important for women of all ages. The type of exercise, however, may need to be modified for age and physical condition (Figure 4-1). Exercise should continue during pregnancy to maintain strength and stamina. Stretching also is a good preparation for labor. Pregnant women should avoid leg lifts that may put strain on abdominal muscles after the 4th month. Women should engage in weight-bearing exercise throughout life to maintain bone calcium to help prevent osteoporosis. Swimming and cycling are good aerobic and strengthening exercises but do not strengthen bone. In choosing an exercise program, women need to follow the type of activities they enjoy and to which they are able to adhere. For example, some women are motivated by the social aspects of sports and group exercises, whereas others find a solitary jog is a welcome time alone each day. Many sports and fitness clubs have trainers, kinesologists, or exercise physiologists available for individualized exercise programs.

Specific Exercise or Movement Techniques

A number of specific body techniques is available from teachers who have special training or certification in a particular technique. Some examples are found in Table 4-1.

Body Work

Body work techniques are types of physical manipulation that require a trained therapist. Some of the more popular techniques, such as craniosacral manipulations, massage

Figure 4-1 All exercise should be tailored to the individual's lifestyle and physical abilities.

therapy, Rolfing, and Trager, are described in Table 4-2. Some nurses have acquired additional training and can offer these types of body work to clients.

Nursing Implications

Body work and exercise are very popular and generally have few risks. Most body-work therapists are certified in their training and have been educated to avoid medical risks. It is generally a good practice to ask about certification or preparation of the provider. For women with chronic illnesses and the frail elderly, it is a good idea to consult the physician or nurse practitioner before having body work performed.

Ingested and Applied Substances

Pharmaceuticals are the most commonly applied and ingested substances and are the major focus of biomedical treatment. Many medical pharmaceuticals are derived from plants, and plant-derived products are found in all healing systems. Foods and dietary supplements along with *phyto-medicines* (plant-based medicines) are among the most

Table 4-1 Select Exercise and Movement Techniques

Technique	Description	Uses and History	Providers and Availability	Information
Alexander technique	Form of body technique or postural therapy that works on proper alignment of head, neck, and spine. This alignment is thought to improve physical and psychologic well-being. Relearning better alignment and posture has been associated with reduction in chronic pain from previous injuries or poor posture.	Developed by Frederick Alexander, an actor, to help him project his voice. Became popular with dancers, singers, and other performers.	Classes are available in many cities taught by certified instructors who have completed a 3-year training program.	www.alexandertechnique.com
Feldenkrais	Awareness through movement, this method focuses on various parts of the body while sequencing simple movements. It has been helpful in clients with neuromuscular disorders, such as multiple sclerosis, musculoskeletal pain, cerebral palsy, and stroke, and in older persons and those with spinal injuries (Rosenfeld, 1996).	Developed by Moshe Feldenkrais who investigated various sciences to treat his knee injuries.	Certified Feldenkrais instructors have training throughout the country.	www.feldenkrais.com
Pilates	Method that aims to create balance, flexibility, and coordination by focusing on specific muscles. Very individualized technique. Also is useful for rehabilitation from injury.	Developed by Joseph Pilates in the early 1900s to assist dancers' performance and help recovery from injuries.	Local trainers and classes.	www.pilates.net

popular forms of CTs. An estimated 60 million Americans used herbal therapies. In 1996, Americans spent approximately \$3.24 billion on these products.

Numerous dietary plans to lose weight, improve health, and cure diseases are available by way of the popular media. A number of proposed curative diets are popular with the public. Many have not been researched, and nurses should exercise caution in providing dietary advice that may interfere with a therapeutic diet or guidelines for healthy nutrition. (See Chapter 8 for basic nutritional

guidelines and information about vitamins, minerals, and micronutrients.) Another popular health practice is fasting, which is relatively safe for healthy people for a short duration (less than 3 days). Frequent or long-term fasting may deprive the client of adequate nutrients.

Dietary Supplements

Other ingested or applied substances include various enzymes, hormones, and other biologic products. These generally are not recommended unless under a physician's di-

Table 4-2 Select Body Work Techniques

Technique	Description	Uses and History	Providers and Availability	Information
Craniosacral manipulations	Based on theory that unimpeded flow of cerebrospinal fluid (CSF) is key to good health. Gentle pressure applied on the client's head to lengthen spine and facilitate flow of CSF. Reported to help with cognition, concentration, and learning disabilities.	Originally described by William Sutherland, OD, in the early 1900s; further developed over the past 30 years by John Upledger, OD.	May be practiced by osteopaths, chiropractors, physical therapists, body workers, and some massage therapists.	www.upledger.com
Massage: may employ a variety of techniques. It is generally safe, except in cases of specific physical conditions, such as bleeding disorders, phlebitis, and some skin conditions.	<p>Massage therapy has long been popular with athletes and recently has gained more general popularity. The American Massage Therapy Association (AMTA) endorses various techniques.</p> <ul style="list-style-type: none"> • Deep tissue and friction massages release chronic patterns of tension using slow strokes and deep finger pressure on contracted areas. • <i>Effleurage</i>, a smooth gliding stroke used to relax soft tissues, is taught in childbirth classes as a relaxation technique for labor. • Sports massage focuses on muscle groups related to particular sports. • Swedish massage uses long strokes, kneading, and friction on superficial muscle layers. • <i>Tapotement</i> incorporates percussion-type movements. • Trigger-point massage applies pressure to active and latent trigger points in muscles; then muscles are stretched to help relaxation. 	Various techniques of massage are used for health maintenance and relief of pain from muscle strain and stiffness. Massage is widely used to treat minor sports injuries because it reduces muscle spasms, increases circulation, and allows for elimination of lactic acid after physical activity. Massage also is useful in hospitalized or immobilized clients because it relieves pain and discomfort, increases circulation, and enhances relaxation. Infant massage has been introduced in many hospitals and often is taught to parents to soothe infants.	Massage therapists are registered and licensed as Registered Massage Therapists (RMT) by state or local boards or Nationally Certified in Therapeutic Massage and Bodywork (NCTMB). Some nurses also are RMTs and certified to provide massage therapies.	www.amtamassage.org
Myofascial release	Form of body work that seeks to rebalance the body and facilitate inherent ability to correct soft tissue dysfunction. This interactive stretching technique uses feedback from client's body to determine force, duration, and direction of therapist's strokes. It releases tension in <i>fascia</i> , (weblike connective tissue within the body), allowing the body to realign to reduce future injury. It helps restore musculoskeletal function, relax contracted muscles, increase circulation, and increase venous and lymphatic drainage.	Originated in the osteopathic literature of the 1950s and is founded on neurophysiologic function.	Many physical therapists are trained in this technique.	www.myofascialrelease.com

(continued)

Table 4-2 Continued

Technique	Description	Uses and History	Providers and Availability	Information
Rolfing	Rolfing, or structural integration, uses various body manipulations to work on fascia. Chronic stress and inactivity cause the normally loose, mobile fascia to become thick and fused. Muscles react by painful spasms. Rolfing stretches the fascia to re-establish proper alignment and thus improve function. Treatment usually involves a series of 10 2-h sessions 1–2 wk apart.	Developed by Ida Rolf. Some studies have demonstrated efficacy in range of motion, general body movement, posture, and pain.	Certified Rolfers who have completed a course of classroom and practicums can be found through the institute. They are licensed in some states but requirements vary.	www.rolf.org
Trager	Approach that uses simple self-induced movements and passive movement, guided by a practitioner, to assist clients in recognizing and unlearning physical and mental habits that limit movement, cause pain, and prevent optimum function. It consists of gentle rhythmic body work to loosen stiff joints and muscles, and dancelike exercises to increase awareness of body movement.	Developed by Milton Trager, MD, an American physician, in the 1940s. It was used to release deep-seated physical and mental patterns to facilitate deep relaxation and improve function.	Certified by the Trager Institute.	www.trager.com

HERBAL THERAPY PRECAUTIONS

There are many species for one genus, which may have various therapeutic or side effects. Keep in mind the following:

1. Not all parts of the plant are active.
2. The levels of active ingredients vary with growing conditions (e.g., soil and climate).
3. The amounts of active ingredients vary among and within brands.
4. A lack of standardized manufacturing exists.
5. Some plant ingredients are toxic.

rection. A number of products are sold for weight loss. The active ingredient in many of these products is *ephedra* (as in Ma Huang), a pharmaceutical drug that acts as a stimulant. Some persons have suffered elevated blood pressure and strokes while using products that contain ephedra without medical supervision. Other effects that have been reported are seizures, kidney stones, myocarditis, vasculitis, and cardiovascular events. Deaths have been associated with the use of these products. Currently, these products are marketed as nutritional supplements and thus do not come under the regulatory arm of the FDA.

Herbal Medicine or Phytotherapies

The World Health Organization estimates that over 80% of the world's population uses herbal medicine for some aspect of primary care (National Institutes of Health, 1994). **Phytotherapy** refers to the therapeutic use of plants, often meaning herbal remedies. A number of herbal medicines currently are available and can be ingested or applied in a variety of preparations. Fresh plant parts, including roots, leaves, seeds, and flowers, may be used in cooking or the preparation of foods. Plant parts, often the

Nursing Tip

HEALTH HISTORY AND HERBAL SUBSTANCES

You should always assess clients for use of other ingested and applied substances because clients often will not relate this information when asked about medications. Many of these herbs have biologic effects that may interfere with or add to the effect of medications and produce complications to medical treatment. Always ask clients directly about herbs, vitamins, or other dietary supplements they are taking. Neglecting to ask this question may subject clients to harmful drug interactions and side effects.

dried leaves or flowers, may be crushed and placed in gelatin capsules. Dried leaves, flowers, or roots may be loose or finely ground and used in infusions or teas. The plant parts may be prepared in tablets or liquids for ingestion or in poultices, lotions, salves, or oils for topical application. There are few risks with the culinary use of herbs, other than individual sensitivities or allergic reactions; however, potentially harmful amounts may be ingested when herbs are concentrated in pill or capsule form. Many consumers, thinking that these are natural products, do not feel there are risks. Many consumers also feel that because a product is natural, it cannot be harmful. Thus, they will take exceptionally large amounts. Herbal products may have therapeutic effects but also can have toxic effects if taken at the wrong time, in the wrong amount, in the wrong combination, or by the wrong person.

An overview of the more popular herbs, their known actions, and uses are given in Tables 4-3 and 4-4. Although nurses generally should not recommend herbs, it is important for nurses to be knowledgeable about them to advise

Nursing Tip

INFORMED CONSUMERS

Nurses can help clients be prudent consumers by teaching them to read labels carefully and avoid taking excessive doses of potentially dangerous products.

Nursing Alert

RESTRICTION OF HERBAL PREPARATIONS

Clients taking anticoagulants or antiplatelet agents should be cautioned against using certain herbal preparations. Bioflavonoids found in feverfew, ginkgo biloba, grape seed extract, and bilberry possess antiplatelet activity. These clients also should avoid herbal preparations of ginger, garlic, and ginseng (Glisson, Crawford, & Street, 1999).

Table 4-3 Herbs of General Use for Women

Name	Actions and Uses	Side Effects	Contraindications	Classification	Research
Bilberry (<i>Vaccinium</i>)	Vasoprotective, antidiarrheal, and astringent actions. Used for circulatory and eye disorders and healthy eye function. Used for dyspepsia and diarrhea.	None known		Commission E–approved AHPA Class 1	
Capsicum (cayenne pepper, chili pepper)	External: acts as counter-irritant, increasing blood flow; used for peripheral neuropathies and herpes zoster. Internal: acts as an antispasmodic and antifatulent; used for GI disorders and hyperlipidemia.	Irritant and hypersensitivity	Do not use on injured skin.	Commission E–approved FDA-GRAS Approved as over-the-counter drug (capsaicin, Zostrix) AHPA Class 1 (Internal) AHPA Class 2d (External)	
Chamomile	Internal: digestive aid sometimes used for inflammatory bowel disease. Oral: used as mouthwash for mouth irritations. Topical: used for inflammatory eczema, insect bites, and poison ivy.	None known	Avoid if allergic to ragweed, asters, and chrysanthemums.	Commission E–approved	
Cranberry (<i>Vaccinium macrocarpon</i>)	Antibacterial and acidifier. Used for prophylaxis and treatment of UTIs.	Diarrhea (with large doses)		Not evaluated by Commission E Not rated by AHPA	Reduces bacteriuria and pyuria and lowers pH of urine.
Echinacea (<i>Echinacea angustifolia</i> and <i>E. purpurea</i>)	Immune stimulant, antibacterial, antiviral, and anti-inflammatory. Internal: used for colds, respiratory infections, and arthritis. External: used for eczema, herpes, and burns. Oral: used for vaginal yeast infections.	Tongue numbness Allergic reactions	Autoimmune diseases and some systemic disease, such as MS and TB. Avoid if allergic to daisies.	Commission E–approved FDA-GRAS	Equivocal; some studies show efficacy and decreased incidence and severity of colds and flu, whereas others show little difference.

Evening Primrose (fever plant)	Essential fatty acid (omega-6) and prostaglandin precursor. Decreases inflammation and dilates coronary arteries. Used for eczema, PMS, menopausal symptoms, psoriasis, MS, asthma, diabetic neuropathy, and cancer.	GI disturbances Headaches		Not evaluated by Commission E FDA dietary supplement AHPA Class 1	Promising use of essential fatty acids in decreasing PMS symptoms, pain in mastalgia, symptoms of psoriasis, and cholesterol in hyperlipidemia.
Feverfew (<i>Tanacetum parthenium</i>)	Migraine prophylactic, anti- inflammatory, antipyretic, and antispasmodic. Used for prevention and treatment of migraine, fever, arthritis, and menstrual cramps. Long-term treatment required: 4–6 wk.	Rebound migraine Mouth ulcers GI irritation	Avoid if allergic to daisies. Avoid in pregnancy.	Not evaluated by Commission E FDA-GRAS AHPA Class 2b	Some studies indicate reduc- tion in number of migraines.
Garlic (Kwai)	Allicin is the active ingredient. Used for hyperlipidemia, prophylaxis of athero- sclerosis, hypertension, and respiratory infection. Lowers cholesterol, triglyce- rides, and BP; decreases intermittent claudication; and increases resistance to infection and possibly stomach and colorectal cancers. Similar to dicyclomine (Benocol) and some of the new butter substitutes. Enteric coating enhances allicin availability.	Nausea and vomiting Flatulence GI burning	Use caution because of possible interaction with anticoagulants. Avoid in lactation. Avoid in pregnancy.	Commission E–approved FDA-GRAS AHPA Class 2c	Several studies found mild effectiveness in lowering low- density lipopro- tein cholesterol; long-term pro- tection against cardiovascular disease is in- conclusive.

(continued)

Table 4-3 Continued

Name	Actions and Uses	Side Effects	Contraindications	Classification	Research
Ginger	<p>Volatile oil promotes secretion of saliva and gastric juices. Used as antiemetic, especially for morning and motion sickness.</p> <p>Used in India for years as antiemetic and digestive aid.</p>	In large doses, may cause heartburn	<p>May interact with warfarin (antiplatelet).</p> <p>May interfere with antidiabetic agents.</p> <p>Avoid with gallstones.</p> <p>Avoid prolonged and excessive use in pregnancy.</p>	Commission E–approved FDA-GRAS AHPA Class 1	Inconsistent results.
Chinese ginseng (<i>Panax schinseng</i>)	<p>Expensive.</p> <p>Has long history as general tonic, stimulant, and antioxidant.</p> <p>Used for stress, fatigue, debility, diabetes, depression, hyperlipidemia, and to improve physical performance and enhance immunity.</p> <p>Note: Be sure to distinguish from American ginseng (<i>P. quinquefolius</i>)</p>	<p>Hypertension</p> <p>Irritability</p> <p>Hypoglycemia</p> <p>Diarrhea</p> <p>Rash</p>	<p>May interact with antipsychotics, monoamine oxidase inhibitors, stimulants, and anticoagulants.</p> <p>Avoid with hypertension.</p>	Commission E–approved FDA-GRAS AHPA Class 2d	Not effective as an exercise enhancer; in reviewing the literature be sure to clarify which type of ginseng was used.
Ginkgo biloba	<p>Active ingredients 6% lactones and 24% glycosides.</p> <p>Improves circulation and acts as antioxidant.</p> <p>Used for dementia, memory enhancement, cardiovascular insufficiency, intermittent claudication, peripheral neuropathy, depression, tinnitus, retinopathy, and in early Alzheimer's disease.</p> <p>Need to build up dosage over time for effects.</p>	<p>Nausea and vomiting</p> <p>Headache</p>	May interact with anticoagulants.	Commission E–approved FDA-GRAS	Some efficacy in controlled trials for treatment of dementia and memory deficit.
Goldenseal (<i>Hydrastis canadensis</i>)	Used for upper respiratory conditions, flu, and menorrhagia.	<p>GI effects</p> <p>Uterine contraction</p> <p>Blood vessel contraction</p> <p>Hypoglycemia</p>	<p>Avoid with diabetes.</p> <p>Avoid with hypertension.</p> <p>Avoid in pregnancy.</p>	Not evaluated by Commission E FDA-GRAS AHPA Class 2b	None for URIs.

Grape seed extract	Antioxidant and anti-inflammatory. Used for inflammatory conditions and circulatory disorders. Used as antioxidant for disease prevention.	None known		Not evaluated by Commission E FDA dietary supplement Not rated by AHPA	No human studies.
Kava kava (<i>Piper methysticum</i>)	Similar to valerian. Active ingredient is kava lactones (70% kava lactones in standard preparation). Used as antianxiety and tension-reducing agent. Currently very popular with teenagers.	Yellowing of skin Allergic reactions	Acts as sedative and may interfere with driving and other types of performance. May interact with antidepressants and barbiturates. Avoid with depression. Avoid in pregnancy.	Commission E–approved	
Milk thistle (<i>Silybum marianum</i>)	Used as liver tonic since the days of Pliny. Used to treat viral hepatitis, hepatitis C, and other liver diseases, and for exposure to environmental toxins.	Transient laxative		Commission E–approved	
St. John's wort (<i>Hypericum perforatum</i>)	Increases neurotransmitter levels of serotonin and norepinephrine. Internal: used for depression, anxiety, and dyspepsia. External: used for wounds and burns. May have mild antiviral activity.	GI disturbances Photosensitivity	Interacts with antidepressant drugs, and when used together could alter dosage. May require dietary restriction of tyramine. May interfere with AIDS medications. May increase size of cataracts. Avoid in pregnancy.	Commission E–approved FDA-GRAS AHPA Class 1	In a meta-analysis found to be effective in treating mild to moderate depression.
Valerian root (<i>Valeriana officinalis</i>)	Action of binding benzodiazepine receptors. Used for insomnia, nervous excitability, hysteria, rheumatic pain, and dysmenorrhea.	Sedation and paradoxical reactions	Should not be paired with other drugs or herbal preparations with the same effects.	Commission E–approved FDA-GRAS AHPA Class 1	Some efficacy in clinical trials.

The authors thank the following persons for their advice and help with the preparation of this table: Sherri Konzem, PharmD, University of Houston, College of Pharmacy and Memorial-Hermann SW Family Practice Residency Program, Houston, Texas; and Roberta Anding, MS, RD/LD, CDE, Instructor, Section of Adolescent Medicine, Baylor College of Medicine and Texas Children's Hospital, Houston, Texas.

GI—gastrointestinal; UTIs—urinary tract infections; MS—multiple sclerosis; TB—tuberculosis; PMS—premenstrual syndrome; BP—blood pressure.

American Herbal Products Association (AHPA) Botanical Safety Rating: Class 1, internal use. Class 2nd, avoid with hypertension. Class 2b, avoid in pregnancy. Class 2c, avoid in lactation. Class 2d, external use. Commission E–approved, FDA-GRAS, Food and Drug Administration

Table 4-4 Herb Use in Perimenopause

Name	Actions and Uses	Side Effects	Contraindications	Classification	Research
Black cohosh (<i>Cimicifuga racemosa</i>), also called snakeroot and squawroot	Action appears to reduce luteinizing hormone and may potentiate hormonal production with a mild estrogenic action and uterine tonic. Used for reduction in menopausal symptoms, such as hot flashes, sleep disturbances, and irritability. Was one of the primary ingredients in Lydia Pinkham's woman's tonic, popular remedy in the early 20th century.	Headaches Increased menstrual bleeding Central nervous system depressant	Avoid in pregnancy because may cause uterine contractions.	Commission E–approved	Some studies show effectiveness in reducing perimenopausal symptoms.
Chaste berry (<i>Vitex agnus-castus</i>) also called chaste tree	Assumed to increase progesterone if insufficient. Thought to act as hormonal balancing agent during hormonal fluctuations. May affect anterior pituitary and increase progesterone production in luteal phase. Used for premenstrual syndrome (PMS), menopausal problems, especially for heavy menstrual flow and to reduce hot flashes caused by high levels of follicle-stimulating hormone.	None known	Concomitant use with oral contraceptives may result in diminished effect. Avoid in pregnancy.	Commission E–approved	
Dong Quai (<i>Angelica sinensis</i> or <i>A. phymorpha maxim</i>)	Contains phytoestrogens (plant estrogens). Acts as coumarin and affects blood clotting and hematopoiesis. Is a uterine relaxant. Used for menopausal symptoms.	Photosensitivity May cause heavy menstrual bleeding May cause heart palpitations	Avoid in women with heavy menstrual periods, spotting, or uterine fibroids. Avoid taking blood-thinners. Avoid during menstruation. Avoid in pregnancy.	Not evaluated by Commission E AHPA Class 2b	No more effective than placebo in some studies; more research needed.
Motherwort	Mild cardiotonic and aid to female reproductive system. Used for menopausal symptoms, PMS, menstrual cramps, and sleep disturbances.	May cause heavy menstrual bleeding	Avoid in pregnancy.	Commission E–approved	
Sage (<i>Salvia officinalis</i>)	Contains bioflavonoids and phytoesters for weak estrogenic and progesteric effects. Mild antibacterial and antifungal properties. Used for excessive perspiration and relief of hot flashes, night sweats, and mood swings.	May dry mucous membranes in mouth and vagina	Excessive use may cause kidney or liver problems. Avoid in pregnancy.	Commission E–approved

American Herbal Products Association (AHPA) Botanical Safety Rating: Class 2b, avoid in pregnancy.

Commission E–approved.

clients of risks or alert other members of the medical team about potential problems. Because research information is being published rapidly, the nurse should look for updates on descriptions of herbs, official classifications, labeling statements, possible uses, dosages, preparation, research, and risks. Additional information may be found in *The Commission E Monographs* and *The Physicians Desk Reference (PDR) for Herbal Medicine*.

Regulatory Issues and Herbal Remedies

Recognizing a need to standardize approval of herbal medicines, the European Economic Community developed guidelines for quality, quantity, production, and labeling of herbal preparations. In Germany, over 70% of physicians use phytomedicines as supportive medicines for chronic diseases and minor illnesses. Herbal production is more regulated in Germany than in the United States. The *Commission E Monographs* (Commission E was appointed by the German Federal Health Office to investigate the scientific literature regarding herbal products and identify herbal products approved for use) recently have been translated into English and are available in the United States (Blumenthal et al., 1998). *The Commission E Monographs* are one of the best resources on safety and efficacy of herbal products. *The Physicians Desk Reference (PDR) for Herbal Medicine* also is a good resource for clinicians. Medical journals also are publishing more reports of research on herbs.

Biomedical pharmaceuticals often are derived from plants used in folk medicine. Isolating active ingredients and chemically synthesizing them in a laboratory ensures purity and dose standardization. Some herbal preparations involve complex mixtures of several plants or several parts of a plant. One of the beliefs of herbalists is that the whole plant, rather than extracted or synthesized ingredients, includes substances that modify side effects and may potentiate therapeutic action. This controversy remains unresolved for both researchers and practitioners. These additional ingredients, however, pose problems for researchers and for standardization of products on the market.

Currently, the FDA regulates most herbal products in the United States under the classification of food supple-

ments. The 1994 Dietary Supplement Health and Education Act (DSHEA) allows manufacturers to advertise benefits of the products as long as they do not claim the products cure or prevent specific illnesses. The products are regulated by safe handling and labeling; however, because they often are natural products, considerable dosage variation may occur. Currently in the United States, the Food and Drug Administration (FDA) classification for use generally is recognized as safe and effective (FDA-GRAS). The current DSHEA regulation allows for labeling that includes structure and function claims without going through full FDA review. Labels can claim that the product affects the structure or function of the body but cannot make disease claims that involve treatment, cure, mitigation, or diagnosis of a medical condition without FDA evaluation. The manufacturer needs to be able to substantiate all claims it makes, and the label needs to state that the product is a supplement and has not been evaluated by the FDA. The FDA has proposed a limit on the amount of ephedra that can be present in supplements or purchased at one time and has issued warnings on potentially dangerous herbs, including chaparral, comfrey, yohimbe, lobelia, germanader, willow bark, Jin Bu Huan, and magnolia (Harvard Health Letter, 1997). The herbal industry has attempted to regulate itself. A classification system has been proposed by the American Herbal Products Association (AHPA) Botanical Safety Rating to address safety issues in the use of herbal products, ranging from Class 1 (no restrictions) to Class 4 (insufficient data on safety), that can be accessed on the AHPA website. During pregnancy, a conservative approach is best, as many of the effects of herbal ingestion are unknown; some herbs that should not be used in pregnancy and lactation are found in Box 4-2. They are classified as follows:

Class 1 considered safe—no restrictions

Class 2 safe but with restrictions

2a external use only

2b avoid use in pregnancy

2c avoid use in lactation

2d miscellaneous restrictions

Class 3 recommend to be used only under guidance of an expert

Class 4 Insufficient data available

(McGuffin, M, Hobbs, C, Upton, E, Goldberg A [Eds] [1997] *American Herbal Products Association's Botanical Safety Handbook*, Boca Raton, FL CRC Press.)

The Food and Drug Administration has a classification: Generally Regarded as Safe (GRAS). Commission E—approved means that they were reasonably safe when used according to the dosage, contraindications, and other warnings specified in the monographs. Efficacy was based on reasonable verification of historical use.

Nursing Alert

DRUG REACTIONS

If a client has an adverse effect or drug interaction to an herbal product, you should report it to the Food and Drug Administration's MEDWATCH (1-800-FDA-1088).

Box 4-2 Herbal Use in Pregnancy and Lactation**Pregnancy**

The most conservative approach is to avoid all but ginger because the purity and dosages of products cannot be ensured.

The following *should not* be used in pregnancy:

- Pennyroyal*
- Tansy*
- Rue*
- Black cohosh* and any of the herbs that cause uterine contractions
- Ma Huang
- Cascara sagrada and other harsh laxatives

Lactation

A number of herbs have been used in folk culture to enhance or reduce milk flow. The following *should not* be used during lactation:

- Aloe
- Black cohosh
- Buckthorn
- Cascara sagrada
- Cocoa[†]
- Coffee[†]
- Kava kava
- Ma Huang
- Sage
- Senna
- Tea[†]
- Wintergreen

*Abortifacients and should be avoided by childbearing women.

[†]Avoid excessive consumption.

Hardy, M. L. (2000). Herbs of special interest to women. *Journal of the American Pharmaceutical Association*, 40, (2), 234–242.

Negative results were given where there was no plausible evidence of efficacy or safety and weighed potential benefits (Blumenthal, 1998).

Applied Substances

Essential oils have been used for centuries and are used in perfumes and in body and bath products. Essential oils can be applied to the skin through lotions, salves, oils, poultices, plasters, or taken sublingually; these oils also are in-

**Nursing Alert****MEDICAL SUPERVISION REQUIRED**

The following herbs are considered dangerous and should not be used without medical supervision:

- Borage
- Coltsfoot
- Life root
- Germander
- Ma Huang
- Calamus
- Comfrey
- Chaparral
- Licorice (herbal, not the candy form)

haled by placement in a diffuser where they are heated by a light bulb. Many are placed in carrier oils of high-quality vegetable oil, such as almond, grape seed, or sesame oil. Essential oils are very concentrated and should not be used without dilution in a carrier oil. Once diluted, the oil may then be used directly on the skin, in bath water, or in a diffuser. Flower essences, such as Bach Flower Remedies often are diluted with brandy or an alcoholic base and taken by dropper sublingually. These oils should be stored away from extreme heat and often are kept in colored glass containers to maintain freshness. Essential oils are highly concentrated and therefore one can get a very high dose. In certain oils, a high dose can be very toxic. Aromatherapists advise not using undiluted oils on the skin. Lavender or tea tree oil, however, can be used on burns and skin eruptions as long as one does not have extremely sensitive skin. Testing for sensitivities, with a patch test of a 2% dilution and observing for 12 hours, is recommended. Citrus oils can cause uneven pigmentation with sun exposure. Contact with the eyes and sensitive mucous membranes should be avoided when using certain oils, and most should not be ingested. Caution should be exercised when used in preg-

**Nursing Alert****DRUG ABSORPTION**

Another risk of using essential oils is an allergic reaction that can be very severe because many oils are very concentrated. In addition, substances taken sublingually are absorbed into the bloodstream very quickly.

nancy because some oils may contribute to miscarriage. Oils that are considered safe in pregnancy are rose, neroli, lavender, ylang-ylang, chamomile, citruses, geranium, sandalwood, spearmint, and frankincense (Kevile & Geenen, 2000). The American Holistic Nurses Association, (AHNA) has endorsed educational programs in aromatherapy such as the Pacific Institute of Aromatherapy and the National Association for Holistic Aromatherapy.

Energy-Based Therapies

Energy is a concept that is used to explain forms of healing touch, therapeutic touch, Reiki, and laying on of hands. These treatments may involve actual touching or noncontact touch, such as placing the hands several inches from the body. The focus is the “energy field” rather than the physical body. The proposed theoretic basis for this modality is electromagnetic fields or quantum physics.

Magnetic Healing

Magnetic healing includes use of magnets for pain relief and the use of transcutaneous electrical nerve stimulation (TENS), which involves passing low-voltage current through pads applied to the skin. Some research has demonstrated efficacy in pain reduction. A number of magnetic products is available on the market, and many pain clinics use magnets therapeutically. TENS has been used to aid in the start of healing of fractured bones, promote healing and tissue regeneration, and reduce pain. TENS has been used with some effectiveness in reducing labor pain (Kemp, 1996). Magnetic and electromagnetic therapies have been used in a number of treatments and are sometimes used to provide electrical stimulation of acupuncture points to reduce pain.

One theoretic framework on which magnetic therapies are based is that they stimulate the body’s production of endorphins and close the pain gate, as proposed by Melzack and Wall (1965). Reversal of effects from the use of naloxone, which is an opiate antagonist, has supported this theory. Another theoretic framework is the principle that magnets alter the orientation of the chromosomes within cells, which has been observed under electron microscopes (Rosenfeld, 1996). This shift is thought to relieve acute and chronic pain.

Touch Therapies

Touch therapies have been used historically and across cultures. The use of human touch for healing has been recorded in early records and archeological data across cultures. Healing by laying on of hands is a key element in many spiritual traditions, including Judeo-Christian scriptures. Touch has been shown to be vital to human devel-

Figure 4-2 Laying on of hands is one means of touch therapy.

opment (Figure 4-2). Infants and young children may develop pathologies and may even stop eating and die if they do not receive caring touch. Nurses have embraced touch as integral to caring for clients.

The therapeutic use of touch has been understood as operating through universal healing, life energy, or by means of spiritual intervention. Slater (1996) has linked these earlier descriptions of prana, chi, and vital energy with physicists’ descriptions of quantum and electromagnetic fields. A number of physicists (Bohm, 1980; Capra, 1984; and Zukav, 1979) have written about quantum physics, compared it with Eastern mysticism, and challenged the existence of matter as being distinct from energy. As touch therapies began to be taught within nursing, these theories and the vocabulary of frequencies, waves, energy, vibration, and balanced or congested fields were commonly used.

Two groups have promoted touch therapies within the nursing profession: Therapeutic Touch (TT), founded by Dolores Krieger; and Healing Touch International (HTI), founded by Janet Mentgen. Both these groups provide education and training for nurses interested in practicing this modality. Reiki is another form of touch therapy that is practiced by both nurses and laypersons.

Therapeutic Touch

Therapeutic touch was brought into nursing by Dolores Krieger, PhD, RN. She had worked with healers Oskar Estebany and Dora Kunz. Krieger’s research on the increase of hemoglobin after therapeutic touch was one of the first studies conducted on this modality. In learning this technique, the practitioner is taught to enter a calm state through a process of “centering” and to hold an “intention” of desiring to help the client. The practitioner is taught to assess the client’s energy field and then modulate or correct the deficient, congested, or unbalanced areas. The practitioner’s hands are placed a few inches above the

Research Highlight

Electroacupuncture for Control of Myeloablative Chemotherapy-Induced Emesis: A Randomized Controlled Trial

Purpose

To determine the efficacy of acupuncture plus antiemetic drugs in controlling nausea and vomiting from chemotherapy in women with breast cancer compared with antiemetic drugs alone.

Method

Randomized controlled trial.

Findings

Among the 104 women undergoing high-dose chemotherapy for breast cancer, those randomized to the acupuncture plus antiemetic drugs group experienced less than half the number of nausea and vomiting episodes over the 5 days of treatment compared with women receiving antiemetic drugs alone.

Nursing Implications

1. The complex and multifactorial nature of chemotherapy-induced nausea and vomiting suggests that no single treatment will completely control these side effects.
2. Acupuncture may provide a degree of control of nausea and vomiting by affecting chemicals of the central nervous system. This may be particularly helpful in women who experience significant toxicity from antiemetic agents or in whom such agents render ineffective control of nausea and vomiting.

Shen, J., Wenger, N., Glaspy, J., Harys, R. D., Albert, P. S., Choi, C., & Shekelle, P. G. (2000). Electroacupuncture for control of myeloablative chemotherapy-induced emesis. *JAMA*, 284, 2755–2761.

physical body, which is felt to be the optimal area to work with the energy (Figure 4-3).

Healing Touch

Healing touch also uses touch to influence energy. Along with touch, it employs a number of additional techniques the practitioner can use in working with clients. These techniques are used to align and balance the energy field, thus facilitating the client's self-healing. Proponents claim that these techniques are healing in a holistic manner because they act on physical, emotional, and spiritual domains. This program is taught in a series of classes as the practitioner advances to different levels. The program is available to nurses as well as laypersons. HTI is one of the most rapidly growing healing organizations in this country.

Reiki

Reiki is based on the Tibetan Sutras (ancient sacred texts) and was reintroduced into Japan by Usui in the 1800s (Stewart, 1995). Takawa, a Japanese woman who moved

Figure 4-3 Therapeutic touch involves centering and assessing the client's energy by placing the hands a few inches above the client's body.

to Hawaii, trained several healers who then brought the technique to the United States. Novice practitioners are initiated through a ritual involving ancient symbols. The healer channels universal healing energy through the hands, which can be placed directly on or held at a distance from the client. The healer does not direct the energy, but holds the intent to heal. The energy then goes to where it is needed. This modality also uses a technique for distance healing. Preparation is through weekend seminars and work with a Reiki Master. The Master level involves a lifelong commitment to healing and to Reiki. Many nurses and laypersons are Reiki healers.

Nursing Implications

Nurses and clients often cite anecdotal reports of the benefits of touch therapies; however, relatively few research studies have established their efficacy. Most nursing research into touch therapies has been conducted in therapeutic touch. Research supports decreased anxiety and increased relaxation; results on wound healing are equivocal. Some recent studies demonstrate that exposure to touch therapies may increase humoral immunity; however, results are preliminary (Wardell & Engebretson, 2001; Olsen et al., 1997). The lack of a testable theory and the references to energy alien to biomedical thinking may explain the difficulty in understanding this modality and identifying appropriate research designs to capture effectiveness. Touch modalities are of particular interest to the profession of nursing and warrant further study and theoretic development. They remain low-cost and low-risk strategies that many clients claim have benefit. Many hospitals have integrated these modalities into their care delivery and have sponsored nurses' preparation in them.

Although little research has been done on the use of touch therapies in pregnancy and labor, many nurses have used these techniques to aid in comfort and relaxation. Touch therapies also have been used in infants. Noncontact or light touch may be particularly useful in infants in the neonatal intensive care unit for whom rigorous physical contact, such as massage, may lead to overstimulation (Figure 4-4). These areas currently are under research.

Psychologic or Mind-Body Therapies

Psychologic therapies are related to cognitive thought or the function of the brain. Mind-body medicine recently has become established in health care with the understanding of the effect of thoughts and emotions on the body and the effect that the physical body has on emotions. The recent understanding of psychophysiologic mechanisms has provided a firm base for many of these strategies to be well researched. Much of the research has been based on

Figure 4-4 Infants in the NICU can benefit from calm, warm, nondisruptive touch therapy.

stress reduction and relaxation. Other strategies include cognitive repatterning, behavioral modification, psychotherapy, group therapy, and coping strategies. Many of these techniques are incorporated into the therapeutic relationship that nurses establish with clients and use in wellness counseling.

Additional clinical interventions of stress reduction are being tested. Relaxation strategies, such as autogenic training, progressive muscle relaxation, distraction techniques, and paced breathing, have been used in the care of women during pregnancy and in preparation for labor over the past 40 years (Figure 4-5). Many of these techniques may be used to promote general relaxation other than in labor.

In addition to the relaxation strategies taught in childbirth preparation, some additional techniques that nurses can use to promote relaxation are biofeedback, mindfulness, self-reflection, mental imagery, affirmations, and music therapy. Research has demonstrated such techniques to be effective adjuncts in reducing pain and anxiety related to surgery or invasive procedures, and with symptom control related to specific treatment side effects. The AHNA has described several practices that are part of holistic nursing care, many of which are felt to facilitate stress reduction and relaxation. *Holistic Nursing: A Handbook for Practice* (Dossey, Keegan, & Guzzetta, 2000) is a good reference for additional guidance on how to develop and use these skills in clinical practice.

Figure 4-5 Childbirth preparation classes often include techniques wherein the partner helps the woman to relax, focus, and breathe deeply.

Mental imagery, a therapeutic process in which imagination and memory are used to mentally taste, smell, see, and hear images that suggest a state of health are used for promoting both health and healing. AHNA endorses a program for learning the techniques of visual imagery, which is directed by nurses and offers certification.

Spiritual Healing

The literature is clear that spirituality and religion are not synonymous, although spirituality often is described in terms of religious belief or practice. *Spirituality* is the essence of who we are as human beings and includes but is not limited to the process of discovering purpose, meaning, and inner strength throughout life's journey. Spirituality is experienced and expressed in many ways outside the context of *religion*, which can be identified as an organized system of beliefs and practices shared by a group of people. According to Burkhardt and Jacobsen (2000), elements of spirituality can include connectedness to an Absolute or Higher Power, to nature, to others, and to self.

Both illness and wellness activities have been derived from spiritual practices. Spiritual issues often concern suffering, redemption, forgiveness, faith, hope, grace, and love. Within the context of spirituality, healing is much more than the recovery from illness and absence of disease. Healing can imply a restoration of wholeness, establishment of internal and external resources, a sense of transcendence, or a feeling of interconnectedness (Burkhardt & Jacobsen, 2000). Many rituals and health practices have been described that focus on the attainment or restoration of balance between mind, body, and spirit. Some of these may seem quite appropriate within Judeo-Christian traditions, such as worship and prayer; whereas others from

Native American or Southwestern cultures, such as chanting or use of a medicine wheel, may be unfamiliar.

Religious practices, such as participating in church activities, have demonstrated positive health benefits (Levin, 1994). Other religious practices, such as forgiveness, have historically been used as a means of spiritual purification. Meditation has been used in many spiritual traditions as a way of attaining balance both internally and with the environment. Meditation also has been researched for its efficacy in relaxation and stress reduction. Prayer and primal religious experiences are spiritual actions found in many cultures and are associated with healing. Many CAMs have their roots in spiritual traditions and practices (Kinsley, 1996).

Because no consensus exists on the definition, scope, and measurement of spirituality, it is vital that nurses recognize all forms of spiritual expression to provide professional and holistic care. The connectedness inherent in the therapeutic nurse-client relationship is an avenue of nurturing spiritual awareness for both the nurse and client. Spiritual elements of health and illness can be expressed through story (Cohen, Headley, & Sherwood, 2000), presence, touch, listening, creative expression, ritual, and use of sacred space. Instruments and guides are available to aid the nurse in spiritual assessment, although story sharing often provides a vehicle through which clients gain insight and meaning for emotions, issues, and conflicts (Burkhardt & Jacobsen, 2000; Liehr & Smith, 2000).

Client Education

Questions for Consideration for Clients Interested in Taking or Engaging in Complementary Therapies

- Do they make claims to cure cancer, enhance treatment, or relieve symptoms or side effects?
- What are credentials of those supporting the therapy?
- Have they published or referenced trustworthy journals?
- What are the costs of the treatment?
- Is it widely used in the health care community, or is access limited?
- Is it used in place of standard therapies and if so will the delay affect a chance for effective treatment?

Adapted from the American Cancer Society.

NURSING IMPLICATIONS

Nurses must be aware of the types of health-related activities in which their clients may be engaged. This awareness is important for safety and to assess the interaction of these activities with biomedical care. Nurses can conduct their assessment in a manner that engages clients in the most appropriate planning and incorporation of complementary strategies. If the nurse is knowledgeable about complementary therapies, appropriate referrals may be made that can help clients augment their treatments, cope with symptoms and unpleasant side effects from treatments, and maintain and promote their health. A number of strategies that currently are labeled as CTs have been part of nursing care and are well documented in the nursing literature. Table 4-5 lists some of these interventions described by Snyder and Lindquist (1998) and listed in the *Nursing Interventions Classification* (McCloskey & Bulechek, 1996).

Implications for Women's Health

Women seek care more frequently than do men from both CTs and traditional medicine. In many cultures, women are central to the physical and emotional health of the family. Women prepare most of the food, purchase dietary supplements, and provide the majority of childcare. Women generally are the caregivers and tend to the sick of the family, both old and young. Many CTs are likely to be well received by women and meet many of their needs and those of their families. Promoting the health of women over the life span improves not only the client's health but also that of the entire family.

Implications for Research

Because many of these modalities mirror autonomous nursing actions, nurses should welcome interdisciplinary interest in researching these modalities. It is important for nurses to keep abreast of the research not only published in nursing journals but in medical, psychological, public health, and specialty journals for alternative and complementary medicine. Because many of the modalities present challenges to biomedical research methods, nurses must read the research critically.

Implications for Practice

As they incorporate these complementary therapies into practice, nurses must ensure they have adequate education, training, and experience. Nurses attempting to engage in these interventions may need additional training or certification for some techniques. Nurses not educated in the

Client Education

Complementary Approaches for Women

Nausea in Pregnancy

- Acupuncture
- Sea bands
- Ginger
- Vitamin B₆
- Visualization
- Relaxation techniques

Premenstrual Syndrome

- Good nutrition: reduce intake of sugar, caffeine, dairy products, and animal fats
- Exercise
- Body work
- Herbal: chaste berry, black cohosh, wild yam, ginkgo biloba, and progesterone creme
- Supplements: vitamin B₆, vitamin E, magnesium
- Acupuncture

Menopause

- Good nutrition
- Exercise: strengthening, flexibility, weight-bearing, and mild aerobic
- Movement therapies: Pilates, Feldenkrais, Alexander technique, and yoga
- Body work: massage and various therapeutic techniques
- Mind-body: Stress reduction, relaxation, and biofeedback
- Spiritual: prayer, meditation, and religious rituals
- Social: connections with family, friends, and other groups
- Herbal: black cohosh, vitex, and other herbs, depending on symptoms
- Acupuncture and acupressure

technique have the professional responsibility to obtain the proper preparation, either from the literature or from continuing education. The AHNA website provides a current listing of endorsed educational and certificate programs. All clients should be assessed regarding supplements or substances they may be taking. Nurses must be very

HOLISTIC NURSE-CERTIFIED

Registered nurses with a baccalaureate degree (BSN) or higher can become certified as holistic nurses (HNC). This certification acknowledges nurses' knowledge of holistic practices and complementary therapies. This certification *does not* certify the nurse to practice specific modalities, which generally require separate certificates. More information may be obtained by calling American Holistic Nurses Certification Corporation headquarters at 1-877-284-0998.

cautious in recommending herbal remedies. It is imperative that nurses be in compliance with the Board of Nurse Examiners scope of practice regulations of their state.

NURSING PROCESS

The nursing process can be applied to clients seeking or engaging in alternative and complementary therapies.

Assessment

In assessing clients, it is important to ask specifically what they are taking in the way of vitamins, minerals, herbs, and over-the-counter medications in addition to prescribed medications. Clients also should be asked about therapies that they are considering taking, their financial resources for such therapies, and modalities that they would consider acceptable or unacceptable.

Nursing Diagnoses

North American Nursing Diagnosis Association (NANDA) –approved nursing diagnoses for clients seeking or engaging in CTs might include the following (NANDA, 2001):

- ✿ Deficient knowledge regarding the potential benefits and applicability of CTs.
- ✿ Deficient knowledge regarding the types and availability of CTs.
- ✿ Deficient knowledge regarding the potential risks associated with CTs.
- ✿ Decisional conflict related to the accessibility and efficacy of standard therapies and CTs.
- ✿ Chronic pain.
- ✿ Ineffective coping.
- ✿ Hopelessness.
- ✿ Powerlessness.

- ✿ Anxiety.
- ✿ Fear.
- ✿ Spiritual distress.
- ✿ Fatigue.
- ✿ Ineffective health maintenance.
- ✿ Interrupted family processes.

Specific nursing diagnoses in women may include the following:

- ✿ Stress urinary incontinence.
- ✿ Imbalanced nutrition.
- ✿ Sexual dysfunction.
- ✿ Disturbed sleep pattern.
- ✿ Caregiver role strain.
- ✿ Impaired parent-infant attachment.
- ✿ Risk for constipation.
- ✿ Rape-trauma syndrome.
- ✿ Ineffective breastfeeding.
- ✿ Ineffective thermoregulation.

Outcome Identification

In partnership with the client, the nurse should outline the desired results of care and therapy. Targeted goals should be prioritized according to the client's physical and emotional state and needs and to the client's wishes. Family members and significant others can be included in the goal-setting as requested by the client.

Planning

In planning interventions, it is important to engage the client in mutual planning of appropriate use of CTs and discuss expected outcomes. Referral sources for certified practitioners of specific modalities with regard to the client's financial resources are crucial. Integration of selected CTs into the medical plan of care also is advised.

Nursing Intervention

Appropriately prepared nurses may provide the intervention, particularly for CTs that may relate to client education for self-care. Many nurses are able to guide clients in relaxation techniques or provide touch therapies. Nurses need to be knowledgeable about the risks, benefits, and indications of specific CTs. Clients should be informed that behavioral interventions take practice and lifestyle changes are most effective when accomplished gradually. Efficacy of such therapies, as well as those of ingested and applied substances, may not be apparent for several weeks.

Case Study/Care Plan

USE OF COMPLEMENTARY THERAPY

Mary is a 55-year-old married woman who is having mood swings, fatigue, insomnia, vaginal dryness, hot flashes, and muscular stiffness related to perimenopause. After discussing the issue with her health care provider, she has decided not to take hormone replacement therapy. Mary approaches you for advice regarding nondrug therapies for her symptoms, which are interfering with her daily living and ability to perform her work as a professional seamstress.

Assessment

- Mary has no difficulty in falling asleep but wakes up several times at night perspiring and tossing off her bed covers. She is often too tired to complete her usual workload or engage in social activities.
- Mary is taking no medications other than a daily multivitamin and occasionally an over-the-counter laxative. Her medical history is unremarkable, and she denies having allergies.
- Mary has numerous hot flashes daily, which interrupt her work and ability to concentrate.
- Mary states that she often is irritable about situations that previously would not have bothered her and has also had regular episodes of feeling “down.”
- Mary is increasingly reluctant to engage in sexual intercourse owing to dyspareunia.
- Mary has noted increasing muscular stiffness, especially when the weather is cold; she denies joint pain.
- Mary is interested in therapies other than prescribed estrogens or progestones and a regular exercise routine.

Nursing Diagnosis

Disturbed sleep pattern related to night sweats, hot flashes, and muscular stiffness.

Expected Outcomes In 3 weeks, Mary will report decreased frequency and severity of hot flashes, decreased muscular stiffness, and decreased awakening during sleep.

Planning Work with Mary to plan sleep and exercise activities that will fit into her routines and lifestyle.

Nursing Interventions	Rationales
1. Inform Mary of herbal preparations such as black cohosh, Evening Primrose oil, and vitamin E supplements, and to use soy-based dairy products.	1. Use of these preparations may relieve her hot flashes.
2. Instruct Mary in forms of exercises such as yoga, tai chi, or Pilates along with resources for certified instruction in such methods.	2. These exercises will reduce muscle tension and diminish muscle stiffness.
3. Assist Mary in planning daily activities to allow for intermittent rest periods.	3. Rest periods during the day will help diminish fatigue; they also can help make up for lost sleep at night, until Mary's nighttime sleep routine is re-established.

Evaluation Goal will be evidenced by client self-report on a list of menopausal symptoms, including symptoms for insomnia, and hot flashes.

(continued)

Nursing Diagnosis

Ineffective role performance related to fatigue, irritability, decreased mental concentration, and diminished sexual activity.

Expected Outcomes In 2 months, Mary will report decreased irritability, re-establishment of usual work routine, and overall improved quality of life.

Planning Help Mary identify those areas in which she has positive role involvement and those areas (such as work and spousal relationship) where she feels there is a need to improve.

Nursing Interventions

Rationales

1. Instruct Mary in deep breathing exercises to use regularly and when feeling irritable.
2. Advise Mary of the need to continue social and other activities that are enjoyable for her.
3. Advise Mary to use a water-based lubricant for sexual intercourse and as needed in between, and to engage in regular intercourse as desired.

1. Controlled breathing releases tension and has a calming effect.
2. Maintaining social contacts will reinforce a sense of normalcy and help Mary keep a balanced perspective on her life.
3. Lubricant will reduce feeling of vaginal dryness.

Evaluation Progress will be evidenced by a self report of fewer menopausal symptoms including irritability and fatigue, and by work productivity and client report of quality of life rating of 8 or more on a 1 to 10 scale.

Evaluation

Evaluation of the effectiveness of the intervention depends on the therapeutic indications and goals. Evaluation can be obtained by client follow-up reporting, although many self-reporting instruments are available for clients to document changes in symptoms in the interim and over time. Nurses should keep in mind that many behavioral interventions have therapeutic effects beyond symptom relief in that effectiveness of biologic response to medical treatments sometimes improved.

Web Activities

- Search the Internet for alternative therapies for the discomforts of pregnancy. Critically analyze the source, information, and potential effect the information might have on clients.
- Go to the AHNA website. Explore the endorsed programs and other information.
- Pick a modality that interests you, and search the Internet.
- Go to the National Institutes of Health Center for Complementary and Alternative Therapies website and read about current research.

Key Concepts

- Complementary therapies are those used in conjunction with biomedical therapy, whereas alternative therapies are those used in place of standard biomedical therapy.
- Traditional healing systems are closely tied to cultural and religious influences and are generally thousands of years old.
- Biomedicine is an example of a healing system.
- Many complementary therapies are congruent with autonomous nursing interventions in that they support self-care and self-healing of the client.
- The complexity and technology of modern medicine, lack of effective standard therapies for chronic illnesses, the crisis in health care delivery in Western society, and increasing availability and advertising are factors contributing to the use of complementary therapies by clients and their families.
- The lack of an established theoretic basis for many modalities, such as energy-based modalities, or the limitations of quantitative methodology may account for the difficulty in applying standard biomedical research to document the effectiveness of complementary therapies. Outcome-based research is needed for such therapies to become reimbursable, affordable, and accepted by the medical community.
- Some complementary therapies have been accepted as nursing interventions, such as relaxation, therapeutic use of self, range-of-motion exercise, spiritual support, touch therapies, cognitive therapies, and nutritional counseling. Other techniques may require additional training and certification. It is vital that nurses are in compliance with the Board of Nurse Examiners scope of practice regulations of their state.
- Complementary therapies can be helpful and should be permitted if they are not harmful in general or do not interfere with standard biomedical treatment. It is important that nurses familiarize themselves with indications and contraindications before encouraging or recommending these therapies to clients.
- Resources for further information include the American Holistic Nurses Association, National Institutes of Health, Center for Complementary and Alternative Therapy, and American Botanical Council.

Review Questions and Activities

1. Which one of the following reasons might *best* explain the appeal of alternative therapy to women with chronic illnesses?
 - a. Alternative therapies are generally health-oriented
 - b. Alternative therapies are relatively inexpensive
 - c. Alternative therapies usually are efficacious and nontoxic
 - d. Alternative therapies generally involve self-care
 The correct answer is d.
2. Many clients use alternative and complementary therapies in addition to standard treatments. Which of the following clients who are using such therapies might you be most concerned about?
 - a. A healthy perimenopausal woman who is taking black cohosh for relief of hot flashes.
 - b. A woman using acupuncture for control of nausea related to morning sickness.
 - c. A woman receiving standard chemotherapy for ovarian cancer who is taking weekly colonic irrigations.
 - d. A woman who has had an uncomplicated pregnancy continuing her yoga classes into her third trimester.
 The correct answer is c.
3. Which is the nursing diagnosis *most* applicable to an adolescent girl who is concerned about her weight, although she is within normal range for her height, and is considering taking an ephedra-based herbal product to lose weight?
 - a. Deficient knowledge related to risks and benefits of complementary therapies
 - b. Imbalanced nutrition, more than body requirements
 - c. Ineffective health maintenance related to adequate nutrition
 - d. Deficient knowledge related to availability of complementary therapies
 The correct answer is a.

4. Which of the following statements is true regarding the role of the nurse in recommending or administering complementary therapies?
- Nurses should recommend only herbs and vitamin or dietary supplements that have been approved by the Food and Drug Administration
 - Nurses should recommend or practice only those complementary therapies whose efficacy has been scientifically documented
 - Nurses should encourage the use of alternative therapies that do not interfere with biomedical treatment
 - Nurses should seek additional education or certification before recommending or practicing complementary therapies that are unfamiliar
- The correct answer is d.
5. How can the efficacy of mind-body therapies best be measured?
- By measurement of biochemical markers of immune function
 - By self-reporting of symptom relief
 - By the absence of disease states

- By measurement of clients' performance accuracy for such therapies

The correct answer is b.

6. Body work is most likely to be contraindicated in which women?
- Those with a history of degenerative joint disease
 - Those with the human immunodeficiency virus
 - Those with bleeding disorders
 - Those with osteopenia
- The correct answer is c.
7. Which persons are most likely to use complementary and alternative therapies?
- Those with limited education
 - Those with an acute life-threatening illness
 - Those with access to practitioners of such therapies
 - Those with higher income
- The correct answer is d.
8. Visit a local holistic health center, natural food store, or book store and explore the offerings for complementary or alternative health.

Ethics, Laws, and Standards of Care

While ethical and legal issues are present in many aspects of nursing practice, special issues exist when working with childbearing clients. An awareness of personal and professional values facilitates discussion of issues related to caring for perinatal clients. Ask yourself how you would respond to the following questions:

- *What values do I hold to be important in my life?*
- *What beliefs about professional nursing serve as a basis for my practice?*
- *How do I respond when a client's value system is different from mine?*
- *What happens when I find I have conflicting ethical responsibilities?*

As you read this chapter, continue to think about how your values influence practice decisions. Special boxes raise specific questions about your values and experiences when caring for perinatal clients.

Key Terms

Autonomy	Due care	Liability	Standards of care
Beneficence	Ethics	Malpractice	Tort
Categorical imperative	Ethic of care	Material principles of justice	Universalizability
Civil law	Fidelity	Negligence	Utilitarianism
Criminal law	Harm	Nonmaleficence	Veracity
Code	Informed consent	Paternalism	Virtue
Deontology	Justice	<i>Prima facie</i>	Virtue ethics
Dilemma	Law		
Doctrine of the golden mean			

Competencies

Upon completion of this chapter, the reader should be able to:

1. Describe common ethical and legal issues in maternal-child nursing.
2. Discuss basic ethical theories that potentially guide decision making, including utilitarianism, deontology, virtue ethics, and nursing ethics.
3. Identify four ethical principles that can be applied in ethical thinking.
4. Use the basic steps that lead to dilemma resolution.
5. Describe documentation safeguards that should be used to adequately document care for childbearing clients.
6. Discuss standards of care commonly used in maternal-child nursing.

Who has more rights during a pregnancy—the mother or the fetus? Can anything be legally done to make pregnant women stop using illicit drugs during their pregnancies? Do all women have a right to prenatal care? What measures should be taken so that care given to clients during the perinatal period is safe and appropriately documented? What care standards should guide care given during the perinatal period?

While ethical and legal considerations are a component of all aspects of nursing care, some unique issues exist in maternal-child nursing. Many of these issues occur because two parties, inextricably linked, are involved—the mother and the developing fetus. This chapter focuses on basic concepts related to ethical and legal considerations, including relevant ethical theories and principles; a method for dilemma resolution and specific dilemmas that nurses may encounter; legal concepts, standards of care for maternal-child nursing, and guidelines for practicing within legal boundaries. Readers will find guidance for practice issues that nurses face in maternity nursing.

What is meant when the term “ethics” or “laws” is used? **Ethics** refers to the branch of philosophy that pro-

vides rules and principles that can be used for resolving ethical dilemmas. **Laws** are rules that govern the behavior of individuals and represent the minimum standard of morality (Hall, 1996).

Since this chapter concerns both ethical and legal issues, a good beginning would be to examine the similarities and differences between law and ethics. The relationship between ethics and laws includes similarities and differences. First, both laws and ethics identify social sanctions and provide guidance for actions. In fact, many laws are derived from ethical considerations. Laws generally define the minimum ethical principles that must be followed (Hall, 1996). Both laws and ethics provide mechanisms through which disputes can be settled. However, laws and ethics can differ in important ways. Laws are rules that are external to an individual and that members of society must obey. On the other hand, ethics tend to be personal and involve values, beliefs, and interpretations to guide behavior. Laws are written with the interests of society as the major consideration, whereas ethics focus on the interests of an individual within the society. Laws are enforced through law enforcement agencies and the judicial system. Ethical decisions are more reflective, and ethics commit-

Figure 5-1 Many institutions have ethics committees designed to provide guidance and support in the critical issue of client care. (Photo courtesy of Photodisc.)

tees often serve as a forum for discussion, persuasion, and recommendations for action (Figure 5-1).

Some actions are both ethical and legal. For example, informed consent of clients is an ethical obligation for health care providers as well as a legal one. Some actions are legal, but may not be considered ethical. One possible example of an ethical and legal conflict, depending on the individual's point of view, would be abortion; an individual who feels abortion is unethical may have difficulty with its legality. Finally, some actions that are illegal might be considered ethical. An example of this situation would be assisted suicide. Although some care providers consider assisted suicide to be within the realm of ethical behavior, such assistance is currently illegal.

ETHICAL ISSUES

Nurses frequently encounter ethical dilemmas. In a survey by the American Nurses Association Center for Ethics and Human Rights, 79% of nurses reported encountering ethical issues in practice on either a daily or weekly basis (Scanlon, 1994). Many of these issues were related to cost containment that jeopardized client welfare, end-of-life issues, breaches in confidentiality, and incompetent or unethical practices of colleagues. Unfortunately, 59% of the nurses surveyed indicated that their educational programs had not sufficiently prepared them for managing ethical issues found in practice. This section focuses on some basic ethical theories and principles and suggests a method that nurses can use for resolving ethical dilemmas in practice.

Bandman and Bandman (1995) suggest that ethics are concerned with doing good and avoiding harm. Certainly, nurses have opportunities to promote client welfare and prevent harm. However, just what constitutes good and what can be defined as harmful is open to interpretation.

For example, is it better to promote fetal health at the expense of overriding the expectant mother's right to make decisions about her care?

Why are some dilemmas considered to be ethical dilemmas? Ethical dilemmas can arise out of a conflict in duties. For example, nurses have obligations to many parties—their clients, their employing institution, physicians, and most importantly, themselves. Unfortunately, these obligations sometimes conflict. Clients may demand one thing, a hospital or clinic another, and the profession of nursing another. It can be difficult to identify the obligation that is the most important and act on it. Ethical dilemmas deal with human concerns. Making an ethical decision is different from determining what kind of car you might like to buy or which color is your favorite. A dilemma sometimes encountered in practice is how to protect the health and safety of a fetus while promoting a mother's right to make choices about her pregnancy. Perhaps the most apt description of a **dilemma** is that it is making a choice between two unsatisfactory alternatives (Davis, Aroskar, Liaschenko, & Drought, 1997). Regardless of the choice, the desired happy ending cannot occur. Nonetheless, ethical dilemmas are resolvable situations that demand attention and thoughtful reasoning. Understanding ethical theories and principles can be useful in helping to resolve dilemmas and in discussing the rationale for our actions with others. Each of the ethical theories presented below offers different perspectives about how a dilemma may be viewed and how right actions can be selected.

Basic Ethical Perspectives

The concept of bioethics, or the application of ethics to health care, was popularized in the late 1960s and early 1970s because care providers felt a need to have better methods to resolve dilemmas. Ethical conflicts have always existed, but increased use of technology in health care has increased the number and visibility of dilemmas. Initially, two major classes of theories, derived from existing studies of ethics, were used: utilitarianism and deontology. As the field of bioethics began to grow, providers were concerned that while these perspectives provided guidance for ethical decision making, they did not reflect the characteristics of care providers. Another class of ethics was revived: virtue ethics, an ancient theoretical perspective. Nursing theorists also began to explore the unique relationships that nurses have with clients and to examine the basis for their care. Out of this tradition, an ethic of care, linked to nursing ethics, was proposed to encompass some of the unique perspectives that nurses bring to the health care arena. Because nurses work collaboratively in health care, they must understand the perspectives that each of these theories brings to ethical decision making,

because these perspectives can guide thinking and provide a mechanism for explaining and justifying actions. Although these theoretical perspectives can serve as a guide for action, each has some shortcomings.

Utilitarianism

Utilitarianism is a type of ethical theory focusing on the consequences of actions. Individuals who were prominent in the development of utilitarian theory during the 19th century included Jeremy Bentham, a social reformer, and John Stuart Mill. Although the theories they produced were not exactly identical, the overarching themes are similar. In utilitarianism, acts are right if they produce the greatest possible balance of good when everyone is considered (Mappes & DeGrazia, 1996). No action in itself is considered to be right or wrong. Rather, right actions are those that produce the best possible outcomes.

Utilitarian thinking involves a certain amount of calculation. Whenever a decision is being considered, an individual tries to predict all of the possible good and bad consequences arising from each action that could potentially be taken. Once those are identified, the decision-maker would weigh the outcomes and select the action that would produce the best results and the least number of bad results for everyone involved. Utilitarian theory requires that the decision-maker be impartial and the decision not be based on personal interests. Utilitarian theory is sometimes classified as “act utilitarian,” in which the principle of utility is applied to each specific act considered, or as “rule utilitarian,” in which rules are developed that, if followed consistently, usually provide the greatest good. Act utilitarianism is sensitive to individual cases, but rule utilitarianism holds that following the rules produces the greatest degree of social utility, but not necessarily individual good (Beauchamp & Childress, 1994). One difficulty with utilitarian theory is that it might permit the interests of the majority group to override the interests of a minority group (Beauchamp & Childress, 1994). A positive aspect of utilitarianism is that it works to promote good.

For example, it is good for women to receive prenatal care during pregnancy because it helps both mothers and their babies to be healthier. We also have technology available to provide care for low-birth-weight babies. However, resources are limited and there is not enough funding to pay for both prenatal care for all pregnant women and high-technology care for all low-birth-weight infants. From a utilitarian perspective, this problem would be weighed to find a solution that would promote the best outcomes for the greatest number of individuals. In this situation, would better outcomes for more people be produced by provision of early prenatal care to all expectant mothers or by provision of “high-tech” care to a smaller number of

low-birth-weight infants? Based on the benefits to the greatest number of individuals, a utilitarian solution would be to provide prenatal care to all expectant mothers.

Deontology

Deontology is another type of ethical theory that is concerned with people doing the right thing. The word “deontology” is derived from *deon*, which means duty. Rather than focusing on whether or not actions bring about the best outcome, deontology strives to identify the best possible action directed by one’s duty or obligations, without considering rather than based on the consequences of actions.

The utilitarian theory previously discussed had many critics. Immanuel Kant considered utilitarianism as providing a “wavering and uncertain standard” for action (Mappes & DeGrazia, 1996; p. 16). To remedy this situation, Kant proposed what is known as the **categorical imperative**, or supreme rule, that should govern actions. Simply expressed, the categorical imperative is to act only on that maxim (or rule) that can be willed to become universal law (Kant, 1981). In other words, the rule used to guide actions should be one that could be followed in all other similar situations. This concept is called **universalizability** because it refers to the concept that the rule should be generalizable to other situations. For example: Is telling a lie to a client ever acceptable? To answer this question, an individual would have to decide if telling lies to clients was acceptable in other situations. Since telling the truth is better in most situations, lying would not be acceptable in any specific instance.

Kant identified several formulations of the categorical imperative. Another formulation that is of interest to health care providers is to always act to treat humanity, either yourself or others, as an end rather than as a means (Kant, 1981). This formulation recognizes that because of their rationality, human beings have inherent worth and dignity. Therefore, we should have respect for all persons, including ourselves. Also, we should never use others simply as a means to an end. For example, clients are a means to our livelihood as nurses. If we care for clients simply as a means to earn a paycheck, we are treating them as only a means. However, if we treat clients with the respect they deserve because they are human beings with inherent worth, then even though clients help us earn a living (means), we are also treating them as an end as well. While Kant’s theory provides clear guidelines for action in many situations, it is sometimes criticized for offering such a rigid system of choice that it is difficult to follow.

Other deontologists feel that a supreme rule, such as the categorical imperative, is insufficient to guide decision making in all ethical situations, particularly when a conflict of duties exists. W. D. Ross (1994) proposed the concept

of conditional duties, or *prima facie* duties, as a guide for correct action. Rather than asserting that there is a supreme duty, a *prima facie* duty is a conditional duty that can be overridden by a more stringent duty. Ross suggests that some duties are derived from previous acts, such as a promise; acts done by others for which we may owe an obligation; special relationships to families or employers; or acts that serve as a mechanism for personal growth or for benefit to others. From the perspective of Ross, the moral decision-maker would decide which obligation or duty was the most important and then act accordingly. For example, as nurses, we have an obligation to follow hospital policies. However, we also have a professional obligation to render safe care for clients. When working in an understaffed environment, a nurse may feel that safe care cannot be given, potentially putting clients at risk for harm. The nurse would then have to choose which obligation was the most stringent, either following the institutional policy of accepting assignments given or rendering safe care to clients. The nurse would act on the basis of which obligation was perceived to be the most important.

Virtue Ethics

A **virtue** is a character trait that is valued; a moral virtue is a trait that is morally valued. **Virtue ethics** focus on the personal characteristics of the moral agent or person and the way in which these virtues guide moral action. Virtue ethics are attributed to Aristotle (Singer, 1994), the ancient Greek philosopher who believed that a virtuous life would be a happy one. According to Aristotle, all living things are endowed with certain capacities or potentialities. For human beings to live a happy life, they must live a life that is distinctive from other creatures through the development of intellectual and moral virtues. Intellectual virtues enable humans to discover and recognize rules of life that should be followed. Moral virtues deal with feelings, emotions, and impulses that make the effective use of intellect possible.

Virtues are not attributes that humans are born with, but characteristics that are perfected. Aristotle proposed the **doctrine of the golden mean** as a guide for virtue development. This doctrine suggests that many virtues develop at the midpoint between extremes of less desirable characteristics. For example, one is not born brave, but becomes brave by conquering fear. However, if fear is diminished too much, then dangerous risks may be taken. The virtue of courage demonstrates the doctrine of the golden mean: too little courage would make us excessively fearful, but too much would place us in extreme danger. The virtue of courage would be the midpoint between those two extremes. Virtues that may be useful for health care providers to embrace include compassion, benevolence, respectful, honesty, and kindness. Beauchamp and Chil-

Critical Thinking

Virtue Ethics and Respect for Clients

Virtue ethics suggests that respectfulness is a worthwhile virtue to be embraced by nurses. How would acting on the virtue of respectfulness make a difference in the way you treat clients and their partners during the perinatal period? Would you listen to client concerns or suggestions differently? What special considerations might be needed for clients with different cultural backgrounds?

dress (1994) suggest that virtue ethics can serve as a useful adjunct to other theories and principles of ethics that enable individual perspectives on both the right action and the right motive.

Nursing Ethics

As bioethics has developed, nursing has begun to question whether there is a unique set of ethics for nursing and how those ethics might be embodied. Based on the work of Noddings (1984), who helped to link caring to ethics; Benner and Wrubel (1989), who linked caring and nursing in a very practical sense; and others, an ethics of caring that is applicable to nursing practice has emerged. The **ethic of care** is a perspective that recognizes the personal concerns and vulnerabilities of clients in health and illness. Nurses, operating under the tenets of an ethic of care, would be willing to provide care to achieve therapeutic goals without expectation of reciprocity, because of a desire to be a caring individual.

Gadow (1988) suggests that nurses have a covenant to care by alleviating another's vulnerability. Wicker (1988) indicates caring may help bring clients' lives into balance, even if curing cannot occur. Benner and Wrubel (1989) propose that caring creates possibility because it focuses on others and identifies personal concerns. To be considered moral, caring must be an overriding value to guide action and apply to all persons in similar circumstances. Additionally, caring considers the welfare of others and incorporates empathy, support, and compassion (Fry, 1988). An ethic of care enables nurses to respond to others as worthy, with no expectation of reciprocity (Benner, Tanner, & Chesla, 1996). Bishop and Scudder (1996) propose that rather than merely applying principles, the moral sense of nursing is articulated through the "caring presence of nurses that achieves the therapeutic intent of nursing practice" (p. xi).

According to Noddings (1984), the ethical self exists in relationship with others. Caring relationships are grounded in an ideal vision, in which we hold our best selves. Caring involves reciprocity; our desire to care is rooted in previous relationships, where others have cared for us and we have cared for others. Moral behavior arises from a natural impulse to care, preserving the fundamental goodness of these experiences. Ethical caring occurs because of the desire to be a caring person. Caring relationships permit the caregiver to view the world from the perspective of the recipient of care. From that perspective, the one caring is able to set aside personal agendas and place herself or himself at the disposal of the recipient.

Benner, Tanner, and Chesla (1996) perceive that the ethical and clinical knowledge of the nurse are inseparable and are learned experientially. Through experience, nurses develop an ethical comportment that encompasses a practical “know-how” of relating to clients in a respectful and supportive way. The ethical comportment aids in protecting those who are vulnerable, promoting growth and health, or fostering a peaceful death. These skills can be developed within a socially based practice, through the stories of others, and through other experiences, permitting nurses to move from the status of a novice to that of a skilled practitioner (Figure 5-2).

Nursing ethics are therapeutic in the sense that they promote the well-being of clients “Nursing ethics should evoke thinking about concrete practice in ways that help nurses individually and collectively to fulfill the moral sense of nursing” (Bishop & Scudder, 1996; p. 135). Nurses, working from a framework of caring, should consider the individual needs of clients and attempt to respond in a caring, personalized manner. Advocacy on behalf of clients should be an example of engaging in a therapeutic ethic of nursing. Treating clients holistically—

Figure 5-2 Consultation with health care team members is an important part of maintaining an autonomous practice. Good communication promotes safe care and facilitates discussion of ethical issues.

not simply as a body in need of repair—is another way of engaging in ethical nursing practice. Recognizing that nursing is practiced in a context with many players, including administrators, physicians, and other care providers, nurses should feel a particular sense of commitment to clients and their families and be an advocate on their behalf.

Ethics and Holism

Holistic ethics is a philosophical perspective that merges the concept of unity and wholeness of all people and nature (Keegan, 1995). Acts are performed by people who have a desire to do good and to contribute to the unity of the self and the universe. Correct acts are ones that reflect the enlightened consciousness of the individual and are judged by the effects that the act has on the nature of the individual and the larger self. From this perspective, holistic ethics encompasses elements of both utilitarian and deontological thinking. Outcomes are important, but there is also a concern for the intrinsic nature of the act.

The *Code of Ethics for Holistic Nurses* provides guidance for action and identifies responsibilities for self and others (American Holistic Nurses Association, 1995). The code expresses that nurses have fundamental responsibilities for health promotion, facilitation of healing, and alleviation of suffering. It suggests that nurses have an obligation to self, demonstrated by modeling health behaviors and achieving harmony in life. Nurses have a primary responsibility to clients that reflects an awareness of the holistic nature of human beings. Nurses are responsible for cooperating with co-workers and maintaining competence. Nurses practicing within a holistic framework should work to meet the health-related and social needs of

Critical Thinking

Caring and Personal Agendas

According to the tenets of an ethic of care, nurses should be able to set aside their personal agendas when caring for clients. This may be difficult to achieve. Is it possible to put aside personal agendas and focus on the needs of the client? How might you go about leaving your personal agenda behind when giving care? What are the risks of setting aside a personal agenda? What are the potential rewards?

the public and facilitate healing by manipulating the environment to promote peace, harmony, and nurturance.

Ethical Principles

Four major principles guide ethical thinking in nursing practice. These include respect for autonomy, nonmaleficence, beneficence, and justice. These principles may be used in conjunction with the theoretical perspectives discussed as guidelines to help resolve ethical dilemmas. Each of these ethical principles is equally important in the consideration of ethical dilemmas, although some dilemmas may cause us to focus more emphasis on one principle than another.

Respect for Autonomy

Autonomy refers to individual independence in holding a particular view, making choices, and taking action based on values and beliefs (Beauchamp & Childress, 1994). Respect for autonomy requires that others be treated in a way, such as noninterference in decision making or actions, that enables autonomous action. The concept of respect for autonomy recognizes the inherent worth of the individual and that a competent human being is qualified to make decisions in his or her own best interests. Autonomy should encompass aspects of free action, which are voluntary and intentional, and authenticity, in which choices are congruent with the person's attitudes, values, and life plans (Miller, 1981). For autonomous choice to occur, individuals must be aware of the alternatives and consequences. The concept of informed consent is firmly rooted in the principle of respect for autonomy and is discussed later.

Although respect for autonomy implies that individuals have the right to make choices, it also focuses on the relationship of individuals to the communities in which they live (Figure 5-3). For example, while individuals can

Figure 5-3 Providing information plays a significant role in promoting the autonomy of pregnant women and their families. (Photo courtesy of Bellevue, The Women's Hospital, Niskayuna, NY.)

anticipate that community members will respect their autonomy, they also must respect the autonomy of others. We are not given license to perform any act simply because we have autonomous choice. In fact, there are some specific instances where autonomy may be limited. Autonomy of children is routinely restricted because parents believe a child's welfare is promoted by making decisions on behalf of the child. An individual may not be competent to make decisions. For example, clients who are confused or lack the mental capacity to make decisions may have limited autonomy. Another reason for limiting autonomy is when an action could generate harm or when benefit would be derived from restricting autonomy (Mappes & DeGrazia, 1996).

Nonmaleficence

Nonmaleficence refers to the concept of preventing harm to others and is an important principle for nurses. **Harm** is the interference with the mental or physical well-being of others (Beauchamp & Childress, 1994). Many basic rules are nonmaleficent, including not killing, not causing pain, not disabling, and not depriving of freedom. Nonmaleficence encompasses both harm and the risk of harm. The harm may be either intentional or unintentional. As nurses, we have the obligation to exercise due care in professional practice so that unintentional harms do not occur. **Due care** is a legal and ethical standard of performance by which professionals abide. As professionals, nurses must possess sufficient knowledge and skills and render care that is cautious, diligent, and thoughtful.

Critical Thinking

Autonomy

Sometimes competent clients make decisions that may be potentially harmful. When this situation occurs:

- Can health providers ever overrule the client's decision? If so, under what circumstances?
- How would you work to promote this client's autonomy?

Beneficence

Beneficence means doing good and may include: prevention of harm, removal of evil, and promotion of good (Frankena, 1973). As nurses our goal is to promote the welfare of clients in our care, so beneficence is a key to our actions. Because the goods and services we have to offer are sometimes limited by our resources, unlimited beneficence is not always possible. In these instances, combining the principle of beneficence and the principle of justice may be helpful.

An issue related to beneficence is what happens when the health care provider's desire to promote client welfare clashes with the client's autonomous decisions. **Paternalism** is the interference with the liberty of another in which the interference is justified by promoting the well-being of that individual (Beauchamp & Childress, 1994). One example of paternalism would be a situation in which a person coerces another to do something that is perceived to be beneficial. This situation frequently causes conflict in health care. For example, maternal-child nurses possess knowledge and expertise about care during and after pregnancy. Education and experience allow these nurses to make suggestions to clients about behavioral modification that should be made to promote a healthy pregnancy. These might include recommendations regarding diet, exercise, smoking, and alcohol intake. How should nurses respond when clients fail to make the changes suggested, even when clients know the potential consequences of failing to modify behavior? The principle of autonomy would suggest that nurses support the client's choices, whereas the principle of beneficence would suggest that nurses override the mother's autonomy to ensure that sug-

gested changes are made. The second choice could be considered paternalistic in nature.

Justice

Justice refers to how we divide benefits and burdens in our society (Beauchamp & Childress, 1994). For example, health care is a benefit that promotes the health and well-being of individuals in our society. However, paying for health care is a burden. Because our health care resources are not unlimited, we must decide on the fairest system for allocation of both the benefit and resources of health care and the burden of paying for care. A basic principle of justice is that, in distribution of resources, equals should be treated equally and nonequals treated unequally. In health care, pregnant women need access to prenatal care. So all pregnant women should be treated equally in terms of access to care. However, some pregnant women experience greater complications during their pregnancy, causing them to need more sophisticated care. According to this rule, these women would receive additional care not given to women who do not need them (i.e., nonequals are treated unequally).

Depending on the benefit or burden to be divided, the material principles of justice may be invoked to decide how to distribute society's goods. The **material principles of justice** provide a set of guidelines that can be used to justify the distribution of benefits. They offer the following concepts to defend distribution decisions:

- ✦ Equality, in which everyone receives an equal share
- ✦ Need, for which those who need more receive more
- ✦ Contribution, in which goods are received in proportion to productive labor
- ✦ Effort, in which the amount of work is rewarded
- ✦ Merit, for which rewards are given according to achievement
- ✦ Free market exchange, in which wealth and income would be derived from a natural distribution of talent and abilities (Beauchamp & Childress, 1994)

Critical Thinking

Client Request for Information about Treatment Options

A client who is in her second pregnancy has been told by her physician that she must have a second cesarean section with this pregnancy because she had one for her first birth. She asks you if repeated cesarean sections are always done for subsequent births. You know that her physician always does this without giving clients an option. Other physicians you know do not do this. What would you tell her? How would the principle of respect for autonomy influence your thinking?

Veracity and Fidelity

Other principles or rules that affect ethical decision making and conflict resolution include veracity and fidelity, both important concepts for nurses. **Veracity** is truthfulness: nurses are truthful with clients in their care. **Fidelity** is keeping promises: if nurses make promises to clients, they keep them. Both these rules reflect respect for others and are essential for establishing trust in relationships.

Code for Nurses

Another guide for nurses in making ethical decisions is the *Code for Nurses with Interpretative Statements* published

Research Highlight

The “Real World” of Hospital Nursing Practice as Perceived by Nursing Undergraduates

Purpose

This study investigated expectations of senior nursing students regarding the ethical dimensions of their nursing role. Nurses who are able to maintain their personal and professional integrity are less likely to burn out. However, new graduates are vulnerable to role compromise.

Methods

Twenty-three senior baccalaureate students completing their program were interviewed and asked to complete written clinical logs regarding professional values, guidelines for conduct, application of a professional code, and thoughts about the nature of future nursing practice. Data collected were subjected to the grounded theory methodology of constant comparison and refinement of interview questions based on prior data analysis.

Findings

Most students were realistic about their future practice but felt relatively powerless as they entered practice. Students indicated a commitment to the principle of respect for clients, which they would promote through listening, accepting clients, providing information, and providing a climate for self-determination. Students felt guilty if they did not advocate for clients and also expressed disappointment when other nurses failed to do so.

Nursing Implications

New graduates lack confidence in their role as ethically competent nurses who can advocate for clients. To reduce the frustration that might result from compromise of integrity, a supportive environment that permits students to build their skills and confidence in their capabilities would be beneficial. Constructive feedback and a transition to greater self-reliance on self-evaluations would assist new nurses in accepting professional responsibility and accountability.

Kelly, B. (1993). The “real world” of hospital nursing practice as perceived by nursing undergraduates. *Journal of Professional Nursing*, 9(1), 27–33.

by the American Nurses Association (1985). **Codes** represent people’s acceptance of the obligations and responsibilities entrusted to them by society. The purpose of codes is to provide guidance for action, although codes are not necessarily binding. The *Code for Nurses* has evolved over the past 40 years and currently includes 11 principles for nursing practice: The American Nurses Association Code (Box 5-1) clearly identifies that the fundamental principle of respect for persons is central to nursing practice. According to the code, nurses are to support human dignity and to safeguard the client’s welfare.

Ethical Decision-Making Model

Many ethics texts or articles suggest a series of steps that can be used to resolve an ethical dilemma (Davis et al., 1997; Thompson & Thompson, 1990; Silva, 1990; Waithe, et al., 1989). These steps encourage individuals to focus on the situation, gather information, apply ethical theories and principles to guide reasoning, and propose actions for dilemma resolution. By engaging in critical thinking, guided by the model, dilemma resolution can occur.

Box 5-1 American Nurses Association Code for Nurses

1. The nurse provides services with respect for human dignity and the uniqueness of the client, unrestricted by considerations of social or economic status, personal attributes, or the nature of health problems.
2. The nurse safeguards the client's right to privacy by judiciously protecting information of a confidential nature.
3. The nurse acts to safeguard the client and the public when health care and safety are affected by the incompetent, unethical, or illegal practice of any person.
4. The nurse assumes responsibility and accountability for individual nursing judgments and actions.
5. The nurse maintains competence in nursing.
6. The nurse exercises informed judgment and uses individual competence and qualifications as criteria in seeking consultation, accepting responsibilities, and delegating nursing activities to others.
7. The nurse participates in activities that contribute to the ongoing development of the profession's body of knowledge.
8. The nurse participates in the profession's efforts to implement and improve standards of nursing.
9. The nurse participates in the profession's efforts to establish and maintain conditions of employment conducive to high-quality nursing care.
10. The nurse participates in the profession's effort to protect the public from misinformation and misrepresentation and to maintain the integrity of nursing.
11. The nurse collaborates with members of the health professions and other citizens in promoting community and national efforts to meet the health care needs of the public.

Although the number and sequence of steps may vary, similarities exist among models. A composite framework incorporating common aspects of decision-making models can be found in Box 5-2. One of the things that the framework requires is ascertaining which ethical theories and principles are to be applied for dilemma resolution. Additionally, the decision-maker must determine how to weight the theories and principles, i.e., which theory or principle should be the most influential in deciding the correct action? This process is necessary because theoretical perspectives or ethical principles may be in conflict with one another.

To apply the model to a dilemma, nurses should review the case with which they are dealing by responding to the suggested questions. Sometimes nurses feel impatient with having to stop and answer questions, particularly when they are in a situation that may be emotional or frustrating. However, efforts will be rewarded because issues will be clarified, and reasoning based on ethical principles and theories offers perspectives to approach the problem and helps provide a rationale for action. Unfortunately, nurses sometimes find themselves engaged in dilemmas that require resolution over short periods—from seconds to minutes. For this reason, it is helpful to discuss case scenarios with others and practice using the ethical decision-making framework, to increase awareness of is-

Nursing Tip

GETTING SUPPORT WHEN AN ETHICAL DILEMMA OCCURS

Sometimes you may find yourself dealing with an ethical dilemma. In addition to using the dilemma resolution format suggested in this chapter, you may feel that you need some additional support. Support may come from several places.

- There may be administrative support on your nursing unit or clinic.
- Some institutions have a nursing ethics committee for the purpose of providing a forum for nurses to discuss ethical dilemmas they encounter.
- Many institutions have more generalized ethics committees, which are multidisciplinary bodies that discuss and make recommendations about actions that would be appropriate to resolve a dilemma.

Find out what resources your institution has and how nurses can use them.

Client Education

Advance Directives

Ordinarily, nurses specializing in women's health care do not think about teaching clients about advance directives. However, completion of these documents helps clients ensure that their wishes are carried out in circumstances in which they are no longer considered competent. Knowledge of advance directives helps both providers and clients to consider the encompassing totality of the life cycle from birth to death. Consider the following teaching points:

- A Living Will, or a Directive to Physicians and Family or Surrogates—as it is known in some states, permits individuals to indicate their wishes about the medical care that they want to receive in the event of a terminal illness or irreversible condition.
- A medical power of attorney (sometimes known as a durable power of attorney for health care) permits individuals to appoint someone to make decisions regarding medical care when he or she is no longer able to do so.
- Each state has specific laws regarding completion of advance directives. Information regarding specific regulations regarding advance directives can be obtained from health care institutions or from organizations, such as Choice in Dying.
- Copies of a living will or medical power of attorney should be given by the client to the person designated as the decision-maker and to health care providers.
- Having these documents in place helps to ensure that wishes are followed, even if client is no longer competent.

sues and potential resolutions. A case study applying the decision-making framework is provided later in this chapter.

Selected Dilemmas in Maternal-Child Practice

Several dilemmas and controversial issues relating to maternal-child practice are now discussed.

Box 5-2 Ethical Decision-Making Framework

Context

- Who is involved and how are they involved?
- What is the setting of the situation?
- What other information is needed for dilemma resolution?
- What personal beliefs of the nurse may have an impact on this situation?

Clarification of Issues

- What are the ethical issues involved?
- Who should decide the issue?

Identification of Alternatives and Potential Outcomes

- What are the possible alternatives and the potential outcomes of each?

Ethical Reasoning

- What ethical theories and principles have bearing on this situation? How?
- Should some principles or theories be given greater weight in the decision-making process? Why?
- What legal or social constraints are factors in this decision?
- What special obligations might be present in my role as a nurse?

Resolution

- Based on the reasoning above, what is the best action in this situation?
- What would be the best strategy for carrying out this action?

Evaluation

- What were the outcomes of the action?
- Should the same action be chosen when a similar dilemma arises in the future? Why or why not?

Abortion

Abortion, the willful or purposeful termination of a pregnancy, usually within the first trimester, is a controversial issue. The ethics of abortion have been debated, especially considering the question: “up to what point of fetal development and under what circumstances is abortion morally

acceptable, if ever?” Individuals with a conservative view toward abortion would propose that abortion is always wrong. A more liberal perspective suggests that abortion should be available to those who desire to terminate their pregnancies, while a moderate view would advocate abortion in selected instances.

Consider some of the following situations: Mary G., an unmarried 16-year-old, discovers she is pregnant; after amniocentesis disclosed the presence of Down syndrome, Shirley B., a 38-year-old woman, is considering terminating her pregnancy; although she did not report it, Fay C. was raped 3 months ago and is now pregnant. Each of these is a scenario in which a woman might want to consider an abortion. However, decision making in this process can be complex and lonely to navigate. Maternal-child nurses often find themselves in a position of providing support for women who are making decisions about whether to terminate a pregnancy. The client education box suggests interventions for nurses working with clients who are considering abortion.

Since the 1973 U.S. Supreme Court decision in the case of *Roe v. Wade*, the right of women to choose abortion has been available in the United States and the debate over the ethical implications has continued. The *Roe v. Wade* decision permitted women to choose abortion within the first trimester, but permitted states the option to regulate abortion to protect the life of the mother during the second trimester. States were also permitted to regulate or prohibit abortion after 28 weeks of pregnancy—the age

of fetal viability. Subsequent Supreme Court decisions (*Beal v. Doe* and *Mahe v. Roe*) suggested that states were not required to spend federal funds to pay for elective abortions, thereby restricting access to abortion for women who do not have money.

Despite persistent efforts to limit abortion through denial of Medicaid funding for abortions, gag rules prohibiting care providers who are working in clinics that receive federal funding from offering abortion as an option to pregnant women and (unsuccessfully) proposed legislation to limit late-term abortions, abortion remains a legal option for women in this country. Although the U.S. Supreme Court recognized personal privacy derived from constitutional amendments as a legal basis for permitting women and physicians to elect pregnancy termination, ethical debate continues to be divisive. Some opponents of abortion feel that life begins at conception, and therefore, it deserves protection similar to that extended to other humans. Opponents feel abortion is killing and deprives the victim (fetus) of the basic right to life, including the experiences, activities, and enjoyment constituting an individual's future (Marquis, 1996). Those who support the right to choose abortion argue that the fetus does not necessarily have the right to use a woman's body during pregnancy (Thompson, 1996). Another argument supporting the right to choose abortion suggests that there are two senses of being human—a biologic one derived from genetics and a moral one that is contingent on being a full-fledged member of the moral community. If one uses the moral sense of being human, a fetus would never qualify for equal protection of life (Warren, 1996).

Client Education

Working with Clients Considering An Abortion

- Provide relevant information about the pregnancy when it becomes available.
- Remember that religious beliefs and effects on other family members may influence abortion decisions.
- Allow clients time to make the decision. A clinic or office visit is usually not sufficient time for most clients.
- Identify potential sources of client support and assess the adequacy of these sources.
- If clients choose to have an abortion, help them recognize that it is normal to feel a sense of loss after the procedure.

Maternal-Fetal Conflict

The following situations are examples of maternal-fetal conflict:

- ✿ Annie Z., a pregnant client in your care, continues to use cocaine in spite of education about the harmful effects on the fetus and referrals to a drug abuse program.
- ✿ Bess Y. is still smoking during her pregnancy even though she is aware the habit can adversely affect her pregnancy.
- ✿ As a result of extended labor, Betty O. has been scheduled for a cesarean section; however, Betty wishes to continue with the labor process and have a vaginal delivery.
- ✿ During her second trimester, Nancy D. has been told that she needs to have intrauterine fetal surgery. She considers the procedure risky and wants to refuse.

In each of these instances, pregnant women are being asked to modify behavior or to submit to treatment to benefit their developing fetus. Although most pregnant

Critical Thinking

Late-Term Abortions

Reflect on how you feel about clients who want an abortion during the second trimester when they discover a major defect in the developing fetus? How would you support this woman and her family? How would you manage this situation if the client's decision was different than the decision you would make?

women would say they want a healthy baby, modifying behaviors or submitting to unwanted intervention during pregnancy is not easy. Maternal-fetal conflict occurs when the interests of a pregnant woman are divergent from the interests of the fetus. For example, a client who smokes may have difficulty stopping a habit that she knows is unhealthy for her fetus. One role of health care providers is to make recommendations that in their opinion are beneficial to the pregnancy. When the pregnant woman disagrees, conflict is inevitable. One way of describing this situation is that there is a conflict between the ethical principles of respect for autonomy (the pregnant mother's decision) and beneficence (what health care providers perceive as beneficial to the fetus). Maternal-fetal conflict has become a more prominent problem with the advent of technology that enables fetal diagnosis and management. The ethical question becomes whether a pregnant woman and her fetus represent one client, and the pregnant woman serves as the decision-maker, or the mother and fetus are really two clients, each with rights and privileges that may compete with one another. In a two-client model, decision-making control could be removed from a pregnant woman and given to another individual who would be responsible for making decisions on behalf of the fetus.

Consider the situation in which a physician has told a woman that she must have a cesarean section and she refuses the intervention. In such a time-limited and potentially risky situation, attempts to use the legal system for problem resolution have ensued. In fact, court-ordered cesarean sections have occurred (Lindgren, 1996). Unfortunately, such court-ordered treatments are coercive and create a conflict between the perceived interests of the woman and the fetus (Lindgren, 1996).

Three competing values may be present in maternal-fetal conflicts: autonomy of the pregnant woman, protection of the fetus, and protection of the common good (Andrews & Patterson, 1995). Ordinarily the right of the person to make autonomous decisions is the most highly

valued. The principles of nonmaleficence and beneficence are used to justify mandating intervention for protection of the fetus. Another argument supporting fetal intervention is that if a woman has chosen to continue a pregnancy, then she has a responsibility to make her pregnancy and therefore her fetus as healthy as possible. A woman's failure to do so may leave her open to more coercive tactics. An argument to support the mother's autonomy is that the fetus maintains its life though the woman's body and as such is inseparable from it. Therefore, a pregnant woman should have sufficient autonomy to make decisions on her own behalf and on behalf of the fetus. Pregnant women do have a responsibility to protect their fetuses, but it does not follow that coercive public policies should force them to do so. Chervenak and McCullough (1992) suggest that a combined approach, based on the viability of the fetus, be a guide in consideration of maternal-fetal conflict. Viable fetuses that could survive outside the uterus should be treated under a beneficence-based obligation to promote fetal welfare. However, if the fetus was pre-viable because of gestational age or not viable because of the severity of a defect, then the mother's autonomy should prevail in decision making.

Whether nurses support the one-client or two-client model of the pregnant woman and fetus, they should work to maximize the client's understanding of behaviors that support good fetal outcomes. They should continue to work to get substance abusers into treatment programs. If a woman is refusing a cesarean section, care providers should seek to find out why. A better understanding may facilitate a resolution that is agreeable to both mother and care provider. Mishkin and Povar (1993) suggest that health care decision making is a joint enterprise between

REFLECTIONS FROM FAMILIES

"It was like a nightmare. I found out that my pregnancy might not be normal and then had to have an ultrasound. Waiting to find out the results was really hard . . . I couldn't sleep. Once I knew for sure there was a problem, I had to decide what to do—whether to keep the pregnancy—and that was even harder than waiting. I wanted to do the right thing, but making the decision to terminate the pregnancy was hard, even though I always have thought of myself as pro-choice."

Case Study/Care Plan

APPLICATION OF AN ETHICAL DECISION-MAKING FRAMEWORK

Marcella G. is a 26-year-old woman who is 5 months pregnant. She has been coming to your clinic for prenatal care since her third month of pregnancy. On her initial visit, another nurse identified that Marcella has a history of active cocaine use. At that time, counseling was given regarding the destructive effects that cocaine could have on the fetus and mother, and a referral to a drug treatment program was made. Now, 2 months later, you discover that the referral appointment has not been kept and that Marcella continues to use cocaine.

Context

Marcella, the client, and the nurse are the primary players. The fetus may be considered a player, if the two-client model, consisting of the fetus and the mother, is used, rather than the one-client model, in which the mother is responsible for decisions on behalf of both herself and the fetus. There may be other health care providers, such as a nurse practitioner, physician, or social worker, who would also be concerned about the continued drug use. The setting is a prenatal clinic. Your personal beliefs are also important: you may feel that maintaining the autonomy of pregnant clients is important or that protection of the fetus has priority.

Clarification of Issues

You must decide your action based on the information that drug use continues. You feel that expectant mothers should make autonomous decisions, but you also recognize that the fetus is at physiologic risk if drug use continues. While the client is a participant in the dilemma, the nurse should decide what her (own) next actions should be.

Identification of Alternatives and Potential Outcomes

1. The nurse could do nothing and let the clinic visits continue, with Marcella using drugs throughout her pregnancy. The potential outcome is that Marcella would continue her prenatal care but the fetus would suffer harm because of the drug use. Also, Marcella would not receive help for her addiction.
2. The nurse can try to persuade Marcella to enter a drug treatment program for the remainder of her pregnancy. This action would support Marcella's autonomy and promote a better pregnancy outcome. Trust for the nurse-client relationship would be maintained.
3. The nurse could report Marcella's continued drug use and see if she could force Marcella to enroll in a treatment program. Coercive behaviors would negate Marcella's right to privacy and autonomy. Trust in the nurse-client relationship would be eroded. However, the fetus would benefit from a drug-free environment.

(continued)

Critical Thinking

Maternal-Fetal Rights: One-Client Or Two-Client Model

Do you perceive pregnant women to fit the one-client or the two-client model? Why?

caregivers and their clients, in which client autonomy and professional standards of care are complementary. In the instance of refusal of fetal surgery, procedures are not routine and involve risk thus the maternal considerations should be thoroughly addressed. Care providers should seek to provide accurate information and support the mother's autonomous decision.

Genetic Mapping

As mapping of the human genome continues, rapid advances are being made in the nature and amount of information that is available to health care consumers. Genetic

Ethical Reasoning

If a two-client model—where the mother and fetus have an equivalent moral status—is assumed, arguments would center around the obligation the mother has to the fetus. If you approached this problem from a utilitarian perspective, you would try to examine the action that would produce the best possible outcome for all concerned, but with a real concern that the mother meet her fetal obligations. Using a one-client model, the autonomy of Marcella in promoting the welfare of the fetus would be important. The nurse favoring a fetal-rights stance would believe that if Marcella wanted to procreate, then she has a special obligation to the fetus. Reporting Marcella and forcing drug program enrollment would probably improve fetal outcome. However, the outcome would be better for all three parties—mother, fetus, and nurse—if the nurse could convince Marcella to enroll in the program on her own volition. The principle of respect for autonomy would help to focus on the unity of the mother and fetus and their mutual welfare. The body of the mother is integral to maintaining fetal safety. Doing nothing to intervene in the process would be the worst option because both the welfare of the mother and the fetus are negated. From a deontologic perspective, the nurse would have to decide the correct action that promotes the autonomy and welfare of pregnant women who use drugs. If the virtue of integrity is considered paramount for practice, the nurse must intervene. The second option of voluntary entry into a drug program would preserve professional integrity of the nurse as well as support maternal autonomy and promote maternal and fetal welfare. Using an ethic of care, the nurse would feel an obligation to promote client well-being and advocate on behalf of the client. This action would be further supported by the *Code for Nurses*, because the nurse would act on behalf of the client to promote the welfare of mother and fetus in the context of respecting client choices. Coercion would be difficult under these circumstances. One legal consideration would be Marcella's parental status if she has positive results on a drug screen at the time of delivery. Potentially, the child could be placed in custody until drug rehabilitation is successfully completed. In this circumstance, if Marcella does not remain drug-free, she could permanently lose custody of her baby.

Resolution

The second option of voluntary entry into the drug program is the best option of the three. To try and coercively modify behavior would be counterproductive. Efforts to maintain the nurse-client relationship should continue. Blaming and hostility on the part of the nurse discourages further efforts to seek help.

Evaluation

Ideally, the outcome would be that Marcella entered the treatment program. Even if Marcella did not initially agree to enroll, the nurse should continue to monitor her pregnancy and continue to encourage help-seeking behaviors. Care should include education, treatment referral, complication prevention, and promotion of optimal parenting.

mapping identifies individual genes, their function, and DNA sequences. It is estimated that mapping of the human genome will be completed by the year 2005, with a complete identification of 70,000 to 100,000 genes (Jones, 1996). Many benefits can potentially be derived from this newfound knowledge. Preventive treatments may be available in more instances, and cures for lethal diseases may be found. For example, parents at risk for Huntington's disease—a progressive neurologic disorder—could elect to have preimplantation genetic testing. In this testing, an embryo developed through *in vitro* fertilization would have a genetic analysis completed on one

or two cells before cell differentiation. Only embryos without the gene for Huntington's disease would be implanted.

However, genetic information could also be used to great detriment. Insurance agencies or employers may discriminate against individuals or groups who carry particular genes. A central ethical issue in genetics is how to balance the need for genetic information with an individual's right to privacy, particularly when the health care system is moving toward a client-based longitudinal electronic health record (Gostin, 1995). A longitudinal health record would be an electronic database containing all data

Critical Thinking

Pregnancy Termination for Genetic Defects

Reflect on what you believe about genetic defects.
Are there defects that should always be terminated?
Are there other genetic defects that never should be terminated?

relevant to an individual's health status over a lifetime. Such a database would be available to a wide variety of individuals or institutions, permitting a loss of confidentiality regarding personal health information. Potentially, an individual could lose health benefits or employment or face stigmatization if sensitive genetic information were disclosed.

In addition to privacy, there are other issues related to genetic testing. If testing resources are inadequate—which is often the case with a new technology—it may be difficult to determine who should have priority for testing. Should testing be done for genetic disorders that are currently untreatable? Or should testing be done for parents who wish to choose the gender of their child? Prenatal testing can also create agonizing choices, such as when parents face the choice of whether to terminate a pregnancy because genetic screening indicates the presence of a defect (Penticuff, 1996).

Although many of these questions are difficult to answer, some suggestions about how to approach genetic screening are offered (Penticuff, 1996). Before screening, consideration should be given to the benefits that will be derived and the therapeutic capabilities of treating identified disorders. Laboratory facilities must be adequate and tests should be reliable. Counseling should be available before and after testing so that the need and appropriateness for testing can be explained and the explanation of the findings and their implications can be given. Genetic screening should be voluntary, done with the informed consent of the individual. Findings should remain confidential, disclosed only with the consent of the person tested. However, to ensure confidentiality of information, rigorous safeguards must be legislated; otherwise, insurance providers could secure information and deny coverage (Penticuff, 1996; Gostin, 1995).

Reproductive Technology

The availability of reproductive technologies has produced a new set of ethical dilemmas. These technologies encompass a broad range of techniques, including *in vitro* fertil-

ization, gamete intrafallopian transfer, zygote intrafallopian transfer, ovum transfer, embryo adoption, embryo hosting, and surrogate parenting (see Chapter 14 for a discussion of these techniques). Questions about the use of reproductive technologies have produced a number of court cases because ethical resolution of issues is lacking. The Roman Catholic Church has rejected many of these techniques because of the belief that procreation is the function of marriage and because multiple zygotes must be developed to secure a viable one (Hall, 1996). An alternate perspective supporting the use of technology in insemination is that sexual intimacy and procreation are separate activities (Bandman & Bandman, 1995).

Surrogate motherhood, in which one woman contracts to carry a pregnancy to term for another woman, also poses many problems. Cases have ended in court proceedings, with the surrogate mother not wanting to give up the newborn to the biologic father and his wife. In another instance, none of the contracting parties wanted to keep a newborn with multiple disabilities. Who should be responsible for the emotional welfare and cost of care for this child? At issue is the surrogate mother's right to make an agreement to bear a child and whether that agreement can be broken. Beneficence is a useful ethical principle when considering the welfare of the child born into a surrogate situation.

Unanswered questions surrounding reproductive technologies include:

- ✱ To whom should reproductive technologies be available—all who request them or only to married individuals or to those with adequate financial resources?
- ✱ Who has ownership of the remaining frozen embryos—the father, the mother, or the potential infant who would be represented through state protection? Lawsuits have occurred during divorces to prevent one spouse from obtaining ownership of frozen embryos.
- ✱ Should donors remain anonymous and can they be compensated?

HIV Status Determination

During pregnancy, women infected with untreated human immunodeficiency virus (HIV) have a 25% to 35% chance of transmitting the infection to their unborn child. Transmission can potentially occur via the placenta, during delivery, or through breastfeeding. While many states have instituted anonymous testing of all newborns to establish the prevalence of HIV infection, prenatal testing is not mandated. Prenatal testing has become a more urgent issue since treatment with the antiviral drug zidovudine (AZT or ZDV) has decreased perinatal transmission of HIV (Downes, 1995).

Critical Thinking

HIV Testing for Pregnant Clients

The issue of HIV testing for all pregnant women is controversial. One issue surrounding mandatory testing is what would be done for women who are found to be HIV-infected. Treatment with AZT has been found to reduce the incidence of perinatal transmission. Should pregnant women who are infected be required to submit to treatment to reduce the possibility of HIV transmission to the fetus? What consideration should be given to the wishes of the pregnant woman regarding treatment preferences?

The ethical conflict of HIV screening is related to the client's right to privacy and autonomy to make decisions regarding care versus the benefit that might potentially be derived from accurate knowledge regarding HIV status of the population. Advantages to knowing HIV status include knowing that infected mothers could be at greater personal risk because the pregnancy may alter cell-mediated immunity. Knowledge of HIV status during pregnancy could promote correct diagnosis and treatment, which would decrease complications and the risk of perinatal transmission. However, diagnosis of HIV infection has special social and financial considerations. In addition to the emotional impact of such a diagnosis, employment and insurance may be lost once the diagnosis is disclosed. Also, fear of being tested may prevent some women from seeking prenatal care. Although it may be medically beneficial to establish the diagnosis, policies mandating HIV testing may deter women from receiving care. Insisting that testing be done would undermine the client's autonomy, her right to privacy, and restrict her liberty to control her body.

Nurses need to maintain an open mind when counseling HIV-infected pregnant women. The risk of HIV transmission must be considered in light of the significance of the pregnancy to this woman and the availability of treatment. Women should be informed about the risks of HIV and counseled accordingly. Nurses must be careful to listen to client concerns about testing and treatment options. Treating clients with respect and developing trusting relationships may facilitate testing and treatment (Downes, 1995; Schmeltzer & Whipple, 1991).

Female Circumcision

As more women from other countries immigrate to North America, nurses are seeing a greater incidence of female

circumcision, which is also sometimes termed "female genital mutilation" (Gibeau, 1998). Female circumcision is a cultural practice that can involve removal of the prepuce and clitoris or may extend to excision of the labia minora, excision of the labia majora, and closure of the vagina, leaving a small opening (infibulation). Sometimes considered a rite of passage or a mechanism for socialization into the role of a woman, the practice has persisted, particularly in Northern Africa. Female circumcision is considered by some to be a sign of purity and is essential to maintain family honor and to be a desirable mate for marriage (Lane & Rubinstein, 1996; Lightfoot-Klein & Shaw, 1991). Opposition to female circumcision has occurred because it is perceived as subjugation of women.

Female circumcision has also come under criticism because of significant short- and long-term health implications. Short-term complications include hemorrhage, shock, infection, and damage to urethra, vagina, and anus. Long-term complications include recurrent vaginitis and urinary tract infections, keloid scar formation, persistent infection, cysts, vulvar abscesses, dysmenorrhea, painful intercourse, and increased morbidity and mortality related to childbirth (Gibeau, 1998; Lightfoot-Klein & Shaw, 1991). During childbirth, the infibulation must be cut and then resutured following delivery.

National and international groups (including the World Health Organization and UNICEF) have opposed female genital circumcision on the basis of it being a health risk and a human rights violation (Gibeau, 1998). In 1997, federal laws became effective that prohibit female genital surgeries from being performed in the United States on girls under age 18. Yet, the dilemma remains: how can nurses be sensitive to cultural beliefs and also promote practices that enhance the well-being of clients? Nurses may encounter clients who request to be reinfibulated following delivery or may have clients who request female circumcision for their daughters.

The cultural significance of practices must be recognized, even when they differ from the nurse's cultural norms. Women who practice female circumcision come from cultures in which the practice is considered to be normal. While Western concerns make ending female genital surgeries a priority, in the context of other cultures, other priorities, such as ending physical abuse, education, or economics, may prevail (Lane & Rubinstein, 1996). Nurses should recognize that practices exist in Western culture that could be considered equally destructive. For example, breast augmentation to meet a Western cultural standard that large breasts are desirable may be considered abnormal. Often, the principle of autonomy guides the care that nurses provide. However, when cultural practices are physically harmful, such practices are difficult to support. One strategy to resolve the ethical dilemmas of this issue is to express respect for cultural practices but

also work to shed new light on the negative health outcomes of female genital surgeries (Lane & Rubinstein, 1996).

Alternative or Complementary Therapies

Alternative or complementary therapies are health-related techniques and practices that are meant to promote healing and, in some instances, complement mainstream medical practices. The focus of these therapies is to treat the person holistically, recognizing that the mind, body, and spirit interact with the environment as a whole. Examples of complementary therapies can include, but are not limited to, healing touch, acupuncture, massage therapy, use of guided imagery, nutrition, yoga, dance, aromatherapy, and folk remedies. The use of complementary and alternative therapies is increasing in health care, and some nurses now incorporate these care modalities into their practices (Simon, 1999). Although client use of alternative therapies is increasing, clients do not necessarily inform their care providers that they are undergoing these therapies, because these practices have been devalued in the past (Nash, 1999). Nurses must be sensitive to client needs with respect to alternative therapies. The principle of respect for autonomy indicates that clients have a need to be informed about potentially useful therapies and make decisions regarding their use. The principle of beneficence indicates that positive acts to improve the welfare of clients should be supported; the principle of nonmaleficence indicates that care should be taken so that harm is not done to patients through either the provision of or withholding of potentially therapeutic opportunities (Nash, 1999). Nurses need to investigate client use of alternative therapies and explore how these practices may be beneficial.

LEGAL ISSUES

As professionals, nurses are both ethically and legally accountable for their practices. Care of pregnant women and newborns requires specialized knowledge, communication, and teamwork among health care providers. Accurate assessment, reporting, and documentation are essential to safe and effective nursing care. When pregnancy and childbirth are involved, most people anticipate normal deliveries and healthy babies. However, adverse events resulting from poor nursing care in the labor room accounted for 128 (17.4%) of a total of 747 malpractice cases in a study conducted by Beckmann (1996). In these cases, poor nursing assessment and medication errors contributed to maternal injuries and death. The purpose of this section is to examine basic aspects of the laws and standards that govern nursing practice, including suggestions for promoting quality care throughout pregnancy.

Basic Legal Concepts

We live according to laws that set minimum standards for behavior. Laws are derived from federal, state, or local sources and provide a necessary order for individuals living within a society. Laws also extend to professional nursing practice that have developed along with laws governing medical practice.

There are two major divisions of law: criminal and civil. **Criminal law** addresses public concerns and punishes the wrongs that threaten a group or society; **civil law** is concerned with and punishes wrongs against the individual (Hall, 1996). Laws are derived from three major sources: statutory law, or those laws passed through legislative process; regulations, which are established by the executive branch (such as President or Governor); and case law, sometimes referred to as common law, which is derived from judicial decisions on specific cases. Some laws from each of these sources concern nurses. Statutory laws, through nurse practice acts, define what constitutes the scope and practice of nursing and determine educational qualifications and titling for registered nurses. The Board of Nurse Examiners for each state helps to establish regulations governing nursing practice and can make decisions regarding issuing or suspending licenses for practice (Figure 5-4). Case law may identify a minimum standard to which a health care provider is expected to adhere. For example, the need for institutions to identify an effective chain of command for dealing with emergencies has been set through case law (Mahlmeister, 1996).

A **tort** is a civil wrong that may be caused either intentionally or unintentionally. **Negligence** occurs when there is an unintentional wrong caused by the failure to act as a reasonable person would under similar circumstances (Mahlmeister, 1996). **Malpractice** is a type of negligence

Figure 5-4 Nurses must be involved in legislative activities that are a means of regulating nursing practice. (Photo courtesy of the New York State Nurses Association)

involving the actions of professionals who failed to perform as other competent professionals would in the same set of circumstances. Four components must be present to demonstrate malpractice, including duty, breach of duty, client injury, and proximate cause (Hall, 1996; Mahlmeister, 1996). In a case of malpractice, the defendant must have a duty toward the injured person. For example, a nurse has a duty to provide safe care for a client. That duty must have been breached. In other words, the professional must have failed to act in such a way that the standards of practice were upheld. A common question asked in cases of a breach of duty is: Did the nurse act in a way that a reasonable, prudent nurse would act in a similar situation? Next, an injury must have occurred. The potential for injury is not adequate for establishing malpractice, there must have been an actual injury. Last, the resulting injury must be directly caused by the negligence that occurred. Consider the example of a postpartum client, who had an epidural block, and, while under the influence of the drug, fell and sustained a head injury, because the nurse left the bed rails down and had not instructed the client to seek assistance in walking. The nurse would be considered negligent for not providing safeguards that a reasonable and prudent nurse would have provided under similar circumstances.

Another way of looking at causation is through proving the injury would not have occurred except that the nurse failed to act in a reasonable and prudent manner. As professionals, nurses are expected to possess specialized knowledge and are liable for their actions. The concept of **liability** means that each person is accountable for his or her acts that fail to meet the standards of the profession (Mahlmeister, 1996).

Standards of Care

In addition to laws, standards of care also guide nursing practice. **Standards of care** are documents developed by professional groups to establish a level of practice agreed upon by members of the profession. In many instances, these standards reflect the minimum expectations required of professionals for a safe practice. Because standards are based on current knowledge, they are dynamic and may be subject to change as new information becomes available. Standards of care are sometimes used in legal situations as a yardstick for determining if negligence occurred. Nurses should be knowledgeable about professional standards of practice in their specialty and practice within those guidelines. This professional accountability serves nurses well when issues of liability arise (Mahlmeister, 1996).

A standard used in women's health is published by the Association of Women's Health, Obstetric, and Neonatal Nurses (AWHONN, 1998). These standards are divided into

standards for care and professional performance; guidelines for women's, perinatal, and newborn health; acute care; community and home care; and administration. The standards of care section uses the nursing process format and addresses assessment, diagnosis, outcome identification, planning, implementation, and evaluation. The section on professional performance addresses quality of care, performance appraisal, education, collegiality, ethics, collaboration, research, resource utilization, practice environment, and accountability (AWHONN, 1998). The guidelines suggest actions appropriate to nursing practice in specific areas of maternal-child nursing.

Additional sources of standards are the scope and standards for nursing practice developed by each state's Board of Nurse Examiners, and standards developed by individual institutions and found in policy and procedure manuals. Sometimes it is difficult for nurses to assess whether they are practicing within the scope and standards of nursing. Suggested questions that nurses may ask to determine the acceptability of their practices or any given activity include (Flores, 1997, pp. 6–7):

- ✱ Is the activity consistent with the state's Nurse Practice Act and rules and regulations of the Board of Nurse Examiners?
- ✱ Is the activity in accordance with established policies and procedures of the institution?
- ✱ Is the act supported by research or in the scope and standards of practice statements?
- ✱ Does the nurse possess the required knowledge and demonstrated competency in performing the activity?
- ✱ Would a reasonable and prudent nurse perform the activity in this setting?
- ✱ Is the nurse prepared to assume accountability for the provision of safe care and the outcomes rendered?

If nurses are knowledgeable and able to respond affirmatively to each of these questions, then the activity in question should be within the scope and standards of practice. Flores suggests that referring to a decision-making model such as this one becomes more automatic with routine use, ensuring more critical thinking about practice issues and empowering nurses to be proactive.

Practicing Safely in Perinatal Settings

A holistic, interpersonal approach to care and adequate documentation are essential components of safe nursing practice and serve to reduce the risks of liability. Competent care requires a team approach, with nurses playing a key role in assessment and communication (Fiesta, 1995).

McMullen and Philipsen (1995) offer suggestions to decrease litigation and to improve care throughout a client's pregnancy (Philipsen & McMullen, 1994a; 1994b). Believing that interpersonal care and communication are important factors in reducing liability, McMullen and Philipsen (1995) suggest that nurses must establish good rapport with clients and their families. Nurses should encourage input from clients and families, allowing sufficient time for questions and dialogue. These measures enhance communication, health teaching, and interpersonal relationships. Good rapport with clients helps them to feel respected and well cared for during pregnancy (Philipsen & McMullen, 1994b). These measures also improve continuity of client care and reduce potential liability.

Policies and procedures are also an important factor in safe nursing practice. Policies and procedures should be updated regularly and should be realistic within the framework of practice (McMullen & Philipsen, 1995). When new practices become accepted, institutions should revise existing policies to reflect correct practice guidelines so that nurses are not left in the position of trying to implement updated practices that are not in the hospital procedure manual. Nurses also should be able to perform the outlined procedures within the context of the work setting. Otherwise, the policy should be examined and a safe, but more feasible, policy substituted. Nurses should be aware of what constitutes safe practice and know how policies are changed in their institution.

As institutions cut costs, the skill mix of the nursing staff may change, leading to greater use of unlicensed assistive personnel (UAPs) for providing client care. To efficiently practice, registered nurses are responsible for delegating selected care tasks to UAPs. The function of UAPs is to complement performance of nursing functions rather than to substitute for the registered nurse. To promote safe

practice, nurses should be familiar with state regulations governing delegation, so that appropriate tasks are delegated for UAPs to carry out. The *Standards and Guidelines for Professional Nursing Practice in the Care of Women and Newborns* (AWHONN, 1998) suggest that task delegation should be based on client needs and the knowledge and skill of the provider designated to perform the task.

During pregnancy, the prenatal care offered should meet nationally established standards and be documented accordingly. An area of particular concern during the first trimester of pregnancy is giving adequate information to the client regarding the availability of prenatal tests, such as chorionic villus sampling, amniocentesis, triple screen of alpha-fetoproteins, and screens for some teratogenic communicable diseases (Philipsen & McMullen, 1994a). Not only should this information be given to clients, but their response should also be documented in the medical record. If testing is done, findings should be communicated to the client and, if necessary, options explored. Once again, this information, including options and the client's response, should be documented. Another area of concern during the first trimester is that pregnancy and possible risks be correctly diagnosed so that early intervention can begin. Remember when working with all women of childbearing age to consider the possibility of pregnancy, especially women presenting with abdominal pain and a potential ectopic pregnancy.

Later in pregnancy, testing remains a significant issue. Once again, nurses should be careful to inform clients about the availability of specific testing, including the potential risks and benefits, and record the expectant mother's response (Philipsen & McMullen, 1994b). Even routine test results, such as those from urinalysis, blood cell counts, and blood pressure measurement, should be documented. Other common tests include nonstress, contraction stress, oxytocin challenge, and biophysical profiles. Communication of results, assessment of client understanding, provision of health education, and documentation of client response remain important. When there is a lack of documentation and an adverse outcome, it is difficult to demonstrate that standards of care have been met, creating an opportunity for liability to be assessed.

Another legal issue centers around antepartum clients being discharged from labor and delivery because they are not yet ready to deliver. Before discharge, there should be documentation of at least two assessments, noting any change in client condition and a baseline fetal monitor strip from 20 to 30 minutes of observation. Assessment should include vital signs and examination of the cervix. The physician or nurse-midwife must be notified of the client's presenting condition and reassessment before discharge (Rommel, 1996). If clients are discharged before delivery, written discharge instructions should be re-

Critical Thinking

Unrealistic Hospital Policy

You are a nurse working in labor and delivery. One of the policies of your institution is that all women in the first stage of labor be monitored every 15 minutes and a charted entry regarding their status be made. Checks may include vital signs, assessment of fetal heart rate, and vaginal examination. While you feel that frequent checks are important, the staffing of your unit does not allow nurses sufficient time to meet this policy. Consequently, nurses do not follow this policy. How would you respond to this situation?

viewed, signed by the mother, and a copy given to the mother (McMullen & Philipsen, 1995). This opportunity presents an excellent chance to answer any questions a mother may have.

Nurses must be knowledgeable about the expected practices of physicians and question the appropriateness of physician orders when deviations from standards occur. These activities can be called affirmative duty actions, in which nurses are expected to protect clients from harm (Mahlmeister, 1996). In the process of reporting emergencies, nurses must be familiar with the established chain of

command in the institution. For example, the chain of command for a staff nurse may begin with the nurse manager and then the nurse supervisor. If the complaint concerns an obstetrician and cannot be resolved at that level, then the Chief of Obstetrics may be called. The hospital administrator may be a part of the chain of command. Nurses should know when to activate the chain of command and when it is appropriate to move up the chain of command (Mahlmeister, 1996). When seeking help, nurses should remember that prompt reporting facilitates problem resolution and that persistence can help ensure that clients

Research Highlight

Informed Consent for Maternal Serum Alpha-Fetoprotein Screening

Purpose

To determine if pregnant women who received information regarding measurement of maternal serum alpha-fetoprotein (MSAFP) levels understood information sufficiently to sign an informed consent.

Methods

Fifty-three inner-city pregnant women were given an explanation of screening for MSAF by a care provider and viewed an explanatory videotape. An interview using open-ended questions to assess understanding of the screening process followed the information-giving process.

Findings

Although most women were able to correctly identify that MSAFP required a blood sample and had no risks, only 74% were able to correctly identify that it tested for "birth defects" and 62% could identify what MSAFP was and what the tests are used for. Only 45% recognized that a positive test result required follow-up, and only 22% respectively could identify what a high-positive and low-positive MSAFP test result meant.

Nursing Implications

These findings revealed that women in this study met only part of the criteria for informed consent. While the consent may have been voluntarily given by a competent woman who had been given information regarding the test, a substantial portion of the women did not understand the meaning and implications of the test. Nurses should request information from clients to ensure their understanding. Suggested questions might include:

- What do you call your condition?
- Which treatment is being recommended?
- What is the treatment supposed to do for you?
- Are there risks associated with the treatment?
- What alternatives are there to the treatment?

Freda, M., DeVore, N., Valentine-Adams, N., Bombard, A., & Merkatz, I. (1998). Informed consent for maternal serum alpha-fetoprotein screening in an inner city population: How informed is it? *JOGNN*, 27(1), 99–106.

receive appropriate care. Following these guidelines should promote safe client care and reduce opportunities for negligence to occur.

Legal Issues in Maternal-Child Practice

Two issues that nurses often encounter in maternal-child practice are informed consent and the right to privacy.

Informed Consent

Informed consent is an issue that has well-defined legal and ethical foundations. Based on a client's right to self-determination, **informed consent** demands that information regarding treatment procedures be given to clients and their consent secured. To obtain a valid consent, clients must be presented with information regarding the course of treatment; methods by which the treatment is carried out; any alternative forms of treatment available, including the inherent risks and benefits of each option; and risks of nontreatment. If any of these areas is not included, then the consent process is incomplete.

The amount of information clients must be given to consider the consent to be informed varies according to the standard used. The most commonly used standard is the community standard in which the amount of information given would be similar to what other health care professionals would give in similar circumstances. Another option, the reasonable client standard, requires the amount of information given be sufficient for a hypothetical reasonable client to make a decision. The reasonable client standard is becoming more commonly accepted. A third standard, the individual client standard, asks what information this individual client needs to make a decision (Bernzweig, 1996); this subjective standard tends to be the least used.

Physicians are responsible for determining the competency of clients and providing information to clients for consent. If permissible by hospital policy, nurses can witness consent documents, but should witness the physician obtaining the signature on the form (Figure 5-5). If nurses feel that a valid consent is lacking, then the nursing supervisor or physician should be notified (Fiesta, 1994). For example, clients facing a cesarean section should be informed of the nature of the procedure, the risks involved, and options before signing a consent. Nurses should work to ensure that clients are well-informed.

Closely related to informed consent is the right of competent individuals to refuse treatment. In maternal-child nursing, treatment refusal carries particular significance because the well-being of the fetus may be affected by maternal decisions. The issue of viewing pregnant women by a one-client or two-client model affects the

Figure 5-5 Nurses can play an important role in a client's informed consent.

right of refusal. Every effort should be made to ensure that pregnant women are well-informed of their options and that treatment decisions are not coercive.

Right to Privacy

In recognition of care providers having access to sensitive information about clients, certain legal, professional, and ethical standards have been developed to help ensure a client's right to privacy. A client's right to privacy means that nurses should not unnecessarily expose a client's body or disclose information to unauthorized parties. During labor and delivery, many personnel may be in and out of the client's room. To protect privacy, only those responsible for care should have room access. Measures, such as drawing a

REFLECTIONS FROM NURSES

"In the United States, fathers are encouraged to play an active role during pregnancy and the birth process. However, in other cultures men do not participate in the event of birthing. As a nurse, I find it challenging to manage family dynamics when caring for a family whose values differ from mine. To provide sensitive care, I make an effort to ask the pregnant woman if she will have a partner or coach during the labor and delivery process. Her answer helps me better understand her expectations of support during the childbirth experience."

curtain or closing doors during examinations, should be taken to afford privacy. Casual conversation in the hall or elevators about clients under care should be avoided. Health care providers should access information only for clients in their care. It is often tempting to review a chart of a friend or colleague receiving care. However, a client's right to privacy would prohibit securing this information.

PRACTICE IMPLICATIONS FOR MATERNAL-CHILD NURSING

Maternal-child nurses face a complex array of ethical and legal issues in practice. With some reflection and planning, nurses can prepare themselves to manage difficult clinical situations proactively. First, nurses need to identify their practice values and identify the ethical stances that are the most compatible with practice and think about how these can be incorporated into daily practice. Would a utilitarian perspective focusing on outcomes be the best decision guide? Or is a primary goal of practice to deliver care that maintains a sense of personal and professional integrity? Consider the implications of being a caring advocate for clients. Remember that even though nurses are charged with promoting the client's best interest, not all clients share the same value system.

BUILDING KNOWLEDGE AND EXPERIENCE

Knowledge and experience are powerful tools in practice. Be knowledgeable about maternal-child nursing and about the standards of care and policies that govern practice. Make critical analysis of client care part of a daily routine. Find expert practitioners who integrate ethical practice and promote high standards of care. These tasks strengthen the quality of your practice and provide a mechanism for you to become an experienced nurse.

Nurses also need to function within the context of a legal framework. Nurses should be familiar with regulations governing their practice and should incorporate an understanding of the regulations of the Board of Nurse Examiners, have a thorough grounding in delegation, and be familiar with the Standards of Practice for Maternal-Child nurses.

Web Activities

- Explore the Internet Encyclopedia of Philosophy: <http://www.utm.edu/research/iep/>. Many of the selections here reflect a more theoretical aspect of ethics. Review the portion of this chapter that discusses ethical theories and principles. What more can you discover about these areas on this website?
- Visit and explore the website for advanced directives: <http://www.choices.org>. How might this information be useful to you personally as well as to you in your role as a nurse working in women's health?
- Visit the American Nurses Association website: <http://www.nursingworld.org>. Click on the ethics site. What kind of position statements do you find there that are related to the topic of ethics and women's health? Think about women's health from a broad perspective and remember to include issues such as childbearing, violence against women, genetics, HIV, and eldercare.
- Explore the health law resource: <http://www.netreach.net/%7Eewmanning/>. Click onto the bioethics section. What topics here might provide useful knowledge regarding women's health nursing practice?

Key Concepts

- Ethics provides rules and principles that can be used for resolving ethical dilemmas. Ethical decisions tend to be reflective and may be influenced by values, beliefs, and personal interpretations.

- Laws are rules that represent the minimum standard of morality and govern the behavior of individuals. Laws are written to promote the welfare of society.

(continued)

- Standards of care are developed by professional groups to establish a level of practice agreed upon by members of the profession.
- Utilitarianism is an ethical theory that focuses on the consequences of action. Actions bringing about good consequences are considered the best.
- Deontology is an ethical theory that is concerned with doing the right action rather than with the consequences of the action. Actions selected should be ones that could be followed in other similar situations.
- Virtue ethics focus on developing desirable personal attributes and acting in a manner that is congruent with those attributes.
- An ethic of care is a nursing perspective that recognizes the personal concerns and vulnerabilities of clients in health and illness. Nurses, operating under the tenets of an ethic of care, would be willing to provide care to achieve therapeutic goals without expectation of reciprocity.
- In holistic ethics there is a concern both for the outcome of a decision and the intrinsic nature of the act itself. Acts are selected based on a desire to do good and to contribute to the unity of the self and universe.
- Respect for autonomy recognizes the right of competent individuals to make informed choices on their own behalf.
- Nonmaleficence suggests that health care providers must exercise due care to prevent client harm.
- Beneficence is an ethical principle focusing on promoting the welfare of others.
- Justice provides a mechanism for making decisions about dividing benefits and burdens within society.
- The American Nurses Association *Code for Nurses* supports the concept of respect for persons and safeguarding a client's welfare. The code offers guidance for nursing actions.
- Ethical decision making is best when conducted in a systematic manner that carefully examines characteristics of the situation and uses ethical theories and principles as tools.
- Malpractice occurs when professionals are negligent and fail to perform as other professionals would in a similar set of circumstances. Malpractice consists of a breach of duty, resulting in client injury that is directly related to the negligence.
- Interpersonal care and good communication are key factors in reducing the risks of liability.
- Nurses should be proactive in their care approach, i.e., be knowledgeable about perinatal nursing practice, legal issues, and standards of care. Adequate patient assessment, communication with other care providers, and documentation are essential to safe practice.

Review Questions and Activities

1. Discuss informed consent with your classmates. Have one group describe the kinds of information that might be disclosed about a cesarean section when using the reasonable person standard. Another group can describe the information that might be given when using the community standard. The third group should describe information to be given when using the individual client standard. Share your information with the other groups and compare the nature of the information divulged. What ethical principles support the concept of informed consent?
2. Review the case study. What other arguments or viewpoints might be considered for trying to persuade Marcella to enter the drug rehabilitation program or for coercing her into the program? In this situation, what type of actions would the one-client model support? What actions would a two-client model permit? Which would be the best model to use in your ethical thinking? Why?
3. The ethical perspective focusing on a sense of commitment to clients and advocacy on their behalf is:
 - a. Virtue ethics
 - b. Deontology
 - c. Ethic of caring
 - d. Utilitarianism
 The correct answer is c.
4. The ethical principle concerned with distributing benefits and burdens is:
 - a. Respect for autonomy
 - b. Justice
 - c. Nonmaleficence
 - d. Beneficence
 The correct answer is b.
5. Due care is both an ethical and legal concept that indicates that care providers should:
 - a. Encourage client decision making
 - b. Promote client autonomy
 - c. Divide benefits carefully

d. Exercise caution to prevent unintentional harms
The correct answer is d.

6. A health care provider interferes with the decisions of a competent person for the purpose of promoting the competent person's welfare. This statement is an example of:
- Paternalism
 - Beneficence
 - Autonomy
 - Due care
- The correct answer is a.
7. While a client was in labor, health care providers failed to note early signs of fetal distress, although

a later review of fetal-monitor readouts clearly indicated that distress occurred. Following delivery, the baby appears to be healthy and has Apgar scores that are within normal limits. As a nurse, you are being pressured to omit those sample monitor strips from the labor and delivery record. What legal and ethical obligations should you consider as you respond to this situation? How will these obligations influence your response? Are there ever circumstances where modifying the medical record would be appropriate? Why or why not?

Home Visiting Programs and Perinatal Nursing

Nurses working in home care develop a unique and special relationship with the clients and families they serve. For many nurses, this helping relationship is particularly memorable.

- *How do I feel about entering a stranger's home to provide care?*
- *How do I provide nursing care in the home compared with the hospital or clinic setting?*
- *What are my feelings about cultural and spiritual differences in family life?*
- *What can I do if I cannot address the client's needs in the home?*
- *What can I do if my clients become too attached to me?*
- *How do I terminate a long-term home visiting relationship?*

Home visit

Competencies

Upon completion of this chapter, the reader should be able to:

1. Discuss the history of home visitation, and describe how current trends in home visitation parallel or differ from the historical effort.
2. Define home visiting.
3. List at least three principles of home visiting, and discuss how they might be incorporated into home visiting practice.
4. List three advantages and disadvantages of home visiting.
5. Discuss the process of providing a home visit in terms of assessment, nursing diagnosis, outcome identification, planning, intervention, and evaluation.
6. List three essential skills for home visitation, and discuss how these skills might be integrated into each phase of the home visiting process.
7. Describe at least two proven outcomes from home visitation, and apply this research to the development of an evaluation plan for a home visiting program.
8. Discuss termination of the home visiting relationship, and describe how the nurse can set the stage for termination throughout each phase of the home visiting process.

Home visitation has long been used as a strategy to provide direct health care services, health education, and psychosocial support to clients and families. Recent changes in the health care environment, emphasizing cost containment and shifting of care to nonhospital settings, have resulted in an even larger number of clients receiving services in their homes for a variety of reasons. Home visiting interventions frequently are employed to care for women and newborns during the postpartum period and to provide education and support to new families. Proponents believe that this service delivery strategy offers unique benefits to clients and their families.

Owing to the increase in home-based services, nurses must be familiar with home care concepts. This chapter focuses on the *process* of serving clients and families in their homes, emphasizing the nursing process in terms of assessment, nursing diagnosis, expected outcomes, planning, intervention, and evaluation.

HISTORICAL BACKGROUND

Informal home visiting efforts have been ongoing throughout time as family members, friends, and significant others

have helped care for sick and less fortunate persons. In the late 1800s, home visiting efforts became more organized in response to the increase in immigration and industrialization in the United States. Lay women, known as “friendly visitors,” visited immigrants and the poor to provide friendship and “moral and behavioral guidance” (Hoover et al., 1996). These charitable efforts, aimed at what was perceived as the need to improve the character of poor people, were seen as a way of resolving the pervasive societal problems caused by urban poverty, personal irresponsibility, and classism (Boyer, cited in Weiss, 1993). The need for a more organized approach to these issues led to the development of settlement houses designed to provide more formal assistance to new immigrants in acculturating to American life. Indeed, these settlement programs can be viewed as a precursor to current nationwide home visitation efforts to promote family support (Klass, 1996).

The 20th century brought a firm commitment to social reform and the field of social work. In 1909, Theodore Roosevelt convened the first White House Conference on Children, which focused on the necessity of maintaining a good home environment for children (Bremner, 1971). This conference led to the development of the Child Welfare League of America. The League sanctioned the use of public funds for home visiting for the purpose of fostering

Figure 6-1 Lillian Wald. (Photo courtesy of the American Nurses Association.)

family life. This era of social reform lasted well into the 1920s, when a focus on efficiency led to a shift from home to office-based services (Wasik, Bryant, and Lyons, 1990). The War on Poverty in the 1960s again saw home visiting being promoted as a means of assisting low-income families to overcome the multigenerational problems associated with poverty (Klass, 1996). In the child welfare arena today, home visitation often is the cornerstone of efforts to promote family preservation and support.

The nursing profession has a long history of involvement in home care. Florence Nightingale, as well as others, argued that nurses should be trained to provide care to the sick in their homes (Wasik, 1993). Lillian Wald (Figure 6-1) established the Henry Street Settlement House in the 1890s where nurses provided both preventive and acute health care to the needy. By 1910, visiting nurse associations (VNAs) had developed in urban areas focusing primarily on maternal-child health. VNAs continued to thrive, in many cases functioning as a cornerstone for community health efforts in large cities and towns. Today, home health care is emerging as one of the fastest-growing specialties in nursing. Nurses continue to provide an increasing array of acute care services in the home for adult and pediatric clients and to use the home as a base for delivering preventive health services and health education to pregnant and parenting families.

COMMUNITY HEALTH CONCEPTS

For the most part, traditional nursing practice focuses on health maintenance and disease prevention for an individ-

ual client. Community health practice moves beyond this focus on the individual to encompass the health of the entire community. Health is defined quite broadly to include not only the absence of disease but the promotion and maintenance of wellness in the physical, emotional, social, cultural, and spiritual domains. Community or public health practice ensures a high-level of wellness and quality of life for all members of a given population. A report by the Institute of Medicine entitled “The future of public health” (1988) describes this function as “assuring conditions in which people can be healthy.”

Given this focus, it is not surprising that most efforts in community or public health are preventive in nature, because the best way to *be* healthy is to *stay* healthy. The three levels of community health prevention can be defined as primary, secondary, and tertiary. Preventive efforts can target the individual or the community as a whole. *Primary prevention* describes interventions that promote general health or well-being or those that prevent the development of health problems (Woods & Mitchell, 1997). Primary prevention related to maternity care can include education about folic acid use preconceptionally and during early pregnancy to decrease the incidence of neural tube defects in the fetus and promotion of early access to and use of prenatal care. These interventions can be initiated at both the individual and community level. For example, every woman of childbearing age should be counseled by her health care provider about the benefits of folic acid. At the community level, a local or state health entity may initiate a campaign to inform the community at large about the benefits of folate. Secondary prevention focuses on early diagnosis and treatment of existing health problems with the goal of preventing serious sequelae (Woods & Mitchell, 1997). Efforts relative to secondary prevention include screening a prenatal client for signs and symptoms of preeclampsia at every home visit (individual level) or initiating a series of smoking cessation classes for pregnant women in the community (community level). *Tertiary prevention* consists of efforts to reestablish a high level of wellness after amelioration of a health problem or to prevent recurrence of a previous health problem (Woods & Mitchell, 1997). Recommending prenatal diagnosis and genetic counseling to a family with a previous history of Down syndrome illustrates tertiary prevention at the client level. At the community level, an example of this third level of presentation would be the development of a public information campaign about the importance of genetic counseling that targets women who have delivered babies with congenital anomalies.

Home visitors intervene at both the individual and community level. At the client level, the visitor usually has a specific purpose or indication for the visit, whether it is to examine the new mother and infant during the early postpartum period or to provide ongoing support and anticipatory guidance to new families during the first 2 years

of the child's life. Home visiting programs, as a whole, may be part of a community-implemented intervention to decrease low-birth-weight infants or child abuse and neglect within a given region or health district. The home visitor provides services and education to clients to impact individual health outcomes but also intervenes as a member of the community in an attempt to maintain, and hopefully improve, health status indicators for the community as a whole.

DEFINING HOME VISITATION

Any discussion of home visitation must focus on the unique aspects of providing care in the home for pregnant and parenting women and families. The nature of home visiting can be further explored by focusing on the home as a site of service delivery and by examining the development of a special helping relationship between the client and visitor.

Site of Service Delivery

A **home visit** occurs in the family's place of residence or in any such facility at which a family may be housed, such as a homeless shelter, group home, church, or halfway house (Gomby, Larson, Lewit, and Behrman, 1993). Having services provided in the home is convenient for clients. Lack of transportation and childcare along with language barriers can make accessing care difficult, especially for low-income populations. In addition, some clients are physically or emotionally incapable of leaving home, making them unlikely to receive care in other settings. Ambulatory care settings typically feature an appointment-only structure, with moderate to lengthy waiting times, that many times is designed to meet the needs of providers and not clients. Home visiting also brings nurses in contact with client groups who, for whatever reason, might not have accessed health care in more traditional settings. This case finding aspect, then, is a particularly important function of home visitation; nurses have contact not only with the client or family initially referred for service but also with neighbors, extended family, and friends.

The home as a site of service delivery also provides a unique opportunity to assess the client and family in their own environment. The nurse can observe how physical, psychosocial, and spiritual factors (such as housing, interpersonal relationships, and religious beliefs), resources (such as finances and support systems), and potential environmental hazards (such as improper food storage and faulty electrical wiring) relate to and impact health status. Health-related issues can be evaluated within the context of daily life. Given this opportunity to fully assess the environment and the way in which the client interacts within

it, the nurse can more readily understand the needs, strengths, motivations, and desires of the client and family. This knowledge allows the nurse and client, in partnership, to formulate an appropriate nursing diagnosis and develop a more effective plan for intervention. Services also can be personalized and individualized more than is possible in the clinic or hospital setting, using the family, significant others, and the surrounding community as sources of assistance or referral. Finally, the nurse can subsequently evaluate the success of the intervention strategy within the same setting. For example, a pregnant client with an inadequate weight gain may relate a diet history in the clinic that is consistent with standard prenatal recommendations. When the nurse visits the home and finds no food in the refrigerator, the problem of inadequate weight gain becomes attributable to an issue much different from simple knowledge deficit. The nurse can then mobilize the client and community resources (food banks, food stamps, and community food share programs) to address the real problem. In like manner, the client may report in clinic that she is taking supplemental iron tablets regularly. When questioned about the unopened bottle of tablets during a home visit, however, she admits being unable to swallow large pills.

Relationship Building

At the core of home visiting is the relationship between the client and family and the home visitor (Klass, 1996). In the home visiting situation, control is in the hands of the client. At all times, the nurse is a guest in the client's home (Hoover et al., 1996). This concept can be a difficult one for health care providers who often perceive themselves as experts, confident in their ability to solve other people's problems. Mutuality is key. The client and nurse must work together as a team to develop the care plan (Figure 6-2).

One of the primary purposes of any home visiting program is to foster the client's and family's ability to eventually provide self-care and make decisions independently. The nurse, recognizing that the client is in control, **empowers** the client and family. **Empowerment** is the process of assisting the client and family to care for themselves. Through the use of **enhancement**, the nurse identifies and builds on the client's and family's existing strengths to increase their ability to solve problems and provide self-care. Finally, the nurse functions as an enabler. **Enablement** is the process of assisting the client and family in locating and accessing the services and resources necessary for success, in short, helping clients help themselves. The nurse and the client-family unit function as a team, within a relationship that is collaborative, not authoritative, resulting in a plan for intervention that is developed jointly. This team approach is more likely to be successful.

Figure 6-2 The client and home care nurse will work collaboratively to develop a plan of care.

Owing to the nature of their work, home visitors form a special helping relationship with their clients that is based on trust, especially when home visiting intervention is ongoing. Because clients feel at ease in their own environment, communication flows more easily and often is more truthful. Many times, nurses learn more about a client and family in a 2-hour home visit than a provider might learn during 7 months of prenatal care. Given the potential richness of this service setting, good assessment and communication skills are paramount.

INDICATIONS FOR HOME VISITATION

Home visitation is undertaken for a variety of purposes to meet a variety of goals. Home care is provided by independent home health care agencies, hospitals, public health departments, schools, and other institutions as a single intervention or as an adjunct to other types of care. For the purposes of this discussion, indications for home visiting will be classified as acute care focused or health promotion/disease prevention focused. The acute focus is one in which the provision of medical and nursing care is paramount. Health education, family preservation and support, and case management fall under the broader rubric of health promotion. In many cases, however, these indications overlap. It is difficult to administer any type of nursing care without providing health education. Conversely, the need for acute care might arise during a home visit initially indicated for health promotion. While accepting that this is true, home visitation still will be characterized according to these broader indications for purposes of discussion.

Provision of Acute Care

Regardless of the indication, home health nursing practice requires a broad base of skills. Knowledge of assessment (physical, psychosocial, and spiritual), communication, case management, health education, teaching and learning principles, and community resources are paramount. For women of childbearing age, provision of direct health care services during the prenatal or postpartum period often is the primary indication for a home-based nursing encounter. In response to increasing health care costs and third-party payment for home health care, the field of perinatal home care has developed over the past few years (Association of Women's Health, Obstetric, and Neonatal Nurses [AWHONN], 1994). Perinatal home care focuses most commonly on the provision of acute care services to women before conception, during pregnancy, and after delivery, along with care for their neonates (AWHONN, 1994). Fiscal considerations usually dictate that services be restricted to high-risk populations, although perinatal home care nurses can potentially serve all childbearing women. Encounters may be single or multiple, and the number of visits is dictated by client need and the insurer. For example, women who are at risk for preterm labor can access perinatal nurse specialists to assess contractions, evaluate the condition of the cervix, monitor fetal well-being, and manage medications that cause tocolysis, such as terbutaline delivered by pump. In response to early hospital discharge after delivery, a perinatal home care nurse may visit in the first 24 to 48 hours postpartum to assess maternal-newborn physical status and adjustment. AWHONN has developed a set of suggested clinical skills for professional nurse providers of perinatal home care; activities should be "philosophically directed" toward the following (AWHONN, 1994):

- Assisting women in optimizing their state of health before conception.
- Assessing and managing actual or potential problems of pregnancy that can be managed safely on an outpatient basis.
- Facilitating postpartum physical restoration and adaptation to parenthood.
- Promoting the achievement of maximal health for the neonate and family.

Interventions usually involve single or multiple encounters on a short-term basis. Whereas the visit care is focused on acute care, the nurse still focuses on issues germane to health promotion and disease prevention, such as environmental assessment, health education, and anticipatory guidance.

HEALTH PROMOTION

In the public health arena, home visitation has been used as a strategy for delivering both preventive and interventional services. Visitation programs with a focus on health promotion and disease prevention may use home contacts as a means of identifying clients and families in need of medical care or services (case finding). Referrals to existing resources usually follow. In the childbearing age population, visitors can provide social support and health education to promote optimal pregnancy outcomes and healthy parent-child relationships, and to prevent future child abuse. Home visitation also is employed as an intervention strategy once risks have been identified, such as substance abuse during pregnancy or child abuse and neglect. Health promotion or public health home visitation programs rarely focus on the provision of acute health care. Interventions usually involve multiple encounters on a long-term basis. For instance, a community-based program may provide nurse home visits to families identified at risk for child abuse and neglect on a regular basis for the first 2 years postpartum to teach and model appropriate parenting skills. Similar programs have been initiated

for pregnant women who abuse substances, beginning during pregnancy and extending into the postpartum period.

PRINCIPLES OF HOME VISITATION

In order to be effective, home visiting programs should conform to existing standards. The Colorado Department of Public Health and Environment has proposed a set of Home Visiting Program Standards (1994) for programs providing these services:

1. Home visiting services are community-based and designed with the demographic and cultural characteristics of the community in mind.
2. Home visiting services are purposeful and goal-oriented. These services relate directly to the defined mission of the home visitation program.
3. Home visiting programs have a focus that recognizes the strength of families and promotes self-sufficiency of clients.
4. Home visiting programs utilize appropriate community services and resources to promote coordination and avoid duplication of services.
5. Home visiting programs ensure that the discipline and background of the home visitor is identified and that adequate training and oversight are provided.

In designing programs, consideration should be given to the language and cultural characteristics of the community being served. For example, programs serving a primarily non-English-speaking Latino community should employ nurses who are bilingual in English and Spanish and, ideally, bicultural. Similarly, services should target identified needs within a community. For example, developing services for childbearing women is probably not a priority in a small retirement community. Knowledge of the needs and cultural characteristics of the community is important in determining whether health needs can be adequately addressed by home visiting.

Home visiting programs should have a sense of purpose and be goal-oriented. Clear, written guidelines are key. Such guidelines should articulate the goals and purposes of the program, the population targeted, eligibility criteria (if applicable), content of services, and frequency and intensity of the home visiting intervention. Expected outcomes and criteria for evaluating outcomes also should be stated.

Skilled home visiting program staff should be able to promote self-sufficiency for the clients served, helping clients learn to help themselves. In order to meet this goal, the client must be involved and invested in the process.

REFLECTIONS FROM FAMILIES

"I didn't pay much attention to this program at first. My nurse came over to my home just to talk, to see how I was doing, to see what was up and how I felt. I thought, 'Okay, well I get it now, they are actually here to help me.' I never encountered anything like that—ever! People don't just come to your home and say, 'How are you? How do you feel? Are you living in a safe environment? Is your home stable? Do you have something to cook on? If you don't, we need to help. We need to make this pregnancy as stress-free as possible so if we can be a support system and be there for and with you, it will make this pregnancy easier for you.' I was blown away to see someone care like that."

Trierweiler, K., Ricketts, S., Kent, H., & Albert, S. (1994). *The helping moms program: A case management approach to delivering enhanced prenatal services*. Denver, CO: Colorado Department of Public Health and Environment.

The visitor and client-family unit work jointly as a team to develop a set of goals and a plan for intervention. Given this blueprint, it is best if client participation is voluntary, not mandatory. Plans tend to be one-sided when the client is compelled to participate as in cases of court-ordered visitation for child abuse and neglect. In order to ensure a successful intervention, every effort should be made to address goals that the client and family may have for themselves along with goals that the home visitor has for the client. For instance, a pregnant client may agree that smoking cessation is desirable during pregnancy; however, this goal may not be realistic for the client who, at the same time, is struggling to pay her rent. In this case, a program that is narrowly focused on prenatal smoking cessation may not be able to address the client's more urgent needs for housing. Smoking cessation during pregnancy along with adequate housing are short-term goals that impact the long-term goal of a healthy pregnancy outcome. Programs offering a broad range of services that encompass the client's needs as well as the nurse's objectives enhance the chance for mutual success. As illustrated in the previous example, once the client has adequate housing, energies may be better focused on behavior change, thus satisfying the goals of both the client and the home visitor. However, the nurse must always recognize that the client and family are the ultimate decision-makers regarding care. Doing so is relatively easy when the client makes decisions that seem rational. In contrast, it may be difficult for the nurse to support a decision she thinks may be "wrong." A client may simply decide that she cannot or will not stop smoking during pregnancy. In this case, efforts may be better focused on helping the client decrease the number of cigarettes smoked each day.

A client's value system forms the basis for decision-making. When the client's values differ from those of the

mainstream or the providers, difficulties can arise. For example, a 36-year-old pregnant woman may decide against having an amniocentesis during pregnancy because she says she would not terminate her pregnancy no matter what the test results show. This viewpoint is not in line with current medical recommendations regarding amniocentesis during pregnancy and may clash with the provider's own personal values. Clients have every right to refuse testing and treatment. The nurse must first determine that the client fully understands the recommendations. If so, the client's decision should be documented and respected. Nurses also should reflect on their own feelings and prejudices relative to the issue. Any legal (e.g., violation of the nurse practice act) or ethical implications (e.g., violation of client confidentiality) to the client's decision also should be considered.

Along these lines, home visiting programs should focus on the strengths of clients and families, not their weaknesses. Doing so can be challenging given that risk status usually is based on a deficits model. For example, the nurse may determine that a pregnant woman is at psychosocial risk because she is an unmarried high-school dropout with two children and three jobs changes in the past year. Her lack of education and work inconsistency might initially be viewed as weaknesses. However, further assessment may reveal mitigating factors. The client may have changed jobs frequently to finish her high-school education and enroll in junior college. Working at a place located closer to her childcare provider may have necessitated a job change. When deficits are evaluated in this fashion, strengths may emerge. In this example, the client is completing her education, from which new job opportunities can arise. She also has supportive family available to ease the stresses of single parenthood and to assist with a new baby. Identifying her motivation to finish school and her solid support network serves as a cornerstone in developing a plan of intervention for self-sufficiency during pregnancy and the postpartum period.

Identification of client strengths is helpful in determining the need for community resources and referrals. In the example above, based on deficits only, the client appears to be in need of a variety of resources, such as job training, subsidized childcare, and possibly parenting classes. In actuality, given the client's motivation and support system, few resources are needed. Referrals and resources also may have been provided by another provider. The popularity of home visiting as an intervention strategy gives rise to the possibility that a client or family may be working with multiple home visitors. In these cases, collaboration is key. All who provide care and services to the client and family should communicate regularly, including the medical care provider. In order to facilitate this process, one home visitor should be designated as the case manager, who coordinates the activities of all caregivers. Case

Critical Thinking

Immunizations

A pregnant client tells you at a home visit that she is planning on refusing all newborn and pediatric immunizations for her infant.

- How would you respond?
- What additional information do you need, if any?
- How does this make you feel?
- What are your feelings toward this client?
- What are your responsibilities as a care provider in this situation?

management will be discussed in more detail subsequently.

The staff of the home visiting program must have access to adequate training, consultation, and supervision. Supervision should be available in accordance with the discipline and experience level of the visitor and the complexity of the client's case. New staff should receive an ex-

tensive orientation on the goals, objectives, and purposes of the home visiting program as well as on the program's guidelines and expectations for providing care and services to clients and families. New staff should make several home visits under the watchful eye of a mentor or supervisor until the desired skill level is achieved and documented. All home visitors should be aware of the re-

Research Highlight

Long-term Effects of Home Visitation on Maternal Life Course and Child Abuse and Neglect

Purpose

To determine the long-term effects (15 years) of nurse home visitation during pregnancy and postpartally for the first 2 years relative to maternal life course and child abuse and neglect.

Methods

A randomized controlled trial was conducted in a semirural town in upstate New York in which women received an average of 9 home visits during pregnancy and approximately 23 home visits postpartally for the first 2 years. Of 400 women originally enrolled in this study, 324 participated in a follow-up investigation when their children were 15 years old.

Findings

Compared with a control group, women with low incomes who received home visitation during pregnancy and postpartally

- Were less likely to be reported for child abuse and neglect during the 15-year period after delivery: 0.29 reports compared with 0.54 reports in the control group ($P = 0.001$).
- Who also were single had fewer additional children, with longer periods between having children: 1.3 children compared with 1.6 children in the control group ($P = 0.02$), and 65 months compared with 37 months in the control group ($P = 0.001$).
- Received public assistance for a shorter amount of time: 60 months compared with 90 months for the control group ($P = 0.005$).
- Had less substance-related misbehavior: 0.41 reports compared with 0.73 reports in the control group ($P = 0.03$).
- Had fewer arrests as verified by state records: 0.16 arrests compared with 0.90 arrests in the control group ($P = 0.001$).

Nursing Implications

Prenatal and postpartum home visitation by nurses to women who are single with low incomes can lead to a decrease in the incidence of child abuse and neglect, a longer interconceptual period, fewer months on welfare, a decrease in behavior problems related to substance use, and less frequent criminal behavior for up to 15 years after the birth of the index child. Consideration should be given to wider implementation of long-term nurse home visitation.

Olds, D., Eckenrode, J., Henderson, C., Kitzman, H., Powers, J., Cole, R., Sidora, K., Morris, P., Pettitt, L., Luckey, D. (1997). Long-term effects of home visitation on maternal life course and child abuse and neglect. *Journal of the American Medical Association*, 278, 637–643.

sources available for consultation in the event high-risk medical or psychosocial conditions develop. Agency-specific systems for continuing education and quality assurance are paramount. Peer review and chart review should be ongoing quality assurance measures taken by the home visiting program. Opportunities for continuing education must be made available to all staff on a regular basis.

EFFICACY OF HOME VISITATION

The effectiveness and cost benefits of providing acute medical and nursing care services in the home for perinatal clients are subjects of ongoing investigation. Cost savings as measured by a reduction in inpatient hospital days

has been postulated. Findings from several recent studies support this notion. Cooper et al. (1996) noted that newborns in the inner city whose mothers received at least one postpartum home visit from a nurse had fewer emergency room visits during the first 3 months after delivery. A universal postpartum nurse home visiting program resulted in a twofold reduction in acute care visits during the first 2 weeks of the postpartum period (Braveman et al., 1996). The effectiveness of perinatal in-home interventions in terms of health outcomes, however, has not been proven.

Research supporting the benefit of public-health-related home visitation also is limited. Until recently, the results have been somewhat mixed. When looking at home-based health promotion activities, researchers have noted differences in pregnancy outcomes, parenting and

Research Highlight

Effects of Prenatal Home Visitation by Nurses

Purpose

To determine the effect of home visits made by nurses during pregnancy and postpartally for 2 years on the incidence of pregnancy-induced hypertension (PIH), preterm birth, maternal life, childhood behavior and development, immunizations, and injuries.

Methods

A randomized controlled trial was conducted in 1,139 women receiving care within the public health system in Memphis, Tennessee, the majority of whom were African American, at less than 29 weeks' gestation, without a previous live birth, who exhibited at least two of the following risk factors: unemployment, unmarried, and less than 12 years of education. Each participant received an average of 7 home visits during pregnancy (total number of visits ranging from 0 to 18) and 26 visits from birth and postpartally for 2 years (total number of visits ranging from 0 to 71).

Findings

Compared with a control group, women and their infants were visited by nurses during pregnancy and postpartally for 2 years. It was found that

- The women were less likely to have PIH: 13% compared with 20% in the control group ($P = 0.009$).
- The women were less likely to become pregnant again during that time: 36% compared with 47% in the control group ($P = 0.006$).
- The women had fewer medical visits during that time: 0.43 visits compared with 0.55 visits in the control group ($P = 0.05$).
- The infants had fewer hospital days for childhood injuries: 0.03 days compared with 0.16 days in the control group ($P < 0.001$).

There were no effects on preterm delivery, maternal life course, child cognitive development or behavior problems, or maternal education and employment.

Research Highlight continued

Nursing Implications

This study replicates an earlier randomized controlled trial of home visiting conducted in a rural, Caucasian population in Elmira, New York. While prenatal effects were noted only for PIH, the postpartum results for this minority urban population found a decrease in children's medical visits and hospitalizations for injuries as well as fewer subsequent pregnancies among the study participants. These results were not as dramatic as were those in the Elmira study; however, long-term nurse home visitation programs can result in measurable differences in selected postnatal outcomes in different populations. Wider dissemination of public-health-related home visiting efforts deserves consideration.

In addition, a review of the literature has shown that successful public-health-related home visiting programs do have several characteristics. Successful programs address a broad range of client and family needs as opposed to having a single narrow focus (Gomby, Larson, Lewit, and Behrman, 1993). Using home visitation as an adjunct to other intervention strategies, such as medical care, peer counseling, and drug and alcohol treatment, also appears to enhance outcomes. Broad-based programs usually offer services that are ongoing and intense. Olds and Kitzman (1993) feel that at least four home visits must be made before any gains can occur; and more if a major change in health or behavioral status is desired. These authors also believe that using nurses instead of lay or paraprofessional home visitors leads to more efficacious outcomes. This assumption has been supported in Olds' most recent research (see Research Highlights: Long-Term Effects of Home Visitation). Currently, a randomized clinical trial in Colorado is investigating the effectiveness of professional compared with lay or paraprofessional home visitors in serving women during pregnancy and early postpartum. Finally, high-risk populations appear to benefit more from home interventions than do low-risk groups. In other words, women at high risk for delivering low-birth-weight infants should benefit more from programs designed to decrease or ameliorate this risk than would the general population (Olds & Kitzman, 1993).

Kitzman, H., Olds, D., Henderson, C., Hanks, C., Cole, C., Tatelbaum, R., McConnochie, K., Sidora, K., Luckey, D., Shaver, D., Engelhardt, K., James, D., & Barnard, K. (1997). Effect of prenatal and infancy home visitation by nurses on pregnancy outcomes, childhood injuries, and repeated childbearing. *Journal of the American Medical Association*, 278, 644–652.

caregiving, child development, prevention of child abuse, and enhancement of maternal personal development (Graham, as cited in Hoover et al., 1996). An additional study suggests a relationship between nurse-community worker team home visiting during the first year postpartum and decreased postneonatal mortality (Barnes-Boyd et al., 1996). Two recent randomized, controlled trials have demonstrated benefits in reducing pregnancy-induced hypertension (PIH) along with a long-term reduction of child medical and hospital visits related to injuries.

ESSENTIAL SKILLS FOR HOME VISITING

The home visitor uses a variety of skills in providing home care. Good communication is key along with proficiency

in the nursing process: assessment, nursing diagnosis, outcome identification, planning, intervention, and evaluation. The home visitor also often functions as a case manager, or care coordinator, and therefore familiarity with community resources is imperative.

Nurses must be good communicators. Speaking clearly, directly, honestly, and nonjudgmentally should be second nature. Communication skills are particularly important in home visiting because the nurse must fully engage the client to set the stage for the development of trust and mutuality throughout the course of the home visiting relationship. Each nurse develops a particular personal style of communication; however, certain principles are universal (Figure 6-3).

Listening provides the means for good communication. Novices often are so concerned with their response that they fail to hear what the client is saying and fail to

Figure 6-3 The seeds of trust and a good working relationship are planted during the first encounter between the client and visiting nurse.

observe nonverbal cues. True listening is difficult, requiring utmost attention to what is being said verbally and nonverbally. The nurse must attempt first to understand, then to respond. Listening can be put into operation by maintaining good eye contact and facing the client with an open and accepting posture with arms uncrossed and the body leaning slightly forward. Attention is centered on the client, not the chart. Focused, caring attention, especially in the home environment, can enhance the client's self-concept and put a client at ease so that a richness of information results. Listening is a learned skill that often is underemphasized; however, listening is vital in establishing rapport and creating a climate of caring concern.

Critical Thinking

Personal Opinion

A client who is in her first trimester of pregnancy confides to you during a home visit that she has decided to have an abortion. You feel that abortion is morally wrong.

- How would you respond?
- What additional information do you need, if any?
- How does this make you feel?
- What are your feelings toward this client?
- What are your responsibilities as a care provider in this situation?
- How is this situation similar or different from the one in Critical Thinking: Immunizations?

Listening often is impaired by the fear of silence, especially when the nurse is practicing in an environment that may not be completely comfortable, such as the home. The power that silence can bring to the communication process should not be underestimated. Frequently, the client's words are only half acknowledged as the nurse uses this time instead to plan a response. Employing silence after the client stops speaking allows an opportunity for the client to clarify without any further prompting from the nurse. Often, more will be expressed if another question is not asked immediately. Silence also can be affirming, especially when accompanied by gestures on the part of the nurse, such as head shaking or touching. These techniques reflect empathy or an understanding of the client's viewpoint. Silence also gives the nurse an opportunity to process the information and briefly plan a response.

When more information is needed, the nurse may elect to paraphrase what the client has said to validate understanding and encourage additional dialog. Using open-ended questions or statements also is effective. For example, the nurse might respond, "I heard you express your concerns that this pregnancy will be normal. Tell me about your last pregnancy." Acknowledging the client's feelings is helpful. "You seem scared about being pregnant."

Body language and nonverbal cues speak loudly. Experienced home visitors attend to what is not verbalized by observing the client's expression, posture, and gestures. The client may state that her partner would never strike her, while nervously looking over her shoulder to see if he can hear her response. A question or comment here may elicit the truth.

The development of rapport and trust occurs over time. Good communication fosters the development of a long-term therapeutic relationship (Figure 6-4). Employing these techniques consistently while working with a client

Figure 6-4 Active listening, concentrating on the needs of the client, will enhance communication.

or family can lead to the development of the rapport and eventually the trust necessary for the successful completion of goals. Rapport, however, is difficult to establish in a single home visit. Good communication will result in the efficient use of the time available for home assessment.

Many barriers exist to good communication. In the interest of time, some providers may anticipate what the client will say and thus may finish the client's sentences. The client may interpret this action as an attempt to wade through what the nurse sees as extraneous information to get to "the point." A respectful approach dictates that the client be allowed to speak without interruption. Similarly, the nurse may interject advice and counseling after each client comment. It is important to note that assessments, including data gathering, must be completed before a plan can be developed and initiated. Giving information this readily does not allow for client-generated or mutually derived solutions.

Nurses may also attempt to validate a client's experience by relating a similar personal experience of their own. This technique can be helpful when used in brief (e.g., the nurse can say, "I had that same problem with my baby."); however, it is important to remember that the focus is on the client, not the provider.

Being judgmental is a powerful deterrent to communication and future interaction. Further data gathering is useless because the nurse has already made a determination about the client. Judging influences the nurse's ability to arrive at an appropriate nursing diagnosis and thus influences the subsequent plan for intervention. For example, a pregnant woman may refuse to have blood drawn for testing during pregnancy and this action may result in the nurse initially labeling her as a "bad mother." Further probing may reveal that the client is actually afraid of needles. Being judgmental is damaging. Nurses in their roles as

client advocates must guard against being judgmental by making objectively based client assessments.

NURSING PROCESS

Nurse home visitors must be skilled in using the nursing process; each of the steps is discussed as they relate to the process of home visitation.

Assessment

Home-based activities should be individualized based on an assessment of the physical, psychosocial, spiritual, and cultural attributes of the client or family (Hoover et al., 1996). These detailed assessments form a database from which a nursing diagnosis and ultimately a plan for intervention can be developed. Assessment information is derived from subjective sources (e.g., the client's medical history, chief complaint, feelings, and perceptions) and objective sources (e.g., the client's physical examination and laboratory data and the nurse's observations).

Nursing Diagnoses

For a client receiving home visits as a result of being on complete bedrest for placenta previa, relevant nursing diagnoses might include impaired physical mobility, ineffective role performance, and deficient diversional activity. These diagnoses will be reevaluated at each encounter and most likely will continue to be applicable until the client delivers the infant. The diagnosis in this case also indicates a need for health teaching and counseling. The client may exhibit deficient knowledge relative to labor and delivery information because her imposed bedrest precludes attendance at childbirth education classes.

Outcome Identification

Once a diagnosis is made, both short- and long-term outcomes should be identified. In preceding examples, the short-term outcome is avoidance of preterm labor and birth and the long-term outcome is a healthy, full-term infant.

Planning

Based on the diagnosis, the plan is developed in collaboration with the client and family (Figure 6-5). Their needs and desires must be prioritized. Issues identified by the client should take precedence unless clear threats to safety are present. For instance, a pregnant client may be concerned

Critical Thinking

Making Judgments

Some people feel that women with low incomes should not become pregnant and access federal entitlement programs such as Medicaid to finance their health care.

- How does this situation make you feel?
- What is your responsibility as a nurse caring for this population?

Figure 6-5 The plan of care for a client often includes instructions to family members.

about job training but may first need a restraining order against her abusive ex-husband. The client will be more receptive to addressing other concerns if her priority needs are met first. Other issues can then be ranked in order of importance according to mutual agreement. Prioritizing will result in interventions being developed for the most important issues first, leaving others for later follow-up.

Once priority needs have been agreed on, the nurse must ascertain that the plan reflects both short- and long-term expected outcomes. In the preceding example, the long-term outcome is for the client to live without fear of abuse and the short-term outcome might be achieving success in obtaining a restraining order.

Nursing Interventions

Nursing interventions may be preventive, such as providing anticipatory guidance or health education. Interventions may address specific health concerns, such as performing nursing procedures in response to a specific physician order. Interventions also may take the form of referrals, especially in the home visiting program. Home visiting done during the early postpartum period includes activities pertinent to all three types of interventions. For example, the new mother receives information from the nurse about normal newborn care, behavior, feeding, and parenting. The nurse also performs a physical assessment of both the mother and baby to rule out abnormalities (Figure 6-6). When a problem is discovered, such as noting that the newborn has significant jaundice, an appropriate intervention would be a referral to the pediatrician for bilirubin screening. Similarly, the mother may be referred to a new mothers' group to increase her social support systems.

Figure 6-6 Postpartum home visits will include physical assessment of the mother and newborn.

Evaluation

Evaluation is probably the most underused step of the nursing process in home-based care. Criteria established before initiating the intervention must be analyzed to evaluate the effectiveness of the intervention employed relative to the nursing diagnoses identified. For example, in the example cited previously, the woman on bedrest needed childbirth education owing to a knowledge deficit regarding labor and delivery information. If the nurse provides this teaching and notes that the client is subsequently more knowledgeable, the intervention can be deemed successful. On a larger level, nurses should be involved in setting overall home visiting program evaluation criteria. For example, an agency providing home-based services to pregnant and postpartum women might attempt to increase breast-feeding initiation and continuation rates or attempt to reduce the incidence of unintended pregnancy within their population.

When reviewing the efficacy of the plan and activities initiated, the nurse must assess progress in meeting both the short- and long-term outcomes identified earlier. For example, the pregnant client with an abusive ex-husband decided, in consultation with the home visitor, to obtain a restraining order. The nurse may phone the client several days later to verify that she has contacted legal aid. At the next encounter, the nurse will again ask if the client has spoken to the lawyer and filed the paperwork. Follow-up is ongoing until the restraining order is filed and the short-term outcome achieved. Further analysis will determine whether or not the existence of the restraining order enables the client to function without fear of abuse, which is the long-term outcome.

The efficacy of home visitation as a service delivery strategy for use with a particular client also should be

evaluated. Was home visiting the best strategy for addressing the issues? Was the nurse prepared with the appropriate information to assist the client? Would referral to a social worker have been more effective? In some cases, client needs may be better served in the ambulatory or inpatient setting. The nurse is responsible for determining which site of service would be most effective.

CASE MANAGEMENT

The nursing process shares many similarities with the process of case management. Nurse home visitors may find themselves functioning as case managers, or care coordinators, for clients and families. **Case management**, or **care coordination**, refers to the process of coordinating care and services to ensure that clients receive appropriate care and services in a timely manner. The case manager performs a comprehensive assessment, develops a plan of care, assists the client to access needed care and services, and follows up to evaluate the success of these strategies in meeting client needs (Trierweiler, Ricketts, Kent, & Albert, 1994). Underlying the process is a commitment to an active partnership between the client and case manager, with the ultimate goal of self-sufficiency.

Over 40 states have approved funding through Medicaid for prenatal case management programs for high-risk pregnant women. Case managers assist pregnant women in addressing all aspects of their life that may affect pregnancy outcome and maternal and child health in general (Trierweiler, Ricketts, Kent, & Albert, 1994). These care coordinators ensure that clients attend prenatal medical visits; assist clients in accessing nutrition and social work counseling as needed; and ensure client access to transportation, childcare, and health education.

The home is an ideal site for case management. Because the steps of the case management process are similar to the nursing process, nurses can use their full professional role to ensure that client needs and desires are identified and met.

MAKING THE HOME VISIT

The home visit consists of three phases: previsit preparation, visiting the home, and postvisit activities. The previsit and postvisit phases are as important as the visit itself. Without adequate planning and follow-up, the nurse may miss the opportunity for successful interaction and intervention. Careful preparation is paramount.

Previsit Preparation

The nurse must be familiar with the population served by the home visiting program in terms of demographics, culture, language, and religion. Agency orientation should in-

clude these vital issues; however, the nurse should review these issues again before entering the home. Further planning includes reviewing the chart and the indication for referral, assembling necessary equipment and supplies, and contacting the client or family to schedule an appointment. Familiarity with community resources is required. The issues of dress and personal safety also require careful consideration before visiting the home.

Chart Review

First, the nurse must be familiar with the indication for the home visit. Careful review of all available client information is recommended, with attention to basic client demographics, such as age, gravity, parity, number and age of children in the home, and presence of the partner and significant others. When provision of acute care is the purpose of the visit, review of the hospital discharge summary will highlight the client's physical status. When the client will be receiving a postpartum home visit, labor and delivery data (date, time and type of delivery, complications, postpartum course, and date and time of discharge) as well as newborn status (date and time of birth, birth weight, weight at hospital discharge, type of feeding, circumcision status, and problems or complications during hospitalization) are crucial. Frequently, the nurse will receive paperwork from the referring agency that addresses most of this information. Access to this data enables the nurse to begin assessing the potential needs of the client and family based on the information assembled to date.

When the client has been receiving home care services, the current home health chart should be reviewed before the visit. In this way, the new home visitor is aware of previously initiated goals, objectives, plans, and interventions and can continue following the current plan of care. The client will not be required to repeat information to a new practitioner.

Chart review is especially important in scheduling the amount of time needed for the visit, in planning potential activities or interventions, and in assembling the equipment that may be needed. For example, the assessment and plan will likely be different when a home visit is to be made to a 14-year-old primipara with premature twins compared with a 34-year-old multipara with a term newborn and supportive partner. Given this information, the nurse may anticipate spending more time visiting the teen mother than the multipara mother. The potential activities and interventions also will differ. The adolescent may be in need of extensive teaching about newborn care and a discussion of available resources, whereas the older mother may need only reassurance about infant health and reinforcement of parenting information. Flexibility is key because this situation may not play out as expected. It could be that the older mother is experiencing a problem

with postpartum depression while the adolescent is receiving the help and support of her extended family.

Assembling Equipment and Supplies

Necessary equipment and supplies must be assembled before the home visit. Knowing something about the family demographics (e.g., if any children will be present), the physical environment (e.g., if there are running water and a private space for talking or performing an examination) along with the indications for the home visit will allow the nurse to gather adequate supplies. The nurse should always carry rudimentary medical and nursing supplies, even if the purpose of the home visit is primarily oriented toward education. A stethoscope, blood pressure cuff, thermometer, small light source, sterile and unsterile examining gloves, paper towels, Handiwipes, and alcohol swabs are supplies that should be routinely carried. Other medical supplies may be needed, depending on the indication for the visit (e.g., a baby scale or medications). A supply of commonly used teaching materials and brochures also should be assembled. Veteran home visitors often carry a resource or referral directory containing the names, addresses and phone numbers of neighborhood health care providers, health and human services agencies, and support groups. The ability to supply the family with the appropriate contact information at the time of the visit enhances follow-through.

When children will be present in the home, the nurse may bring a small assortment of age-appropriate toys. These should be easy to clean and should be disinfected after each home visit. Toys distract children, allow evaluation of growth and development, and provide opportunities for assessment of parent-child interaction and teaching regarding age-appropriate play and stimulation.

Scheduling the Visit

Once the referral has been received and the preparatory data collected, the nurse contacts the client and family to establish a mutually acceptable time for the home visit. Timing of the visit is important. In cases in which acute care will be provided, the timing must be such that critical medical needs are addressed and the scheduled regimen of care initiated. For example, in the case of a postpartum family experiencing a hospital stay of 18 to 24 hours, it is crucial to visit during the first 24 to 48 hours after discharge because newborn jaundice or feeding problems may be evident at this time. This fact should be emphasized when phoning the family to set an appointment time. Similarly, the nurse may need to visit a pregnant woman on bedrest for PIH daily or every other day to closely monitor her condition and response to bedrest. When the home visit has a preventive health or psychoso-

SCHEDULING THE HOME VISIT

1. When calling to schedule an appointment, give your name and title and identify the agency you represent.
2. Discuss how and when the client was referred and the purpose of the home visit.
3. Briefly outline what will be done during the visit and estimate the amount of time required.
4. Write down detailed directions to the client's house. Consult a map before leaving the office if you are uncertain about the location.
5. End the phone call by verifying the date and time of the visit. Confirming the visit the day before will help avoid missed appointments.
6. Plan to keep your scheduled appointments and arrive on time. Notify the client as soon as possible if you will be late or if you need to reschedule the home visit.

cial focus, it is best to visit when the client and family are responsive and ready to accept the home visitor. In this situation, the nurse may call and discuss the home visiting program with the client and family and then allow them to suggest appropriate times and schedules. It is best to give a deadline for a response, such as a week or 10 days. An example of such a program might be one in which a pregnant woman at psychosocial risk agrees to receive home visits during pregnancy and postpartally to promote optimal pregnancy outcome and increase parenting skills.

Dress

The home visitor should dress professionally and appropriately. Although a uniform or laboratory coat is not necessary (but often is supplied by the employer), it is important to avoid being underdressed or overdressed for the occasion. Jeans, shorts, and revealing clothing are as inappropriate as are dressy, designer ensembles. In general, casual slacks or skirts with low-heeled shoes should be worn. Jewelry should be kept to a minimum. Expensive personal items should not be taken into the client's home. An identification badge with a photograph should always be worn, listing the visitor's name, title, and agency affiliation. The nurse should also attend to the client's own standard of dress, which may vary according to culture. The nurse may decide to dress more formally or casually based on her observations during the initial visit.

Safety

Being knowledgeable about maintaining personal safety is paramount. Safety issues should be taken into consideration when planning for the home visit. The agency and supervisor should be aware of the visitor's schedule for the day. A copy of the appointment schedule can be posted centrally within the agency, including clients' names, addresses, telephone numbers, visit times, and estimated times of completion. Cellular phones should be available for staff use. Gather information about the neighborhood to be visited. If the area is potentially unsafe, working in pairs may be an option. In addition, a call to the police or sheriff's department might result in an escort. While driving to the client's home, the nurse should look for public

places where aid could be requested if necessary, such as gas stations, grocery stores, and police or fire stations. Some agencies supply an identification card that can be mounted on the dashboard when the car is parked outside the client's home, alerting others to the car's official status. Activity near the home, such as groups gathering, shouting, and fighting, or a complete absence of activity should be observed while approaching. When leaving, the visitor should pay attention to how these activities might have changed. Client input also can be helpful when assessing threats to personal safety. Clients may advise visits at certain times to avoid potential confrontations. If the visit is to take place in a high-rise building, the nurse should try to ride the elevator either alone or with a group of peo-

Nursing Tip

PERSONAL SAFETY ON A HOME VISIT

1. Keep your car in good working order and the gas tank filled. A flashlight, first aid kit, emergency flares, and items appropriate for a weather emergency should be kept in the trunk. If car trouble develops, raise the hood and stay inside the car with the doors locked. Use a cellular phone if available to call a local gas station or towing service. If someone stops to help, ask the person to call the closest gas station.
2. Park as close to the client's home as possible, ideally in a space that is visible from the home. Avoid dark streets, concealed driveways, and alleys. Keep the car doors locked at all times. Remember where your car is parked.
3. Make certain that all supplies and client records are stored in the trunk or out of view.
4. Carry as little money as possible but keep change for a pay phone handy or carry a cellular phone. Carry your purse close to your body, or conceal it in a briefcase or file. If possible, avoid carrying a purse at all; carry your wallet in a coat pocket.
5. Request that pets be restrained before you arrive at the home. Be cautious about entering the yard, even if an animal is restrained.
6. Avoid walking close to buildings, doorways, dumpsters, or any place that could conceal a person. Walk confidently, with your head up, scanning the area for possible threats. If you are being followed, cross the street or zig-zag back and forth. Walk toward people or lighted areas.
7. When returning to the car after the visit, have car keys ready to quickly unlock the doors and start the engine. Look in the back seat and on the floor to ensure no one has broken into and is hiding in your car.
8. Watch for any cars that might be following you as you leave the home. If you are being followed, proceed to a well-lit public area or a police station. Never stop, even if someone indicates they are having a medical problem.
9. If you are accosted, use any means possible to get away including biting; scratching; kicking the shins, groin, or instep; screaming; yelling "Fire"; or blowing a rape whistle attached to a key ring. Carrying concealed weapons is not recommended.
10. If a situation feels unsafe, it probably is unsafe. Promptly leave any situation that may pose a threat to personal safety.

Sometimes, a threat to safety develops after the nurse has entered the home. Potentially dangerous situations might involve an abusive spouse or family member or the presence of weapons or illicit substances. Again, the nurse should quickly assess the situation and leave as circumstances dictate. The nurse may need to report these instances to the proper authorities, depending on the dictates of agency policy and state or federal laws.

ple. Stairwells often are safer than elevators. The home or apartment should not be entered if there are safety concerns. Most agencies have policies addressing safety issues.

Visiting the Home

The initial visit to the home sets the stage for future interactions between the client, family, and nurse. The home visitor confronts the unknown at this first encounter, entering into an environment controlled by others. The client also may be apprehensive about inviting a “stranger” inside, concerned about what the nurse may say and do while in the home. Thus, it is vital that the visit be conducted in a professional fashion to set the client and fam-

ily at ease and to allow the nurse to meet both agency and client objectives for the visit.

Initiating the Encounter

On arrival, the nurse should always knock before entering, even if the door is open. The visit begins with introductions (Figure 6-7). The nurse should identify herself by title and the agency represented, state the purpose of the visit, and estimate the amount of time required for the encounter. Giving the client a business card also is a good practice, reinforcing the nurse’s position as a professional as well as providing a means for future contact. The client usually will introduce children and any other family members or friends who may be present. If not offered, these additional introductions should be requested.

Consent for services must be obtained before any services are performed. Most agencies require that the client sign a release of medical information request, allowing home visit data to be shared with other agency

BLOODBORNE PATHOGENS AND HOME VISITING

The nurse home visitor must use precautions in providing nursing care in the home to protect against exposure to bloodborne pathogens. Precautions (Occupational Health and Safety Administration, 1991) for home visiting include the following:

1. Wearing gloves when exposure to blood or body fluids is possible.
2. Washing hands immediately after any contact with potentially infectious materials.
3. Using eye or mouth protection when splashes, splatters, or droplets of potentially infectious materials may pose a hazard to the eyes, nose, or mouth.
4. Using the proper procedures with needles. Used needles should not be recapped, bent, or otherwise manipulated after injection. Used needles must be placed in a puncture-resistant container that has been brought into the home for this purpose. This container should be removed from the home for disposal at the agency.
5. Discarding items contaminated with blood or bodily fluids appropriately. Dressings, bandages, gloves, eyewear, and so on, that have been contaminated with blood or bodily fluids during the home visit should be discarded in appropriately marked biohazard bags and removed from the home by the nurse.

Figure 6-7 A warm greeting sets the tone for a positive house visit.

Critical Thinking

Performing Physical Assessments in the Home

Some nurses feel uncomfortable examining a client in a nonmedical setting. Ask yourself how you could best facilitate an examination in the client's home.

- Should you use the client's bed or would the couch suffice?
- How will you deal with children if they need to be present while the examination is being done?
- Could any supplies, such as pillows, screens, or drapes, be brought into the home to facilitate this process?
- Should you practice examining clients in the clinic to feel more confident of your skills before attempting a home visit?
- Would observing another nurse's technique be helpful?

providers, referral sources, and third-party payers. The client and family should be assured that all information, except as indicated, will remain confidential. Families must be informed of the nurse's responsibility as a health care provider, under most state laws, to report any cases of suspected child abuse or neglect. Any other discussions about the client or family with program staff, health care providers, or referral sources should occur solely for the purpose of client or family assistance.

A discussion of the purpose and goals of the visit, the role and responsibilities of the home visitor, and the rights and responsibilities of the client should occur early on. Client and family expectations should be elicited and clarified. The nurse then will attend to the business at hand by employing the nursing process, as discussed previously, in collaboration with the client's input to develop a mutually derived plan.

Distractions

The efficiency and effectiveness of home visiting can be compromised by distractions. The television or radio may need to be turned off to enhance attentiveness. If other family members are present, the visit may need to be moved to another room to allow for more privacy. The needs of small children cannot be ignored. Having toys available can facilitate uninterrupted conversation. It may be more efficient to schedule the visit at a specific time, for

example, when the baby usually is napping or the 3-year-old is at preschool.

The client may respond to distractions to avoid talking with the nurse, especially if she is apprehensive about the reason for the visit. This behavior often can be prevented by a careful explanation of the intent and purpose of the visit at the beginning of the encounter. As rapport and trust develop over time, this behavior should be less of an issue. However, the nurse should explore these feelings with the client and family when they surface.

The nurse may be distracted during the encounter for other reasons. There may be a perceived threat to personal safety, which inhibits or halts the interaction. The nurse also may be overwhelmed by the volume of work to be accomplished at the visit and may not be attending to client input regarding needs, wants, and desires. For example, the visitor may only be able to provide one visit to a new postpartum mother. In this time, complete maternal-newborn physical assessments and maternal-newborn teaching must be accomplished; the client, however, may be focused solely on breast-feeding and sore nipples.

The client's lifestyle, culture, and value system may be in such contrast to those of the nurse that meaningful interaction is difficult. These situations usually are rare if the nurse has taken time to inventory her own values, beliefs, and biases. Once these issues can be put aside and rational assessments made, the nurse should be able to distinguish a situation that is potentially hazardous from one that is simply different. Developing a familiarity with the culture and values of the population that is being served can foster a nonjudgmental approach.

Nursing Tip

WHEN A NURSE'S VALUES AND BELIEFS ARE IN CONFLICT WITH THOSE OF A CLIENT

1. Clarify your feelings. Why are you reacting to the client's decision and lifestyle? Is the decision or behavior dangerous or different from that of your own belief system?
2. Identify your legal, moral, and ethical responsibilities to the client.
3. Recall your role as client advocate.
4. Consult with other professionals about your feelings and responsibilities.
5. Maintain a nonjudgmental attitude.

Ending the Visit

At the end of the visit, the nurse should reiterate the specific plans for follow-up, highlighting the responsibilities of the nurse and the client and family. For example, if the mutually derived plan includes the client deciding to cut down on her smoking during the next week, the nurse should remind the client that she agreed to smoke one fewer cigarette each day for the next week. The nurse should mention that the client will receive a phone call in a few days to support her efforts. Ascertaining that the client knows how to contact the agency if necessary also is recommended. If additional home visits are planned, another appointment should be scheduled at this time and plans for the next encounter reviewed. If only one home visit is planned, the nurse should make certain that the client is aware of other resources for medical care, support, and education as needed.

Postvisit Activities

Postvisit activities include evaluation and documentation. Evaluation is important for measuring whether goals have been met or need revision. Documentation is essential for providing seamless provision of care by the health care team.

Evaluation and Follow-up

Some time usually is spent reflecting on the success of the visit in terms of progress in meeting short- and long-term goals. As discussed previously, progress may be slow, especially early in the home visiting process. In cases in which single encounters are the rule there is no opportunity to see progress. Nonetheless, it is still important to review the success of any interventions implemented. In like manner, the nurse also may examine the effectiveness of home visitation as an intervention strategy given the indications for client service. For example, the nurse may have visited the home to provide instruction in childbirth education to a pregnant woman on bedrest for preterm labor. The client may have been better served by watching a video series on childbirth education, with subsequent telephone follow-up to answer any questions. The most effective method may need to be determined by a research project studying the results of both methods. Evaluation often points to a need for follow-up. To use an earlier example, the pregnant woman who agrees to stop smoking during pregnancy needs close follow-up in addition to her scheduled home visits to be successful. The nurse may need to phone the client three to four times each week to check on progress or provide encouragement. Similarly, a client who is trying to parent preterm twins may need a great deal of assistance in accessing medical care and re-

sources. Frequent phone contact and coordination with other service providers may result in the client keeping her appointments and accessing additional resources.

Follow-up often is neglected or lacking in intensity because nurses may feel that the client should take responsibility for her part of the care plan. Unless the client has the skills to act independently, however, her situation will remain unchanged. Follow-up helps address a client's dependency needs. In order to be successful, the client must have experienced success in the past and thus feel confident of her ability to succeed again. This sense of confidence and competence allows the client to act independently. Follow-up provides the ongoing encouragement and advice that is needed to nudge the client along the continuum of self-sufficiency. Once the client realizes that resources for assistance are available and success is possible, progress toward independence will result.

Documentation

Documentation provides a clinical and legal record of the home visit and serves as a means of communicating with other service providers. Reimbursement is tied to appropriate recording. Payers often designate which services need to be documented for maximum reimbursement to be approved. Most agencies designate specific forms and formats for documentation. All aspects of the nursing process should be recorded.

Organizing information according to a SOAP format (subjective, objective, assessment, and plan) leads to a coherent entry. Each note should begin with the date of the encounter along with the reason for the referral. The goals and objectives for this particular visit are recorded. Subjective data consists of the client's historical information, data collected from other sources (e.g., other health care providers and extended family), and statements made by the client. Objective data consists of data directly observed by the nurse on the date of the encounter. Physical examination data and laboratory results fall into this category. Under assessment, the nurse records the nursing diagnosis or impression based on the subjective and objective data relative to the client's condition. Evaluation data may be included here initially. Subsequently, evaluation data are relegated to the subjective or objective domains, depending on whether the evaluation criteria are reported on by the client or directly observed by the nurse. The plan category details interventions performed during the visit as well as those planned or recommended for the future. Any referrals made or consultations initiated would be documented here along with plans for follow-up. In addition, mutually agreed on goals may be recorded in this section to allow for follow-up at the next encounter. The note concludes with the date of the next encounter. If only one

visit will occur, the plan should note that the client received information about other resources. Each entry must be signed with the complete name and title of the home visitor.

Documentation can be accomplished during or after the visit. Nurses may record assessment information as they interview the client and family. The entire entry is completed once the visit is concluded. Making some rudimentary notes during the visit ensures that all pertinent information is included in the final entry. Keep in mind that the client may review the chart at any time. All entries should be professional in nature, using objective information to arrive at a logical and nonjudgmental assessment.

The chart also is a legal record. Complete documentation protects the nurse and the agency in the event of litigation. The health care provider may have provided the standard of care but may have failed to comprehensively record the information. For legal purposes, an intervention that is not recorded did not occur. Thus, careful attention to charting is crucial.

CHALLENGES OF HOME VISITATION

Despite the benefits of home-based care and services, challenges also exist. Clients and families often present with multiple needs and issues. In addition, home visitors struggle with the issues of dependency versus self-sufficiency in working with clients and families. Home visitors primarily work alone, having fewer on-site resources available than might be accessible in the ambulatory or inpatient setting. The emotional investment required to build a relationship between the client and nurse may make it more difficult to maintain a healthy distance. Home-based interventions, in particular, must be highly individualized to address the cultural, social, and economic diversity among clients within their own environment. Finally, in some cases, the length and intensity of home-based services are dictated by cost and reimbursement issues and not necessarily by client needs or outcomes.

Meeting Multiple Needs

Home visitors providing acute home care services or interventions focused on health promotion often are confronted with a group of clients that are at high risk. Currently, clients are being released from the inpatient setting earlier than ever before in the course of recovery. Consequently, they have more health care needs that require home-based convalescence. As a result, nursing care and procedures in the home are more complex, often requiring longer and more frequent visits. In the face of an overwhelming number of medical and physical care needs, the

client's psychosocial issues often are not being addressed. Nurses visiting the home to provide public-health-oriented interventions face similar challenges, as discussed in Chapter 38. In certain situations, clients and families may face multiple economic and psychosocial hardships so that the predominant mode of care becomes ongoing crisis intervention. Proactive planning and the setting of mutual goals rarely occur because the pressing needs of the moment always take precedence.

Fostering Self-sufficiency

In both acute care and public health settings, overall goals consistently emphasize recovery and self-sufficiency. Most interventions attempt to move the client along the continuum of care to meet these goals. Dependence is viewed as undesirable; however, dependency needs must be met before the client can assume responsibility for self-care. The initial assessment takes these issues into consideration. By mutually deriving a plan of care, the nurse and client can identify overall goals for recovery or self-sufficiency, highlighting specific areas in which assistance is needed to meet those goals. Initially, more assistance is given by the nurse, who provides a role model for the skills and behaviors necessary for independence. Frequently, however, these steps are skipped because the pressures of time and reimbursement limitations push providers toward an end to the intervention. The client outcome or the home visiting strategy as a whole may be viewed as being unmet or unsuccessful when, in fact, the process was simply too short to result in significant behavioral change.

Physical and Emotional Overload

The home care nurse faces more isolation than do other health care providers. In the hospital or ambulatory area, other staff is available for assistance, support, and consultation. In the home, the nurse works alone. The nurse experiences physical and psychological stressors. Clients receiving acute home care often require much from the nurse in terms of physical assessment and monitoring. Their emotional needs are such that social support also is a necessity. Similarly, with health promotion activities, ongoing psycho-emotional issues can be time-consuming for the nurse and difficult to resolve. This isolation coupled with the volume of work and the emotional investment required to establish trust and mutuality can lead to frustration, depression, and feelings of guilt or low self-esteem on the part of the nurse. Home visitors need an opportunity to discuss their case load with peers, supervisors, and other providers. Regularly scheduled case conferences and staff meetings provide an outlet to express feelings and a

chance to obtain peer support. Peer support also decreases staff burnout and turnover. However, administrators sometimes view these non-revenue-producing activities as superfluous. Time allotted for consultation and oversight is critical to the provision of quality care.

Responding to Client Diversity

Home visitors interact with populations of great cultural, social, and economic diversity. The nurse must be familiar with the cultural practices of a variety of groups and respond sensitively and appropriately (Wasik, 1993). Home visitors must be aware of the characteristics of the communities that they serve and demonstrate an understanding and appreciation for cultural differences. For example, assigning a male nurse home visitor to provide care for a Muslim woman would be culturally inappropriate because religious tenets forbid Muslim women to receive care from male providers. In some cases, administrators have been slow to authorize recruitment and hiring of bilingual or bi-cultural personnel. An interpreter should always accompany the nurse on a home visit if bilingual professional staff is not available.

Cost and Reimbursement

Appropriately, with the advent of managed care, the health care arena has been called on to demonstrate a cost-effective approach to client care and service. A balance must be achieved between management of costs and provision of quality service. Third-party reimbursement is tied primarily to the provision of technical and procedural nursing care rather than health promotion, health education, and support. Nurses find themselves providing preventive health services while attending to the acute health care needs of the client, the so-called billable service. Many agencies use reimbursement from acute home health care to fund health promotion and education in the home. Additional outcomes-based research is necessary to establish the cost benefits of preventive home care to ensure reimbursement solely for these valuable activities. Given the recent research of Olds et al. (1997) supporting the long-term cost-effectiveness of these types of home visit interventions, however, focused on prevention reimbursement.

TERMINATING THE HOME VISITING RELATIONSHIP

Home visiting services are terminated when the service plan has been accomplished, the strategy is not resulting in problem resolution and alternatives are available, reim-

bursement is exhausted, or the client no longer desires or needs care. The process of termination often is difficult for both the client and the nurse, especially if the relationship has been a long one. Because the nurse-client relationship has involved a great degree of trust and mutuality, a sense of loss may ensue for both the nurse and the client-family. Preparation for termination best begins at the initial encounter. The client must be made aware of the expected length of service, which may vary according to agency or reimbursement policies; the amount of special funding or grant funds available; and the amount of time estimated to accomplish the stated goals and objectives. The termination date should be reiterated at regular intervals throughout the home visiting relationship. The last few encounters should focus on identifying other resources for care and services and planning for follow-up once visitation ends. This information also should be completely documented.

It is helpful to discuss the affective aspect of the home visiting process with the client to facilitate a successful termination. The client should be encouraged to voice her feelings and reflect on the process and the home visiting relationship. The nurse should verbalize the positive aspects of the relationship.

Termination issues are virtually nonexistent with single encounters or when clients refuse services. The nurse may feel a sense of responsibility if the home visiting intervention is terminated for ineffectiveness. When a case is not progressing smoothly, it is helpful to review the plan of care with a peer or supervisor to confirm that the plan is a valid one. A therapeutic relationship usually is not terminated without consultation and discussion by the staff involved.

Critical Thinking

Terminating the Home Visiting Relationship

A client for whom you provided ongoing home visitation services continues to call you several times a week approximately 2 months after the relationship was terminated owing to reimbursement limitations.

- How would you respond to this client on the phone?
- Which problems might arise if this relationship were to continue?
- What is your professional responsibility in this case?

When the relationship is terminated as a result of reimbursement limitations, the client may feel abandoned, especially if care ends before goals and objectives have been accomplished. In this situation, the nurse must ensure that the client is well acquainted with existing resources and service alternatives. Termination, if planned and executed proactively, can provide a fitting end to a satisfying and hopefully successful helping relationship.

Web Activities

- Locate your state's Visiting Nurse Association (VNA). Does it have a web site? What type of professional information is offered regarding regulations for home visits in your state? Compare these regulations with those listed for a neighboring state.
- Visit a local hospital's web site for information on its home visiting program.

Key Concepts

- Home visitation is a means to providing direct health care services, health education, and psychosocial support to clients and families.
- The growth of social reforms and the expansion of the field of social work contributed to the rise of home care programs in the early 20th century.
- The home as the site of delivery provides the nurse with a unique opportunity to assess the client and family in their own environment.
- Home care can be provided by home health care agencies, hospitals, public health departments, schools, and other institutions.
- Cost savings in the form of reduced inpatient hospital stays is one of the many benefits of home care.
- The home visit consists of three phases: previsit preparation, the visit, and postvisit activities.

Review Questions and Activities

1. Why is it important for the home visitor to be culturally sensitive?
2. List two important principles of home visiting and give examples of how these might be put into operation by the nurse during the home visit.
3. List three tasks the nurse should perform before making a home visit.
4. Identify three strategies to promote communication during a home visit.
5. You are visiting a pregnant woman at home. Identify three nursing observations that might be made to assess the following: living necessities, coping and stress tolerance, and nutritional status.
6. List three strategies for ensuring personal safety during a home visit.
7. You have just completed a home visit where you provided extensive breast-feeding education and support to a new mother. How can the outcomes of this visit be evaluated?
8. Identify important areas for documentation after the home visit.
9. Discuss two limitations of home visits.
10. Discuss the challenges involved in terminating the home visiting relationship.

UNIT II

Health Care of Women

Development of Women Across the Life Span

“So much has happened during the past 40 years. I feel as though I’ve been through so many changes; something was always happening. When I was in my teens, I had a hard enough time dealing with my changing body, let alone the relationships that were constantly changing with friends, boy-friends, parents, and grandparents. Now that I’m a parent, I understand why my parents acted as they did. They were looking out for my interests. I think that the best years are yet to come. I’m finally comfortable with myself, and my body. I feel good. I love my job, and I am very happy with my relationships. I know that I have to manage my stress, exercise, and eat right to take proper care of myself, but overall, I’m very pleased with my development as a woman.”

Key Terms

Adolescence	Hypothalamic-pituitary- ovarian axis	Ovulation	Stress incontinence
Anovulatory cycle	Menarche	Perimenopause	Tanner Stages
Corpus luteum	Menopause	Pseudomenstruation	Thelarche
Gonadotropin-releasing hormone (Gn-RH)	Osteoporosis	Puberty	Urge incontinence

Competencies

Upon completion of this chapter, the reader should be able to:

1. Describe the hypothalamic-pituitary-ovarian axis.
2. Determine physiologic development using the Tanner Stages.
3. Understand the three phases of the menstrual cycle.
4. Discuss the rationale behind adolescent risk-taking behavior.
5. Discuss adolescent emotional development.
6. Describe the hormonal and physiologic changes during pregnancy.
7. Understand the psychosocial changes that occur during pregnancy.
8. Name three cultural differences in women across the life span.
9. Discuss the physiologic changes of the peri- and postmenopausal periods.
10. Name five psychosocial issues of the aging woman.
11. Describe self-care methods across the life span.

Women experience many changes throughout their lives. Women learn behaviors in the context of their experiences in their cultural environments that affect socialization of the roles they participate in and their choices with respect to their lives, including choices relating to health care. Their environment and responsibilities may affect their ability to access the health care system for preventive care, health education, and prenatal care compared with their ability to access emergent care for acute onset and late-stage illnesses.

As women age, their health care choices may be abundant or dependent on lifestyles and careers. Resources may be limited by fixed incomes, chronic illness, and loss of family and life partners. There are more women in the U.S. population than there are men, and a woman's life expectancy is 79 years compared with 72 years for men (Commonwealth Fund, 1997). As a result, additional health resources are used by women. By understanding the physiologic and psychosocial needs of women who are aging, nurses can better direct clients to the most appropriate resources available.

This chapter focuses on female development in utero through senescence. The discussion begins with the cellu-

lar changes that differentiate the female from the male reproductive system and continues to the hormonal effects at birth. Next, the female adolescent's physical, emotional, and cultural development are examined. The discussion proceeds to the young adult, the woman during midlife, and the mature woman. Included are specific self-care and cultural cues to assist the nurse in providing culturally appropriate health care to women throughout their lives.

PRENATAL THROUGH EARLY ADOLESCENT YEARS

Initial differentiation between genders begins at fertilization at the time in which the genetic sex is determined by chromosomes XX (female) or XY (male). After the female genetic sex is determined, development of the reproductive system occurs in three phases: ovarian development, duct development, and the development of the external genitalia. By 10 weeks' gestation, the ovaries can be identified. By approximately 16 weeks' gestation, the cells that will later make up the ovarian follicles can be identified (Blackburn & Loper, 1992).

Genital duct development leads to the development of the uterus, fallopian tubes, and vagina. The embryo has two pairs of ducts, the mesonephric duct (wolffian) and the paramesonephric (müllerian) duct. The ducts develop side by side. The paramesonephric ducts are dominant in the female embryo and continue to develop, while the mesonephric ducts degenerate. The opposite occurs in the male embryo. The paramesonephric ducts develop into the fallopian tubes, uterus, and vagina by 16 weeks' gestation (Blackburn & Loper, 1992).

The development of the external genitalia is complete before that of the internal reproductive organs. Differentiation of male from female external genitalia occurs in the absence of androgens. The clitoris develops. The urethra and vaginal orifice open into the vestibule. The labia majora and labia minora develop from the surrounding connective tissue. The development of the external genitalia is complete at approximately 12 weeks' gestation (Blackburn & Loper, 1992).

During the newborn assessment shortly after birth, both female and male infants may exhibit signs of circulating maternal estrogens. The newborn's breasts may seem slightly swollen and enlarged, with nipple size ranging from 1.0 to 1.5 cm. The swelling will resolve in time and rarely lasts beyond the first month of life.

Not only is the breast tissue affected by maternal hormones, the female genitalia also are affected by maternal estrogens. The labia minora and labia majora appear engorged, and the labia minora may be more prominent than is the labia majora. A pinkish-white mucoid vaginal discharge also may be noted in the diaper. This is termed **pseudomenstruation** and is a sign of maternal transfer of estrogen. On resolution of the maternal hormonal effects, the childhood hormonal values are maintained at a static level until the nighttime changes that occur just before the onset of puberty.

ADOLESCENCE

Adolescence can be defined as the passage from childhood to maturity. Adolescence begins with the appearance of secondary sex characteristics and ends with cessation of growth and lasts from approximately ages 11 to 18 years. **Puberty** is the onset of the process of physical maturity. At puberty the secondary sex characteristics begin to develop and the capability of sexual reproduction is attained. The events leading to puberty occur in a timed sequence that is initiated with the secretion of the gonadal hormones and the development of the secondary sexual characteristics (Stedman, 1995). As girls move through adolescence, they become concerned with appearance, beauty, and their changing bodies. As adolescent females begin to mature physically, they look to their peers for recognition and val-

idation. They begin to make choices based on the interaction of the social group and peer relationships rather than on family recommendations. Emotional maturity is related to life experiences and the ability to make appropriate life choices and therefore often occurs many years after physical maturity. The cultural influences of the family and peer group in turn influence the life choices of the adolescent.

The age of pubertal growth ranges from 8 to 14 years. Any visible sign of pubertal development before age 8 years in girls is considered precocious and needs further medical investigation (Rosenfeld, 1997). The age of puberty may be determined by health status, genetics, and nutrition. Theories suggest that a minimum body weight of 48 kg and a minimum percent of body fat, 17%, are necessary for **menarche**, the onset of menstruation, to occur (Speroff, Glass, & Kase, 1999).

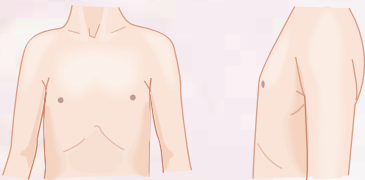

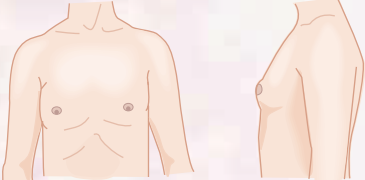

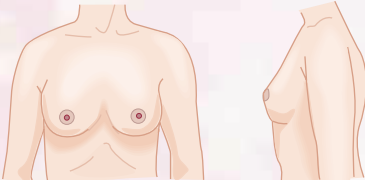

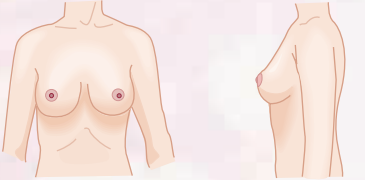

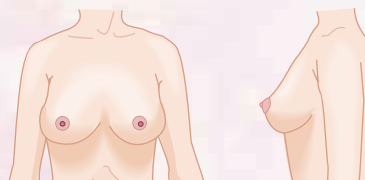

Physiologic Changes

The onset of puberty and menarche occur as a physiologic response to hormonal pulses associated during the sleep cycle. The pulses are cues of the **hypothalamic-pituitary-ovarian axis**, which is the transport mechanism of a hormone from the hypothalamus that stimulates the release of gonadotropins that, in turn, stimulates the ovaries to release estrogen and progesterone. The pulses begin between the ages of 6 and 8 years with the nighttime release of **gonadotropin releasing hormone (Gn-RH)** from the hypothalamus. Gn-RH flows to the anterior pituitary gland by way of the portal circulation, causing the release of the gonadotropins, or luteinizing hormone (LH) and follicle stimulating hormone (FSH). Gonadotropins such as LH and FSH are released from the anterior pituitary gland. LH and FSH stimulate the ovary to release estrogens, progestins, and androgens. Early hormonal stimulation precipitates the developing changes in the female reproductive organs: the breasts, labia, vagina, and uterus. Changes in the reproductive organs typically occur 2 years before the onset of menstruation (Blackburn & Loper, 1992). Hormonal stimulation also leads to rapid growth of the axial skeleton, resulting in the so-called growth spurt frequently experienced before the onset of menses.

External Development

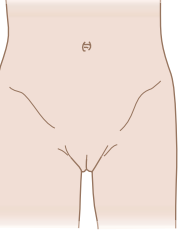

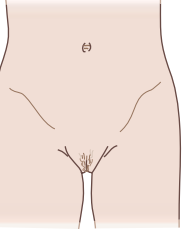

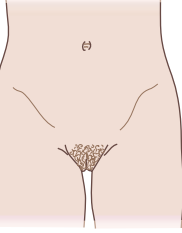

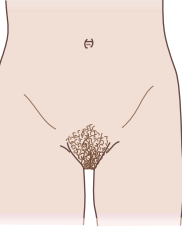

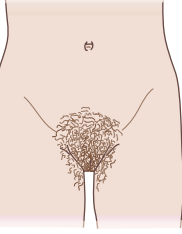

The **Tanner Stages** are the five stages of female and male development developed by Tanner (1981) and recognized today as the standard in adolescent physical development (Tables 7-1 and 7-2). Stage one is the state of preadolescence, in which there are no signs of physical maturity. Stage five represents full maturity of the breast and pubic hair development. The initial visible sign of puberty is **thelarche**, or the prominence of glandular tissue in the breast behind the nipple, also called the breast bud.

Table 7-1 Sexual Maturity Rating for Female Breast Development

Developmental Stage	Description
	1. Preadolescent stage (before age 10) Nipple is small, slightly raised.
	2. Breast bud stage (after age 10) Nipple and breast form a small mound. Areola enlarges. Height spurt begins.
	3. Adolescent stage (10–14 years) Nipple is flush with breast shape. Breast and areola enlarge. Menses begins. Height spurt peaks.
	4. Late adolescent stage (14–17 years) Nipple and areola form a secondary mound over the breast. Height spurt ends.
	5. Adult stage. Nipple protrudes; areola is flush with the breast shape.

Simultaneously, or shortly thereafter, the first sign of pubic hair development is noted sparsely on the labia majora and mons pubis. This is indicative of Tanner Stage two. Stage three reveals further enlargement of the breast mound (the areola and breast as one unit). A slight darkening of the areola pigment may be noted. Sparse, dark, curly hair is noted over the mons pubis. In Stage four, separation of the areola-nipple unit above the breast occurs. The pubic hair appears adultlike but is limited to the mons pubis and labia. The final stage, Stage five, reveals further nipple-areola development, with increased pigmentation and the enhancement of Montgomery’s tubercles and

Table 7-2 Sexual Maturity Rating for Female Genitalia

Developmental Stage	Description
	Stage 1 No pubic hair, only body hair (vellus hair)
	Stage 2 Sparse growth of long, slightly dark, fine pubic hair, slightly curly and located along the labia (ages 11 to 12)
	Stage 3 Pubic hair becomes darker, curlier, and spreads over the symphysis (ages 12 to 13)
	Stage 4 Texture and curl of pubic hair is similar to that of an adult but not spread to thighs (ages 13 to 15)
	Stage 5 Adult appearance in quality and quantity of pubic hair; growth is spread to inner aspect of thighs and abdomen

ducts on the areola. The pubic hair is adultlike, with extension to the inner thighs. By Tanner Stage 5, the labia majora increases to twice the size of the labia minora. The vaginal orifice becomes more prominent, and the urethral

Figure 7-1 External structures of the female genitalia

orifice becomes less prominent (Blackburn & Loper, 1992). The external structures of the female genitalia are shown in Figure 7-1. The Tanner Stages are of great assistance in educating adolescents about the chronologic stages of their physical development.

Internal Development

As the external physiologic characteristics change, the internal structures of the female organs also develop. The vagina lengthens and increases in size. The pH of the vaginal secretions decreases to an acidic pH (pH of 5), and the amount of the vaginal secretions increases. The acidic pH and increase in secretions support conception. The uterus also increases in size and length to prepare for fertility. The ovary increases in size but at a slower rate than does the uterus. The internal structures of the female pelvis are illustrated in Figure 7-2.

As estrogen is released, the ovary develops a complex vasculature network in preparation for ovulation. Once the vasular compartments are fully developed, and a sufficient amount of estrogen is released, the estrogen stimulates the anterior pituitary to release LH that, in turn, causes ovulation to occur.

Breast Development

Breast development is the first visible sign of puberty. The breast is made up of 15 to 20 lobes of glandular tissue supported by fibrous connective and adipose tissues. Within each lobe of glandular tissue there are 20 to 40 lobules lined with epithelial cells called acini cells, which produce milk in lactating women. The lobules are connected by lactiferous ducts that empty into a lactiferous sinus near the nipple. Montgomery's tubercles are located on the lat-

Figure 7-2 Female internal pelvic organs

eral edges of the areola and provide natural secretions for the lactating breast. The fibrous tissue provides support to the glandular tissue of the breasts, as do the suspensory ligaments known as Cooper's suspensory ligaments. Figure 7-3 depicts the internal anatomic structures of the breast. It is not unusual for breasts to develop simultaneously. However, the breasts may develop in an asynchronous manner, with one breast developing faster than the other. As the breasts develop to Tanner Stage 5, it is not unusual for a woman to have one breast that is slightly larger in caliber than the ipsilateral breast.

Menarche

Menarche is the beginning of the menstrual function, or the onset of the first menstrual period as a result of the hypothalamic-pituitary-ovarian axis. The mean age of menarche is approximately 12 years. The age range varies from 9 to 17 years (Speroff, Glass, & Case, 1999). Menarche may be delayed in adolescents who have a very lean habitus owing to physical exertion. Conversely, girls who are obese, that is, whose body weight is 20% to 30% more than their ideal weight, may begin menses early (Wilson, 1998). Initially, menstruation is irregular and sporadic. The duration of the menstrual cycle ranges from 21 to 45 days, with an average of 28 days. The bleeding may vary from very light to very heavy and last from 2 to 7 days. Menstrual bleeding that lasts longer than 10 days is considered abnormal or dysfunctional. Anovulatory cycles account for 90% to 95% of all dysfunctional bleeding that occurs. An **anovulatory cycle** is a menstrual cycle that occurs in the absence of ovulation. An adolescent may have anovulatory cycles for the first several years of menstruation. The cause of anovulatory cycles in the adolescent usually is an

Figure 7-3 Anatomical structures of the female breast

immature hypothalamic-pituitary-ovarian axis; however, in some cases, a pathological cause may be established (Dealy, 1998).

The Menstrual Cycle

There are three phases of the menstrual cycle. The phases occur as a result of the effects of hormonal influence on the ovaries and uterus (Figure 7-4). As menarche approaches, the Gn-RH pulses increase in frequency and intensity. The pulses occur throughout the day rather than solely at nighttime. The first day of the menstrual bleeding is considered day 1 of the cycle and is considered the menstrual phase, or phase one. At this time, levels of estrogen, progesterin, LH, and FSH are relatively low. Gn-RH continues to stimulate the anterior pituitary to release FSH, which acts as a stimulus on the ovary to release estrogen in preparation for the developing follicles and provides thickening of the uterine lining.

By day 5 to 7, a single follicle has assumed dominance (Hatcher et al., 1998). This is phase two, also termed the

proliferative-follicular phase. Estrogen levels in the blood begin to increase, sending a message to the anterior pituitary gland to decrease the circulating levels of FSH. As the woman approaches day 14, or midcycle, the continued increase in estrogen stimulates the release of LH from the anterior pituitary. The LH surge is responsible for **ovulation**, or the release of the dominant follicle in preparation for conception, which occurs within the next 10 to 12 hours after the levels of LH have peaked.

Phase three, or the secretory-luteal phase, begins after ovulation. Once the dominant follicle is released the remnant cyst of the follicle releases estrogens, progesterone, and androgens. The remnant cyst of the dominant follicle left behind in the ovary is termed the **corpus luteum**. The corpus luteum is a yellow mass in the ovary formed by an ovarian follicle that has matured and discharged its ovum. The estrogen levels begin to decrease after the surge in LH, and progesterone levels begin to increase. There is a second increase in estrogen levels that coincides with the release of progesterone from the corpus luteum. The endometrial lining changes in substance to provide a glycogen-

Figure 7-4 Events of the menstrual cycle

rich environment to foster implantation. FSH and LH levels decrease as a result of the increasing estrogen and progesterone levels. If implantation, fertilization, or pregnancy do not occur, the corpus luteum regresses and the estrogen and progesterone levels decrease, which results in menstruation returning to day 1 of the cycle (Hatcher et al., 1998). If pregnancy (implantation) occurs, the corpus luteum continues to produce estrogen and progesterone, thus prohibiting menstruation.

Psychosocial Changes

A young woman approaches normal physical development over a span of years. Her emotional development also occurs as a lengthy process. Changes in body image, function, the onset of menses, and relationships play a role in the perception of what is normal in her eyes. Girls are socialized in the context of their environment and relationships. Erikson (1950) identified the adolescent developmental task as “identity versus role confusion” in his developmental theory. This developmental phase supports the premise that emotional maturity is based on separation and independence, meaning that the adolescent must detach herself from current relationships to be able to grow

and develop a new, productive adult identity. Erikson’s theory has been challenged by feminist theorists, such as Belenkey et al. (1986) and Gilligan (1993), for the lack of inclusion of girls in his research, yet the research continues to be legitimized to both genders. According to Gilligan’s (1993) psychological theory of women’s development, girls are socialized and develop through relationships and the maintenance of those attachments rather than through separation. A young woman who develops without the benefit of relationship-building may feel isolated and would therefore not achieve emotional maturity.

Critical Thinking

Teenage Sexual Behavior

Nearly half of all teenaged girls admit to being sexually active. How accurate do you think these figures are? Given this high percentage, should adolescents have access to contraception without parental consent?

Research Highlight

Teen Mothers' Perceptions of Parenting

Purpose

To describe the parenting perceptions of African American teen mothers based on their own experiences.

Methods

Descriptive, qualitative design was used in data collection. Using a moderator, 17 African American teens were interviewed in 10 focus groups. The sessions were audiotaped. Of the 17 teens, 8 were pregnant and 9 were parenting. The topics discussed came from a school-based teen parenting program and were infant feeding; comforting a crying infant; bathing, diapering, and dressing the infant; infant and child safety; childhood illnesses; an infant's need for play and stimulation; an infant's need for holding and cuddling; childhood discipline; and identification of the teen mothers' needs.

Findings

Seven themes emerged from the data:

1. **Artifacts.** Items considered necessary to parenting, for example, disposable diapers and the television remote control.
2. **Sources of information.** The teens received traditional health care information from nurses and doctors; however, the teens depended on family members to validate the instructions. If there was no validation, the teens took the advice of family members.
3. **Problems.** Special events of concern. The mothers of the teens were very involved in the infant's lives and the teens did not like it if the child referred to the grandmother as mother and the mother as sister. They also voiced concerns of the grandmothers spoiling the child by "picking the child up too much."
4. **Strategies or remedies.** How the teens solved a specific problem, specifically how they stop the baby from crying. Examples included giving a bottle, picking up the child, sleeping with the child, and playing music. The teens also discussed home remedies such as olive oil for skin care and flour browned in a pan on top of the stove for diaper rash.
5. **Unique language.** Terms the teens used consistently that had no meaning to the researchers. Additional dialogue was pursued to gain an understanding of the teens' perceptions.
6. **Lack of information.** Information seeking from the teens regarding infant feeding; breast-feeding; and baby care, such as use of the emergency department for care.
7. **Misinformation.** The teens believed that their babies were already spoiled. The teens did not participate in safe behaviors with their infants, such as using car seats.

Nursing Implications

Teen mothers need appropriate information as to the expectations of parenting after delivery. Involvement of family members would enhance educational processes and provide a sense of support to the teens.

Wayland, J., & Rawlins, R. (1997). African-American teen mothers' perceptions of parenting. *Journal of Pediatric Nursing*, 12, (1), 13–20.

Peer acceptance is extremely important. Behaviors related to dress, activities, and habits follow individual peer norms. Weight is also a factor in development of self-concept. An average weight is valued most by teens. Second is thinness, and least valued is being overweight

(Fogel & Woods, 1995). As the peer group becomes more powerful, girls emphasize their own self-worth in the context of their relationships, further enhancing self-esteem. They see problems differently from being either right or wrong, and will work together to resolve conflicts. Girls

are socialized to establish relationships through creative mechanisms. Even in play, girls will adapt change into games to make them more appropriate for the play group whereas boys play strictly by the rules (Gilligan, 1993).

Adolescent girls often define themselves in response to the reactions of their peers. Feelings of connectedness and intimacy support self-esteem throughout a woman's life (Belenky, Clinchy, Goldberger, & Tarule, 1986). Belenky's research also has revealed that as women learn, they do not segregate their feelings. Women tend to "think what they feel." Nurses providing care for female adolescent clients must gain understanding of the uniqueness of female psychological development as well as physiologic development.

Cultural Influences

The adolescent's sense of self also is dependent on the cultural context in which she lives. Based on data from the Centers for Disease Control and Prevention (as cited in Rosenfield, 1997), adolescent girls' self-esteem varied based on ethnicity. African American girls cited higher levels of self-esteem than did Hispanic or Caucasian girls. Hispanic girls had the greatest decrease in self-esteem and were most likely to report emotional distress. The decrease in self-esteem may be due to discrimination; inadequacy of the education received; and the influence of additional factors, such as poverty and gang involvement.

Self-Care Considerations

The opportunity to provide self-care knowledge to adolescents is tremendous. Through anticipatory guidance and trusting relationships, health information and education can be provided to the adolescent. Because adolescents generally are healthy, the focus should be on primary and secondary preventive practices. Primary preventive practices target those diseases and maladies that can be prevented. Primary prevention consists of practices such as wearing seat belts, receiving immunizations, and following instructions for safe sex. Secondary prevention includes screening for diseases. Secondary prevention practices include breast self-examination and Pap smear screening.

As the adolescent matures psychologically, she will begin making independent choices and pursue a degree of autonomy establishing her identity. Risk-taking behavior is most prevalent during adolescence. Some degree of risk taking during adolescence signifies autonomy and independence. Serious forms of risk taking, however, can lead to disaster. Accidental and unintentional injury is the leading cause of death in adolescents. The second and third causes are homicide and suicide, respectively (Commonwealth Fund, 1997). Risk-taking behavior may occur with or without knowledge of the potential aftermath. The

Figure 7-5 Female Adolescent Risk Behaviors. (J. Rosenfield, *Women's Health in Primary Care*, Lippincott Williams & Wilkins, 1996.)

most serious forms of risk-taking behavior in adolescents are substance abuse and sexual activity. Figure 7-5 depicts female adolescent risk behaviors from grades 9 through 12.

Adolescents report binge drinking as early as the eighth grade (14%), with 23% of high-school seniors admitting to binge drinking. Binge drinking is defined as four to five or more drinks once in a 2-week period of time (Commonwealth Fund, 1997). Alcohol use in adolescents also is related to poor academic performance, early sexual activity, and troubled social environments (Rosenfield, 1997). Cigarette smoking is on the rise in young women compared with young men. One in four women admit to smoking. This year, more women will be smoking than men (Centers for Disease Control and Prevention [CDC], 1995). Teens underestimate the power of nicotine addiction and find quitting difficult. In providing anticipatory guidance to adolescents, nurses should focus on the benefits of abstaining from tobacco products such as fresh breath, whiter teeth, and increased exercise and performance ability (Wallis, Kasper, Reader, & Brown 1998).

Engaging in early sexual activity is another form of risk-taking behavior in adolescents. In young women, early sexual activity can lead to pregnancy, sexually transmitted diseases, and pelvic inflammatory disease. Nearly 50% of all high-school students report engaging in sexual activity, which is a decrease from 70% in 1995 (CDC, 1999). On average, 48% of high-school girls admit to "ever having" sexual intercourse and 52% of high-school boys admit to "ever having" sexual intercourse (CDC, 1999). Although the rate at which U.S. teenagers engage in sexual intercourse is on the decline, as is teen pregnancy, the

United States continues to have the highest teen pregnancy rates of the developed nations. Teen pregnancy continues to be a major health care issue for adolescents.

Adolescence is a time of discovery. In finding a sense of self, the young woman also will find a sense of responsibility. With the support of their environment, adolescents prepare for a productive adulthood through positive choices, accepting responsibility, and ultimately psychological maturity through their relationships. If they are unable to achieve their identity, adolescents will have difficulty making decisions and playing a productive role in society.

YOUNG ADULTHOOD TO PERIMENOPAUSAL YEARS

This period spans roughly the years between 15 and 44, although the childbearing years are typically considered to be from ages 18 to 39 years. Pregnancy outside of this age window historically has been considered high risk. During this time period, a woman often makes major life decisions and seeks independence. She may go to college and leave the nuclear family for the first time. Choices regarding career and potential life partners also are made. Extensive psychosocial development occurs during the childbearing years as women take on new roles and leave former roles behind.

Physiologic Changes

The young adulthood years are typically characterized by good health and further maturity of the body. Nursing care and interventions are geared toward promoting optimal health through healthy diet, exercise, and good habits. The specific physiologic changes of pregnancy are outlined in detail in Chapter 15.

Psychosocial Changes

Further social and moral development occurs during the young adult years. Again, there are differences in the theoretic explanations of social and moral development between men and women. Lawrence Kohlberg (1969) developed the theory of moral development. Kohlberg's theory was based on the premise that individuals progressed through three levels in their moral development: pre-conventional (selfish and egocentric), conventional (based on shared and societal norms), and postconventional (forward thinking and individualistic). The developmental tasks of each stage must be achieved before moving on to the next stage. According to Kohlberg, most individuals do not aspire to the postconventional status. In contrast, Gilli-

gan (1993) questions Kohlberg's theory of moral development that is law- or principle-based, with a theory that is care- or relationship-based. Gilligan's research has revealed that women's moral development is based on the care and acknowledgement of responsibilities in addition to the further development of relationships and that the self and others are interconnected (Gilligan, 1993). Gilligan's theory explains the ease in which women make transitions between roles of wife, mother, daughter, and career person.

The psychosocial changes that occur during pregnancy should be considered from the point of view that pregnancy is a cycle of change in women's lives. Even as partners plan for their pregnancies, ambivalence is present as the woman imagines the new challenges as a mother. As women anticipate their labor and delivery, they ask themselves questions. "Will I be a good parent?" "Will I be able to provide an adequate home?" During the first trimester, a woman must adjust to being pregnant. Some of the physiologic effects of early pregnancy, such as nausea and vomiting, provide a negative experience that may be difficult to understand when the pregnancy is not yet visible. Multiple emotions prevail as a woman discovers she is pregnant and throughout gestation. Women who are not typically prone to mood swings and crying find their moods extremely labile.

Pregnancy has been described as a developmental crisis and a situational crisis, especially if it is high-risk pregnancy or coincides with other family issues such as moving to a new home or changing jobs. Regardless of how strongly the pregnancy is desired, the woman may experience ambivalence when she discovers she is pregnant. Nichols and Humenick (2000) have summarized the work of Rubin and others in discussing the changes during the pregnancy experience. The woman experiences dreams and fantasies throughout the pregnancy that help her prepare for the maternal role and assist her in accepting the pregnancy. Emotional lability is increased throughout pregnancy.

In the second trimester of pregnancy, emotional issues focus on fetal embodiment and altered body image. The mother's mental image of the baby often starts as an older child and regresses through the pregnancy to an infant. The woman becomes more introverted as she accomplishes the maternal tasks of pregnancy and adapts to meet the requirements of motherhood. Her becoming introverted may create confusion among her family and friends. It is important that family and friends accept the pregnancy so the baby will come into a safe and loving environment. If the mother perceives disapproval, she will become even more introverted.

In the third trimester, the pregnant woman often focuses on preparation for the delivery. She may begin to prepare space in the home for the infant. She may also

REFLECTIONS FROM FAMILIES

"I knew that I wanted to be pregnant, but at times I had overwhelming anxiety and fear of the unknown. It was the right time in our lives to have a baby. I thought we were prepared, but I wasn't sure. Initially, I was nauseated and felt bad all of the time. I thought it was some kind of sign that the pregnancy was in trouble. My health care provider explained to me that what I was going through both physically and emotionally was normal. I never realized that pregnancy could be such a time of great joy and anxiety at the same time."

begin to focus on the event of labor and delivery. When her due date approaches, she becomes eager for birth to occur and may become frustrated if she does not deliver by her due date.

Throughout the pregnancy, during the birth process, and immediately postpartum, the mother will further develop the capacity to give and care for her infant. Being cared for by others—family, friends, and health care providers—assists her in making this transition.

The pregnant woman may feel more comfortable asking questions of the nurse rather than other health care providers. It is important to assess for any emotional discomfort or anxiety that the woman or her partner may be feeling. Development of a birth plan may provide a feeling of control and decision-making for the client. Cases of extreme anxiety should be referred to social services (Davis, 1996).

Cultural Influences

The cultural patterns and behaviors the woman had assimilated during earlier years will continue in this period. She may prefer to spend time with friends who share her cultural practices or may seek out those with different ideas as a means of expanding her own viewpoint.

As to pregnancy, it usually is considered a time of expectancy, joy, and hope. Childbearing is a similar process in all parts of the world; however, beliefs, customs, and practices differ.

Jordan's (1982) research on birth practices in different cultures led her to write the following: "Childbirth is an intimate and complex transaction whose topic is physiologi-

cal and whose language is cultural." In providing care for clients in the childbearing years, nurses have the opportunity to gain the wisdom to better provide support when they understand clients in the context their own cultures. Additional insights are offered in Chapters 15 and 17.

Self-Care Considerations

Self-care considerations for women in young adulthood center on achieving and maintaining health. Good health is promoted through practices such as a healthy diet, stress management, exercise, reduced caffeine and alcohol intake, monthly breast self-examination, and yearly Pap tests.

The birth plan is an appropriate form of self-care during pregnancy. A birth plan usually is a written document that outlines the desires of the client and partner or family as she progresses through the trimesters of pregnancy. The plan details the client's desires for antenatal testing, medication use, anesthesia choices, and postpartum care. A broad plan with alternate options has the best opportunity for success. A rigid plan does not allow the opportunity for change. The plan offers the care provider a concise view of the concerns of the client to better tailor the care.

PERIMENOPAUSAL TO MATURE YEARS

The middle years, generally considered to be from 45 to 64 years, may be the most challenging and productive years of a woman's life. She may have completed her childbearing and is now focusing on a career, or she may have initially focused on her career and is now considering childbearing. If her children are young, their demands on her time may need to be balanced with the demands of her career. Her parents may be aging and may require more care and assistance. The woman's physiologic and hormonal changes demand attention; however, many women no longer feel the need to regularly see a care provider. Women may struggle with self-image and physical appearance of staying young, although trends are changing in that there is a resurgence of focus on the woman in midlife. Health education programs are focusing on health risks during this developmental phase to better provide women with the tools to care for themselves and their families. This time also is one in which women are accessing health care for physical changes and perimenopausal symptoms. Women may feel excited or confused by the extensive health care options available with respect to stress management, hormone replacement therapy, and complementary and alternative medicine. There is an abundance of health information available to women on the Internet and in other media sources. The nurse should assist and support women in their quest for

valid knowledge. An example would include the ability to provide assistance in the interpretation of the most recent research findings, because frequently the media will provide a sensational interpretation.

Physiologic Changes

The physiologic and hormonal changes that occur during midlife have also been called perimenopause. **Perimenopause** is the time before cessation of menses or menopause. A woman may be considered to be in perimenopause for 5 to 10 years, or until cessation of menses for 1 year. During this time period, the woman may have normal menses, spotting, or absence of a monthly menstrual cycle. A woman who has not had a menstrual period for 1 year is considered to be in **menopause**. As a woman approaches her 40s, she begins to have fewer ovulatory cycles. The ovary may only have several thousand follicles remaining at this time and may be less sensitive to go-

nadotropin stimulation (Speroff, Glass, and Kase, 1999). In turn, the follicles, by way of the feedback system, produce less estrogen. The decrease in estrogen does not provide for maturation of the endometrial lining, and therefore, menses may not occur. Eventually, estrogen production decreases sufficiently to affect estrogen-dependent tissues, such as the breasts, bone, mucous membranes, heart, neuroendocrine system, and reproductive organs.

The glandular tissue of the breasts atrophies with the loss of circulating estrogen. The glands and lobules are replaced with fat. The skin becomes less elastic, and the breasts become soft and pendulous. The best demonstration of the difference is in the mammographic interpretation of the breast of a premenopausal woman and that of a postmenopausal woman. Figure 7-6 distinguishes the differences between dense breast tissue and breast tissue replaced by fat. The glandular tissue is very dense and appears white on the mammogram. Breast lesions are difficult to visualize in the white glandular tissue. The fatty

A.

B.

Figure 7-6 Mammogram of breast tissue A. Premenopausal B. Postmenopausal

tissue is darker and much less dense, making it easier to see abnormalities.

Women lose calcium from the bone as a normal process of aging. With the loss of estrogen during the peri- and postmenopause periods, the bone loss is dramatic. Decreased levels of calcium intake and high levels of physical activity that results in less than 10% body fat also contribute to bone loss before the midlife years. A woman may lose 1% of her bone density per year for 5 to 10 years after menopause (Cook, 1993). The bone loss may result in back pain and compression. Fractures also may occur with bone stress. When women lose bone either naturally or pathologically, they are diagnosed with osteoporosis. **Osteoporosis** is bone loss owing to a decrease in calcium absorption or the loss of estrogen. Osteoporosis can be a devastating disease, leading to fractures, loss of independence, and potentially death (Society for Women's Health Research, 1999). Although education about prevention of osteoporosis should begin in childhood or adolescence, during the time of bone formation, it is important to continue to provide education to women about their risk for osteoporosis and to develop a plan for prevention (Figure 7-7). An osteoporosis prevention plan would include a diet high in calcium (approximately 1,000 mg for premenopausal women and 1,500 mg for postmenopausal women) and weight-bearing exercise 3 to 4 times a week. Hormone replacement therapy also may be an option for women experiencing menopause.

Heart disease is the leading cause of death in women and is responsible for more deaths than breast, ovarian, and uterine cancers combined (Society for Women's Health Research, 1999). As a woman approaches menopause, her risk for heart disease becomes equal to that of a man's risk. The current thinking is that estrogen provides protection against heart disease because of its

Figure 7-7 As women approach menopause, osteoporosis prevention education is critical in promoting optimal health.

Nursing Alert

RISK FACTORS FOR HEART DISEASE

- Age over 60 years
- Obesity
- Cigarette smoking
- Hypertension
- Diabetes mellitus
- Sedentary lifestyle
- Family history

American Heart Association. (1999). *2000 Heart and stroke statistical update*. Dallas, TX: American Heart Association.

positive effects on serum lipids in reducing cholesterol. Because a decrease in estrogen occurs at menopause, there is an increased risk for heart disease. Additional risk factors for heart disease also must be considered when providing nursing care to the woman in midlife.

Diminished estrogen levels are responsible for atrophy of the skin and mucous membranes of the mouth, urethra, vagina, and bladder. The skin becomes less elastic and taut. It may appear dry and loose, which may lead to increased wrinkling. There is also drying and thinning of the mucous membranes around the mouth and within the urogenital system. Women may notice a change in the appearance of their lips and mouths in that the tissue supporting the lips becomes less taut.

The effects of estrogen loss on the urinary system can be quite disturbing for women. Decreasing circulating levels of estrogen cause a loss of elasticity of the urethra, resulting in frequency and urgency of urination. An overall loss of muscular support within the pelvis may add to the woman's urinary tract symptoms. Complaints of stress incontinence and urge incontinence may occur in this phase of life. Stress incontinence is the most common type of incontinence in women under 60 years of age. **Stress incontinence** is an involuntary discharge of urine with a cough, sneeze, or laughter owing to the loss of muscular support at the neck of the urethra. Urge incontinence is less common than is stress incontinence. **Urge incontinence** occurs when the urge to void is present but the bladder is unable to empty normally. As a result, the bladder can become distended, which results in an uncontrolled loss of urine (Johnson, Johnson, Murray, & Apgar, 1996). Women with urge incontinence cannot postpone urination for more than a few minutes once the need to urinate is sensed. Although nonsurgical and surgical interventions are available, many

women may be uncomfortable initiating a discussion about incontinence. The nurse-client relationship provides a non-threatening mechanism to bring that information forward through the educational process.

The reproductive organs also are affected by the loss of circulating estrogen. The vagina decreases in depth and the uterus decreases in size. The ovaries shrink. The vaginal skin thins, and the rugae diminish. There is an increase in vaginal pH from an acidic state to a neutral or alkaline state, which increases the risk of infection in the perimenopausal woman (Cook, 1993). Sexual intercourse frequently is uncomfortable, and trauma may occur as a result of thinning vaginal epithelium. Water-soluble lubricants may provide comfort during sexual intercourse.

Changing estrogen levels also result in vasomotor instability, causing hot flashes or flushing. The instability occurs as a result of the altered balance of norepinephrine and dopamine. Sympathetic activity increases, resulting in a rapid heart rate. Skin temperature also increases, resulting in a flash or sensation of warmth. When the flash progresses to vasodilation of the skin, it is termed a flush (Cook, 1993). Night sweats may occur as a result of the flushing. Nighttime waking as a result of night sweats may cause sleep deprivation. Hot flashes or flushes are the most common symptoms of menopause.

Psychosocial Changes

Women's perceptions of the midlife period have changed over the past 20 years. Past studies focused on women's

roles in terms of their launching their children into independence or on the time left in their lives. In the past, many women identified their sense of self with the child rearing or spousal role. More recent studies have revealed an understanding of stressful life events, such as physical changes, physical limitations, empty nest concerns, and changes in interpersonal relationships; however, the women are positive in their overall outlook (Woods & Mitchell, 1997). The traditional emotional effects of perimenopause are rooted in physiologic processes. Symptomatology related to sleep disturbances, decreased libido, and mood swings can be associated with decreased estrogen levels. Currently, women's psychosocial issues related to midlife are attributed to managing the busy demands of daily life (Woods & Mitchell, 1997).

Cultural Influences

Cultural perceptions of midlife are not clearly understood. Women's lifestyles and social interactions influence health. Based on culture, as a woman ages her social status may increase and she may be valued as a life expert. In contrast, her social status may decrease and she may be devalued because of her culture. Obermeyer (2000) questioned the symptomatology associated with and leading up to menopause as having cultural differences. The author's findings revealed that there are cultural differences in self-reported descriptions of the menopause process. The difficulty is in the interpretation because there are not validated descriptions of menopause symptoms across cultures. Further cross-cultural research is clearly needed in comparing women's experiences in menopause (Woods, 1994).

Self-Care Considerations

Nurses are ideal candidates to educate clients regarding the self-care measures that can be taken during midlife. As physiologic symptoms begin to occur, the nurse may have the first contact with the client. Clients experiencing nighttime flushing should be advised to wear light-weight cotton clothing to bed to decrease diaphoresis.

In an effort to maintain bone density, all clients should be advised to perform weight-bearing exercises and maintain a minimum calcium intake of 1,000 mg/d of elemental calcium. Bone density testing may be advised to determine a baseline bone density, as well as to determine the client's risk for fracture (Figure 7-8).

Water-soluble lubricants can be used to reduce discomfort during intercourse. Be advised that woman may have difficulty in expressing sexual difficulties. Because nurses are excellent counselors and educators and because communication is a core component of nursing curriculum, nurses should have less difficulty eliciting a sex-

Critical Thinking

Menopause

A 45-year-old woman is beginning to notice changes in her menstrual cycle. Her cycles are increasingly longer (approximately 45 days), with a shortening duration. She is concerned about how these changes may affect her lifestyle and her health. Some of her friends at work have told her that they felt their health was negatively impacted when they went through menopause. As the nurse involved with this client's primary care:

- How would you initiate anticipatory guidance?
- In what key areas would you provide health education?
- How would you address the "concerns of friends"?

A.

B.

C.

Figure 7-8 A bone density scan should be done to determine a baseline as well as to determine a client's fracture risk. A. Positioning the client B. Aligning the scanner C. Reading the results.

ual history than would most physicians. Nurses also may have a greater comfort level with this discussion.

Women should also be reminded to perform monthly breast self-examinations and have annual mammograms after the age of 50. As a woman ages, her risk for breast cancer increases, with the majority of breast cancers being diagnosed after age 50 (American Cancer Society, 1999). Educational information regarding hormone replacement therapy or alternatives should be provided at this time. Women should feel comfortable and confident in performing their own self-examinations. Questions about or clarification of their examination should be referred to the health care provider.

MATURE YEARS

The perceptions of mature women (aged 65 and older) regarding health are not determined by the number of chronic illnesses they might have but by how the women feel. Perry and Woods (1995) asked a group of women ranging in age from 70 to 91 years, "What does being healthy mean to you?" The research of these authors led them to write the following quote about health and women of advanced age (Perry and Woods, 1995, p. 55): "Health involves the appreciation of life, experiencing joy and happiness. To be free from sickness does not guarantee health. Likewise, health can be experienced despite chronic illness and disability, because being healthy is a philosophy or way of living."

Physiologic Changes

Physiologic concerns of the aging woman are multifocal and affect all body systems (Figure 7-9). Some changes in the integumentary system, for example such as wrinkles, spots on the skin and graying hair may have a different social and psychological effect on women than on men related to the expectations and values that our culture has placed on youth and beauty in women. A brief review of systemic of physiologic changes follows.

- **Pulmonary System:** The rib cage and its accessory muscles become less flexible making older women more susceptible to respiratory disorders:
- **Cardiovascular System:** Heart rate slows, cardiac output and recovery time decline. Blood flow to organs decreases, veins dilate and arterial elasticity decreases, which may result in a rise in blood pressure and peripheral vascular disease. The effect of the use of estrogen supplementation for cardiovascular health is under debate and is currently being researched.
- **Gastrointestinal System:** Dental problems related to thinning of tooth enamel and periodontal disease

Figure 7-9 Changes in the skin and hair are some of the more visible effects of aging.

increases. Risks of choking increase related to decreased effectiveness of the gag reflex. Gastric emptying time and peristalsis slows, resulting in constipation. Gallbladder lessens in efficiency, resulting in greater incidence of gallstones. Liver enzymes decrease, slowing drug metabolism and detoxification.

- **Reproductive System:** Estrogen decreases and ovaries, uterus decrease in size. The vagina shortens and secretions decrease and become more alkaline, which can increase the risk of atrophic vaginitis. The supportive musculature of the reproductive organs weakens, increasing risk of uterine prolapse. Breast tissue diminishes and breast cancer risk increases with age. Libido and need for intimacy remains unchanged.
- **Endocrine System:** Changes occur in both the production of hormones and reception of hormones. Thyroid changes may lower basal metabolism. Release of insulin slows, causing an increase in blood sugar. The most common endocrine disorder related to aging is Type II Diabetes.
- **Musculoskeletal System:** Muscle mass and elasticity diminish. Reduced strength, endurance, coordination

are decreased with aging. Bone demineralization occurs leading to osteoporosis. This is a particularly significant problem for post-menopausal women. Exogenous estrogen and avoidance of smoking can reduce the risk or extent of osteoporosis. Joints often degenerate causing pain, stiffness, and loss of range of motion.

- **Integumentary System:** Subcutaneous tissue and elasticity diminish, therefore the skin becomes thinner and less elastic. Melanocytes are less able to produce even pigmentation resulting in hyperpigmentation on hands and wrists, commonly called liver spots. Skin becomes drier and nails become more brittle. Cutaneous sensitivity decreases. Risks of skin cancer, herpes zoster (shingles), and pressure ulcers increase with age.
- **Nervous System:** Cerebral blood flow decreases, the time to carry out motor and sensory tasks increases, short-term memory diminishes more than long-term memory. Night sleep disturbances are more likely with aging.
- **Urinary System:** Kidneys decrease in their ability to filter, excrete, and reabsorb. The reduction in filtration rate decreases in the renal clearance of drugs. Bladder capacity decreases and bladder and perineal muscles weaken. These may contribute to stress incontinence and cystitis.
- **Sensory System:** Presbyopia (trouble seeing object up close) is a common vision problem with aging. Incidence of cataracts and glaucoma increases. Pupil size accommodation decreases, decreasing the adjustment to variations in lighting. Lacrimal secretions decrease, causing dryness itching and increasing risks for infection. Cochlea degenerates and impairment of hearing is often accompanied by a loss of tone discrimination, with loss of high frequency tones first.

Psychosocial Changes

The physiologic processes that occur as a result of aging directly affect the psychological health and social interactions of women who are aging. The woman must make adjustments in her own life owing to changes in functional status; in many cases, the woman also must provide care for an aging partner. Considerations are made for retirement that may cause lifestyle changes for the woman living on a fixed income. The aging woman may choose to either identify with a social group or isolate herself. Independent living may not be an option for some women, yet alternatives may be unsatisfactory. Responsibilities for grandchildren may lie with the aging woman, causing increased stress that may result in added health risks (Rosenfeld, 1997).

Depression is more common in women than in men. The lifetime risk for major depression in women is 20% to 25%; at any point in time, 5% to 10% of women are suffering from a depressive disorder (Byyny & Speroff, 1996). Depression is not related only to physiology but to the social and economic factors unique to women. Because of decreased physical abilities related to aging, social isolation, and economic problems, older women should be screened for depression.

Rosenfeld (1997) outlined some of the sociologic tasks of older women, including the following:

- ✿ Adjusting to declining physical strength and health.
- ✿ Adjusting to retirement and its reduced income.
- ✿ Adjusting to changes in the health of one's spouse.
- ✿ Establishing an explicit affiliation with one's age group.
- ✿ Adopting and adapting social roles in a flexible way.
- ✿ Establishing satisfactory physical living arrangements.

Cultural Influences

Although aging in American society often has been devalued, in some cultures women gain social status after child-bearing and as they age. This may be a source of conflict. For instance, researchers have suggested a sense of fatalism within the aging African American and Hispanic populations (Haynes, 1996). Some may say, "Why seek health care? You're going to die from something." Unfortunately, women in the United States who are aging and belong to a minority group have had little choice in their health care decisions in the past. Negative experiences have led them to a lack of understanding and fear of health care and the provider (Haynes, 1996). The negative experiences may contribute to inadequate or inappropriate use of health care. Hispanic women are more likely to value the care provided when the family is involved. In the case of women who are aging, instructions and health education must be delivered in a trusting personal manner. When provided respectfully, the information is more likely to be valued and the advice followed (Caudle, 1993). Health information and education relayed in a kind, caring, and respectful way can be successful in breaking down cultural barriers.

Self-Care Considerations

Safety is a major self-care focus for mature women. Nurses providing care for the aging population must become proficient in assessing functional and cognitive status. Clients with osteoporosis are at risk for fractures. Initial assessments of the aging woman can be done from the waiting room as she walks to the exam room.

HEALTH CARE VERSUS FAMILY CARE

It is important to consider culture and familial influence when carrying out nursing interventions. Individuals are more likely to adhere to nursing care instructions and health education when their family members also are instructed and believe in the process.

During the interview/health history for an office visit or admission to the hospital, a medication history should be taken. Because of the nature of many chronic illnesses, multiple medications may be prescribed. Self care education should be provided in an easy to understand format using printed materials with a large font. The instructions must extend beyond prescription medication to include over the counter medications as well. The client can be encouraged to use a single pharmacy with computerized records to reduce the risk of adverse drug interactions.

NURSING IMPLICATIONS

There are many gender-related issues in the development of women. These are physiologic, psychological, and social in nature. A number of health-related issues surround reproduction and nurses should be sensitive to the multifaceted processes by which women become mothers. The hormonal changes in women from menarche through

Web Activities

- Where would you find information specific to nursing care of women with incontinence? Which nursing resources are available for practice as well as client education?
- Which resources can you locate on the Internet for families of women who have breast cancer? Is there a listing of support groups in your local area?
- Where would you find information specific to the risk for osteoporosis on the Internet in an effort to better educate your midlife clients on their risks?

menopause have manifestation beyond the reproductive organs. Nurses are in a position to educate women about these developmental changes and to provide counseling and support. Many times women may be more comfortable discussing these issues with a nurse than other health care providers. Nurses can apply their understanding about women's developmental issues to female clients in

whatever arena they encounter clients. It does not need to be restricted to maternity care. Nurses can provide information and support about these issues for individual clients or to groups of clients. Many times nurses are asked to speak to community groups about woman's issues. This is an excellent opportunity to give sound health information about women's development.

Key Concepts

- Physiologic gender differentiation occurs at fertilization at the time in which the genetic sex is determined by chromosomes XX or XY.
- The maternal transfer of estrogen causes changes in the newborn's breast tissue and genitalia that resolve shortly after birth.
- Physical maturity and emotional maturity do not occur simultaneously, which frequently leads to adolescent conflicts.
- Female adolescent emotional and moral growth differs from that of males because females mature through their relationships rather than their separations.
- The early trimester physiologic effects of pregnancy are sometimes difficult for the expectant mother to understand when the pregnancy is not yet visible.
- Individual cultural beliefs may impact the care of the woman throughout pregnancy.
- Hormonal changes during the midlife years bring on additional physiologic changes to most organ systems.
- The physiologic changes that occur during midlife also may have a negative psychological impact.
- Health education and self-care measures are key in providing positive support to women during the midlife years.
- Physiologic and psychosocial issues continue to affect women as they age. Functional assessment is key in providing self-care and maintaining a safe environment for the client.

Review Questions and Activities

1. What causes dysfunctional uterine bleeding during adolescence?
 - a. abnormal periods
 - b. anovulatory cycles
 - c. poor diet
 - d. poor grades
 The correct answer is b.
2. What is the most visible sign of puberty?
 - a. social withdrawal
 - b. weight gain
 - c. enlargement of the breast bud
 - d. anger
 The correct answer is c.
3. How can the Tanner Stages be defined?
 - a. emotional changes of the aging woman
 - b. thelarche
 - c. stages of adolescent physical development
 - d. menarche
 The correct answer is c.
4. What is the second phase of the normal menstrual cycle?
 - a. ovulation
 - b. secretory-luteal phase
 - c. menstruation
 - d. proliferative-follicular phase
 The correct answer is d.
5. The corpus luteum regresses with decreases in estrogen and progesterone, resulting in menstruation, when what does not occur?
 - a. ovulation
 - b. cysts
 - c. menarche
 - d. implantation
 The correct answer is d.
6. Which type of theory of development in women was identified by Gilligan?
 - a. psychological
 - b. physiologic

- c. questionable
- d. activity

The correct answer is a.

7. In what context are women socialized?

- a. families
- b. colleagues
- c. friends
- d. all of the above

The correct answer is d.

8. What is the Birth Plan?

- a. list of birthing centers
- b. a document that outlines the desires of the client and partner during pregnancy
- c. postpartum contraceptive choices
- d. a list of anesthesia choices in the delivery room

The correct answer is b.

9. On what does a reduction in circulating estrogen have an effect?

- a. heart
- b. breast
- c. bones
- d. all of the above

The correct answer is d.

10. Which is not a major focus for the aging woman?

- a. safety
- b. retirement
- c. social interaction
- d. Internet access

The correct answer is d.

Nutrition for Women Across the Life Span

The Malone family consists of Sam and Julie and two children, ages 5 and 9. Julie is pregnant with her third child. Sam is a truck driver and Julie is active in the children's school and other activities. Their eating patterns are typical of their community. A meal commonly consists of meat, potatoes, canned vegetables, and dessert. Many of their meals contain fast foods, which are convenient when they are busy with other activities. Julie was 25 pounds overweight before this pregnancy. She is in her second trimester and has gained an additional 20 pounds.

- What nutritional concerns do you think this family has?
- What implications does this nutritional pattern have for Julie's pregnancy?
- How does this family's diet differ from your diet?
- How do you think a family can change its eating patterns?
- What do you think a nurse can do to facilitate a change in nutritional patterns?

Key Terms

Amylophagia	Dietary Guidelines for Americans	Herbs	Pica
Anencephaly	Encephalocele	Hypochromic anemia	Plumbism
Anorexia nervosa	Fetal alcohol effects (FAE)	Insoluble fiber	Recommended Dietary Allowances (RDA)
Basal metabolism	Food Guide Pyramid	Microcytic anemia	Reference Daily Intakes (RDIs)
Binge eating	Geophagia	Nonheme iron	Soluble fiber
Body mass index (BMI)	Heme iron	Nutrition Facts Food Label	Spina bifida
Botanicals	Hemochromatosis	Obesity	Upper intake level (UL)
Bulimia nervosa	Hemosiderosis	Pagophagia	Vegan
Calorie		Phytochemicals	
Carotenoids			
Daily Reference Values (DRVs)			

Competencies

Upon completion of this chapter, the reader should be able to:

1. Describe the common nutritional guidelines used to advise normal, healthy women on recommended eating practices to provide optimum nutrition.
2. Use the Food Guide Pyramid to plan a healthy, culturally appropriate meal for a Hispanic woman, an African American woman, an Asian American woman, a woman of Mediterranean descent, and a vegetarian.
3. State the three most important factors to consider when evaluating a woman's dietary pattern.
4. Identify key nutrients of importance in a woman's dietary intake pattern.
5. Calculate the average ideal body weight and body mass index (BMI) for a woman.
6. Classify a woman's body size based on her BMI.
7. Calculate the average caloric needs for a woman, based on her ideal body weight.
8. Calculate a woman's prepregnancy BMI and set optimum weight gain goals for the pregnancy.
9. State the additional caloric requirements for pregnancy and describe food selections to meet those needs.
10. State the additional caloric requirements for lactation and describe food selections to meet those needs.
11. Give four of the dietary guidelines for cancer prevention.

Nutrition is a vital aspect of the health of women at all ages and is particularly important during the childbearing years because it affects the health and development of the child. Nutrition has also been identified as an area of lifestyle that can be modified to reduce risks for chronic diseases. Nurses have long been engaged in nutritional counseling interventions, and a good nutritional assessment and appropriate interventions should be a part of every nursing plan. Nurses who are providing care to women should

be especially concerned with this area, because women generally procure and prepare the food for the entire family. Nutrition during pregnancy has implications for both the mother and the fetus. The mother's nutrition before pregnancy is also important for the health of the fetus.

Healthy People 2010 is the disease prevention agenda for the United States. This document has set the overall health goals for the nation. The two all-encompassing goals are:

- Goal 1: Increase quality and years of healthy life
- Goal 2: Eliminate health disparities

One of the sections relevant to all Americans and of particular significance to women across the life span is related to nutrition. The nutrition and overweight section has as its goal to promote health and reduce chronic disease associated with diet and body weight. There are 18 key objectives in this section dealing with healthy weight, optimum food and nutrient intakes, locations where food is most commonly consumed, and safety in food preparation. Six of the top 10 leading causes of death in the United States in 1997 had a direct link to nutritional practices. These causes included heart disease, cancer, stroke, diabetes mellitus, kidney disease, chronic liver disease, and cirrhosis. Osteoporosis, another disability affecting millions of Americans, is influenced by dietary and lifestyle choices. Truly optimal nutrition is a positive factor for our health status and fights disease.

This chapter focuses on the nutritional concerns of women throughout their life cycle, with a major focus on needs during pregnancy. Emphasis is placed on the factors contributing to healthy lifestyles during the stages of a woman's life. Nutrients of special concern to women and nutritional needs during select times of a woman's life are highlighted. Prevention of major illnesses is the focus. Finally, there is a brief discussion of the major nutritional concerns related to the primary causes of morbidity and mortality in women.

NUTRITIONAL GUIDELINES

Nutritional guidelines can come in different forms. The Dietary Guidelines for Americans, the Food Guide Pyramid, culturally adapted food guides, and Nutrition Facts food labeling are discussed here.

Dietary Guidelines

Dietary Guidelines for Americans was the first joint publication effort of the Department of Health and Human Services and the Department of Agriculture. They are mandated by public law to be revised every 5 years (USDA, 2000). *Dietary Guidelines for Americans* provides guidance on diet and health to the general population with practical recommendations that meet nutritional requirements, promote health, support an active lifestyle, and reduce the risk of chronic disease.

Dietary Guidelines for 2000 includes the following 10 recommendations:

- Aim for a healthy weight.
- Let the food pyramid guide your food choices.
- Eat a variety of grains daily, especially whole grains.
- Eat a variety of fruits and vegetables daily.
- Keep food safe to eat.
- Choose a diet low in saturated fat that is also low in cholesterol and moderately low in total fat.
- Choose beverages and foods that limit intake of sugar.
- Choose and prepare foods with less salt.
- Drink alcoholic beverages in moderation.
- Be physically active each day.

Food Guide Pyramid

The **Food Guide Pyramid** was first introduced in 1992, published by the Department of Agriculture and Department of Health and Human Services (USDA/HS, 1992). This guide is an easy way to recommend adequate servings from the various food groups every day for the entire population. The Food Guide Pyramid translates the dietary guidelines for Americans into practical eating portions that meet the dietary guidelines and, if foods are chosen carefully, they also meet the recommended daily allowances (RDA) and Dietary Reference Intakes (DRI). The National Academy of Sciences Food & Nutrition Information Center is in the process of replacing RDA with DRIs (Nutrient Data Laboratory, 2001).

The Food Guide Pyramid was designed to graphically illustrate the dietary guidelines for Americans, emphasizing balance, moderation, and variety. The Food Guide Pyramid can be modified to fit the cultural preferences of clients by using foods customary to their culture and to fit differing age groups by modifying the types of foods, and the serving sizes. Depending on cultural food preferences, food groupings may be modified to adequately adjust for a client's nutrient requirements. Figure 8-1 presents the traditional Food Guide Pyramid.

Culturally Adapted Food Guides

While the basic nutritional requirements and guidelines generally apply to all people, nutritionists and nurses have long been aware of cultural differences in eating patterns and food preferences. Translating nutritional requirements into cultural food practices has sometimes been challenging. The Oldways Preservation and Exchange Trust, (1994, 1995, 1996) the World Health Organization (WHO) European regional office, and Food and Agricultural Organization (FAO) Collaboration Center in Nutritional Epidemiology at Harvard University's School of Public Health have adapted the food pyramids to be used with clients from various cultures or with specific dietary practices, such as those common to Asian, Mediterranean, and Latin American diets (Townsend & Roth, 2000).

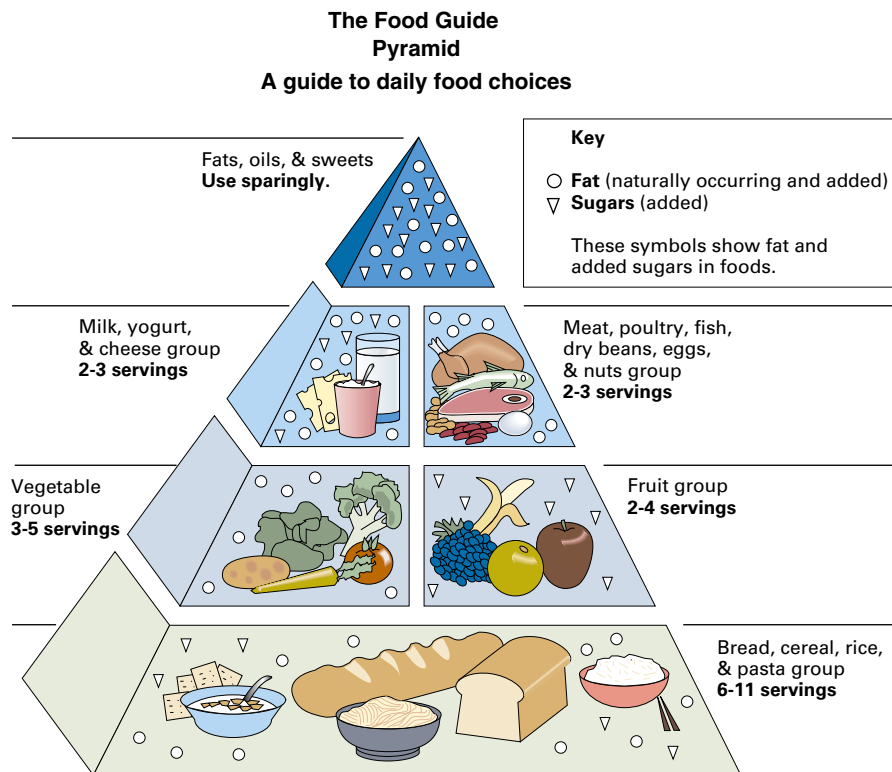

Figure 8-1 Food Guide Pyramid. (Courtesy of United States Departments of Agriculture and Health and Human Services (1992). The food guide pyramid: A guide to daily food choices. Washington, DC, (leaflet no. 572).

All of the pyramids limit saturated fats to protect against heart disease. The Asian, Mediterranean, and Latin American plans give greater daily predominance to heart-healthy monounsaturated fats. As *Dietary Guidelines for Americans* (USDA, 2000) suggests, the fat content of the diet should be kept low: total fat, saturated fat, and cholesterol. The total daily fat intake should be no more than 30% of the total calories, and saturated fats should comprise no more than 10% of total calories.

The following section briefly discusses some food patterns typical of various cultures and regions. While enormous variations exist within any classification, some culturally influenced patterns are recognizable.

Native American

Approximately half of the edible plants commonly eaten in the United States today may have origins in the Native American diet. Examples are corn, potatoes, squash, cranberries, pumpkins, peppers, beans, wild rice, and cocoa beans (Figure 8-2). In addition, Native Americans used wild fruits, game, and fish. Foods were commonly prepared as soups and stews or were dried. The original Native American diets were probably more nutritionally adequate than are current diets, which frequently consist of a high proportion of sweet and salty, snack-type foods that are low in nutrient density. Native American diets today

may be deficient in calcium, vitamins A and C, and riboflavin.

Southern United States

Hot breads, such as corn bread and baking powder biscuits, are common in the South because the wheat grown in the area does not make good-quality yeast breads. Grits and rice are also popular carbohydrate foods. Favorite vegetables include sweet potatoes, squash, green beans,

Figure 8-2 Traditional Native American food

and lima beans. Green beans cooked with pork are commonly served. Watermelon, oranges, and peaches are popular fruits. Fried fish is served often, as are barbecued and stewed meats and poultry. These diets have a great deal of carbohydrate and fat and limited amounts of protein, in some cases. The diet may be deficient in iron, calcium, and vitamins A and C.

Mexican

Mexican food is a combination of Spanish and Native American foods. Beans, rice, chili peppers, tomatoes, and corn meal are favorites. Meat is often cooked with vegetables, as in chili con carne. Cornmeal or corn flour is used to make tortillas, which serve as bread. The combination of beans and corn makes complete protein. Corn tortillas filled with cheese (called enchiladas) provide some calcium, but the consumption of milk should be encouraged. Additional green and yellow vegetables and vitamin C-rich foods would also improve these diets.

Puerto Rican

Rice is the basic carbohydrate food in Puerto Rican diets. Vegetables include beans, plantains, tomatoes, and peppers. Bananas, pineapple, mangoes, and papayas are popular fruits (Figure 8-3). Favorite meats are chicken, beef, and pork. Milk is not used as much as would be desirable from the nutritional point of view.

Italian

Pastas with various tomato and cheese or fish sauces are popular Italian foods. Fish and highly seasoned foods are common to southern Italian cuisine; meat and root vegetables are common to northern Italy. The eggs, cheese,

tomatoes, green vegetables, and fruits common to Italian diets provide excellent sources of many nutrients, but additional fat-free milk and low-fat meat would improve the diet.

Northern and Western European

Northern and Western European diets are similar to those of the U.S. Midwest, but with greater use of dark breads, potatoes, and fish, and fewer green vegetable salads. Beef and pork are popular, as are various cooked vegetables, breads, cakes, and dairy products. The addition of fresh vegetables and fruits would add vitamins, minerals, and fiber to these diets.

Central European

Citizens of Central Europe obtain the greatest portion of their calories from potatoes and grain, especially rye and buckwheat. Pork is a popular meat. Cabbage cooked in many ways is a popular vegetable, as are carrots, onions, and turnips. Eggs and dairy products are used abundantly. Limiting the number of eggs consumed and using fat-free or low-fat dairy products would reduce the fat content in this diet. Adding fresh vegetables and fruits would increase vitamins, minerals, and fiber.

Middle Eastern

Grains, wheat, and rice provide carbohydrates in Middle Eastern diets. Chickpeas, in the form of hummus, are popular. Lamb and yogurt are commonly used, as are cabbage, grape leaves, eggplant, tomatoes, dates, olives, and figs. Black, very sweet coffee is a popular beverage (Figure 8-4). There may be insufficient protein and calcium in this diet, depending on the amounts of meat and calcium-rich foods eaten. Fresh fruits and vegetables should be added to the diet to increase vitamins, minerals, and fiber.

Chinese

The Chinese diet is varied (Figure 8-5). Rice is the primary energy food and is used in place of bread. Foods are generally cut into small pieces. Vegetables are lightly cooked, and the cooking water is saved for future use. Soybeans are used in many ways, and eggs and pork are commonly served. Soy sauce is extensively used, but it is very salty and could present a problem for clients on low-salt diets. Tea is a common beverage, but milk is not. This diet may be low in fat.

Japanese

Japanese diets include rice, soybean paste and curd, vegetables, fruits, and fish. Food is frequently served fried. Soy sauce (shoyu) and tea are commonly used. Current

Figure 8-3 Traditional Puerto Rican food

Figure 8-4 Traditional Middle Eastern food

Japanese diets have been greatly influenced by Western culture. Japanese diets may be deficient in calcium, given the near total lack of milk in the diet. Although fish is eaten with bones, it may not supply sufficient calcium to meet needs. Japanese diets may contain excessive amounts of salt.

Indian

Many Indians are vegetarians who use eggs and dairy products. Rice, peas, and beans are frequently served. Spices, especially curry, are popular. Indian meals are not typically served in courses, as Western meals are. The meals generally consist of one course with many dishes.

Thai, Vietnamese, Laotian, and Cambodian

Rice, curries, vegetables, and fruit are popular in Thailand, Vietnam, Laos, and Cambodia (Figure 8-6). Meats and fish are used in small amounts. The wok (a deep, round pan)

Figure 8-5 Traditional Chinese food

is used for sautéing many foods. A salty sauce made from fermented fish is commonly used. These diets may contain inadequate amounts of protein and calcium.

Nutrition Facts Food Label

Another tool designed to aid people in selecting a healthy diet is the **Nutritional Facts food label**, which was introduced in 1993 (FDA, 1993). Nutrition labeling on processed packaged foods includes credible health and nutrient content claims and standardized serving sizes (FDA, 1999).

The items, with amounts per serving, that must be included on the food label are:

- Total calories
- Calories from fat
- Total fat
- Saturated fat
- Cholesterol
- Sodium

Figure 8-6 Traditional Thai food

- Total carbohydrates
- Dietary fiber
- Sugars
- Protein
- Vitamin A
- Vitamin C
- Calcium
- Iron

The food manufacturer can voluntarily include additional information on food products. Figure 8-7 shows a sample food label. The percent daily values (DV) are based on a 2000-calorie diet. Clients must adjust their intake of nutrients based on their estimated caloric consumption each day and on the serving size they consume. The DVs are based on two sets of standards. One is based on the **Daily Reference Values (DRVs)**, which are the standards for daily intake of total fat, saturated fat, cholesterol, total carbohydrate, dietary fiber, and protein. The total fat DRV is based on diets that provide 30% of total calories as fat; saturated fat is set at 10% of total calories. The DRV for total carbohydrates is based on 60% of the total calories, and for protein, on 10%.

Figure 8-7 Sample nutrition facts food label

The other standard used to calculate percent daily values on nutrition labels is the **Reference Daily Intakes (RDIs)** Nutrient Data (2001). This standard addresses the vitamin and mineral content of foods. It provides legal standards set by the U.S. Food and Drug Administration (FDA) for labeling foods and supplements uniformly. The RDIs generally represent the highest values of vitamins and minerals in the 1968 **Recommended Dietary Allowances (RDA)** (Food & Nutrition Board, 1989) tables for nutrients in any age group over age 4, excluding pregnant and breast-feeding women. The RDA lists the average daily nutrient intake levels recommend for healthy Americans. The Nutrition Facts labels make it possible for consumers to compare products easily, based on the product's contribution of fat, cholesterol, sodium, and other major nutrients.

NUTRITIONAL NEEDS ACROSS THE LIFE SPAN

Nutritional needs vary with age, gender, and reproductive status. These nutritional variations generally reflect additional needs, such as the need for additional Kcal and nutrients during pregnancy and lactation and concerns for eating patterns that may be prevalent at certain stages, such as adolescence. Nutritional needs for newborns and infants are discussed in detail in Chapter 33. The nutritional needs for girls during childhood do not differ from those for boys.

Adolescence

For women, adolescence is a special time of growth and development. In this discussion, adolescence covers ages 11 to 18.

Nutritional Needs

Nutrient requirements increase greatly during this time as a result of rapid growth, the onset of puberty, and an increase in body mass. Sufficient dietary calories must be provided so that protein is available for growth. Adequate calcium intake is another main concern for the adolescent because 45% of the skeletal mass is formed during this period; calcium is also important in the prevention of future osteoporosis. The new Daily Reference Intake (DRI) Adequate Intake (AI) for calcium is 1300 mg/day for girls aged 9 to 18 (Food & Nutrition Board, 1997). This is equal to at least four and one-half servings of calcium-rich foods each day.

The typical food habits of adolescents are characterized by an increased tendency toward skipping meals, snacking, inappropriate consumption of fast foods, dieting, and fad diets (Table 8-1). Adolescence is a time when peer influence is often greater than parental influence. The teen's search for independence, challenge of existing values, concern about body image, search for self-identity, and coping with the pressures of a quickly changing world enter in to the milieu of factors influencing dietary behavior.

Nutritional Concerns

Eating disorders frequently begin during adolescence in girls. When dealing with the rapid physiologic and psychologic changes experienced in this stage of life, adolescent females tend to alter their eating behavior to gain control over this aspect of their life (Giannini, Newman, & Gold, 1990). The medical community's attention to eating disorders increased in the mid-1970s. The groups affected by eating disorders have expanded from the traditional young, Caucasian, affluent girl or woman, whose illness is

a reflection of disturbed family relationships, to include women and men of all ethnic backgrounds. The national chapters of Anorexia Nervosa and Related Eating Disorders, Inc. (ANRED) and Anorexia Nervosa and Associated Disorders (ANAD) estimate that 20% of the population between ages 12 and 30 is experiencing a major eating disorder. Today's society promotes the ideal physique for males and females as being thin with a high lean body mass ratio. Western society's media images and high fashion industry perpetuate and reinforce these often unattainable body images, which stereotype slim and obese people. The incidence of anorexia nervosa and bulimia in a society is proportional to the value placed on thinness by that society. The disparity between what is seen as ideal and what is normal for the individual leads to great emotional discontent. Many normal-weight teens and women are not satisfied with their weight.

Anorexia Nervosa

Anorexia nervosa is self-starvation motivated by excessive concern with weight and an irrational fear of becoming fat; it was first reported as early as 1868 (Frisch & Frisch, 1998). People with anorexia excessively control and restrict their caloric intake and have an unrealistic view of their body fat stores and body shape. They are often perfectionists in their daily lives. The medical complications of anorexia nervosa are similar to those seen in starvation: slow resting heart rate, low blood pressure, amenorrhea (disruption of the menstrual cycle), and hypothermia (complaints of being cold). The skin is often cool and there may be a loss of scalp hair. Soft lanugo (fine, soft, blonde) hair may appear on the face and trunk area. The normal amount of body fat for females (20% to 25%) decreases to an extremely low level (7% to 13%).

The most serious medical complications of anorexia nervosa are damage to the cardiovascular system and sudden death (Kaplan and Sadock, 1998). Irregular heart rhythms may occur, especially with deficiencies in potassium, magnesium, or phosphorus. Treatment for anorexia nervosa is successful in about 50% of cases. The focus of treatment is on gradually restoring body weight, improving self-esteem and attitudes about weight and body shape, and normalizing eating and exercise patterns and behavior. Antidepressant medications and family therapy are often used.

Bulimia Nervosa

Bulimia nervosa is characterized by behaviors that are the opposite of those seen in anorexic clients. Binge eating, which is excessive consumption of calories over a short period of time; purging by self-induced vomiting; use of laxatives or diuretics, or both; excessive exercise; and periods of severe caloric restriction are the typical patterns

Table 8-1 Nutrient and Calorie Content of Some Fast Foods Compared with Recommended Daily Allowances (RDA) for 16-Year-Old Girl

	Weight (oz)	Calories	Protein (g)	Fat (g)	Calcium (mg)	Iron (mg)	Sodium (mg)	Vitamin A (RE)	Thiamin (mg)	Riboflavin (mg)	Niacin (mg)	Vitamin C (mg)

of the bulimic client. The client with bulimia often eats in secret, is depressed, and is a substance abuser. In contrast to the close-knit, orderly, often rigid family of clients with anorexia, instability and conflict characterize the families of clients with bulimia. Clients with bulimia appear impulsive and out of control and usually have a normal body weight or are slightly overweight. Bulimia is more common in athletes and ballet dancers than in other groups. The medical complications related to the anatomic and physiologic changes characteristic of bulimia are often severe. The body is constantly adjusting to the feast or famine cycle. As a consequence of self-induced vomiting, severe erosion of the dental enamel, loss of teeth, esophagitis, hiatal hernia, esophageal tear or rupture, hypochloremic alkalosis, hypokalemia, shock, and other symptoms may occur. If ipecac is used to induce vomiting, myocardial ipecac toxicity may develop, causing fatal dysrhythmias and potentially fatal myocarditis. Laxative abuse may result in chronic hypokalemia, along with renal tubular damage. Binge eating may also create marked gastric dilation, gastric rupture, or post-binge pancreatitis. Enlargement of the parotid glands may occur and can become disfiguring. Treatment for bulimia consists of nutritional counseling to replace the disordered eating patterns with regular meals and snacks and psychologic counseling to improve self-image and attitudes toward body weight. Antidepressants are often useful in the treatment plan.

Binge Eating

Binge eating is a disorder of periodic binge eating that is not normally followed by vomiting, the use of laxatives, or excessive exercise. Several thousand calories are consumed within a short period of time. Binge eating twice a week for 6 months is usually required for diagnosis. Stress, depression, anger, anxiety, and other negative emotions usually prompt the binge eating episodes. Nutrition and psychologic counseling help focus on the disordered eating pattern and the underlying feeling or circumstances surrounding the event. Antidepressants may again be part of the treatment plan.

Eating disorders are often seen in fashion models, wrestlers, figure skaters, gymnasts, dancers, drill teams, competitive athletes, flight attendants, actors, and persons training to be dietitians, all of whose careers may depend on their ability to maintain a particular body weight. Close attention should be given to the degree of body-size conformity placed on adolescents by their coaches, agents, peers, or parents. The evaluation and treatment of clients with eating disorders often requires an interdisciplinary team approach that includes professionals in psychiatry, psychology, general medicine, nutrition, nursing, and social work. The family must be involved in the treatment and care of the patient over an extended period.

Adulthood and Childbearing Years

The nutritional needs of women in the reproductive phase of their life are set forth in the Recommended Dietary Allowances and the Dietary Reference Intakes (Food & Nutrition Board, 1997, 1998, 2000). Updates to the nutrient needs of all individuals are continually being reviewed and periodically published. The key nutrients of concern to women are addressed in the following section, with specific nutritional concerns for pregnancy, lactation, and old age. Therefore, periodic review of the nutritional literature is essential to keep practice and guidance current.

The body weight of a client reflects her past history of nutritional habits. The current recommendations are to determine a client's ideal body weight based on the **body mass index (BMI)**. The BMI represents a ratio of the relationship between height and weight. BMI is calculated by the formula:

$$\text{BMI} = \frac{\text{weight (kg)}}{\text{height (m}^2\text{)}}$$

$$\text{or weight (lb)} \times \frac{700}{\text{height (in}^2\text{)}}$$

Conversions: 2.2 pounds = 1 kg; 1 inch = 2.53 cm

Example: For a 125 lb (56.8 kg), = 5'6" (66 inches, or 167 cm) woman:

$$\frac{56 \text{ kg}}{(1.67 \text{ m}^2)} = \frac{56}{2.7889} = 20.007 \text{ BMI}$$

or

$$\frac{125 \text{ lb} \times 700}{(66 \text{ in}^2)} = \frac{875000}{4356} = 20.087 \text{ BMI}$$

The interpretation of the BMI calculation is as follows: less than 18, severe underweight; 18 to 20, low body weight; 20 to 25, normal body weight; 30 to 40, overweight; and more than 40, gross obesity. Tables are available for a quick calculation.

Nutritional Needs

The Food and Nutrition Board, National Academy of Sciences Institute of Medicine, and National Research Council, published the Recommended Dietary Allowances (RDA), revised in 1989, and the Dietary Reference Intakes, in 1997, 1998, and 2000. These values reflect the new Dietary Reference Intakes (DRIs) published by the National Academy of Sciences in 1997, 1998 and 2000. The DRIs include two sets of values from the Recommended Dietary Allowances (RDA) and Adequate Intakes (AI). The tolerable **upper intake level (UL)** for selected daily nutrients is

also provided. Table 8-2 presents these recommendations for women in the childbearing years and for pregnancy, lactation, and postmenopausal women. Overall, a pregnant woman's nutritional needs increase by 15% during the second and third trimesters of pregnancy.

Calories or Energy Needs

A kilocalorie is unit of measure for energy; it is the amount of energy needed to raise the temperature of 1 kilogram of water from 1° C. The amount of energy provided to the body by food is measured in calories. Kilo-calorie is the proper term, but calorie is commonly used. The body uses the energy from foods for growth, tissue repair, maintenance; to fuel muscular activity; to process nutrients; and to maintain body temperature. **Basal metabolism** is the energy used to support the body functions while the body is at rest. To calculate the basal metabolic rate (BMR) for females, multiply body weight by 10. Physical activity also requires calories. The activity level can be multiplied by a factor to determine the calories usually expended in activity.

The final category of energy needs of the body is dietary thermogenesis, also called specific dynamic action

(SDA) of foods, diet-induced thermogenesis, and thermic effect of foods, which is the heat or energy expended during digestion of food and the absorption and use of nutrients. Dietary thermogenesis requires approximately 10% of the body's total energy needs. By adding these three categories of energy needs by the body, a good estimate of caloric needs can be determined.

The composition of energy nutrients found in foods determines their caloric content. Each gram of carbohydrate or protein contains four calories. Each gram of fat contains nine calories. Alcohol contains seven calories per gram. The information in Nutrition Facts food labels assists consumers in determining the number of calories per serving of food.

The average caloric requirement of a full-term pregnancy is 55,000 calories, which is consumed throughout the course of the pregnancy. There is no increased requirement during the first trimester, unless there was severe starvation before conception or the woman has severe hyperemesis gravidarum, which would deplete the bodily nutrient reserves. A 200- to 300-calorie per day increase over prepregnancy caloric needs is recommended during the second and third trimesters of pregnancy for women entering pregnancy at a normal BMI. The calculation is 200 calories/day \times 7 days/week \times 40 weeks' gestation = 56,000 calories.

The increased nutritional needs of pregnancy can be met by consuming one additional serving of a skim milk product, one additional serving from the bread and cereal group, one additional serving of fruit or vegetable, or one additional ounce of meat or meat substitute beyond the basic food guide plan for adult women. Pregnant adolescents should add one additional serving of dairy foods for increased calcium requirements, because their own skeleton is still forming.

Protein

The protein requirement for adult women is 0.8 kg body weight. The need for increased protein for the pregnant woman is 30% greater than when nonpregnant. This translates into an increase of 10 to 14 additional grams of protein per day during the last half of pregnancy. The increased need should be expected as a result of the increase in both maternal and fetal tissue formation. Adequate calories must be consumed so that protein can be used for the body's building and synthetic processes (Table 8-2). If calories are not consumed in adequate amounts, the protein in the diet is used to meet the energy needs of the body, rather than the building and synthesizing needs. Additional calories provide protein-sparing effects that are greater than in the nonpregnant woman.

Calcium

Calcium is a mineral needed for strong bones and teeth, neural transmission, and muscle contractions; it also plays

Critical Thinking

Determining Caloric Needs

The following formula may be used to determine caloric needs:

$$\begin{aligned}
 130 \text{ lb woman} \times 10 &= 1300 \text{ calories for BMR} \\
 + 1300 \text{ calories} \times 30\% & \text{ (average activity level)} \\
 &= 390 \text{ calories for activity} \\
 + 1690 \text{ calories} \times 10\% & \text{ (SDA)} \\
 &= 169 \text{ calories} \\
 \text{Total caloric needs/day} &= 1859 \text{ calories}
 \end{aligned}$$

Therefore, approximately 1859 calories per day would be necessary for this woman to maintain her body weight. Since each pound of body weight equals 3500 calories, to lose 1 pound a week, this woman would need to consume 500 fewer calories per day or to consume 250 fewer calories per day and increase her activity expenditure by 250 calories per day. If this woman desired to gain 1 pound of weight per week, she would need to increase her caloric intake by 500 calories per day. What are the caloric needs for a woman weighing 145 lb?

Source: Institute of Medicine. *Nutrition During Pregnancy*. Washington, D.C.: National Academy Press, 1989.

a role in cells and cell membranes, blood clotting, and other functions. Nearly 99% of the body's calcium is in the bones and teeth. Calcium is in a dynamic state in the body, always being moved from the bloodstream to the bones, according to the body's needs. The remaining 1% of calcium is found in body fluids. Calcium is required to maintain normal blood pressure and for the absorption of vitamin B₁₂. In 1997, the Food and Nutrition Board recommended that the adequate intake level for females ages 19 to 50 remain the same at 1000 mg/day of calcium, even during pregnancy and lactation. This may seem strange, but this represents an increase of 400 mg/day over the 1989 RDA. The calcium recommendations were increased primarily because of the increase in recognition of osteoporosis in women. The Food and Nutrition Board, in 1997, increased the calcium recommendations for adequate intake to 1300 mg/day for ages 9 through 18 and 1000 mg/day for ages 19 to 50, for both males and females. The benefit of increased calcium intake on weight-bearing

sites, such as the hip, is enhanced in women with high levels of physical activity. Urinary calcium loss is increased by excessive intake of sodium or protein. This is especially true of animal proteins, which are high in the sulfur amino acids, methionine and cysteine. Epidemiologic studies demonstrate that countries with the highest consumption of animal protein have the highest rate of hip fractures.

It is recommended that pregnant and lactating girls less than age 18 consume 1300 mg of calcium per day. Women should be encouraged to consume three to four servings from the dairy group daily. If women are lactose-intolerant, they should be advised to use lactase tablets or drops with dairy products; drink lactose-digested milk; use fermented milk products, such as buttermilk or yogurt; or take calcium supplements. Table 8-3 offers an overview of calcium needs.

If a woman does not regularly consume dairy products or other foods high in calcium each day, a calcium supplement of at least 600 mg/day is recommended. Calcium in the form of calcium carbonate, calcium citrate, or calcium

phosphate, in supplements that carry the United States Pharmacopoeia (USP) symbol, have been shown to be highly absorbable. Each client should discuss possible interactions among calcium supplements and prescription or over-the-counter medications with their doctor or pharmacist.

Vitamin D

Vitamin D plays an important role in calcium absorption and bone mineralization. Vitamin D allows calcium to leave the intestines and enter the bloodstream to be absorbed and allows the bones to release more calcium and the kidneys to retain more calcium in the body. It is essential to have sufficient quantities of this vitamin on a regular basis. Because it is a fat-soluble vitamin, it is stored in the liver. Vitamin D intake is recommended at 5 μg (200 IU) per day for adults over age 19, even during pregnancy and lactation. For adults between ages 51 and 70, the (Daily Recommended Intake) is 10 μg (400 IU) per day, increas-

ing to 15 μg (600 IU) per day for individuals over age 70. The tolerable upper intake level for vitamin D is 50 μg/day (Table 8-2).

Sources of vitamin D include vitamin D–fortified cow's milk or margarine, eggs, and butter. Most commercial yogurts are not fortified with vitamin D. Complete vegetarians who consume no animal products at all should consider supplementation if their exposure to sunlight is limited. Not all soy-containing products are fortified with vitamin D. Reading labels is important. Adequate exposure of the skin to sunshine, i.e., about 30 minutes of direct sunlight on the hands and face without sunscreen two to three times weekly, may be enough for the body to produce an adequate amount of vitamin D. Synthesis of vitamin D may be reduced in winter months, in darker-pigmented individuals, and in those living with high concentrations of atmospheric ozone. For women in northern climates or those with little exposure to sunlight, such as office workers, nursing home residents, and house-

Research Highlight

Food Consumption by Americans

Purpose

To examine the contribution of energy-dense, nutrient-poor (EDNP) foods to the diet of Americans and to examine the relationship between EDNP food intake and the availability of macronutrients and micronutrients.

Method

Twenty-four-hour recall data from the National Health and Nutrition Examination Survey (NHANES) were analyzed ($n = 1561$, ages ≥ 20). Linear logistical regressions were used to examine relationships with serum profiles of vitamins, lipids, and carotenoids.

Findings

EDNP foods accounted for 27% of the total energy intake; alcohol accounted for another 4%. One third of the population consumed an average of 45% of energy from EDNP foods. The relative odds of consuming foods from all five food groups and meeting the RDA for protein and micronutrients decreased with increased EDNP intake. Serum concentrations of vitamins A, E, C, and B₁₂; folate; several carotenoids; and HDL cholesterol were inversely related ($P \leq 0.0005$). Serum homocysteine was positively related to EDNP food intake ($p = 0.002$).

Nursing Implications

This study indicates that assessing for EDNP foods, such as visible fats, nutritive sweeteners and sweetened beverages, desserts, and snacks may be a good indicator of more general nutritional problems. As these foods tend to substitute for, rather than supplement, more nutrient-dense foods, clients who consume them in large amounts are at risk not only for obesity and problems of fat and caloric excess, but for nutrient deficiencies as well.

Source: Kant, A. K. (2000). Consumption of energy-dense, nutrient-poor foods by adult Americans: Nutritional and health implications. The 3rd National Health and Nutrition Examination Survey, 1988–1994. *American Journal of Clinical Nutrition*, 72(4), 929–936.

bound persons, supplementation should be considered if the diet is inadequate. In addition, women with closely spaced, multiple pregnancies; people with fat malabsorption syndromes; or individuals who regularly use topical sunscreens are in a group with higher needs. Vitamin D₃, synthesized in the skin from 7-dehydroxycholesterol with ultraviolet radiation, is the naturally occurring form and is needed by the body to absorb calcium and phosphorus and deposit these minerals in the teeth and bones to maintain skeletal integrity. The recommended intake of vitamin D for individuals with osteoporosis may be increased by the physician to 10 μg (400 IU) per day. Rich sources of vitamin D include fortified milk (400 IU per quart), high-fat fish (250 to 800 IU per serving), canned fish (200 to 500 IU per serving), and cod liver oil (400 IU per teaspoon). Table 8-3 provides an overview of vitamin D.

Folate

Folate, sometimes referred to as folacin or folic acid, is a B vitamin found in many vegetables, beans, fruits, whole grains, and fortified breads and cereal products. Routine supplementation with folate should occur at least 1 month before conception through the first trimester of pregnancy. All women in the reproductive years should consume at least 400 μg of folic acid per day from fortified foods, vitamin supplements, or a combination of the two, in addition to a varied, healthful diet. Since January 1, 1998, the FDA and the Department of Health and Human Services (DHHS) have required the enrichment of all cereal and grain products to provide 10% of the RDA per serving, or 1.4 mg folate per kilogram of flour or cereal or grain product (1.4 μg folate per gram of cereal or grain product), and not to exceed the recommended maximum of 1 mg/day

intake of folic acid. Synthetic folic acid has been shown to be twice as absorbable as dietary folate. The folic acid fortification of widely consumed cereal and grain products should have a remarkable effect in reducing the number of pregnancies affected by neural tube defects (NTD), when these products are consumed with synthetic supplements of folic acid (Lewis, Crane, Wilson, & Yetley, 1999). The incidence of occlusive vascular diseases may also be decreased by higher intakes of folic acid lowering plasma or serum homocysteine concentrations. Clients should be evaluated for pernicious anemia and vitamin B₁₂ deficiency before being given large doses of folate.

Dietary sources of folate include meat, fish, poultry, eggs, fortified whole-grain breads, fortified cereals, peanuts, leafy green vegetables, and yeast extract. Liver is an excellent source, with 3.5 ounces of chicken livers containing 770 µg of folic acid and 3.5 ounces of beef liver containing 217 µg of folic acid.

Sufficient body supplies of folic acid before and during conception and for up to 13 weeks after conception help guard against birth defects of the brain and spine (NTDs) that occur when the neural tube does not close completely, as in spina bifida (in which the spinal canal does not close and protrudes out of the back), **encephalocele**

REFLECTIONS FROM A YOUNG ADULT

"My grandmother recently fell and broke her hip for the second time. All her life she's been a heavy smoker and coffee drinker and not very big on dairy products, especially milk. I guess I never really appreciated the link among good dietary habits, a healthy lifestyle, and overall physical health and well-being. Most of my life I've done what I've wanted and been very healthy, but seeing my grandmother's troubles really motivates me to watch my habits and consider their impact on my long-term health."

(in which the brain protrudes through a defect in the skull), and **anencephaly** (a fatal condition in which a baby is born with a severely underdeveloped brain and skull and dies shortly after birth). In the United States, more than 3000 infants per year are born with NTDs, about 4 of every 1000 births. Babies with the other NTDs live longer, with paralysis, neurologic damage, and possibly bowel and bladder incontinence. Women who have had one infant with an NTD are considered to be at high risk for having another infant with an NTD. Four mg of folate per day is recommended for these women, beginning at least 1 month before pregnancy and throughout the first trimester of pregnancy. This treatment has been shown to reduce the risk of the mother having another NTD-affected child by about 70%.

As a coenzyme, folate serves a role in the synthesis of ribonucleic acid (RNA) and deoxyribonucleic acid (DNA) and, therefore, is necessary for the proliferation of cells and the transmission of inherited characteristics. Folic acid also functions in the formation and maturation of red and white blood cells and the synthesis of enzymes. Folate deficiency results in macrocytic or megaloblastic anemia, which is characterized by immature, large red blood cells. Glossitis, gastrointestinal irritation, depression, and other neuropsychiatric disturbances are also found in children of women with folic acid deficiency. Alcohol also interferes with folate use by the body and thus increases folate requirements even more. Anticonvulsants, some antacids, antihypertensive agents, and aspirin also interact with folic acid. Adequate body stores of folic acid and vitamins B₆

and B₁₂ may protect against high blood levels of homocysteine, a chemical that, at an elevated level, has been linked to damaging arteries and setting the stage for atherosclerosis and stroke (Mills, McPartlin, Kirke, Lee, Conley, Weir, & Seoth, 1995).

Without an adequate amount of folic acid, women, especially those who are poorly nourished and from low-income groups, have a higher proportion of premature, low birth weight babies. Currently, researchers are studying the role of genetics in how women metabolize food folates and how folic acid is transferred from the placenta to the fetus (Locksmith & Duff, 1998). Identifying women who are at risk for having babies with NTDs before conception and improving ways to treat them are long-term goals.

The (Bailey, 1998) DRI expresses the new recommended intakes for individuals for folate in dietary folate equivalents (DFEs). The DFEs account for the difference in the absorption of naturally occurring food folate and synthetic folic acid, which is more bioavailable. The following formula was used to calculate DFEs of sources of folate.

$$\begin{aligned} \text{Folic acid content} &= \text{total folate content of fortified food} \\ &\quad - \text{food folate content.} \\ \text{Dietary folate equivalents} &= \mu\text{g of food folate} + (1.7 + \\ &\quad \mu\text{g folic acid}) \end{aligned}$$

The Nutrition Facts label is based on a recommended daily 400 μg of folic acid. To find out the number of micrograms of folic acid per serving size, multiply the percentage of the daily value times 400 μg (the daily value for folic acid). Then, multiply the result by 1.7 to obtain dietary folate equivalents.

As stated in Table 8-2, women aged 19 and older need 400 μg of DFE per day. One DFE = 1 μg food folate = 0.6 μg folic acid (from fortified food or supplement) consumed with food = 0.5 μg of synthetic (supplemental) folic acid taken on an empty stomach. During pregnancy, the recommendations increase by 200 μg per day to equal 600 μg DFE per day. During lactation, the recommendations increase by 100 μg over the basic recommendations per day to equal 500 μg DFE per day. Table 8-3 gives an overview of folate needs.

Vitamin B₁₂

Vitamin B₁₂ is needed to build red blood cells and to keep the nervous system healthy. It is also essential for the normal use of folate and helps protect against the risk factors characteristic of heart disease and atherosclerosis. This vitamin is only found in animal food sources. The best sources of this vitamin are meats, fish, poultry, shellfish, eggs, milk, and milk products. Some brands of soymilk products are fortified with vitamin B₁₂. Vegetarians consuming no animal products (vegans) need 2.4 μg per day of vitamin B₁₂. Care should be taken to get adequate

amounts of this vitamin, either through the diet or a multi-vitamin and mineral supplement. Vitamin B₁₂ is absorbed in the ileum and requires intrinsic factor (IF), produced and secreted in the parietal cells of the stomach mucosa, for absorption. IF is a glycoprotein that protects vitamin B₁₂ from degradation as it moves through the intestinal tract to the ileum, the site of absorption. Impaired absorption of this vitamin accounts for more than 95% of the cases of vitamin B₁₂ deficiency in the United States. With adequate intake, the liver can store vitamin B₁₂, which is somewhat unique for the B vitamins.

Deficiency of vitamin B₁₂ in the diet or in individuals lacking the intrinsic factor can mean the development of pernicious anemia. The name was given to this deficiency disease in 1822 when pernicious meant “to lead to death.” This deficiency causes macrocytic, megaloblastic anemia, in which red blood cells have delayed and abnormal nuclear maturation.

Vitamin B₁₂, known as cyanocobalamin, was the last water-soluble vitamin to be isolated and have its structure identified. It is required in very small amounts in comparison to other water-soluble vitamins. The RDA is 2.4 µg per day for this vitamin, for both adolescents and adults. In pregnancy, the recommendation increases to 2.6 µg/day, and in lactation to 2.8 µg/day. The next lowest recommended intake for a B vitamin is for folate, for which the requirement is 167 times greater than that of vitamin B₁₂ for women. Strict vegetarians (vegans), breastfed infants of vegans, vegan children, elderly persons, and individuals with past gastrointestinal surgeries are at high risk for vitamin B₁₂ deficiency.

Vitamin B₁₂ is involved in the conversion of homocysteine to methionine (Gerhard, Malinow, DeLoughery, Evans, Sexton, Connor, Wander, & Connor, 1999). If there is inadequate vitamin B₁₂, or methylenetetrahydrofolate (THF), or lowering level reduced folate, which is needed for nucleic acid metabolism than this causes a combination of events that is responsible for the megaloblastic anemia, characteristic of both vitamin B₁₂ and folate deficiency. The red blood cells look identical in both types of deficiency. Symptoms accompanying pernicious anemia include weakness, indigestion, abdominal pain, constipation alternating with diarrhea, sore and glossy tongue, and damaged nerve fibers. Treating individuals with folate supplementation may reverse the megaloblastic anemia, although the B₁₂ deficiency may worsen. Prolonged deficiency can result in irreversible nervous system damage. The determination of folate and vitamin B₁₂ deficiency is therefore necessary before initiating treatment. Deoxyuridine suppression tests differentiate between folate and vitamin B₁₂ deficiency. Serum levels reflect early reduction in tissue stores. Macrocytic anemia appears months or years after depletion. Doses of up to 1000 µg/day are used to treat deficiency. Doses greater than this can mask more

obvious signs of vitamin B₁₂ deficiency. If the deficiency is caused by inadequate absorption, such as a client with gastrectomy, monthly injections of 100 µg are appropriate. Such clients should have their serum vitamin B₁₂ levels monitored every 6 to 12 months. Table 8-3 provides an overview of vitamin B₁₂ needs.

Iron

Iron is a trace mineral that functions to transport oxygen to the cells as a component of hemoglobin and myoglobin. Iron is also required by several enzyme systems and helps convert energy for normal cell activities. Iron is stored intracellularly as ferritin and hemosiderin, primarily in the liver, spleen, bone marrow, and other organs. Table 8-2 lists the recommended intake of iron for each age group. In general, for menstruating females, the iron recommendation is 15 mg/day. The recommendation decreases past the age of 51 to 10 mg/day. For pregnancy, the recommended level doubles to 30 mg/day, and during lactation, the recommended level returns to the menstruating female level of 15 mg/day.

If dietary intake is inadequate, the stored iron is used to meet the body's need for iron. Only after depletion of iron stores do hematocrit levels begin to fall. Signs of iron deficiency are the depletion of the iron stores, microcytic (small cell size) anemia, **hypochromic** (lacking in color) anemia. Iron deficiency anemia is the most common nutritional deficiency in the United States. The incidence in high-risk populations ranges from 10% to 50%: in menstruating women, 5% to 14%; in males in early adolescence, 4% to 12%; in children, ages 1 to 2, 9%. There is currently an interagency group, consisting of the Micronutrient Initiative and the University of Toronto, presenting the technology to fortify salt with iron, in addition to iodine, to address the severe levels of iron deficiency anemia existing worldwide.

Because women are consuming fewer calories and losing iron during menstruation, they often enter pregnancy with depleted iron stores. During pregnancy, the increased blood volume and fetal requirements reduce the iron stores even further. The fetal tissues take predominance over the mother's tissues with respect to use of the iron stores. During the last trimester of pregnancy, when the iron stores are being laid down in the fetus, 3 to 4 mg of iron is transferred to the fetus from the mother daily.

Ferrous iron supplements of 30 to 60 mg/day are recommended for the general population of pregnant women beginning the 12th week of pregnancy and continuing throughout the pregnancy, assuming an omnivorous diet with adequate intake of vitamin C. The proper dose of iron may be provided by 150 mg of ferrous sulfate, 300 mg of ferrous gluconate, or 100 mg of ferrous fumarate. Iron supplements should be continued for 2 to 3 months postpartum. Full-term neonates do not require

ORAL CONTRACEPTIVE AGENTS

Millions of women use oral contraceptive agents (OCAs), commonly known as “the pill,” to prevent unplanned pregnancy. The effect of OCA use on nutritional status is that OCAs reduce menstrual flow by approximately half, therefore conserving nutrients normally lost during menstruation, especially iron. The different OCAs affect the absorption or excretion rate of nutrients according to the hormone types and concentrations of the pill. For some OCAs, the rate of metabolic conversion changes the nutrient status in the body. Most women can correct these changes by paying close attention and eating a well-balanced and varied diet. Supplements are indicated only if a deficiency exists and symptoms are apparent.

Women are advised to stop taking oral contraceptive agents 6 or more months before planning to become pregnant, because oral contraceptives can alter nutritional status. Table 8-4 presents the effect of these agents on the nutritional status of women. When women stop taking OCAs before trying to conceive, alternate methods of birth control are recommended while the woman's body is rebuilding and readying for conception. Some other forms of birth control methods commonly used are the condom, rhythm method, diaphragm, intrauterine device, and morning-after pill. Intrauterine devices double the menstrual loss, and consequently, also affect nutrient stores in the body.

iron supplementation until 4 months of age, but should have iron supplements as long as they are fed from the breast or with formula without iron supplements in it. Premature infants should begin iron supplementation earlier.

Iron in the diet consists of two forms. **Heme iron** (iron from animal sources) constitutes about half of the iron in the diet animal sources. **Nonheme iron** (dietary iron sources other than from meats, in which the iron is not bound to hemoglobin). comprises the remaining half of the iron found in animal sources and all of the iron found in plant sources, including grains and cereals. There is greater absorption of nonheme iron when it is taken with a good dietary source of ascorbic acid, like orange juice or oranges. Nonheme iron is less absorbable when taken with tea (tannic acid), dairy products (calcium phosphate), many cereals (phytates), bran, oxalates, and antacids. Heme iron is absorbed four to five times better than nonheme iron. Nonheme iron accounts for a larger percentage of total human iron intake. On the average,

Table 8-4 Effects of Oral Contraceptive Agents on Nutritional Status

Nutrient	Effect of Agent	
Vitamin B ₆	↑ requirement	↓ blood levels
Riboflavin	↑ requirement	↓ blood levels
Folic acid	↓ absorption	↓ blood levels
Vitamin B ₁₂	↑ requirement	↓ blood levels
Vitamin C		↓ blood levels
Vitamin A	↓ carotene	↑ blood levels
Calcium	↑ absorption	
Iron	↑ serum levels	
Copper	↑ serum levels	
Magnesium	↓ blood levels	
Zinc	↑ erythrocyte levels	

Compiled and copyrighted by Jeanne B. Martin, PhD, RD, FADA, LD.

about 10% of iron consumed is absorbed. The rate of absorption varies with need and the form of the iron consumed.

Administration of the iron supplement between meals or at bedtime increases absorption rates. If a client has iron-deficiency anemia and therapeutic levels of iron (more than 30 mg/day) are given to treat the anemia, the client should also be given 15 mg of zinc and 2 mg of copper because of the interference of iron with the absorption and use of these trace minerals.

Hemochromatosis (a rare genetic defect in iron metabolism, in which excess iron is deposited in the tissues, causing skin pigmentation, hepatic cirrhosis, and decreased carbohydrate tolerance, which eventually ends in multiple-system organ failure) and **hemosiderosis** (increase in iron stores without associated tissue damage) are iron-storage diseases that result from iron toxicity. Alcohol consumption enhances iron absorption, sometimes by as much as 50%, which may also result in a toxic overload of iron. Signs and symptoms of acute iron poisoning include gastrointestinal cramping and pain, vomiting and nausea, convulsions, and coma (Table 8-3).

Fiber

Dietary fiber is a complex carbohydrate, mainly composed of the indigestible parts of plant cell walls. Dietary fiber is connected to better colon health, a reduced incidence of type 2 diabetes mellitus, lower blood pressure and cholesterol levels, and less risk of cardiovascular disease. Individuals who eat a lot of whole grain cereals and bread products and fruits and vegetables with the skins seem to have less constipation and diverticulitis. Although no dietary recommendations exist for fiber for pregnant women, they should consume the same amount as recommended for the general population. This is 20 to 35 g/day of dietary fiber from a wide variety of food sources, such

as fruits, vegetables, legumes, and whole grains. When fiber intake is increased, it should be done gradually. In addition, 1 to 2 quarts of additional fluid should be consumed with the additional fiber. This helps with possible constipation problems characteristic of supplemental iron intake and normal pregnancy. Participating in regular physical exercise is recommended to manage constipation.

There are two types of fiber: insoluble and soluble.

Insoluble fiber resists absorption into the body. It moves quickly through the digestive tract, absorbing water and making the stools softer and bulkier. The rapid passage of food through the intestines is believed to reduce the potential for carcinogens to interact with the intestinal surface. However, this hypothesis is under study. Insoluble fiber is found primarily in whole grains, nuts, seeds, vegetables, cooked dried beans, and dried peas or legumes.

Soluble fiber reduces blood cholesterol levels. It can bind bile acids or coat the intestines, thus inhibiting the absorption of cholesterol. Soluble fiber includes pectins, gums, and mucilages that dissolve in water. Some key sources of soluble fiber are oat bran, barley, apples, fruits, seaweed, and cooked dried beans and peas (legumes).

Water

Water is an essential, vital nutrient, often overlooked in recommendations. It is an essential nutrient because it is required in amounts that exceed the body's ability to produce it. It is necessary for the transport of nutrients in the body and for body temperature maintenance and serves as a solvent for minerals, vitamins, amino acids, and glucose. Water provides a means for the elimination of waste materials and toxins from the body in urine. Approximately 60% of the adult's body is composed of water with two-thirds of this water distributed intracellularly and one-third extracellularly. Water accounts for 50% to 80% of body weight, depending on the level of lean body mass. Usual recommendations for adults are to drink 8 to 10 cups (1 cup = 8 oz = 237 mL) of water per day, or 30 mL/kg of body weight, with a minimum of 6 cups (1500 mL) for small individuals. Another way to calculate water needs is based on 1 mL/kcal of energy consumption per day (2200 kcal diet = 2200 mL/day of water = approximately 9.28 cups/day of water). More daily fluid is required: (1) in hot, dry climates or high altitudes; (2) with a high-fiber diet; (3) with a diet high in alcohol or caffeine; and (4) with increased activity. Early symptoms of dehydration include headache, fatigue, loss of appetite, flushed skin, heat intolerance, lightheadedness, dry mouth and eyes, a burning sensation in the stomach, and dark urine with a strong odor.

Because the pregnant woman's blood volume is expanding, water and other fluids should be increased. The pregnant woman needs an additional daily 30 mL of water per kilogram of body weight gained. Alternate sources of

water should be obtained if there is concern about the lead content of the water pipes. Lead intake has been linked to decreased stature and deficient neurocognitive development of the fetus. The local or state public water department can direct clients to facilities for testing the lead content in their household water supply.

Vegan Diets

Vegans are "pure" vegetarians who do not consume any animal-containing product, including eggs, milk, or milk products in addition to meats, poultry, or fish. Vegans can get enough calcium from plant sources alone, with careful diet planning, by including sufficient quantities of calcium-rich foods, such as tofu processed with calcium, calcium-fortified soy beverages, broccoli, seeds, nuts, legumes, some dark greens (kale, collards, mustard greens), okra, rutabagas, bok choy, dried figs, tortillas made from lime-processed corn, and calcium-fortified orange juice and breakfast cereals. Some plant foods (e.g., beet greens, rhubarb, spinach, Swiss chard, and amaranth) contain oxalates and some grain products contain phytates, which bind to calcium and block its absorption. Therefore, these foods should not be relied on as the sole source of absorbable calcium in the diet.

Pregnancy and Lactation

The nutritional status of women entering the reproductive phase of life may be one of the most important nutritional stages of life. The mother's nutritional history plays a direct role in the development of the fetus. Women must plan nutritionally for their pregnancy to help achieve healthy full-term newborns. There are many events outside a woman's control during the conception and development of the fetus, but the woman's capacity to conceive should motivate her to follow sound nutritional advice from health professionals to ensure a successful outcome of pregnancy. This is critical to the mother's health, her baby's prenatal development, and the development of the child long after its birth. All women in their teens and throughout their 40s should be cognizant of their potential to conceive, and therefore, optimize their nutritional status prior to conception. Health professionals in any setting should try to help women in all age groups form sound, lifetime nutritional practices.

Prepregnancy nutritional status is most easily evaluated in the clinical setting using the prepregnancy weight-for-height index. The measurement is easy to make and provides systematic methods for evaluating women's weight. The health care professional can use a chart for estimating BMI or can use the formula: weight (kg)/height (m^2) to determine BMI. This can help the woman and health care professional set realistic, appropriate weight-gain goals. Table 8-5 provides the recommended ranges

Table 8-5 Recommended Total Weight Gain Ranges for Pregnant Women in Second and Third Trimesters According to Prepregnancy BMI

Prepregnant BMI	Total Weight Gain (kg)	Gain in 4 Weeks (kg)	Total Weight Gain (lbs)	Gain in 4 Weeks (lbs)
Underweight (BMI < 19.8)	12.7–18.2	2.3	28–40	5.0
Normal (BMI = 19.8–26.0)	11.4–15.9	1.8	25–35	4.0
Overweight (BMI = 26.1–29.0)	6.8–11.4	1.2	15–25	2.6
Obese (BMI > 29.0)	6.8	0.9	<15	2.0
Twin gestation	15.9–20.4	2.7	35–45	6.0

BMI, body mass index = weight (kg)/height (m²)

for total weight gain for pregnant women, based on their prepregnancy BMI.

The first 6 weeks after conception are extremely important for optimum fetal development. Therefore, the woman must be aware of and avoid as many as possible of the nutritional risk factors that are related to poor pregnancy outcome. These include consumption of alcohol, tobacco, and prescription, over-the-counter, and illegal drugs. Currently the recommendation is for supplementation of folic acid prior to conception to lower the risk of neural tube defects (Cuskelly, McNulty, & Scott, 1999). A well-planned pregnancy should ideally include an initial health examination 8 to 12 weeks before conception. This period is critical for establishing a prepregnancy baseline weight.

Weight Gain in Pregnancy

At the first prenatal visit, the health professional should measure height and weight, determine the prepregnancy BMI, and explain the importance of adequate weight gain during pregnancy. The weight gain of the pregnant woman should be recorded, plotted, and monitored at

each prenatal visit. Weight gain during the first half of the pregnancy is reflective of increasing maternal stores. In the second half of gestation, the weight gain is primarily attributable to fetal growth (Box 8-1).

Under no circumstances should a woman lose weight during her pregnancy. If this happens, or if an excess rate of weight gain occurs, the cause should be assessed and referral made to a registered dietitian. During the second and third trimesters of pregnancy, underweight women (pregnancy BMI of less than 19.8) should gain slightly more than one pound per week. Women with normal or moderate prepregnancy BMI of 19.8 to 26.0 should gain about 1 lb/wk. Women with a high prepregnancy BMI of 26.1 to 29.0 are encouraged to gain two-thirds of a pound per week. Very obese women (pregnancy BMI of more than 29.0) should have their total weight gain determined on an individual basis. The date of the office visit, the weeks of gestation, the mother's weight, and any significant findings should be recorded at each visit. Weight should be plotted at each visit to assure no weight loss is occurring and, if it does, an explanation for the loss can be found. A copy of this information should also be given to the mother, if she also wants to keep track of this.

Weight gain for pregnant women under the height of 62 inches (less than 157 cm) should be toward the lower end of the recommended range for BMI. Adolescents should try to achieve the upper recommended range of weight gain for their BMI because their bodies are still growing and need additional nutrients for this as well as for their pregnancy. The recommended range for a twin pregnancy is 35 to 45 pounds (16 to 20 kg). In a 1997 (Sutor, 1997) review of the Institute of Medicine's (IOM) report, *Nutrition During Pregnancy*, an expert group recommended that, contrary to the 1990 report (Institute of Medicine, 1990), which suggested that African-American

Box 8-1 Weight Gain Distribution During Pregnancy

5.0 kg (11 lbs)	Fetus, placenta, and amniotic fluid
0.9 kg (2 lbs)	Uterus
1.8 kg (4 lbs)	Increase in blood volume
1.4 kg (3 lbs)	Breast tissue
2.3 to 4.5 kg (5 to 10 lbs)	Maternal stores

Total = 11 to 13 kg (25 to 30 lbs) gained
For women at their ideal BMI at conception

Adapted from Cunningham et al., 1997

women should strive for the upper end of the recommended range of weight gain because of their higher likelihood of delivering low-birth-weight babies, African American women should be advised to stay within the IOM-recommended BMI-specific weight-gain range for optimum pregnancy outcome. This was recommended because African American women had an increased likelihood of low prenatal weight gain in each BMI category and a decreased likelihood of gaining more weight than recommended overall (Sutor, 1997).

In 1992 the Committee on Nutritional Status During Pregnancy and Lactation proposed eight recommendations in their book, *Nutrition Services in Perinatal Care*, 2nd edition (Institute of Medicine, 1992). These key recommendations are relevant today and are listed below.

1. Basic, client-centered, individualized nutritional care should be integrated into the primary care of every woman and infant—beginning prior to conception and extending throughout the period of breast-feeding.
2. All primary care providers should have the knowledge and skills necessary to screen for nutritional problems, assess nutritional status, provide basic nutritional guidance, and implement basic nutritional care.
3. Nutritional care should be documented in the permanent medical record.
4. When health problems that benefit from special nutritional care are identified, there should be consultation with and often referral to an experienced registered dietitian or other appropriate specialists.
5. Attention should be directed toward aspects of nutritional care that have been seriously neglected in the past: providing care prior to conception and in support of breast-feeding and ensuring the continuity of nutritional care despite changes in providers.
6. Action should be taken to make appropriate policy and structural changes for the promotion and support of breast-feeding.
7. Where not already in place, mechanisms should be established to pay for basic and special nutrition services in both the public and the private sectors.
8. Cost-effective strategies for implementing the nutritional care recommended in the report should be developed and tested.

Dietary Supplements in Pregnancy

For pregnant women who are unable to consume an adequate daily diet and for those in high-risk categories, the Subcommittee on Nutritional Status and Weight Gain During Pregnancy and on Dietary Intake and Nutrient Supple-

Table 8-6 Recommended Daily Prenatal Multivitamin and Mineral Supplement for Pregnant Women at Increased Nutrient Risk

Iron	30–60 mg	Vitamin B ₁₂	2 µg
Zinc	15 mg	Folate	400 µg
Copper	2 mg	Vitamin C	50 mg
Calcium	250 mg	Vitamin D	10 µg (400 IU)
Vitamin B ₆	2 mg		

Source: Morgan, S. & Weinsier, R. L. (1998). *Fundamentals of Clinical Nutrition*. 2nd Ed. St. Louis: Mosby.

ments During Pregnancy recommends a daily multivitamin and mineral preparation containing the nutrients listed in Table 8-6, beginning in the second trimester. Pregnant women who are considered to be at high risk for vitamin and mineral deficiency would include the following: those who smoke or are alcohol or drug abusers; those who have frequent, closely spaced, or multiparous births; those who are carrying more than one fetus; those who experience hyperemesis gravidarum; those who have an eating disorder or are obese or underweight; and those who are adolescents or strict vegetarians.

Over-the-counter prenatal vitamin and mineral supplements are readily available. Generic brands should be compared with name brands for price and nutrients.

Nutritional Needs during Lactation

Breast-feeding should be strongly encouraged. Breastfeeding only is adequate for the first 4 to 6 months in almost all healthy infants. Lactation is the physiologic completion of the reproductive cycle. An adequate volume of breast milk with optimal nutrient composition can be produced, even with suboptimal dietary intake, by drawing on the maternal nutrient stores and tissue reserves. Nutrient needs of the client are increased during lactation, according to the volume of breast milk produced and the duration of breast-feeding.

For the vegan breast-feeding mother, vitamin B₆ and vitamin B₁₂ supplements are needed because meat, eggs, and dairy products are the primary source for these B vitamins. The lactating woman needs to replace the fluid lost in breast milk. The increased fluid need of the lactating woman is 750 to 1000 mL/day above the basic requirement.

Well-nourished breast-feeding women need an additional 200 calories per day over pregnancy energy requirements to adequately initiate and maintain lactation. Therefore, 500 calories more than the nonpregnant calorie intake must be consumed. Young adolescents, underweight women, and women who gained an inadequate amount of weight during their pregnancy or who are highly active physically will require greater energy intakes while lactating; an additional 650 calories per day are needed.

At least 1800 calories are needed per day from the major food groups for a well-balanced diet that provides the increased protein and nutrients needed (Table 8-2). The increase can be met by consuming one additional serving each from a skim milk product, from the bread and cereal group, and from the fruit or vegetable group. Some dietary guidelines for lactating women include the following:

- ✱ Consume enough fluids (especially milk, juice, water, and soup) to keep from getting thirsty.
- ✱ Try to keep intake of coffee, tea, cola drinks, or other sources of caffeine to two servings or less per day.
- ✱ Avoid alcohol consumption, and be aware that beer drinking does not aid lactation.
- ✱ If you use beverages containing sugar substitutes, use moderation and do not use them to substitute for more nutritious foods, such as milk or fruit juices.
- ✱ Continue the multivitamin and mineral supplement prescribed during pregnancy.

Breast-feeding has many positive benefits for the mother and the infant besides offering the infant ideal nutrition. Besides the beneficial nutritional aspects of breast milk (e.g., increased antibodies, ideal protein content, ideal profile of amino acids for the neonate's developing brain, and appropriate lipids and cholesterol levels), breast-feeding an infant offers increased maternal-infant bonding, immunologic protection, allergy prophylaxis, more rapid maternal postpregnancy weight reduction, and suppression of ovulation.

Nutritional Concerns in Pregnancy

Many substances pose a risk to the mother or fetus during pregnancy and should therefore be avoided. Nutritional disturbances of pregnancy and suggested remedies are discussed in this section.

Mercury. Contaminated grains and fish may contribute to mercury toxicity, which has been associated with cerebral palsy, mental retardation, and multiple organ failure in newborns. If mercury contamination is suspected, the pregnant woman should wash all vegetables and fruits (if the skin is eaten) with a weak soap solution and scrub the skin with a brush and rinse well. Otherwise, the skin should be peeled and disposed of before consumption. Likewise, raw fish (e.g., sushi) or fish caught in contaminated waters should be avoided during pregnancy.

Toxic Doses of Vitamin A. A pregnant or lactating woman should not take high doses of retinol (preformed vitamin A) or a potentially teratogenic medication, such as isotretinoin (Accutane) (a vitamin A analog used to treat severe acne). Large doses of vitamin A can cause sponta-

neous abortion or fetal anomalies. Excessive intake (over 10,000 IU per day of vitamin A) from food and supplements should be avoided. No apparent toxicity or teratogenicity exists for beta carotene: harmless yellow skin pigmentation occurs with higher doses. One retinol equivalent (RE) = 1 μg retinol = 6 μg beta carotene.

Alcohol. Women and elderly persons have lower levels of total body water and, therefore, intake of smaller amounts of alcohol achieve higher blood alcohol concentrations than in men. Moderate drinking is defined as 1 or 2 drinks per day for men and 1 drink a day for women and persons over age 65. One alcoholic drink is defined as a 12-ounce bottle of beer or wine cooler, a 5-ounce glass of wine, or 1.5 ounces of 80-proof distilled spirits. These quantities of alcoholic beverages contain approximately 17 grams of alcohol, equal to 119 calories.

Women should avoid alcohol consumption during pregnancy. All alcoholic beverages display the Surgeon General's warning regarding the possible ill effects on the fetus. An absolutely safe minimum limit has not been established. Alcohol increases the urinary excretion of zinc.

Consumption of even small amounts of alcohol during pregnancy may cause fetal alcohol syndrome (FAS) in the newborn. Babies with FAS are abnormally small at birth and have less brain tissue (smaller head circumference) than normal infants. Babies with FAS may have severe mental retardation, may have heart defects, and other alcohol-related birth defects. Therefore, clients should be advised to avoid alcohol consumption beginning at least 1 month before attempting to conceive and throughout pregnancy to protect their unborn child. The severity of FAS depends on how much alcohol was consumed during pregnancy and whether excessive intake occurred early or late in pregnancy. The incidence of FAS in the U.S. varies between 0.4 and 2.6 births per 1000 live births (Mattson, Riley, Gramling, Delis, & Jones, 1997). FAS is characterized by the following:

1. Prenatal or postnatal growth retardation and weight, length, or head circumference below the tenth percentile on growth charts. Unlike other small-for-gestational age infants, infants with FAS do not experience normal "catch-up" growth.
2. CNS involvement, with neurologic abnormality, developmental delay, or intellectual impairment, including:

Delayed gross motor development	
Low IQ	Hyperactivity
Poor coordination	Fine motor problems
Irritability	Extreme nervousness
3. Characteristic facial disfigurations, including:

Underdeveloped groove in center of upper lip below nose

Low nasal bridge	Short eyelid opening
Small midface	Thin, reddish upper lip
Short nose	Small head circumference

Fetal alcohol effects (FAE) are detectable effects of maternal alcohol consumption but to a more limited extent than seen in FAS.

Caffeine. Again, there is no definite recommendation about caffeine consumption levels for pregnant women. The research is ambiguous regarding the relationship of caffeine intake to pregnancy outcome. Caffeine acts as a CNS stimulant but does not appear to affect a woman's fertility or her ability to conceive. The fetus does not metabolize caffeine. Recent studies show that caffeine does not increase the risk of spontaneous abortions, fetal growth retardation, or birth defects. The infants of breast-feeding mothers do not metabolize the caffeine either.

The FDA recommends that pregnant women reduce their caffeine intake from coffee, tea, colas, and cocoa to not more than two to three servings per day, for a total of 300 mg of caffeine per day. More than 1000 over-the-counter drugs have caffeine as an ingredient, in addition to prescription drugs that contain caffeine. Caffeine can have a diuretic effect, increasing water loss. Therefore, caffeine-containing beverages should not be counted in tallying the daily fluid recommendations for the pregnant or lactating woman. One tablespoon of milk in coffee offsets the interference of caffeine with calcium absorption. Latte or cappuccinos are better choices than espresso brews for the pregnant woman because of the diluting effect of the milk (Table 8-7).

Artificial Sweeteners. Moderation in the consumption of artificial sweeteners is recommended for pregnant and lactating women. Women who do not have phenylketonuria (PKU) generally have sufficient phenylalanine hydroxylase activity in their livers to keep phenylalanine levels in the blood at reasonable levels. Women with elevated serum phenylalanine levels or with PKU should avoid aspartame during pregnancy. The use of saccharine is not recommended because studies have been inconclusive about its safety.

Herbal Supplements Herbal medicines are often referred to as herbs or botanicals. **Herbs** refer to leafy plants that do not have woody stems; **botanicals** are all parts of the plant that have medicinal value: roots, rhizomes, leaves, stems and flowers. The key concern with herbal medicine is the lack of consistent potency in the active material in any given batch of product. The reputable manufacturers try to ensure quality, purity, safety, and reliability. "Natural" does not always mean "safe."

Worldwide, more than 80% of people use botanicals as medicine. More than \$3.87 billion is spent per year in

Table 8-7 Caffeine Content of Beverages and Chocolate

the United States on the herbal therapy industry, with 25% to 50% rate of growth per year. At least 73 out of 440 herbs in the *Physicians' Desk Reference (PDR) for Herbal Medicine* (Gruenwald, Brendler, and Jaenicke, 1998) are common foods or culinary herbs, such as soy, tomatoes, basil, or mint. Since the Dietary Supplement Health Education Act (DSHEA) of 1994 was passed, there has been an explosion in the number and variety of herbal medicines available. Health care practitioners should inquire which, if any, herbal supplements are consumed by their clients on a regular basis and which ones are used on an as-needed basis. Interactions among nutrients, drugs, and herbal supplements must be evaluated by the health care practitioner.

Herbal supplementation should be avoided during pregnancy and lactation because scientific studies that have been conducted have had inadequate results regarding the consequences of use during this time. Class 2 is the safety classification given to herbs that are not to be used during pregnancy and lactation, unless otherwise directed by an expert qualified in the use of the described substance, according to the American Herbal Products Association's (AHPA, 2000) Herbal Safety Rating. The *Botanical Safety Handbook* (BSH), published by AHPA, lists nearly 600 herbs and botanical products sold in the U.S. market with a relative safety rating for each herb formulation. The

BSH's rating classes for the standardization of the safety of herbal products are:

- Class 1: Herbs which, when used appropriately, can be consumed safely without specific use restrictions.
- Class 2: Herbs for which the following use restrictions apply:
 - 2a. For external use only, except under the supervision of an expert qualified in the appropriate use of this substance.
 - 2b. Not to be used during pregnancy, except under the supervision of an expert qualified in the appropriate use of this substance. No other restrictions apply, unless noted.
 - 2c. Not to be used while nursing, except under the supervision of an expert qualified in the appropriate use of this substance. No other restrictions apply, unless noted.
 - 2d. Other specific use restrictions as noted.
- Class 3: Herbs for which enough significant data exist to recommend the following labeling: "To be used only under the supervision of an expert qualified in the appropriate use of this substance." Labeling must include proper use information: dosage, contraindications, potential adverse effects, drug interactions, and any other relevant information related to the safe use of this substance.
- Class 4: Herbs for which insufficient data is available for classification.

The usual recommendation for pregnant and lactating women is not to ingest medicinal amounts of any herb because of possible harm to the fetus. Most herbal digestive aids are antispasmodic, relaxing the smooth muscle lining of the intestinal tract. If medicinal amounts are taken, uterine stimulation occurs, which may lead to contractions.

Nursing Tip

MORNING SICKNESS

For treatment of motion sickness or morning sickness, if there is no history of miscarriage, the following may be tried, with the approval of the obstetrician:

A 12-ounce glass of ginger ale, provided it contains ginger and not artificial flavor, or a prescribed preparation of 500 to 2000 mg ginger, taken 30 minutes before travel. Ginger may be used in the form of capsules, ginger tea infusions, or ginger ale. For ginger tea, add 2 teaspoons of powdered or grated ginger root to one cup of boiling water. Steep 10 minutes.

Ginger has been shown to be safe in the treatment of morning sickness, at a dose of less than 1 g, but causes uterine contractions and triggers menstruation when given at a dose that is 20 times the stomach-settling dose. Women who are attempting to conceive and pregnant women may use culinary amounts of digestion-enhancing herbs, but must have the approval and supervision of their obstetrician or health care provider for any herb used medicinally.

Over-the-Counter Drugs. Drugs taken during pregnancy can cause serious congenital malformations. Potentially more than 500,000 over-the-counter drugs are on the market. Health care providers should be made aware of all such drugs taken intermittently or on a regular basis by women desiring to conceive and after conception.

The effects of these substances on the fetus include low birth weight, CNS disturbances, pulmonary hypertension, neonatal bleeding, renal failure, growth and mental retardation, inhibition of bone growth, discoloration of teeth, drug addiction, FAS, congenital malformations, spontaneous abortions, and fetal death.

Nursing Tip

HERBAL MEDICINES

The German Federal Health Agency established scientific commissions to review various categories of drugs in 1974. Commission E was charged with reviewing herbal medicines to determine the safety and effectiveness of each (Blumenthal et al., 1998). Their monographs have recently been translated into English. These can serve as a useful tool for the health care professional to use in evaluating herbal supplements taken by clients.

Nursing Alert

MEDICATION AND PREGNANCY

Pregnant women must use extreme caution in taking or using any herb, over-the-counter or prescription drug; illicit drug; excessive amounts of caffeine; or alcohol or nicotine immediately before conception and throughout the pregnancy.

Pica. **Pica**, a psychobehavioral disorder, is the persistent ingestion of substances having little or no nutritional value or the craving for nonfood articles as food (Rainville, 1998). There are several hypotheses regarding the causes of pica. One is that a deficiency of an essential nutrient, such as calcium or iron, results in ingestion of nonfood substances that contain these nutrients. Another theory is that the behavior is based on superstitions, customs, traditions, or practices passed down through generations. Pica may indicate anemia, for which the client should be evaluated if the behavior is known to the practitioner, but it is more likely to be a consequence of family traditions.

Commonly ingested nonfood substances include dirt or clay (**geophagia**); laundry starch or cornstarch (**amylolophagia**); lead paint flakes (**plumbism**); ice or ice frost (**pagophagia**); and chalk, mothballs, baking soda, coffee grounds, or cigarette ashes. Some of these items contain toxic compounds or intolerated substances. Eating these items usually displaces the intake of nutritious foods or interferes with nutrient absorption. Other potential complications vary with the items ingested and include lead poisoning, fecal impaction, parasitic infections, prematurity of the infant, and toxemia. Laundry starch and cornstarch consumption can lead to excessive intake of calories and contribute to excessive weight gain. These substances have 4 calories per gram, just as other forms of carbohydrates do. There may be contaminants in laundry starch, since it is not intended for human consumption.

When evaluating a pregnant client's dietary intake, inquiring about pica behavior is essential. The health care practitioner should always inquire about unusual nonfood cravings, even if there is no suspicion of pica. Being culturally sensitive and nonjudgmental when discussing this topic is key to obtaining information about the practices of clients. It is important to know if a woman is consuming these substances, for the safety of herself and her unborn child.

Nausea and Vomiting. Nausea is a common phenomenon during pregnancy; 60% of women experience it during the first trimester of gestation (Lenders & Henderson, 1996). The increased levels of human chorionic gonadotropin (hCG) hormone, which double every 48 hours in early pregnancy, are thought to contribute to nausea. Nausea and vomiting may also be related to hypoglycemia, decreased gastric motility, relaxation of the cardiac sphincter, or anxiety.

Heartburn. Heartburn or indigestion is caused primarily by the reflux of gastric contents up the esophagus after a large meal or upon reclining. Several physiologic changes may contribute to heartburn in pregnant women. A decrease in gastric motility, relaxation of the cardiac sphinc-

Client Education

Relieving Nausea and Vomiting

Women experiencing nausea and vomiting in early pregnancy could try a few of the following ideas:

- Eat small, low-fat meals and snacks, every 2 to 3 hours.
- Eat slowly.
- Drink soups and liquids between meals, rather than with meals, to avoid dehydration.
- Slowly sip a carbonated beverage when nauseated.
- Avoid citrus and tomato products, spearmint, peppermint, and caffeine. For some, peppermint is not nauseating and helps to alleviate nausea.
- Avoid or limit intake of spicy and high-fat foods; avoid greasy or fried foods.
- Avoid eating or drinking for 1 to 2 hours before lying down.
- Avoid aromatic foods and cooking odors that may trigger nausea.
- Avoid drinking coffee or tea.
- Inhale the scent of fresh-cut lemon to refresh the senses.
- Get plenty of fresh air and rest.
- When rising from bed or couch, get up slowly.
- Eat more pasta, bread, and potatoes.
- Eat a few bites of a soda cracker before getting out of bed in the morning.
- Take a walk after meals to help with digestion of food.
- Wear loose-fitting clothing.
- Sleep or rest with head elevated.
- Never take medicines for nausea without first consulting with a health care professional.
- Ginger capsules or herbal tea infusions help some clients with nausea. Consult a health care professional on type, quantity, and safety. Do not exceed 1 g/day.

ter, and pressure of the uterus on the stomach may contribute. The guidelines for dealing with nausea and vomiting also apply here. In addition, avoiding bending over immediately after eating may help.

Constipation and Hemorrhoids. Constipation has been associated with the smooth-muscle relaxation of the gastrointestinal tract, increased progesterone levels, and pressure of the fetus on the intestines. Other causes may include inadequate fluid and fiber intake or a decrease in physical activity. Iron supplements may also contribute to constipation. Constipation often causes gastrointestinal discomfort, a bloated feeling, exacerbated hemorrhoids, and, sometimes, decreased appetite. Strategies to combat constipation and hemorrhoids include increasing fluid intake to 2 to 3 quarts per day; eating high-fiber cereals, whole grains, legumes, fruits, and vegetables daily; and engaging in physical activity. Laxatives and herbal products with laxative effects should be used only with a physician's approval.

Mature Years

The age group that is most rapidly gaining members in the United States is elderly persons (over 65); those over age 85 are in the fastest-growing subgroup. In 1995, there were 3.6 million persons over age 85. By 2040, over 12 million people may be over age 85; and by 2050, two thirds of all Americans over age 85 may be women (Administration on Aging, 2000).

As aging occurs, the nutrients needed to maintain optimal nutritional status stay relatively high, but the caloric needs decrease because of lower levels of activity and decreased rates of metabolism. The diet of aging individuals should be nutrient-dense to obtain essential nutrients in a limited number of calories. Emphasis should be placed on consuming a diet high in fruit and vegetables, low-fat meats, fortified dairy products, and enriched and fortified high-fiber breads and cereals. Limited consumption of fats, sweets, and alcohol is advised, because these foods are high in calories but low in other essential nutrients. The older adult usually needs about 1600 calories daily. The daily calcium intake should increase to 1200 mg/day and vitamin D, to 10 µg/day for women age 50 and older.

The proportion of lean body mass decreases and relative total body fat increases during aging. Usually between ages 25 and 75, the amount of total body fat doubles. Exercise programs assist in slowing the decrease in lean body mass. If muscle decreases, a decrease in the energy requirements also occurs. The elderly client needs to keep well-hydrated by consuming at least 8 cups of water or other fluids a day, with a minimum intake of 25 mL/kg daily. As people age, there is a greater risk for dehydration. Physiologically, there is a decreased thirst perception and a decrease in the kidney's ability to concentrate water, and antidiuretic hormone (ADH) may be less effective. The elderly may decrease their fluid intake because of incontinence and may take drugs that increase their fluid loss (e.g., diuretics or laxatives). The physical symptoms of

dehydration should be especially carefully monitored in the elderly.

Women should determine their nutritional health by watching for signs of poor nutrition. Anyone with three or more risk factors should consult a doctor, registered dietitian, or other health care professional. The risk factors can be remembered by the following mnemonic:

- **D**isease
- **E**ats poorly
- **T**ooth loss or mouth pain
- **E**conomic hardship
- **R**educed social contact
- **M**any medicines
- **I**nvolutionary weight loss or gain
- **N**eeds assistance in self-care
- **E**lderly, over age 80

Nursing Tip

SOY FOODS AND MENOPAUSE

Soy products contain phytoestrogens, in the form of isoflavones, genistein, and daidzein. Much research has been conducted on the beneficial effects of including soy in the diet. Soy foods are commonly consumed in Asian countries. Asian women typically consume 10–100 times more isoflavones per day than Western women (Somekawa, Chiguchi, Ishibashi, & Aso, 2001). Japanese women rarely report symptoms of perimenopause, such as hot flashes, night sweats, insomnia, vaginal dryness, or headache, which are commonly reported in women from Western countries. These symptoms are believed to result from fluctuating levels of estrogen.

In menopause, the decline in estrogen production increases a woman's risk for cardiovascular disease and osteoporosis. It has been suggested that soy foods may be able to replace or enhance hormone replacement therapy (HRT), which is commonly prescribed to prevent negative health effects of menopause (Ramsey, Ross, & Fischer, 1999). Although epidemiologic studies do indicate an association between phytoestrogen intake and a decreased incidence of osteoporosis, cardiovascular disease, breast, ovarian, and endometrial cancer, and perimenopausal symptoms, research on the effect of the soy isoflavone is equivocal (Lissin & Cook, 2000; Somekawa, Chiguchi, Ishibashi, & Aso 2001; Wangen, Duncan, Merz-DeMlaw, & Marcus, 2001).

NUTRITION-RELATED HEALTH CONCERNS

Nutritional status affects a woman's overall health and quality of life. Many health alterations are directly or indirectly tied to dietary practices.

Physical Activity

Physical inactivity characterizes most Americans—be they children, adolescents, adults, or elderly persons. Physical activity is defined as any bodily movement produced by skeletal muscles that requires energy expenditure and produces overall health benefits. Physical activity protects against many morbidities and possibly against mortality, especially from cardiovascular disease, high blood pressure, elevated blood lipid levels, insulin resistance, and obesity. Many factors affect an individual's ability to exercise, among them are socioeconomic status, cultural influences, age, and health status. Environments should support exercise activity—schools, work sites, health care settings, and homes.

National surveillance programs have documented that one of every four adults (more women than men) currently have sedentary lifestyles, with no leisure-time physical activity. Girls become less active than boys do as they grow older. Children become less active as they progress through adolescence. Obesity and type 2 diabetes mellitus are increasing in children. These health problems are related to the energy imbalance of overconsumption of food with inadequate amounts physical activity. A pound of body adipose tissue is equal to 3500 kilocalories. The recommended rate of weight loss is 1 to 2 pounds per week. If a 1-pound weight loss is desired over 1 week, then it would require reducing the daily caloric intake by 500 kcal/day, increasing the amount of energy spent in physical activity by 500 kcal/day or reducing the daily caloric intake by 250 kcal/day and increasing the amount of energy expended in physical activity by 250 kcal/day. If 2 pounds of weight loss per week is desired, then doubling the amount of this would be required.

Most individuals who are successful at long-term weight maintenance combine food intake monitoring with engagement in a physical activity program. Dieting alone does not have lasting positive results in weight maintenance after weight loss. With at least 12 weeks of exercise training, a beneficial rise in high-density lipoprotein (HDL) cholesterol levels has been detected. Likewise, decreases in systolic and diastolic blood pressure, improved insulin sensitivity, and a decreased incidence of osteoporosis and some cancers have been noted with increases in endurance exercise. Reduction in the symptoms of anxiety and depression and improvement in mood and feelings of well-being are seen with regular physical exercise.

The frequency, intensity, and duration of the physical activity are interrelated. The individual's preferences and

what is sustainable with their unique lifestyle and circumstances best determine the appropriate type of activity. The National Institutes of Health (NIH, 1995) Consensus Statement on Physical Activity and Cardiovascular Health proposed the following guidelines for adopting and maintaining a physically active lifestyle. The client must:

- ✿ Perceive a net benefit.
- ✿ Choose an enjoyable activity.
- ✿ Feel competent doing the activity.
- ✿ Easily access the activity on a regular basis.
- ✿ Feel that the activity does not generate financial or social costs that he or she is unwilling to bear.
- ✿ Experience a minimum of negative consequences, such as injury, loss of time, negative peer pressure, and problems with self-identity.
- ✿ Be able to successfully address issues of competing time demands.

Recognizing the need to balance the use of labor-saving devices (e.g., power lawn mowers, golf carts, automobiles) and sedentary activities (e.g., watching television, use of computers) with activities that involve greater physical exertion is important to maintain good activity levels. Support for behavior change from family and friends is very helpful. Policy change and education are critical in increasing physical activity at schools and at the work place.

Obesity

Obesity is defined as a body weight that is 20% over the ideal. Obesity is increasing in the United States at an alarming rate. Many common health conditions are increasing along with overweight and obesity. Recent studies show that 50% of adults in the United States are overweight or obese: this reflects a 25% increase over the past 30 years (Mokdad, Serdula, Dietz, Bowman, Marks & Kaplan, 1999).

Excess weight has been seen in conjunction with increased rates of cardiovascular disease, type 2 diabetes mellitus, hypertension, stroke, hyperlipidemia, osteoarthritis, and some cancers. Concerted initiatives need to be undertaken to prevent and treat overweight in children and in adults, or the health care system will be more and more overwhelmed with individuals seeking treatment for obesity-related health conditions. The physical, social, environmental, and psychologic factors contributing to this malady must be assessed and addressed by a multidisciplinary health care team of doctor, nurse, psychologist, dietitian, social worker, and others.

Heart Disease

One in every ten women aged 45 to 64 has some form of cardiovascular disease. Heart disease is the number 1 cause of death in women and accounts for one-third of all

Client Education

Controlling Food Intake

Controlling food intake can be enhanced by using the following tips:

- Eat slowly; chew your food.
- Put your fork down between bites.
- Keep food intake records as food is consumed. Reflect on the amount of food consumed daily.
- Eat only in one location in your home or office, preferably at a table with no distractions.
- When it is time to eat, do only that.
- Don't overfill your plate.
- Eat off smaller plates than you usually do.
- Try doing something else if you have a food craving. Cravings usually fade after 30 minutes.

deaths. The five major risk factors for heart disease can be changed by changing diet and exercise habits. These factors are high blood cholesterol levels (over 200 mg/dL) especially high LDL cholesterol (over 160 mg/dL); high blood pressure (over 140/90 mm Hg); smoking; inactive lifestyle; and overweight or obesity. Other changeable risk factors are: low blood levels of high-density lipoprotein (HDL) cholesterol (less than 35 mg/dL), high blood level of triglycerides (over 250 mg/dL). Unchangeable risk factors for heart disease include age, sex, race, and family history. Those individuals at greater risk are:

- ✿ Elderly persons
- ✿ Women after menopause
- ✿ African American women
- ✿ Persons with close relatives who developed heart disease at an early age

Coronary heart disease (CHD) is responsible for more than 65% of cardiovascular disease (CVD). Environmental determinants, cigarette smoking, diet, and activity levels play a prominent role in CHD morbidity and mortality. General recommendations for a heart-healthy nonmedical therapeutic lifestyle, which is a combination of dietary and other lifestyle habits that reduce CHD, are as follows:

- ✿ Eat a diet with not more than 30% of calories from fat and less than 10% of calories from saturated fat.

- ✿ Limit average intake of dietary cholesterol to less than 300 mg/day.
- ✿ Reduce dietary salt intake.
- ✿ Increase intake of fruits and colored vegetables.
- ✿ Take antioxidant vitamins if recommended by your health care professional.
- ✿ Stop smoking.
- ✿ Increase physical activity; take part in regular, moderate exercise.

In addition to the above, water-soluble fiber, a component of many fruits, vegetables and grains, is more effective in lowering serum cholesterol than insoluble fibers. The soluble fibers increase fecal elimination of bile acids and cholesterol. These actions stimulate hepatic uptake of low-density lipoproteins (LDLs), thus lowering serum cholesterol. High-fiber diets also displace higher fat foods in the diet, indirectly affecting the total cholesterol intake.

Soy protein tends to lower total serum cholesterol by 12 mg/dL when 20 to 30 g/day are consumed. The phytoestrogen of importance in soy products is isoflavone. Genistein from soy inhibits smooth-muscle cell proliferation, and soy protein inhibits oxidation of LDL cholesterol. Both of these effects help reduce the risk of atherosclerosis. Genistein also inhibits platelet aggregation, interfering with clot formation, and thus, may reduce the risk for stroke and heart attack.

The FDA authorized the use of a health claim connecting the consumption of soy protein to a reduced risk of coronary heart disease on October 20, 1999. This health claim can appear on product packages of foods that contain at least 6.25 g of soy protein per serving. Soy products include soy milk, tofu, soy flour, textured vegetable protein, tempeh, soybeans, and others.

Folic acid's role in lowering homocysteine levels has already been discussed. There is a high association of high serum levels of homocysteine with CHD, because of its adverse effects on endothelial cells, abnormal clotting, and platelet adhesiveness and aggregation. Increasing intake of vegetables, legumes, and fortified grains and cereals is recommended.

There is a growing number of studies that suggest phytochemical antioxidants (e.g., vitamins C and E, carotenoids, selenium) may inhibit LDL oxidation, which decreases atherosclerosis and its clinical sequelae. Prospective studies have revealed a 77% decrease in the risk of nonfatal heart attacks with consumption of 400 to 800 IU of vitamin E in supplements over 18 months. Women have a reduction in risk with as little as 10 IU of vitamin E per day. Studies also show that people eating more fruits and vegetables containing these antioxidants have a lower rate of cancer.

Finally, garlic supplements may have significant effects on reducing total cholesterol without affecting HDL cholesterol levels. The benefits of the allium compounds contained in garlic and vegetables in the onion family are being studied extensively.

Osteoporosis

Osteoporosis is a systemic skeletal disease, characterized by decreased bone mass that results in a markedly increased risk for traumatic fractures. The consequences can include fractures, pain, and disability, which may result in loss of independence. In most cases, osteoporosis can be prevented and treated. It occurs when too much old bone is removed and not enough new bone is formed to replace it. Even as we age, bone tissue continues to renew itself: bone is a dynamic tissue undergoing constant remodeling throughout life. Some bone loss is normal during aging, but osteoporosis and the fractures it causes are not a normal part of aging. Loss of bone and the changing geometric pattern of bone contributes to a loss of bone strength. Osteoporosis is often called the “silent thief,” because there are no symptoms and women often do not know they have osteoporosis until a fracture occurs.

Osteoporosis affects approximately 28 million Americans, 80% of whom are women. The loss of ovarian estrogens at menopause is accompanied by an accelerated rate of bone loss, so the incidence of osteoporosis greatly increases after menopause. Twenty percent of American women have, by the age of 65, experienced a bone fracture resulting from osteoporosis. The health care costs of fractures caused by the disease are in excess of \$10 billion annually. Women are protected from rapid bone loss before menopause by estrogen, which keeps the bones strong. Postmenopausal osteoporosis begins without notice. Over time, symptoms, such as a curved spine, rounded shoulders, or loss of height as the spine compresses, may occur. Broken hips and wrists are the most common fractures.

Risk factors for osteoporosis include prolonged amenorrhea before menopause, early menopause (before age 45), excessive alcohol consumption, extremely short or tall stature, small body size (less than 127 pounds), a small body frame, and Caucasian race (Wangen, Duncan, Merz-Darlow, Xu, Marcus, Phipps, & Kurzer, 2000). Other risk factors include lack of regular weightbearing exercise or resistance; cigarette smoking; poor nutritional intake, especially minimal intake of calcium-rich foods; and high protein consumption levels. Medically, women who have had a history of fractures as an adult, use glucocorticoid medicines, and are in poor health are more likely to have osteoporosis than others. Glucocorticoid medications often are used to treat rheumatoid arthritis, lupus, and other inflammatory diseases. They decrease the bone mass with

prolonged use. Women needing glucocorticoids should talk with their physician about the safest dosage. Five mg/day has a minimal effect on bone structure.

If a client develops osteoporosis, taking 1200 mg of calcium per day with 400 µg of vitamin D is the current recommended treatment. The health care provider should also assess calcium absorption (Prince, Devine, Dick, Cridle, Kern, Kent, Price, & Randall, 1995). Calcitonin, a hormone produced by the parathyroid gland, is believed to reduce the activity of the osteoclasts, the cells that remove old bone. This allows the osteoblasts to continue to create new bone tissue, and thus, an increase in bone mass is seen. Calcitonin from salmon, now available in nose sprays, has been shown to slow the rate of bone loss and increase the density or thickness of bone in women with postmenopausal osteoporosis. This treatment works best with adequate amounts of calcium and vitamin D in the diet (Table 8-2).

There have been preliminary studies showing that dietary soy protein containing isoflavones prevents bone loss when ingested in sufficient quantity (Somekawa, Chiguchi, Ishibashi, & Aso, 2001). Bone estrogen receptors are largely of the beta type, which has an affinity for genistein. This might explain why diets high in soy protein offer a protective effect against osteoporosis, as seen in Asian women. The phytoestrogens, such as isoflavone, in soy foods mimic the protective effect of circulating estrogen in premenopausal women. The bioavailability of calcium from soybeans is equal to that of milk (Table 8-6).

The following four diagnostic categories have been established for describing bone mineral density (BMD) in women (WHO, 1994):

- ✿ Normal: BMD or bone mineral content (BMC) within 1 standard deviation (SD) of the young adult mean.
- ✿ Low bone mass (osteopenia): BMD or BMC more than 1 but less than 2.5 SD below the young adult mean.
- ✿ Osteoporosis: BMD or BMC 2.5 SD or more below the young adult mean.
- ✿ Severe osteoporosis: BMD or BMC more than 2.5 SD below the young adult mean along with one or more fragility fractures.

Cancer

The World Cancer Research Fund and the American Institute for Cancer Research (AICR) published *Food, Nutrition, and the Prevention of Cancer: A Global Perspective* in 1997. The report reviewed over 4500 research studies. Their recommendations to individuals on the best ways to prevent cancer through diet and lifestyle are summarized in the following list. Sixty to 70% of all cancers can be prevented through lifestyle choices that are made every

day. The AICR diet and health guidelines for cancer prevention are:

- ✱ Choose a diet rich in a variety of plant-based foods.
- ✱ Eat plenty of vegetables and fruits (at least 5 servings a day).
- ✱ Maintain a healthy weight and be physically active (BMI should be between 18.5 and 25).
- ✱ If occupational activity is low, take an hour for brisk walking or similar exercise daily and also exercise vigorously for a total of at least 1 hour per week.
- ✱ Drink alcohol in moderation, if at all. (Men, two or fewer drinks per day; women, one or less. A drink is defined as 12 oz. of regular beer, 5 oz. of wine, or 1.5 oz. of 80-proof distilled spirits.)
- ✱ Select foods low in fat and salt. (Fat consumption should be equal to 15% to 30% of total calories; salt consumption should be less than 6 g/day.)
- ✱ Prepare and store food safely. Wash, refrigerate, and freeze by food safety guidelines. Do not char food.
- ✱ Do not use tobacco in any form, i.e., smoke or chew.

There is an especially strong scientific basis for using plant-based foods, especially fruits and vegetables, to reduce the risk of developing cancers of the gastrointestinal and respiratory tracts, particularly colon and lung cancer. Fruits and vegetables are complex foods, and scientists do not know which of the nutrients or other constituents in these foods are offering the protective effect. The specific vitamins and minerals, fiber, and **phytochemicals** (plant-based chemicals), which include **carotenoids** (a group of pigments in fruits and vegetables, including alpha carotene, beta carotene, lycopene, lutein, and many other compounds), flavonoids, terpenes, sterols, indoles, and phenols, offer possibilities for investigation of their protective effects (Ames, 1999). Until more is known, the recommendation to eat five or more servings of fruit and vegetables each day should be heeded. Do not substitute vitamin pills or supplements for the real food, because it is not known which substance in the food offers the protective effect.

The role of soy foods in cancer prevention is still being elucidated. Epidemiologic studies show that populations that consume a traditional Asian diet have lower incidences of breast, prostate, and colon cancers than those consuming a traditional Western diet. The Asian diet is low in fat and animal foods and high in legumes, fruits, vegetables, and rice. Japan has a 75% lower mortality rate for breast and prostate cancers than the United States.

The compounds in soybeans, which have been identified as anticarcinogenic, include isoflavones, saponins, phytates, protease inhibitors, and phytosterols. Soy is the only significant source of isoflavone, a weak phytoestro-

gen. Isoflavones function as antiestrogens by binding the estrogen receptor (ER) in place of estrogens. Thus, cancers stimulated by estrogen are reduced. Geistein, an isoflavone in soy foods, has been found to inhibit the growth of human prostate and breast cancer cells and tyrosine kinases and, thus, block the growth and proliferation of cancer cells. It also inhibits angiogenesis, the growth of new blood vessels, and is a strong antioxidant, blocking the formation of oxygen free radicals, which are involved in cancer promotion (Ames, 1999). Soy added to the diets of premenopausal women in a recent study decreased serum levels of hormones that might regulate breast cell proliferation, but it also increased the level of prolactin, which increases breast cell proliferation. Thus, it is premature to prescribe moderate consumption of soy to prevent breast cancer. A balanced, varied diet, with soy foods as a component, is still the recommendation for the general public.

NURSING IMPLICATIONS

Women entering the childbearing years enter a phase of life in which their body undergoes many changes. The miracle of birth is unfolded with the delivery of the newborn, but forethought about good nutrition practices before conception and during the pregnancy leads to healthier newborns. The role of nutrition in the mother and infant's lives remains of utmost importance after the birth: the nurse should encourage breast-feeding for up to 6 months. Sound dietary practices learned during pregnancy and lactation can serve as guides for the rest of the mother's and the child's lives.

Women who are past the years of fertility have similar recommended nutrient allowances. Because of a slightly decreased level of recommended calories, the B vitamins also decrease proportionately in relation to calorie intake. Because of the cessation of menses, iron losses are minimized; therefore, the recommendations for iron intake also decrease. The older woman should select nutrient-dense foods to maximize intake of essential nutrients, while slightly reducing caloric consumption. The Food Guide Pyramid is a useful tool to nutritionally guide the aging woman. By adhering to sound nutritional intakes in adolescence, young adulthood, pregnancy, lactation, and adulthood, the woman of today can enter her golden years with an adequate store of nutrients to avoid debilitating disorders.

Many times the nurse has the best opportunity to discuss nutritional issues with clients. To effectively counsel clients about nutritional changes, the nurse must be aware of nutritional needs and be able to assess for nutritional risks of deficiency or excess. In nutritional counseling, the entire family must be considered, as most meals are prepared for the entire family rather than for individual mem-

bers. Women are crucial in nutritional counseling because they generally make all the food choices as they shop, plan menus, cook, and serve the family's food. Eating patterns are infused with cultural beliefs and practices, and these practices are passed on from generation to generation. Eating patterns are also heavily influenced by social networks and activities. For example, teenagers are likely to adopt eating patterns of their peers rather than their family. However, as adults they will revert back to family eating patterns. The availability of food and economic resources are also important in a family's dietary decision making. All of these factors illustrate the complexity of nutritional patterns and the consequent difficulty of instigating dietary changes.

Nurses can follow the nursing process, beginning with an assessment that includes a 24-hour recall of dietary intake, validation of whether this is a typical eating pattern, and assessment of resources for getting and preparing foods. Cultural beliefs and eating patterns should also be assessed. These data should be analyzed for nutritional adequacy. Interventions may consist of connecting the family with available resources for acquisition of food or nutritional services. Providing the family with information about healthier eating behaviors is an important intervention. However, interventions to alter a family's dietary choices

MODEL FOR READINESS FOR CHANGE

Health professionals should keep in mind the stage of readiness for changes their client is in before overwhelming her with dietary recommendations. Prochaska, Norcross, and DiClemente in *Changing for Good* (1994), identify five stages that individuals must go through before making behavior changes. Dietary change is definitely a behavioral change. Consider each step outlined below in assessing what stage your client is in before asking her to change too many behaviors at once. Success will be slower, perhaps, but more enduring, if change is addressed when the client is ready to make the behavioral modification required to adhere to new dietary plans. Remember to encourage a few small, slow changes at a time and give a lot of reinforcement and positive support (Prochaska, Norcross, & DiClemente, 1994).

The stages of change are as follows:

1. **Precontemplation:** Before the client has thought about the behavior change. There is no intention to change behavior in the next 6 months. (Example: The client does not consider consuming dairy foods.)
2. **Contemplation:** The client is "thinking" about making a behavior change, or intending to change, but not too soon. (Example: The client is thinking about purchasing low-fat milk and yogurt to consume daily and is discussing this with her family.)
3. **Preparation:** The client is preparing to implement the behavior change within the next month. (Example: Foods are being bought, recipes modified, and plans made to adjust to the new recommendations.)
4. **Action:** The client begins implementing the behavior change. (Example: The client purchases low-fat milk and vanilla yogurt regularly, for at least the past 6 months. The client includes three servings each day from the dairy group in her meal plan. She consumes the servings in their entirety.)
5. **Maintenance:** The client maintains the new behavioral change for at least 6 months and, hopefully, indefinitely. (Example: The client consumes at least three servings from the milk group daily or eats other foods containing a high level of calcium.)

Client Education

Resources for Food Programs

If clients have difficulty managing their food budget to meet food costs, refer them to a registered dietitian or social worker who can assist them. There are several federal nutrition programs designed to improve the nutritional status of pregnant and lactating women, their infants, and children up to age 5. The Special Supplemental Food Program for Women, Infants, and Children (WIC) certifies individuals meeting the current federal guidelines to be at nutritional risk and living on a household income of 185% or less of the federal poverty level income. Other supplemental nutrition programs may also be available for the client, such as food stamps and the Cooperative Extension—Expanded Food and Nutrition Education Program (EFNEP). These are for lower-income individuals who need to enhance their access to adequate nutrition and receive sound nutrition education.

and methods of food preparation involve more than providing information. The Readiness for Change Model is helpful in working with families over time to promote healthy dietary choices and eating patterns. Evaluation of interventions is necessary and should be undertaken for referrals to community agencies and educational interventions and should be incorporated into an ongoing engagement with the family.

Web Activities

- Visit the U.S. Department of Agriculture website. Use it to plan a daily menu for a: (a) 15-year-old girl; (b) pregnant 31-year-old woman; (c) 65-year-old woman.
- Visit the National Dairy Council home page. Do they outline calcium needs for pregnancy and lactation? What foods do they recommend as the best sources for calcium?

Key Concepts

- A woman's overall health throughout the life span is greatly affected by her nutrition and lifestyle choices.
- Adolescents need to strive for a balanced diet while keeping consumption of junk foods to a minimum.
- Eating disorders are most prevalent in the adolescent years and stem from an unhealthy, distorted body image.
- Women of all ages should work toward a target weight for their height and body type.
- Balancing intake of necessary nutrients and taking a vitamin supplement as prescribed by a health care provider are important steps in maintaining a healthy pregnancy.
- As a woman ages, the nutrient needs to maintain optimal nutritional status stay relatively high but the caloric needs decrease as a result of lower activity level and decreased metabolic rates.
- Many diseases, such as heart disease, osteoporosis, and cancer, are linked to suboptimal nutrition.

Review Questions and Activities

1. Record all the food that you eat for 24 hours.
 - a. Analyze it and compare it to the recommended daily intakes for your age group.
 - b. Calculate your body mass index (BMI).
 - c. Make nutritional recommendations for yourself based on the above data.
2. Design a healthy diet for an Asian woman who is pregnant.
3. On your next trip to the grocery store, check labels and identify 15 popular foods that have over 10 grams of fat per serving. Note the serving size on the label.

Health Care Issues for Women Across the Life Span

A more comprehensive view of women's health has recently emerged, which includes not only reproductive health conditions but also other health conditions that affect women over the life span. These health conditions include those that affect both men and women, such as cardiovascular disease, although these diseases may affect women differently than men. Use the following questions to examine your personal feelings.

- Are women my age likely to live longer than men?
- Are women likely to be healthier in later years than men?
- Is there anything wrong with women taking drugs for which efficacy was based on research that included only male subjects?
- Are more women apt to die from breast cancer or heart disease?
- Am I doing all I can to help women reduce their risk of breast cancer, lung cancer, heart disease, and HIV infection?

Mortality

Osteoporosis
Race
Screening

Competencies

Upon completion of this chapter, the reader should be able to:

1. Discuss the historical perspective of women's health in the U.S.
2. Describe demographic data for American women.
3. Describe the leading causes of death (mortality) and disease (morbidity) in women from childhood to old age.
4. Discuss the factors that put women at an increased risk of death and disease over the life span and describe methods of health promotion, disease prevention, and screening.

Women's health care has become a priority in the United States in the last two decades. This is evidenced by consumer activism and major commitment by governmental agencies, research institutions, and service delivery systems to redefine women's health care, expand the research focus on women's health issues, and implement expanded prevention and intervention programs. Historically, women's health care involved reproductive conditions and diseases of the reproductive system only. Now, women's health involves not only reproductive conditions and issues but also diseases or conditions unique to, more prevalent in, or more serious among women or some subgroups of women as well as diseases or conditions for which the factors or interventions are different for women than for men. Women with different ethnic, cultural, and religious backgrounds have different health beliefs and behaviors that affect their overall health status. Health-seeking behaviors, compliance, prevention and health promotion behaviors, risk factors, and the incidence and prevalence of both gynecologic and nongynecologic diseases also differ among the various groups.

HISTORICAL PERSPECTIVE OF WOMEN'S HEALTH

Until recently, there was no such entity as women's health care. Women received care as adults who happened to have additional health conditions relating to childbearing

and diseases of the reproductive system. This care relied primarily on a disease model in which diagnosis and treatment of reproductive health problems were the focus. Little attention was given to prevention, health promotion, risk factors, and nonreproductive health conditions of women across the life span, including the years before or after the reproductive years. For nongynecologic issues, females received care according to the male disease model. The male disease model used information obtained from teaching, research, and clinical trials that were based on diagnosis, treatment, and outcomes reported from studies on males.

History of Reproductive Health Care in the U.S.

Historically, women's health care revolved around reproduction. Women's gynecologic health care was focused on women of reproductive age and postmenopausal age, involving primarily birth control, pregnancy, delivery, infertility, and diseases of the reproductive system.

Over the centuries, midwives provided most reproductive care. This represented the model of care in most civilizations, in which women, who through experience and handed-down knowledge, cared for the women in their community during pregnancy and childbirth. In the United States, midwifery was a respected profession until the mid-1800s. At about that time, the profession of medicine became better organized, and care of pregnant women became the province of physicians, most of whom

were men. Physicians considered midwives ignorant and unskilled because they received no formal education. In the late 1800s and early 1900s, the medical community, in many states, convinced public health authorities that midwifery should be abandoned. The medical profession blamed immigrant midwives for the high maternal and infant mortality rate of the immigrant population. This was not justifiable, because new immigrants had no or limited access to medical care and were living in extremely unhealthy environments. In reality, the high maternal and infant mortality rate was the result of unsanitary housing, water, food, and living conditions, not inadequate care by midwives (Wertz & Wertz, 1977).

The medical profession's rejection of midwifery denied poor women access to reproductive health care. Women had little political influence on health policy and legislation. The decrease in the influence of midwifery occurred at approximately the same time that the movement towards women's suffrage began. Unfortunately, the suffrage movement did not address the health needs of the poor or immigrant women. One outcome of the suffrage movement was that women began to move into the occupations of social work, nursing, and education but not medicine. Midwifery did not become an academic discipline. The study of medicine incorporated the role of reproductive health care. As a result, reproductive health care became the domain of the male-dominated medical profession, with little input from women in society, women as patients, or female physicians.

In the early 20th century, medical schools began to emphasize the basic sciences as prerequisites for admission, making it difficult for women to enter the medical profession. Women were not encouraged to take science prerequisites in high school or college and were discouraged from entering medical school. As a result, women did not enter the profession of medicine in any great numbers until the late 1970s. It was not until the 1990s that women entered medical school in about the same proportion as men. Concurrent with the increase in enrollment of women in medical schools was the demand for an expanded concept of women's health, a resurgence of the profession of midwifery, expansion of the role of nursing, and support for advanced practice nurses to provide primary health care. In addition, many individuals, groups, and organizations were effective in increasing the focus of the scientific community on women's health. Some of these included the National Women's Health Network, the Society for the Advancement of Women's Health Research, and the Boston Women's Health Book Collective. All these factors helped fuel the demand to address women's health care separately from men's.

Today, women's health care is provided by a broad array of health disciplines, including nursing, medicine, public health, social work, and midwifery. While preven-

tive health care has been viewed as important to the overall health and welfare of society for the past 30 years, little focus has been on women's preventive health care issues. Health care providers have intuitively understood the value of prevention and health promotion but implementation of effective services for women has lagged. It is known that many health problems can be prevented or postponed by immunizations, accident prevention, healthier lifestyles, or detected earlier through screening leading to early treatment. Women's health problems are different than men's and must be addressed appropriately in prevention, early detection, and treatment.

Some reasons for inadequate preventive health care include lack of health care provider time, inadequate reimbursement, lack of provider interest and knowledge, lack of client involvement and knowledge, and lack of delivery systems to promote preventive care (U.S. Department of Health and Human Services [DHHS], 1994).

Current View of Women's Health Care

A newer view of women's health includes not only the reproductive years, but also the years before and after, including the nonreproductive health conditions that occur over the life span. The foundation for the physical and emotional health of adult women occurs in childhood, during which gender differences in diet, exercise, values, and roles have an impact on the biologic and psychological development of women. Diet and exercise affect bone density, growth, and body image in later life. Values and roles affect health-seeking behaviors, economic status, prevention behaviors, nutrition and exercise habits, fertility rates, and potential for domestic abuse. **Fertility rate** is defined as the number of births per 1,000 women, ages 15 to 44. Educational experience affects socioeconomic status, self-esteem, and access to care. Given a normal life expectancy, one-third of a woman's life is lived after menopause. **Life expectancy** is defined as the average number of years for which a group of individuals of the same age are expected to live. Health status after menopause is affected not only by the previous biologic factors but also by psychological development, sociocultural environment, and economic status. Many reproductive and gynecologic issues are intrinsically related to biologic factors. Social Roles, economic level, race, culture, psychological development, and religious beliefs also affect biologic factors. **Race** is a system of classifying people into groups according to physical features, such as skin color, facial features, and texture of body hair. **Culture** is defined as an individual's way of looking at life, encompassing their feelings, beliefs, attitudes, and practices, which in turn affect how the individual views such things as health, nutrition, and health policies.

Women's health encompasses conditions that are not specific to the reproduction system, including those found in both men and women, but which may be expressed differently in women. Some diseases, such as osteoporosis, occur more frequently in women than in men. Some diseases, such as HIV infection, historically occurred more frequently in men, but manifest differently in women; some diseases, such as heart disease, occur commonly in both genders but manifest differently in women (Cohen, 1997).

Generally, women's health care providers have been physicians with training in internal medicine, cardiology, obstetrics and gynecology, family practice or another specialty, who used the male disease model. More recently, a recognition of the effects of biology, genetics, culture, economic level, gender roles, education, and psychological development on women's health status has caused a major shift in the scope of women's health, including research methods, health care delivery systems, prevention, early identification of disease and training of nurses, physicians, and other health care workers (Magrane & McIntyre-Seltman, 1996). The Office on Women's Health, a part of the U.S. Public Health Service, has outlined a strategic plan to develop educational programs to expand the education and training of health care workers to incorporate this new approach to women's health (Blumenthal, 1994).

Sensitivity to gender issues, racial and cultural backgrounds, sexual orientations, personality types, marital status, economic status, patterns of risk-taking behaviors, genetic and environmental risk factors, and age are now considered essential to providing comprehensive health care to women. A newer approach to women's health includes health promotion and health protection throughout the life span (Foster, 1994). Health promotion includes consideration of adequate nutrition intake, development and maintenance of physical fitness, development and use of stress management skills, attainment and maintenance of optimal bone density, and avoidance of hazardous substances, including tobacco, alcohol, and drugs (Figure 9-1). Health protection includes provision of safe child-bearing through adequate prenatal and postnatal care, safe delivery, and effective family planning for child spacing and desired family size; it also includes prevention, early diagnosis, and appropriate treatment for infections, cancer, cardiovascular and respiratory disease, diabetes, and other chronic illnesses (Foster).

Sociocultural Influences

Women's health concerns reflect the diversity of women's cultural, economic, and physical environments, which affect the duration and quality of life. Unfortunately, women continue to experience serious threats to their physical and mental well-being. Despite living an average of 6 years longer than men, women have poorer health and

Figure 9-1 Health promotion for women of all ages includes regular physical exams.

greater disability from disease than men (U.S. Bureau of the Census, 1998). Some factors that may account for women's poorer health relate to the fact that women are frequently victims of poverty, experience unequal access to care, and receive less income for similar work than men. Women who live in poverty and are poorly educated have shorter life spans, higher rates of illness and death, and more limited access to health care services. The majority of single heads of households in the U.S. are women, putting them at a greater risk for poverty. Also, more women live in poverty than men. Women participate in the work force in greater numbers than ever before. Women have less ability to pay for health care, even though they use health care services more frequently than men. Women, in general, have greater problems obtaining access to primary health care. Overall, women have a poorer quality of life and have more acute symptoms, chronic conditions, and disabilities from health problems than do men (Wentz, 1994).

A positive factor influencing women's health care is the growing number of women who are developing political power and consumer interest in changing national policy regarding women's health. Women have become more involved in promoting reproductive choices, which give them control over their bodies and life choices. The availability of the birth control pill in the 1960s gave women the power to make their own choices about when to have children, spacing children, number of children, and combining a career with motherhood. Today, more women are demanding participation in health care decisions on an individual level and in health care policy at local, state, and national levels.

Women's Health as a National Priority

There has been considerable interest in reproductive women's health issues as a result of recent public awareness of advances in scientific knowledge and technology. A number of factors in the last two to three decades have caused major changes in the scope of women's health care. Political, social, and cultural influences have contributed to the emergence of a new perspective toward the study of women's needs. In the 70s and 80s, women entered the work force in record numbers and became more active in politics and policy making. Women became more visible in the public and economic life of the nation. Employers began to pay more attention to the economic and social consequences of women's health care. Women in medicine and other health care professions became more vocal and influential in health care policy development and implementation. As a result, women demanded a change in their medical care.

National Response to Women's Health Issues

In the last 20 years, a variety of federal agencies responded to the national concern that women's health issues were not being adequately addressed. The first major effort was the establishment of the Public Health Service Task Force in 1983 to study women's health issues. In 1985, this task force recommended that biomedical and behavioral research should be expanded to focus on conditions and diseases unique to or more prevalent in women in all age groups (Women's Health Report of the Public Health Task Force on Women's Health Issues, 1985). In 1986, the National Institute of Health (NIH) established a policy to encourage inclusion of women in clinical trials. The major reason women were previously excluded was the potential risk to the fetus if the woman became pregnant while participating in a study or unknown risks for subsequent pregnancies. In 1989, members of the U.S. Congress requested the General Accounting Office (GAO) to investigate NIH to determine whether women were being included in clinical trials as dictated by policy. The GAO found that women continued to be excluded from large scale studies. Examples included the U.S. Physicians Health Study, the Health Professionals Follow-Up Study (Hennekens, 1989), and the Multiple Risk Factor Intervention Trials (MRFIT, 1990). In 1990, the GAO reported to Congress that NIH had made little progress in implementing its policy to encourage the inclusion of women in research. Even when women were included in research, gender analysis was not completed (Wentz, 1994). The publication of the GAO report caused consid-

erable reaction in the popular media, women's groups, and Congress.

In 1990, NIH created the Office of Research on Women's Health (ORWH) in reaction to the public reaction to the GAO findings. The ORWH was established to strengthen and enhance the prevention, diagnosis, and treatment of illness in women and to enhance research related to diseases and conditions that affect women. The mission of ORWH was to:

- Ensure that women's health issues were addressed
- Ensure appropriate participation of women in clinical research
- Increase the number of women scientists in biomedical research and their decision-making authority
- Oversee and coordinate all activities related to women's health including delivery of services, education, and public policy in national and regional offices of the U.S. Public Health Service

Agencies affected by this policy included NIH Centers for Disease Control and Prevention CDC, Food and Drug Administration (FDA), Health Resources and Service Administration, Indian Health Service, Substance Abuse and Mental Health Services Administration (SAMHSA), and Agency for Health Care Policy and Research (AHCPR).

The year 1991 was pivotal in the scientific, political, and public arenas for women's health. In 1991, Dr. Bernadine Healy became the first woman director of NIH. Under her leadership, a research agenda was established to include women and minorities in adequate numbers in research and to address the diseases and disorders that affect women. A new policy was issued requiring inclusion of women and minorities in research unless there were scientifically sound reasons for exclusion. To encourage the inclusion of women and minorities in research, factors such as child care and transportation for women subjects were to be addressed in all research.

In 1992, at the request of Congress, the GAO issued a report regarding the FDA's policy of excluding and restricting women of childbearing age from participating in drug studies. The GAO report concluded that gender-related differences in response do exist for some drugs and that drug trials must include sufficient members of women to permit analysis of these gender-related differences (U.S. General Accounting Office [GAO], 1992). In 1993, Congress passed the NIH Revitalization Act, which mandated the inclusion of women in NIH-funded clinical trials. It did not require studies of enormous populations, but rather that analysis by gender occur or sample sizes of statistical significance be chosen when the existence of gender differences is unknown. In 1993, the FDA lifted its ban on the inclusion of women in clinical trials (FDA, 1993).

In 1992, the NIH undertook the Women's Health Initiative, which is a 15-year study of major diseases and conditions, including heart disease, stroke, breast cancer, colon and rectal cancer, depression, and osteoporosis, in a sample of 160,000 postmenopausal women at 45 centers across the country. This is the largest clinical study ever undertaken in the U.S., with \$625 million appropriated for the initiative. The Women's Health Initiative includes three major types of study:

- Surveillance study to identify specific risk factors for disease
- Clinical trial, involving 45,000 individuals, to study the role of diet modification and hormone replacement therapy in the prevention of cardiovascular diseases, cancer, and osteoporosis
- Prevention study, carried out in 60 communities, to determine effective methods for incorporation of health-promoting behaviors

The Women's Health Initiative provided recognition that women have many nonreproductive years of life, during which they are at great risk for cardiovascular disease, cancer, osteoporosis, and depression. This is the first major study that recognized that heart disease is the leading cause of death for women and that heart disease develops later in life in women than men. The study's premise is that understanding the role of risk factors for cancer, osteoporosis, and cardiovascular disease will provide future treatment recommendations for the care of women who are postmenopausal (National Institutes of Health [NIH], 1994).

In 1993, ORWH was given an expanded mission and mandate. Their mission included the following:

- Coordinating and implementing of the National Breast Cancer Action Plan
- Establishing links between research institutions and service organizations in communities throughout the nation
- Promoting healthy behavior in young women
- Improving the health of minority women
- Preventing domestic violence
- Providing greater access to health services
- Fostering research and education by innovative methods
- Instituting strategies to recruit and promote women in science and health care careers

In 1996, ORWH convened a series of meetings to address women's health for the 21st century. This resulted in the recommendations of the 1997–1998 Task Force for Beyond Hunt Valley, Research on Women's Health for the 21st Century, to determine the most fruitful and useful di-

rections for medical research conducted by NIH. Current research of importance for women includes the following:

Neuroscience and Brain Biology

- Development and degeneration of neurons
- Therapeutic effects of St. John's wort
- Nature of pain
- Behavioral research on obesity, substance abuse, and nicotine addiction
- Development of new drugs for treatment of alcoholism and drug addiction
- Project on molecular anatomy of the brain

Cardiovascular Disease

- Role of hypertension in accelerating vascular disease
- Role of plaque in atherosclerosis and mechanism of formation
- Role of genes in progression and experience of disease of the heart and blood vessels

Asthma

- Prevalence of asthma in women, particularly Hispanic women
- Prevention of environmentally induced asthma in children

Infectious Diseases

- Search for novel approaches to treatment of infectious disease
- Work on genome of the HIV virus

Diabetes

- Role of nutrition and obesity in development diabetes
- Efforts to regenerate insulin-producing cells
- Enhanced methods of drug delivery
- Cause of various types of diabetes

Outreach to Special Populations

- Health promotion for cardiovascular health among Hispanics
- Treatment of hypertension and dyslipidemia for African Americans
- Inducements to increase participation of women and underrepresented minorities in research

Themes revealed in the task force findings and scientific reports include the following:

- Women's health is expanding into the larger concept of gender-specific medicine; it is no longer considered a feminist issue or isolated phenomenon. Studies of women are important sources of new information, which will help to convert male models of

normal function and pathophysiology of disease to accommodate women's needs.

- ❖ Women have changing needs over the course of the life span. Research must take into consideration the biologic life cycles and the physical, mental, and emotional changes that occur over the life cycle.
- ❖ Multidisciplinary research is essential.
- ❖ Social and behavioral science is essential in research on women's health.
- ❖ Collection of first-hand information on women is essential to correct male models of normal function and the pathology of disease.

One outcome of the increased interest in and emphasis on women's health was the emergence of a broader concept of women's health. It incorporates cellular, systemic, individual, and societal perspectives. Rather than perceiving women's health narrowly as reproductive health, the current model integrates basic and social sciences that describes the health of women across the life span from birth to old age and considers other factors, such as ethnicity, race, culture, and religion. This integrated approach uses the biochemical, physiologic, social, behavioral, and environmental sciences to develop and integrate an effective approach to women's health.

DEMOGRAPHIC DATA FOR AMERICAN WOMEN

The overall health of both men and women has improved in the 20th century. Life expectancy has increased for both genders, with life expectancy of women exceeding that of men. A century ago, many women died during their reproductive years from complications of childbearing and infections. Early deaths in men also resulted from infections, but fewer men died of infection than women because of infections from complications of childbirth. Advancements in maternity care, antibiotic therapy, public sanitation, and biomedicine have been major factors in increasing the life expectancy of women. It is estimated that, in the next century, the life expectancy for both gen-

ders will continue to increase (Table 9-1). Longevity will result from technological advances and more effective prevention and treatment of acute and chronic disease. In addition, the intensity of research on the biology of aging, including the study of the cellular aging process, may increase life expectancy in the future. As women live longer, chronic conditions that affect older women will be more prevalent. Health care providers and delivery systems must be prepared for the increased numbers of women needing preventive and restorative care in the future.

Life Expectancy

Life expectancy has increased for both males and females. Life expectancy is defined as the average number of years for which a group of individuals of the same age are expected to live. It is derived from summary measures of mortality and is calculated from age-specific death rates for a population at a particular time (Harper & Lambert, 1994). Even though men and women have different causes of death overall, women outlive men by an average of 5.7 years, based on 1998 mortality data (Table 9-2). Women born in 1900 had a life expectancy of 48 years, approximately 2 years longer than men. In 1998, women had a life expectancy of 79.5 years, whereas all men had a life expectancy of 73.8 years (U.S. Bureau of the Census [USBC], 1998).

African Americans had a lower life expectancy than Caucasians, with African American women having a life expectancy of 74.8 years and African American men 67.6 years in 1998. Caucasian women continue to have the highest life expectancy (79.5 years), followed by African American women (74.8 years), Caucasian men (74.5 years), and African American men (67.6 years). In general, the Caucasian population is expected to outlive the African American population born in the same year by an average of 6.0 years (USBC, 1998). Currently, women make up 51% of the total U.S. population. More than 60% of the population over age 65 are women, and more than 70% of the population over age 85 are women. (USBC, 1996).

Table 9-1 Projections of Life Expectancy, for People Born 2000–2010

Year	Caucasian (yrs)		African American (yrs)		All Other Races (yrs)	
	Female	Male	Female	Male	Female	Male
2000	80.5	74.2	74.7	64.6	77.5	68.3
2005	81.0	74.7	75.0	64.5	78.1	69.1
2010	81.6	75.5	75.5	65.1	78.7	69.9

Adapted from Table No. 118, Statistical Abstract of the United States, 1996.

Table 9-2 Life Expectancy: in Years, by Race, Sex, and Age, 1998

Age	All Races		Caucasian		African American	
	Female	Male	Female	Male	Female	Male
At Birth	79.5	73.8	80.0	74.5	74.8	67.6
10	70.2	64.6	70.6	65.2	66.6	59.0
20	60.3	55.0	60.8	55.5	56.2	49.5
30	50.6	45.7	51.0	46.1	46.7	40.6
40	41.1	36.4	41.4	36.8	37.5	31.9
50	31.8	27.6	32.0	27.9	28.8	23.9
60	23.2	19.6	23.3	19.7	21.0	17.1
70	15.5	12.8	15.6	12.8	14.1	11.5
80	9.2	7.5	9.1	7.5	8.7	7.1
85 & over	6.7	5.5	6.6	5.4	6.6	5.5

Adapted from Table No. 5, National Vital Statistics Report, Vol 48, No 11, July 24, 2000.

Race and Ethnicity

Ethnic and racial diversity has varied over time in the United States. In the early 1990s, approximately 84% of the women living in the United States were Caucasian, 13% were African American, 8% were Hispanic, and 3% were of other races. Projections indicate a continuing change in racial diversity over time, with increases in African American and Hispanic populations. The National Center for Health Statistics (NCHS, 1992) reported that the number of babies born to Hispanic women reached record highs; births to Hispanic women comprised 18% of the total births across the nation in 1995. This increase in births is the result of high fertility rates among Hispanics, particularly recent immigrants. The increased Hispanic birth rate contrasts with birth rates of other groups that have been stable or have declined (NCHS, 1998). **Birth rate** is defined as the number of births per 1,000 population.

Also, there were sharp increases in births among Hispanic teenage girls from 1989 to 1995. There were 106.7 births per 1,000 Hispanic teenage girls in 1995, compared to 100.8 in 1989. In the same period, the birth rate among African American teenage girls dropped from 84.8 births per 1,000 to 74.5. However, Hispanic teenage girls who give birth are more likely to be married than African American teenage girls are (NCHS, 1998).

Population Shift

As the baby boom generation (persons born between 1946 and 1964) reaches age 65, there will be major economic and sociologic changes, resulting in increased demands for health care, fewer workers to support the Medicare program, a large aging population, and an increased interest in healthy living. A major proportion of this generation will

be made up of women, who will live longer than men but not necessarily healthier. Women significantly outnumber men in the over-age-65 group because premature deaths are almost twice as high for men in earlier decades than for women. Men die in earlier years as a result of motor vehicle accidents, homicides, suicides, heart attacks, and AIDS (CDC, 2000). This results in a higher age-adjusted mortality rate for males than females. This trend has been observed throughout the 20th century and results in approximately 70% of persons over age 85 being women. (USBC, 1999). The major shift in the population is the increasing number of elderly women.

Employment

Historically, there have always been more men than women in the labor force. This trend continued throughout the 1990s. However, in the last several decades, more women are participating in the labor force than ever before in the history of the United States. In 1962, 43% of women, aged 25 to 54, were in the labor force and 55% were keeping house full-time. In 1990, 75% of women, aged 25 to 54, were in the labor force; 20% were keeping house full-time (DiMona & Herndon, 1994). This represents an increase of 32% of working women.

Men earn more than women, even when men and women work in the same occupations. Women earn between 60% and 80% of what men in comparable positions earn, regardless of race and ethnicity, although this gap appears to be closing in some areas. On average, men who have completed high school earned \$28,742 compared with \$17,898 for women who have completed high school. The same disparity exists at all levels of education for women. African American and Hispanic women earn less than Caucasian, African American, and Hispanic men.

A portion of that improvement in women's income is the result of the downward trend in men's income (Tauber, 1992). Even when women have a higher level of education, the earning gap is not overcome. However, both men and women are less likely to experience poverty if they are educated. Level of employment and earning power are closely correlated with level of education. Poverty is strongly correlated with a low level of education.

Education

The more education, the better the health status, for both men and women. Educational attainment is defined as the highest grade or degree completed. Education has an important influence on socioeconomic status. The overall trend in the U.S. reflects a more educated population, with the younger population being more educated than the older population (USCB, 1999). In 1999, 83% of all adults, aged 25 or older, had completed at least high school and 25% had at least a bachelor's degree (USBC, 1999). Men and women had the same rate of high school completion (83%). Men had a slightly higher rate of completion of a bachelor's or higher degree, with 27.5% of men and 23.1% of women earning these degrees (USBC, 1999). The percentages of high school completion vary by race. Among Caucasians, 87.7% had earned high school degrees or higher; among African Americans, 77.4%; among non-Hispanic Asian and Pacific Islanders, 84.7%, and among Hispanics, 56.1% (USBC, 1999). At high school, some college, and college graduate levels, the Hispanic population had the lowest proportion of completed education in comparison to all other races. The Hispanic population increased the proportion of the population aged 25 and over with a high school diploma or higher degree by about 5% from 1989 to 1999, and the proportion who had some college increased about 6% during that time. However, the proportion with a bachelor's degree or higher did not change significantly (USBC, 1999). There were fewer foreign born persons with a high school diploma than U.S. citizens, but interestingly, the percentage of these with a bachelor's degree was approximately the same. Of particular importance, the incidence of foreign-born Hispanics with less than a high school education was almost twice that of Hispanics born in the U.S. (56% of foreign-born Hispanics versus 30% U.S. born Hispanic). (USBC, 1999)

Since 1970, there has been a steady increase in the number of women who have completed college. In 1970, 8.1% of women completed college compared to 19.3% in 1993. However there is great variation among racial groups. In 1993, Asian women were most likely to be college-educated, with 27% had college educations in comparison to 12.4% African American women and 8.5% Hispanic women. In 1995, 18.3% of the population did *not* have a high-school degree, 33.9% had graduated from high school,

17.6% had some college but no degree, 7.1% had an associate degree, 15.2% had a bachelor's degree, and 7.8% had a graduate degree. Slightly more females than males are high-school graduates (35.7% females versus 31.9% males). However, there is great disparity on the basis of race for those not completing high school, with 46.6% of Hispanic persons, 26.2% of African Americans, and 24.6% of other races who have not completed high school compared with 17% of Caucasians (USBC, 1996). Educational attainment is higher for employed persons than unemployed persons. Ninety percent of employed persons have completed high school or a higher level (USBC, 1999).

Since education is positively associated with health status, persons who have not completed at least high school are at higher risk for poor health. Lower levels of education are seen in conjunction with poorer nutrition, decreased access to health care, and increased likelihood of risk behaviors, such as smoking.

Marital Status

Both men and women are marrying later in life. They are delaying marriage from the early 20s to late 20s or 30s. In 1993, 30% of women ages 25–29 had never married, compared with only 11% in 1990 (Tauber, 1992). In conjunction with the trend of later marriages, both married and unmarried women are having children later. In 1950, the marriage rate was 11.1 per 1,000 population as compared to 9.9 in 1999 (USDHHS, 2000). As the marriage rate has decreased, the divorce rate has increased from 2.6 per 1,000 in 1950 to 4.1 in 1999 (USDHHS, 2000).

Fertility and Birth Rates

The fertility rates of women in the U.S. have declined from 87.9 per 1,000 women in 1970 to 65.9 per 1,000 in 1999 (National Vital Statistics Reports, 2000). The overall birth rate has decreased from 24.1 in 1950 to 14.5 in 1999 (USDHHS, 2000).

Trends in childbearing differ among women of various ages and are reflected in age-specific birth rates. Women are having children later in life than before. There has been an increase in the birth rate for women aged 30 to 34, from 61.9 per 1,000 in 1980 to 85.4 per 1,000 in 1997, and in women aged 35 to 39 years, from 19.8 per 1,000 in 1980 to 31.7 per 1,000 in 1990 (USBC, 1999). Clearly there has been a trend toward more women giving birth later, when they are in their thirties and forties. Some reasons for this are:

- Ability to control the timing of childbearing through the use of contraception
- Starting careers before having children
- Later marriages
- Development of technology to enhance fertility

The Fertility, Family Planning and Women's Health: New Data From the 1995 National Survey of Family Growth (Abma, Chandra, Mosher, Peterson, 1997) reported that 89.3% of all women aged 15 to 44 had been sexually active. Older women were more likely to be sexually active than younger women. Of the women interviewed, 22.1% were sexually active at age 15, 38% at age 16, 51.1% at age 17, 65.4% at age 18, and 75.5% at age 19. Of women aged 20 to 24, 88.6% were sexually active; of those aged 25 to 29, 95.9%; of those aged 30 to 44, 98.2% (Abma et al, 1997). In the ages 15 to 19 range, African American women were most sexually active (59.5%), followed by Hispanic women (55%), then Caucasian women (49.5%). Mean age at first intercourse for women who were ages 20 to 24 years at the time of the survey was 17.5; for women ages 30 to 34, 17.8; for women ages 35 to 39, 18; and for women ages 40 to 44, 18.6 (USHHSS, 2000). This demonstrates that women are having first intercourse at a younger age and that availability of education about sex, family planning, and prevention of sexually transmitted diseases (STD) is essential for teenagers before their first sexual experience to prevent unplanned pregnancy and STDs.

Birth Rates for Adolescent Mothers

Birth rates for adolescent mothers rose from 1980 to a high in 1992 and dropped from 1992 to 1997. The birth rate for adolescents ages 15 to 17 in 1980 was 32.5 per 1,000; in 1992 was 37.8; and in 1997 was 32.6 (USBC, 1999). The birth rate for adolescents ages 18 to 19 was 82.1 per 1,000 in 1980, 94.5 in 1992, and 84.4 in 1999 (USBC, 1999).

The Centers for Disease Control and Prevention (CDC) reported in 1997 that there had been a decrease in sexual intercourse by teenagers from 1990 to 1995. About 50% of teenagers ages 15 to 19 reported that they had ever had sexual intercourse in 1995 compared with 55% in 1990. This is consistent with the downward trend in the birth rate for teen mothers between 1990 and 1999.

The 1995 National Survey of Family Growth found that 55% of Hispanic, 49.5% of Caucasian, and 59.5% of African American women aged 15 to 19 years had had sexual intercourse. As women age from 15 to 24, sexual intercourse increases (Abma, Chandra, Mosher, Peterson, & Piccinino, 1997):

The percentage of women reporting sexual intercourse for each age are as follows:

- 22.1% at age 15
- 38.0% at age 16
- 51.1% at age 17
- 65.4% at age 18
- 75.5% at age 19
- 88.6% at ages 20 to 24

Critical Thinking

Sexually Active Adolescents

You may feel anxious about asking adolescents if they are sexually active. Before you can help an adolescent make good decisions about prevention of STDs or pregnancy, you need to know what your beliefs and feelings are about sex. What are your beliefs about sex before marriage, sexual activity by adolescents, abstinence from sex, and the role of family, spirituality, and religion in dealing with sexuality? Working through your feelings will reduce your reluctance to discuss sexual experiences with adolescents. Some activities you can do to reduce your reservation or anxiety include:

- Learn current teen slang and lay terms
- Practice asking questions with a friend or family member
- Do some extra readings on the topic, attend a seminar on sexuality
- Talk to an experienced nurse practitioner or other nurse
- Learn how other professionals ask questions and how they approach their clients

Birth Rates for Unmarried Women

Births to unmarried women in the U.S. have dramatically increased, from a total of 399,000 in 1970 to 1,260,000 in 1996 (USCB, 1999). Births to unmarried adolescents under age 15 increased from approximately 10,000 in 1970 to 12,000 in 1994, then decreased to 10,000 in 1996. Births to unmarried adolescents ages 15 to 19 increased from 190,000 in 1970 to a high of 381,000 in 1994, and then decreased to 373,000 in 1996. There has been a dramatic increase in the number of births to women age 20 and older. This is because of the increase in the proportion of women in the population over age 20. In 1970, women over age 20 accounted for 199,000 births, while in 1993, they accounted for 872,000 births. In 1970, 50.2% of all births were to women age 19 or under, in 1993 only 29.7% of all births were to women age 19 or under. The birth rate for Caucasian unmarried women has increased from 43.9% of women in 1970 to 59.8% in 1993. In contrast, the birth rate for African American unmarried women has decreased from 54% in 1970 to 36.5% in 1993 (USCB, 1996).

Unmarried mothers and their children are of concern. Statistically, they are at greater risk for poverty, limited education, poor health, and social problems, such as dropping out of school, behavior problems, and delinquency. Unmarried women under age 25 are at greater risk than their married counterparts as a result of living below the poverty line, not completing high school, having poorer health, and less access to care.

MORTALITY AND MORBIDITY

One way to measure the health of the nation or subgroups within the population is to examine mortality and morbidity data. **Mortality rate** refers to the total number of deaths in a population over a specific period of time. **Morbidity rate** refers to the total number of persons in a population who currently have a specific disease or condition.

Leading Causes of Death

The leading causes of death for both men and women in the U.S. according to the U.S. Bureau of the Census (1999) are:

- ♥ Heart disease
- ♥ Malignant neoplasms (cancer)
- ♥ Cerebrovascular diseases (stroke)
- ♥ Chronic obstructive pulmonary disease (COPD)
- ♥ Accidents
- ♥ Pneumonia and influenza
- ♥ Diabetes mellitus
- ♥ Suicide
- ♥ Nephritis, nephrotic syndrome, and nephrosis
- ♥ Chronic liver disease and cirrhosis

The two leading causes of death in women, cardiovascular disease and cancer, occur in women at different ages and in different ways than in men. Women tend to be protected from cardiovascular disease until menopause. Cancer mortality incidence and prevalence for women differ from men and varies over the lifespan.

Of these diseases, more men than women die from heart disease, cancer, COPD, accidents, suicide, and chronic liver disease. More women die from cerebrovascular disease, pneumonia, diabetes, and nephritis (USBC, 1999). For both men and women, with all ages combined, heart disease is the leading cause of death, regardless of race. Cancer is the second leading cause of death for men and women, and stroke is the third. Together, heart disease, cancer, and stroke account for two-thirds of all deaths for both sexes (Table 9-3)

Table 9-3 Leading Causes of Deaths for Females and Males, 1998

Cause of Death	Deaths Per 100,000 Population		
	Both Sexes	Female	Male
All causes	864.7	853.5	876.4
Heart disease	268.2	268.3	268.0
Cancer	200.3	189.7	213.6
Stroke	58.6	70.4	46.3
COPD	41.7	40.2	43.2
Accidents	36.2	25.2	47.7
Pneumonia	34.0	36.8	31.0
Diabetes	24.0	25.4	22.4
Suicide	11.3	(NA)	18.6
Nephritis	9.7	9.9	(NA)
Chronic liver disease	9.3	(NA)	12.4

Adapted from Table No. 8, National Vital Statistics Report, Vol. No. 11, July 24, 2000.

Cardiovascular Disease

Cardiovascular disease is the leading cause of death for both men and women in the United States. Approximately one of every two female deaths in the U.S. results from cardiovascular diseases. Forty-nine percent of women die within 1 year of a heart attack compared with 31% of men. This may be because cardiovascular disease presents differently in women than in men and is not recognized by health care providers when an emergency situation occurs. Even though there has been a major reduction in the number of deaths from heart disease in the United States, heart disease remains the major overall health problem facing women today.

Even though cardiovascular disease is the leading cause of death for both sexes, there has been a decrease in deaths from cardiovascular disease in the past three decades. Deaths caused by cardiovascular disease have dropped dramatically since 1970, from 496.4 deaths per 100,000 population to 268.2 in 1998 for both sexes (USDHHS, 2000). In 1998, 370,962 women died of heart disease compared with 353,897 men (DHHSKDCP, 2000). There are more than three times more deaths from heart disease than from breast and lung cancer combined.

The prevalence of heart disease increases as women age. The increased risk for cardiovascular disease in women may be the result of the decrease in estrogen at menopause. The prevalence increases to one in three at age 65 and older. Cardiovascular disease typically develops in women 10 to 15 years later than in men. The risk of coronary artery disease for younger women is less than

for men the same age, but as women age, mortality from heart disease increases. By age 75, the incidence of heart disease is essentially the same in both sexes. The prevalence of heart disease varies by race and ethnicity. For both men and women, African Americans have a higher death rate (317/100,000) from cardiovascular disease than Caucasians (285/100,000). Caucasian women have a higher death rate (286.8/100,000) than African American women (224.6/100,000) (DHHSCDCP, 2000).

Most treatment of cardiovascular disease in women is based on the male disease model, since the majority of cardiovascular studies have been conducted predominantly or exclusively on middle-aged men. In the past, women have not been included in studies for several reasons, including potential risks to a developing fetus and the potential for other medical conditions and diseases that would confound study design. As a result, information regarding prevention, screening, diagnosis, treatment, and prognosis for cardiovascular disease in women have been based on the male disease model, even though there are major differences in disease expression and mortality between the sexes.

There has been pervasive inattention by both health care providers and women themselves to the importance of cardiovascular disease in women. Women tend to fear having a heart attack less than having breast cancer. Women who have heart attacks are twice as likely as men to die because they lack access to appropriate medical care, are less aware of symptoms that could be related to cardiovascular disease, and are not provided with appropriate medical interventions. A recent study showed that women, minorities, and elderly clients experiencing a heart attack are less likely than middle-aged Caucasian men to receive potent clot-busting drugs and other advanced procedures to restore blood flow during a heart at-

tack. Women also were found to be less likely than men to undergo bypass surgery and angioplasty (Wong, Froelicher, Bacchetti, Burron, Gee, Selly, Lundstrom, Swain, and Truman, 1997).

Stroke is the third leading cause of death for women. It kills more than twice as many women annually as breast cancer. Three percent of strokes occur in women, and 61% of stroke deaths are women. Stroke and heart disease cause almost twice as many deaths in women than all types of cancer combined (DHHS, 2000).

Cancer

Cancer is uncontrolled growth or spread of abnormal cells, resulting from malfunction of genes that control cell growth and cell division (American Cancer Society [ACS], 2000). The majority of cancerous diseases result from gene mutation; heredity accounts for only for 5% to 10% of cancers (ACS, 2000). Cancer is the second leading cause of death for both men and women living in the United States (ACS, 2000). One of every four deaths results from cancer, with more than 1,500 cancer deaths occurring each day (ACS, 2000). However, when specific age groups are considered, cancer is the leading cause of death in women ages 25 to 64 but not in men. For all types of cancer combined, cancer incidence rates decreased an average of 0.7% per year from 1990 to 1995 in contrast to an increasing trend in earlier years (Wingo, 1998). From 1990 to 1996, cancer incidence decreased for Caucasians by 1.2% per year, Hispanics by 1.7% per year, Native American by 0.7% per year, and remained stable for Asian or Pacific Islanders and African Americans (ACS, 2000).

Mortality and morbidity rates vary according to gender (Figure 9-2).

Among the ten leading cancers, a similar reversal in trends was apparent for lung, prostate, colorectal, bladder, and blood cells cancers. Breast cancer rates increased significantly from 1973 to 1990 but were level from 1990 to 1995. Death rates for the four major cancers (lung, breast, prostate, and colorectal) decreased significantly from 1990 to 1995 (Wingo, Ries, Rosenberg, Miller, & Edwards, 1998). The decline in mortality rates was greater in men than women, largely because of the decrease in male lung cancer rates. There were greater decreases in rates in young males than in older males and greater decreases in African Americans than in Caucasians, although mortality rates remain higher in African Americans (ACS, 1998). As people get older, their cancer risk increases. Americans aged 55 and older receive nearly 80% of all cancer diagnoses (ACS, 2000) (Figure 9-3). Some inroads in prevention and health promotion have been made, which reduces mortality rates. Some of these include reduction in tobacco use, diet modification, cancer screening procedures, and progress in treatment based on research (Wingo, 1998).

Nursing Tip

PREVENTING CARDIOVASCULAR DISEASE

- Quit smoking
- Follow a low-fat, low-cholesterol diet
- Exercise at least three times per week
- Maintain a normal body weight
- Have periodic blood pressure checks
- Consider hormone replacement therapy at menopause

Figure 9-2 Leading sites of new cancer cases and deaths—2000 estimates (*Reprinted from American Cancer Society Cancer Facts and Figures, 1999*)

Figure 9-3 Nearly 4/5 of all cancer cases occur in adults over the age of 55.

More men than women die of cancer annually. The cancer death rate for men was 222.1 per 100,000 in 1993 compared with 189.8 for women. In 1993, out of 2,268,553 total deaths in the United States, 250,529 women and 279,375 men died of cancer (USBC, 1996). African Americans are more likely to develop cancer than any other ethnic or racial group (ACS, 2000). Overall cancer rates per 100,000 from 1990 to 1996 were 442.9/100,000 for African Americans, 402.9 for Caucasians, 275.4 for Hispanics, 279.1 for Asian and Pacific Islanders, and 153.4 for Native Americans (ACS, 2000). Most types of cancer can be treated and cured if detected early. Yet the death rates from cancer have been increasing for both men and women. In 1970, there were 69,500 deaths from lung cancer. In 2000, the American Cancer Society estimated that there were 156,900 lung cancer deaths, which is 28% of all cancer deaths.

Client Education

Recommendations for Early Cancer Detection

- Tell clients that persons ages 20 to 40 should have a cancer-related checkup every 3 years, and clients over age 40 should be seen yearly. Examination should include counseling as well as examinations of the thyroid, lymph nodes, and skin.
- Encourage women age 40 and older to have a mammogram and a clinical breast examination each year. Women ages 20 to 39 should have a clinical breast examination every 3 years.
- Teach clients how to perform a breast self-examination.
- Provide breast self-examination information (appropriate for age, language, and culture of client).
- Teach your client the appropriate time of month for breast self-examination.
- Explain to the client that people age 50 older should be screened for colorectal cancer every 5 to 10 years (depending on the recommendation of their physician).
- Inform all sexually active women and women age 18 and older of the importance of having an annual pelvic examination and Pap Smear.
- Explain to your client what to expect during a pelvic examination, particularly before your client's first pelvic examination.
- Encourage your client to schedule routine office visits for screening.
- Schedule an appointment with your client to reinforce the discussion of the importance of follow-up for early cancer detection and breast self-examination (ACS, 2000).

For women, the increased cancer mortality has occurred primarily in women over age 55. Mortality rates for 1990 to 1996 show that more African American men and women die annually from cancer (223,400) than Caucasian men and women (167,500). Annual Hispanic deaths from cancer were 104,900; American Indian deaths, 104,000; and Asian and Pacific Islander deaths, 103,400 per year. The incidence of most types of cancer in women is also higher for Caucasian women than for African American women. Caucasian women have a higher incidence of

breast, uterine, and ovarian cancer; African American women have a slightly higher incidence of lung and cervical cancer. While there is a higher incidence among Caucasian women, African American women have poorer survival rates (ACS, 2000). Reasons for poorer survival rates of African American women are unclear. One long-held hypothesis has been that poorer survival rates for African American women are caused by lack of access to care, which delays early detection and successful treatment. A recent study conducted at military hospitals, where supposedly everyone has the same access to care, found a gap between the breast cancer death rate of Caucasian and African American women that persisted even when they had equal access to care (Wojeik, 1998). Other factors that may contribute to differing survival rates, include genetic factors, diet, culture, and lifestyle, such as use of alcohol and tobacco (Wojcik, 1998).

Lung Cancer

Since 1985, lung cancer has been the leading cause of cancer death among women in the United States. Over the past 30 years, the lung cancer death rate among American women has increased nearly 400%, almost exclusively from cigarette smoking. From 1992 to 1996, mortality rates from lung cancer decreased significantly in men (down 1.7% per year), but rates for women increased (up 0.9% per year) (ACS, 2000). The dramatic increase in smoking among women has caused lung cancer to surpass breast

Client Education

Promoting a Healthy Lifestyle

- Obtain family history, nutrition history, and exercise or activity history
- Encourage a healthy diet
- Limit intake of high-fat foods
- Promote intake of high-fiber foods
- Limit consumption of alcoholic beverages
- Instruct client to keep a nutrition or diet record
- Encourage physical activity
- Encourage establishing or maintaining a healthy weight
- Discuss stress reduction activities
- Provide access to healthy lifestyle information (appropriate to age, language and culture)
- Schedule a follow-up visit

Figure 9-4 Lung cancer is the leading cause of cancer death in women.

cancer as a cause of death in women. Since 1987, more women have died from lung cancer than breast cancer, which was the major cancer killer of women for more than 40 years (ACS, 2000).

The death rate for lung cancer has risen despite medical advances and early diagnosis, which may be related to women lagging behind men in quitting smoking. Lung cancer symptoms of persistent cough, chest pain, bronchitis, sputum with bloody streaks, and recurring pneumonia usually do not appear until the advanced stages of the disease (Figure 9-4). An additional concern is the increasing use of tobacco among youth. Lung cancer from smoking is the most preventable cause of death today (ACS, 2000). Tobacco use in the United States causes the death of nearly one in every five Americans.

Society is beginning to mount an all-out effort at a major reduction in smoking habits, including legislation and policy regarding elimination of environments where smoking is permitted, public education regarding risks to health, and cigarette advertising targeted to minors. Litigation against tobacco companies and the surrounding publicity has increased the public's awareness of the addictive properties of nicotine and the risks of continued use. The litigation activity has spurred increased efforts at development of a national policy to discourage cigarette smoking. From 1978 to 1995, the prevalence of smoking among Caucasian, African American, Hispanic, and Asian or Pacific Islander men and women decreased, while the prevalence among Native Americans and Native Alaskan men and women did not change (ACS, 2000). The prevalence of cigarette smoking from 1991 to 1997 among high school students increased by 32%, which included an 80% increase among African American students, an increase of 39% among Hispanic students, and 28% among Caucasian students (ACS, 2000). Targeting of specific populations by the tobacco industry has led to an increase in teenage

smoking, with adolescent females for the first time surpassing adolescent males in the rates of starting smoking. Teenage girls' smoking rates have increased from 27% to 37% between 1991 and 1997 (USDHHS, 2000b).

Damaged lung tissue often returns to normal in persons who stop smoking when precancerous changes are found. After 10 years of abstinence, the risk of lung cancer is 30% to 50% lower than that of continuing smokers (ACS, 2000). In 1990, The U.S. Department of Health and Human Services published *The Health Benefits of Smoking Cessation*, in which the Surgeon General of the United States outlined the benefits of smoking cessation:

- People who cease to smoke, regardless of age, live longer than people who continue to smoke.
- Smokers who cease to smoke before age 50 have half the risk of dying within the next 15 years compared with those who continue to smoke.
- Smoking cessation substantially decreases the risk of lung, laryngeal, esophageal, oral, pancreatic, bladder, and cervical cancers.
- Smoking cessation lowers the risk for other major diseases, such as coronary heart disease and cardiovascular disease.

Nurses and other health care providers have both the opportunity and the means to help clients modify smoking behavior. About 70% of the 45 million adult smokers in the United States could be counseled by a health care worker during their ongoing care but often are not (CDC, 1994). The U.S. Preventative Services Task Force (1996) identified, in order of effectiveness, the key elements of effective counseling as follows:

- Providing reinforcement through consistent and repeated advice to stop smoking
- Setting of a specific "quit date"
- Scheduling follow-up contact or visits
- Providing self-help materials
- Making referral to group counseling
- Arranging for advice from more than one health care provider
- Including chart reminders to identify clients who smoke
- Prescribing nicotine-containing products to aid cessation

Historically, smoking prevention efforts have not focused on women, and women tend to be less successful in smoking cessation than men. Women are beginning to smoke in adolescence in greater numbers than ever. Anti-tobacco messages should be included in health promotion counseling of children, adolescents, and young adults (U.S. Preventive Services Task Force, 1996).

Critical Thinking

Lung Cancer in Women

More women die of lung cancer than breast cancer in the United States. Yet most women are far more frightened of breast cancer than they are of lung cancer. Cigarette smoking is the No. 1 risk factor in the development of lung cancer. Other risk factors include exposure to industrial substances, radiation, air pollution, tuberculosis, and second-hand smoke (ACS, 2000).

With lung cancer, early detection is difficult because symptoms often do not appear until the disease is advanced. Diagnosis of cancer is done primarily through chest x-ray films, analysis of sputum cells, and bronchoscopy, which is a fiberoptic examination of the bronchial tubes. Treatment for lung cancer is determined by the specific type and stage of the disease. Treatment options include surgery, chemotherapy, or radiotherapy, or a combination of these. Often by the time lung cancer is diagnosed, it has metastasized.

We know that approximately 75% of lung cancer is caused by smoking. Yet most of the attention in the media and by health professionals is given to breast cancer. All health care providers who care for women must be far more diligent in assessment of smoking status. Women who smoke require counseling, support, and information regarding smoking cessation programs and smoking risks. Far more attention should be given to the dangers of smoking in the public media and from health professionals. Increased public attention is needed for programs to decrease the number of adolescents who are beginning to smoke and the availability of smoking cessation programs that work. Assessment of each client's smoking status is important and counseling regarding cessation is part of nursing practice.

Survival rates for lung cancer have increased. The American Cancer Society (2000) note that 1-year relative survival rates have increased (between 1975 to 1995) from 34% to 41%, but the 5-year relative survival rate for all stages of lung cancer is 14%.

Client Education

Smoking Cessation

- Obtain smoking history from every client regardless of the reason for health care
- Encourage every client who smokes to stop smoking
- Identify benefits of smoking cessation
- Identify risks of smoking
- Help client to set a specific date to stop smoking
- Schedule follow-up visits with client to reinforce cessation
- Provide smoking cessation literature that is appropriate for age, language, and culture
- Develop appropriate collection of literature for client population served and knowledge of community smoking cessation programs
- Reinforce advice to client by arranging for other health care providers to also counsel client
- Chart smoking history and counseling given at each client visit
- Provide access to nicotine patch or other products to reduce nicotine addiction

of computing risk assumes that every woman has an equal chance for breast cancer and that every woman will live to be 110 years old; therefore, the risk cited can be misleading. The chance of developing breast cancer for an average 40-year-old woman is 1 in 1,000. The risk increases as women get older. In 1998 it was projected there would be 178,700 new cases of invasive breast cancer and 43,500 deaths from breast cancer (ACS, 1998). Incidence of new cases of breast cancer increased by about 4% per year during the 1980s, but has leveled off in recent years. The increase in new cases was attributed in part to the earlier detection of breast cancer through increased use of breast self-examination, clinical breast examination, and diagnostic screenings, including mammography (NCHS, 1992).

In the year 2000, approximately 182,800 new cases of invasive breast cancer will affect women in the U.S. and 1,400 men will be diagnosed with breast cancer (ACS, 2000). Early detection and advances in medical treatment of breast cancer have helped to decrease mortality rates in African American women. The incidence of breast cancer is highest in Caucasian woman (113.2 per 100,000) and lowest among Native American women (11.6 per 100,000).

Breast Cancer

Breast cancer is the second most prevalent cancer in women. The American Cancer Society estimates that one of every eight women in the United States will develop breast cancer during her lifetime (ACS, 1998). This method

Figure 9-5 A. Mammographic x-ray unit. B. Client positioning for mammography.

Mortality rates continue to decline with the largest decrease occurring in younger women. These decreases have occurred in both Caucasian and African American women. These decreases are likely due to earlier detection and improved treatment (ACS, 2000). Mammography is the best method for early detection of breast cancer and has attributed to the decrease in breast cancer deaths due to early detection (Figure 9-5).

Breast self-examination is important for detecting physical signs and symptoms of breast cancer. Women can examine their own breasts to detect a breast lump, swelling, distortion, dimpling, nipple pain, scaliness, or retraction (ACS, 2000). Many women experience breast pain or tenderness, which is often seen in conjunction with benign conditions of the breast. Breast pain is not normally the first symptom of breast cancer. The American Cancer Society recommends that women ages 20 to 39 have a clinical breast examination every 3 years and a monthly self-examination.

The risk of breast cancer rises as women age, most notably after age 40. Breast cancer occurs more frequently in Caucasian women over age 35 than in African American women of comparable age. Risk factors for breast cancer include personal or family history of breast cancer, biopsy-confirmed atypical hyperplasia, early menarche, late menopause, recent use of oral contraceptives or postmenopausal estrogens, never having children or having the first live birth at a late age, and a higher level of education and socioeconomic status (ACS, 1998). Alcohol consump-

tion of as many as two to five drinks per day has been associated with an increased risk of breast cancer that is comparable to that associated with having a family history of breast cancer or starting to menstruate before age 12 (ACS, 2000). Alcohol use and poor diet are risk factors that can be modified with lifestyle change, including smoking cessation, regular exercise before menopause, and a low-fat diet. International variability in breast cancer rates sug-

BREAST SELF-EXAMINATION (BSE)

First assess if your client performs monthly BSE. If your client reports to you that she is doing monthly BSE, have her demonstrate to you how she does it. This will tell you whether she is doing it correctly. If she is not doing it correctly, view this as an opportunity to help her learn it correctly. Also, when asking her to show you how she does BSE, she might be more willing to tell you if she is not doing it on a regular basis. You also have an opportunity to explore her reasons for not doing monthly BSE. You may find that she has negative feelings about touching her body, or incorrect information.

Research Highlight

Risk of Breast Cancer with Oral Contraceptive Use in Women with a Family History of Breast Cancer

Purpose

To determine whether the association with oral contraceptive use and the risk of breast cancer are influenced by a family history of breast cancer.

Methods

Historical cohort study of 426 families of women with breast cancer that was diagnosed between 1944 and 1952. Follow-up data on family members were collected by telephone interviews between 1991 and 1996. Follow-up family members included 394 sisters and daughters of the women in the initial study, 3002 granddaughters and nieces, and 2754 women who married into the families.

Findings

There was a significantly increased risk of breast cancer for sisters and daughters of the original group of women with breast cancer if they had ever used oral contraceptives; however, there was no significant increase for granddaughters, nieces, and marry-ins. The elevated risk among women with a first-degree family history of breast cancer was most evident for oral contraceptive use before 1975, when formulations were likely to contain larger amounts of estrogens and progestins.

Nursing Implications

Findings indicate that women who have used earlier formulations of oral contraceptives (before 1975) and who have a first-degree relative with breast cancer may be at a significant risk for breast cancer.

Grebick, D.M., et al. (2000). Risk of breast cancer with oral contraceptive use in women with family history of breast cancer. *JAMA*, 248 (14), 1791–1798.

gests that high-fat diets may correlate with an increased risk of breast cancer. Other factors that may be associated with increased risk include pesticide and other chemical exposures, weight gain, induced abortion, and physical inactivity. Some of the possible risk factors are amenable to lifestyle changes, such as poor diet, lack of exercise, and alcohol use. Because most of the established risk factors are not amenable to change through lifestyle or prevention strategies, the major focus has been on early detection and early treatment. A small percentage of breast cancers (1% to 5%) are associated with a genetic predisposition (genes *BRCA-1*, *BRCA-2* and possibly other as yet unidentified genes).

Genetic screening and gene therapy may be beneficial interventions in the future for women at risk for breast cancer. Genetic screening for the general population is not currently recommended (ACS, 2000).

The American Cancer Society's recommendations for early breast cancer detection include (ACS, 2000):

- Women aged 40 and older should have a screening mammogram every year.
- Between ages 20 and 39, women should have a clinical breast examination by a health professional every 3 years and after age 40, every year.
- Women age 20 or older should perform BSE every month (Figure 9-6). By doing BSE regularly, one learns how one's breasts normally feel and can more readily detect signs or symptoms.
- If a change occurs, such as development of a lump or swelling, skin irritation or dimpling, nipple pain or retraction (turning inward), redness or scaliness of the nipple or breast skin, or a discharge other than breast milk, the health care provider should be seen as soon as possible. However, most of the time, these breast changes are not cancer.
- Although there are some features of a mass that suggest whether it is likely to be benign or cancerous,

Nursing Alert

BREAST CANCER RISK FACTORS

- Family history of breast cancer (first-degree relative, i.e., mother, sister, daughter)
- Biopsy-confirmed atypical hyperplasia
- Early menarche (before age 12)
- Late menopause (after age 55)
- Recent use of oral contraceptives or postmenopausal estrogen therapy
- Never having children or having the first child after age 30
- High socioeconomic status and high level of education
- Alcohol consumption of more than 2 to 5 drinks per day
- Presence of *BRCA-1* or *BRCA-2* gene

women examining their own breasts should discuss any new lump with their health care professionals.

- ✿ Experienced health care professionals can examine the breast and determine whether the changes are benign or a breast cancer. They can determine when additional tests are appropriate to rule out cancer and when follow-up examinations are the best strategy. If there is any suspicion of cancer, a biopsy should be done.

The American Cancer Society believes the use of mammography, clinical breast examination, and BSE, according to the recommendations outlined above, offers women the best opportunity for reducing the breast cancer death rate through early detection. This combined approach is clearly better than any single examination. Without question, physical breast examination without mammography would miss many breast cancers that are too small for a woman or her doctor to feel. Although mammography is the most sensitive screening method, a small percentage of breast cancers do not show up on mammograms but can be felt by a woman or her doctor.

Colorectal Cancer

Colorectal cancer ranks third as a cause of cancer deaths in women and is three times more prevalent than uterine or ovarian cancer. In 2000, there were an estimated 130,200 new cases, including 93,800 cases of colon cancer and 36,400 of rectal cancer. Invasive colorectal cancer is the most preventable visceral cancer. Most cases arise from adenomatous polyps that take approximately 10 years to progress to an invasive stage.

The incidence of colon cancer declined from 1992 to 1996 by 2.1% per year (ACS, 2000). This decline in colon cancer has been suggested by research to be related to the increases in screening and the removal of polyps. Rectal bleeding, changes in bowel habits, and blood in the stool are symptoms of colon cancer.

Colon cancer was estimated to be responsible for 11% of all cancer deaths in the year 2000. Risk factors include family history, ulcerative colitis, first-degree family history of adenomas or colorectal cancer, and a personal history of adenomas or of ovarian, endometrial, or breast cancer.

Figure 9-6 A. Breast exam materials. B. Nurse teaching client breast exam techniques on a model.

Client Education

Breast Self-Examination (Recommendations of the American Cancer Society)

By regularly examining her own breasts, a woman is likely to notice any changes that occur. The best time for BSE is about a week after your period ends, when your breasts are not tender or swollen. Of you are not having regular periods, do BSE on the same day every month. Women who are pregnant, breast-feeding, or have breast implants also need to do regular breast self-examinations (BSE).

Lying Down

- Lie down with a pillow under your right shoulder and place your right arm behind your head (Figure 9-7A).
- Use the finger pads of the three middle fingers on your left hand to feel for lumps in the right breast.
- Press firmly enough to know how your breast feels. A firm ridge in the lower curve of each breast is normal. If you're not sure how hard to press, talk with your doctor or nurse.
- Move around the breast in a circular, up-and-down line or wedge pattern (Figure 9-7B). Be sure to do it the same way every time, check the entire breast area, and remember how your breast feels from month to month.

- Repeat the examination on your left breast, using the finger pads of the right hand. (Move the pillow to under your left shoulder.)

Standing Before a Mirror

- Repeat the examination of both breasts while standing, with your one arm behind your head (Figure 9-7C). The upright position makes it easier to check the upper and outer part of the breasts (toward your armpit). This is where about half of breast cancers are found. You may want to do the standing part of the BSE while you are in the shower. Some breast changes can be felt more easily when your skin is wet and soapy.
- Gently squeeze the nipple to check for discharge (Figure 9-7D)
- For added safety, you can check your breasts for any dimpling of the skin, changes in the nipple, redness, or swelling while standing in front of a mirror right after your BSE each month (Figure 9-7E).
- Raise your arms over your head to visualize the breast contour and the lower quadrants (Figure 9-7F).
- Place your hands on your hips and press inward to flex the pectoral muscles, which may enhance skin dimpling or puckering (Figure 9-7G).
- Repeat the examination on the alternate side.
- If you find any changes, see your doctor right away.

Possible additional risk factors include inactivity, high-fat diets, low-fiber diets, and inadequate intake of fruit and vegetables (ACS, 2000).

If detected at an early stage, colorectal cancer can be successfully treated with surgery (US Preventive Services Task Force, 1996). Recommendations for early detection for both men and women, beginning at age 50, include:

- Performing a fecal occult blood test (FOBT) and flexible sigmoidoscopy; if normal, repeat the FOBT annually and the sigmoidoscopy every 5 years, or
- Performing a colonoscopy; if normal, repeat every 10 years, or
- Performing a double-contrast barium enema; if normal, repeat every 5 to 10 years, and
- Performing a digital rectal examination in addition to the above diagnostic tests

Surgery for the treatment of colorectal cancer is frequently curative for cancers that have not spread. Treatment for clients whose cancer has deeply perforated the bowel wall or spread to the lymph nodes includes chemotherapy or chemotherapy plus radiation in addition to surgery. Treatment can be performed before or after surgery.

Cervical Cancer

Rates of cervical cancer have decreased steadily over the past several decades. The rate dropped from 14.2 per 100,000 in 1973 to 7.8 per 100,000 in 1994. The American Cancer Society notes that in the year 2000, there were an estimated 12,800 new cases. Rates for African Americans decreased more rapidly than for Caucasians; however, from 1992 to 1996, the mortality rate for African American continued to be more than twice that for Caucasian

Figure 9-7 Breast Self-Examination.

Risk factors for cervical cancer include early age at first intercourse, multiple sexual partners or partners who have

It is recommended that all women who are or have been sexually active or have reached age 18 should have annual Pap smears (Figure 9-8). This recommendation has been adopted by the major organizations (U.S. Preventive Services Task Force, 1996). The recommendation permits Pap testing less frequently after three or more normal annual test results, at the discretion of the health care provider and client.

An estimated 36,100 cases of cancer of the body of the uterus, usually of the endometrium, were diagnosed in 2000 (ACS, 2000). Incidence has been relatively constant since the mid-1980s at about 21 per 100,000 women (ACS,

Nursing Alert

RISK FACTORS FOR CERVICAL CANCER

- Early age at first intercourse
- Multiple sex partners
- Sex with partners who have had multiple sexual partners
- Smoking
- History of HPV infection
- Low socioeconomic status

1998). Incidence is higher among Caucasian women than African American women. Mortality rates were also relatively constant in the mid-1990s at about 3 per 100,000 women and about 6,300 deaths in 1998 (ACS, 1998). Although incidence of endometrial cancer is higher for Caucasian women than African American women, African American women have mortality rates that are nearly two times higher (ACS, 2000).

Endometrial cancer is rarely seen in women under age 50, but the risk rises sharply in women in their late 40s to mid-60s. The incidence of endometrial cancer increased rapidly during the years when unopposed estrogen was commonly used to treat postmenopausal women for symptomatic relief. Estrogen replacement therapy (ERT) was more common among Caucasian women, resulting in higher rates of endometrial cancer for Caucasian women than African American women. Unopposed estrogen therapy for menopause is no longer recommended because of the increased risk of endometrial cancer.

Signs and symptoms for endometrial cancer are similar to that of cervical cancer: abnormal uterine bleeding or spotting. Late manifestations of the disease include pain and systemic symptoms (ACS, 2000).

Risk factors for uterine cancer include those factors that expose the endometrium to estrogen, including (ACS, 1998):

- ✿ Unopposed estrogen therapy
- ✿ Therapy with tamoxifen
- ✿ Early menarche (before age 12)
- ✿ Never having children
- ✿ Late menopause (after age 55)
- ✿ History of failure to ovulate
- ✿ Infertility
- ✿ Diabetes

- ✿ Gallbladder disease
- ✿ Hypertension
- ✿ Obesity

There is preliminary evidence suggesting that a high-fat diet increases the risk of developing uterine cancer. Factors associated with a lower risk of endometrial cancer are having multiple children, use of oral contraceptives that combine both estrogen and progestin, and use during menopause of ERT combined with progesterone therapy. A genetic syndrome known as hereditary non-polyposis colon cancer has been associated with endometrial and ovarian cancer (ACS, 2000). Endometrial cancer is treated by surgery, radiation therapy, hormonal therapy, chemotherapy, or a combination of these treatments, depending on the stage of the cancer (ACS, 2000).

Survival rates for women with uterine cancer are good when the disease is treated early. The 5-year survival rate for early-stage endometrial cancer is 95%; for regional (later-stage) cancer, it is 64% (ACS, 2000). The survival rates for Caucasian women are at least 18% better at every stage than for African American women (ACS, 2000).

Ovarian Cancer

One in seventy women develop ovarian cancer. Approximately 23,100 new cases of ovarian cancer occurred in 2000, with an estimated 14,500 deaths (ACS, 2000). The average age at diagnosis is 63. Approximately 90% of cases occur in Caucasian women. Risk factors for ovarian cancer include a family history of ovarian cancer (in first-degree relatives, such as mother, sister, daughter), nulliparity, older age at the time of first pregnancy or live birth, fewer pregnancies, use of fertility drugs, high-fat diet, and a personal history of breast, endometrial, or colorectal cancer. Women who have had breast cancer or have a family history of breast or ovarian cancer are at increased risk. Alteration in *BRCA-1* or *BRCA-2* genes has been noted in women with ovarian cancer, and the use of oral contraceptives and pregnancy appear to reduce the risk of ovarian cancer (ACS, 2000). The American Cancer Society (2000) notes that industrialized countries, except for Japan, have the highest incidence of ovarian cancer.

Ovarian cancer usually shows no signs or symptoms until late in development. Enlargement of the abdomen from accumulation of fluid is the most common sign (ACS, 2000). Usually ovarian tumors are of considerable size by the time they are detectable by pelvic examination. Women over age 40 who present with persistent symptoms of vague digestive disturbances (stomach discomfort, gas, distention) that cannot be explained by any other cause may need an ovarian cancer evaluation, including a thorough pelvic examination (ACS, 2000).

As of 2000, the only screening test available for ovarian cancer is an annual pelvic examination, which includes

bimanual palpation of the ovaries. Even this method may not detect ovarian cancer early enough for adequate treatment. The Pap test rarely detects ovarian cancer, since it samples only cervical cells. Improvements in diagnostic methods continue, including identification of the breast and ovarian cancer gene on chromosome 17.

Only 25% of ovarian cancers are diagnosed early in the localized stage, with the survival rate at this stage being 95% for 5 years (ACS, 2000). For women with regional ovarian cancer, the survival rate is 79%; the survival rate for progressive disease is 28% (ACS, 2000).

Malignant Melanoma

Malignant melanoma is increasing faster than any other cancer. It is now more common than ovarian or cervical cancer. The incidence and mortality rates for women are rising and are greater than for men. Between ages 20 and 25, melanoma is the most common cancer in women and exceeds breast cancer and lung cancer. Between ages 30 and 39, melanoma is second to breast cancer in incidence.

Incidence is 10 times greater in Caucasians than African Americans, with an estimated 7,000 deaths in the year 2000 (ACS, 2000). Signs and symptoms include changes in the color or size of a mole or darkly pigmented spot on the skin, scaliness, oozing, bleeding, or a change in the appearance of a bump or nodule (ACS, 2000). Risks include fair skin, exposure to ultraviolet radiation, occupational exposures to chemical compounds, and family history (ACS, 2000).

The use of sunscreen and limiting exposure to the midday sun are important steps for prevention. The most common treatment is excision of the growth. The 5-year survival rate for malignant melanoma in the early stage is 95%; for regional disease, it is 58%; and for distant metastases, it is 13% (ACS, 2000).

Cancer Prevention

Cancer prevention in women has focused on smoking cessation, reduction of unprotected sex with multiple sex partners, low-fat diets, moderation in alcohol consumption, exercise, and elimination of unopposed estrogen use for menopause. Early detection and treatment has focused on periodic screening, including Pap smears, mammograms, gynecologic examinations, fecal occult blood tests, and sigmoidoscopy.

Chronic Conditions

Women live longer than men, but they are not necessarily living better. This is particularly true during later life, when they are more likely to have chronic disease (Rodin & Ickovics, 1990). Chronic diseases that women are more likely to be effected by include arthritis, osteoporosis, os-

teoarthritis, diabetes mellitus, obesity, urinary incontinence, Alzheimer's disease, fibromyalgia, chronic fatigue syndrome, orthopedic impairments, and vision and hearing problems (DHHS, 2000). In every age group, more women than men experience and seek care for illness and disability. During the reproductive years (ages 15 to 45), women seek care for acute conditions and short-term disabilities more frequently than men. Women in this age group may experience acute illness more frequently than men because women are exposed to school children with childhood infections to a greater degree than men (ORWH, 1992). Also, women are more likely than men to seek care for chronic conditions in middle and late life.

Osteoporosis

Osteoporosis is a disorder characterized by excessive loss of bone density. Osteoporosis affects over 25 million Americans; more than 80% of them are women. This disease affects one-third to one-half of postmenopausal women. The rates for osteoporosis increase dramatically for women as they age (ORWH, 1992). Hip fractures are the most serious consequence of osteoporosis, with more than 250,000 people hospitalized with hip fractures annually. About one-third of these become totally dependent, and one-half never walk again. Risk factors include (Bonnick, 1994):

- Caucasian woman
- Premature menopause
- Lack of exercise
- Excessive caffeine intake
- Regular alcohol use
- Excess dietary phosphate and sodium
- Post-menopause
- Insufficient dietary calcium
- Smoking
- Family history of osteoporosis

Prevention of osteoporosis should span the entire lifetime. Approximately 60% of a woman's bone mass develops by age 18, and peak bone density is achieved by age 35. To build and maintain bone density, women should eat calcium-rich foods, get regular exercise, and avoid tobacco and excessive consumption of alcohol or caffeine. Treatment includes calcium and vitamin D supplementation, estrogen replacement at menopause, and medications to strengthen bone structure.

Alzheimer's Disease

Alzheimer's disease occurs more frequently in women than in men and increases with age—dramatically so after age 85. In 1998, there were 22,725 deaths from Alzheimer's

disease, with most deaths occurring after age 75 (DHHS, 2000). The disease usually begins after age 65, and the risk goes up with age. Younger people may have Alzheimer's disease, but it is less common. About 3% of the population aged 65 to 74 have Alzheimer's disease. Alzheimer's disease is not a normal function of aging, although about 50% of the population over age 85 years may have the disease.

Immune Disorders

Immunologic diseases occur more frequently in females than males. Autoimmune thyroid disease occurs fifteen times more frequently in women than men. Rheumatoid arthritis occurs three times more frequently in women than men, and leads to disability and decreased life expectancy. Systemic lupus erythematosus (SLE) occurs nine times more frequently in women than men and is three times more prevalent in African American women than in Caucasian women. Systemic sclerosis affects women four times as frequently as men. Diabetes mellitus and multiple sclerosis occur more frequently in women (DHHS, 2000b).

Urinary Incontinence

Eleven million older women in the United States have urinary incontinence. Women are more frequently affected than men; approximately 2 million men experience the condition. Approximately 50% of persons residing in nursing homes are incontinent. Urinary incontinence is the tenth leading cause of hospitalization. More diapers are sold in the United States to women over age 65 than are used for babies. Although half of all elderly people experience episodes of incontinence, it is a problem of younger women also. 10–30% of women in 15–65 age group develop incontinent as a result of weakened pelvic muscles or pelvic trauma (Shint & Peggs, 2000). Table 9-4 outlines five types of urinary incontinence.

Urinary Tract Infections

Urinary tract infections are common in women of all ages and account for an estimated 8 million physician visits annually, costing over \$4 billion. Urologic disorders in women have not been studied well. Research in women's urologic disorders lags far behind research in bladder and prostate cancer and urologic disorders of men.

HIV Infection

The risk of becoming infected with HIV has increased in certain populations of women. The number of women who progress from undetected HIV infection to AIDS may be a major contributor to death among young women in certain risk groups. Before 1992, the majority of HIV-infected women were drug users or sex partners of drug

Table 9-4 Types of Urinary Incontinence

Type	Characteristics
Functional	Bladder emptying is unpredictable but complete. Incontinence is related to impairment of cognitive, physical, or psychological functioning or to environmental barriers.
Urge	Incontinence occurs immediately after the sensation to void is perceived.
Reflex	Incontinence is related to neurogenic bladder and central nervous system or spinal cord injury. Bladder fill, and uninhibited bladder contractions cause loss of urine.
Stress	Increased abdominal pressure is higher than urethral resistance. Stress associated with coughing or laughing causes incontinence.
Total	Unpredictable, involuntary, continuous loss of urine.

users. However, because of the dramatic increase in the number of women infected through heterosexual transmission, the number of women with HIV infection is rapidly increasing. Women infected with HIV are predominantly from minority groups (75%) and are likely to have dependent children, be on welfare, and have inadequate access to health care. HIV infection and AIDS present a different clinical course in women than men. Because women have not been included in AIDS clinical trials, understanding of HIV infection in women is inadequate. This results in less effective early identification and treatment of women with HIV infection and AIDS. To prevent HIV infection, the CDC promotes safer-sex behaviors that include postponing sexual activity among youth, restricting sexual contact to a mutually monogamous relationship with an uninfected partner, and consistently and cautiously using latex condoms during intercourse. For drug users who inject, the CDC encourages participation in a drug treatment program and avoiding use of needles used by another person.

Mental Illness

Mental health is crucial to a woman's well-being. Some of the most common mental disorders, including depression and anxiety, occur in approximately twice as many women as men. It is estimated that there are currently 7 million women in the United States with clinical depression. An estimated 12% of women experience a major form of depression at some time in their lives, compared with 7% of men. Women are twice as likely as men to suffer from clinical depression. Suicide was the fourth leading

cause of death among women aged 25 to 44 in 1998 (DHHSa, 2000). Women are more likely than men to attempt suicide but are far less likely to die as a result, primarily because men are more likely to use a firearm. Of women who have depression, about 75% are untreated. Most drugs to treat depression have been studied in clinical trials on men. The effects of hormones on depression and their interaction with psychotropic drugs have not been well-studied and are therefore largely unknown. At least 90% of the eating disorders anorexia nervosa and bulimia nervosa occur in women. Anorexia nervosa causes death in approximately 5% of those affected. It is believed that a combination of biologic, genetic, psychological, social, and environmental factors contribute to the reason women experience these illnesses at a higher rate than men. Women who have had a history of substance abuse or physical or sexual abuse are particularly at risk for depression, eating disorders, and anxiety disorders.

Substance Abuse

The abuse of alcohol and other legal and illicit drugs is a serious and growing problem among U.S. women. There are approximately 10 million alcoholics in the United States, of which 30% to 50% are women. Women are less likely to use or abuse alcohol than men but have a 50% to 100% higher death rate from alcoholism than men. Alcohol use during pregnancy poses a serious threat to the developing fetus. Heavy drinking during pregnancy has clearly been implicated in severe birth defects, including mental retardation, abnormal face and neck features, nervous system disorders, and delayed growth. Use of alcohol during pregnancy occurs more frequently in single women, smokers, teenagers, and those with little education. In 1998, approximately 4.5 million women aged 15 to 44 were currently illicit drug users, of which one-third were raising children. Women tend to be more easily addicted to tranquilizers than men.

Smoking in women has increased as a result of the tobacco industry's aggressive marketing to women, particularly to teenage girls. Smoking contributes substantially to deaths and disability from cancer, lung disease, heart disease, and stroke. Smoking rates have decreased 35% from their peak in 1965. However, over 22 million (22%) of women were smoking in 1997. The number of female teenagers who smoke has increased 10%, from 27% in 1991 to 37% in 1997, which is more than the percentage of male teenagers who smoke. Smoking is the leading cause of premature births and increases the risk of miscarriage, mental retardation, and low birth weight. Exposing children to secondhand smoke increases the risk of sudden infant death syndrome (SIDS), recurrent otitis media, and severe respiratory illness. Smoking cessation programs have been more successful in males than in females. By age 25, one in three

women is a smoker. The number of women who are heavy smokers has also increased in the last two decades.

AGE-SPECIFIC ISSUES

Certain health alterations are more prevalent in certain age groups, and are grouped accordingly in the following discussion.

Infancy to Young Adulthood

Less than 1% of all deaths of females occurs in girls aged 1 to 4. Accidents are the leading cause of death in this age group, followed by congenital anomalies, cancer, homicide, heart disease, pneumonia, septicemia, perinatal disease, stroke, and benign neoplasms (DHHS, 2000a) (Table 9-5).

Between ages 5 and 14, the death rate for female children drops by 50%. Accidents continue to be the leading cause of death, followed by cancer, homicide, congenital anomalies, heart disease, suicides, chronic obstructive pulmonary disease (COPD), pneumonia, benign neoplasms, and stroke (Table 9-6). In this age group, boys have almost twice the death rate from accidents that girls do (National Vital Statistics Report, 2000).

The major cause of death and illness among all children is injury, both intentional and unintentional. Injury accounts for over half of all deaths in this age group (Figure 9-9). Chronic illness is rare and is usually related to the increase in sex hormones during puberty. Women are also

prone to autoimmune diseases, including systemic lupus erythematosus (SLE), juvenile rheumatoid arthritis, and thyroid disease.

Areas for research that have been recommended by NIH in the infancy and childhood years include calcium intake; diet and physical activity; tobacco, alcohol, and other drug abuse; child mistreatment; growth and development; interaction between girls and their parents; hormonal influences; environment; asthma; mental health and depression; and oral health (NIH, 1999).

Young Adulthood to Perimenopausal Years

As girls, ages 15 to 24, become adolescents and young adults, the leading cause of death continues to be accidents. The leading causes of death for this age range are listed in Table 9-7. During this period, males have almost three times the risk of dying of females, with most deaths attributable to accidents, homicide, and suicide (USBC, 1999).

For adult women between ages 25 and 44, the risk of dying is more than double that of the previous age range. For the first time in their lives, cancer is the leading cause of death. The remaining causes of death in this age group are accidents, heart disease, suicide, AIDS, homicide, stroke, chronic liver disease, diabetes, pneumonia, summarized in Table 9-8. In contrast, the leading cause of death for men in this age group is accidents. AIDS and accidents are

Figure 9-9 Injury is the major cause of morbidity and mortality in young children.

more than three times more frequently causes of death in men than women. Homicide and suicide are more than four times more common causes of death in men than women during this period of life (USBC, 1999).

From ages 15 to 44, accidents, cancer, heart disease, suicide, and AIDS are the most frequent causes of death in both genders (Figure 9-10). The most frequent causes of ill health among women are eating disorders, autoimmune diseases, depression, alcohol and tobacco use, STDs, reproductive problems, homicide, and sexual abuse. Intervention strategies that can reduce or prevent serious illness or death in this age group address women at risk and risky

Figure 9-10 Adolescents are most at risk for mortality from accidents, cancer, heart disease, suicide, and AIDS.

behaviors associated with the diseases and illnesses. Alcohol is often a causative factor in motor vehicle accidents and violence that ends in homicide and suicide. Risky sexual behavior puts women at risk for STDs, HIV infection, cervical cancer, unwanted or unplanned pregnancies, pelvic inflammatory disease (PID), atopic pregnancy, and infertility. Smoking puts women at risk for lung and other cancer, heart disease, and COPD.

Perimenopausal to Mature Years

For mature women, ages 45 to 64, the risk of dying is more than five times that of women aged 25 to 44. Approximately 14% of all female deaths occur in this age range. The leading causes of death for men and women are summarized in Table 9-9.

Women in the menopausal to mature years are a fast-growing segment of the population because of the aging of the baby boom generation. These years are important because of menopause and the fact that many chronic conditions first appear. More than 10% of women in this age group have chronic conditions, including arthritis, hypertension, chronic sinusitis, skeletal deformity, and heart disease. Approximately 5% of these women have hearing impairments, chronic bronchitis, hemorrhoids, asthma, and diabetes. Another 1% to 3% of these women have visual impairments, cataracts, ulcers, abdominal hernias, and emphysema (National Center of Health Statistics, 1992). The rates of some of these chronic conditions in-

AIDS	7.2	(NA)	12.1

Adapted from Table No. 8, National Vital Statistics Report, Vol. No. 11, July 24, 2000.

crease markedly in the population between the ages of 45 to 64. During these years, one out of seven women has heart disease. Lung cancer is the leading cause of cancer deaths; breast cancer is the second most common cause. By age 54, one-third of women have had a hysterectomy (National Center for Health Statistics, 1992). Approximately 3% of women in this age group have a major depressive episode. Major reasons for hospitalization of women in this age range include heart disease, cancer, gall bladder disease, benign tumors, psychosis, and diabetes. The most common surgical procedures are hysterectomy, oophorectomy and salpingo-oophorectomy, cholecystectomy, cardiac catheterization, spinal fusion, dilatation and curettage, and biopsies (National Center for Health Statistics, 1992).

The three major risk factors for the diseases that relate to morbidity and mortality during this period are smoking, obesity, and a sedentary lifestyle. The drop in estrogen levels at menopause is a factor in the increased incidence of heart disease and osteoporosis. The Women's Health Initiative is conducting the largest and most expensive clinical trial ever conducted to determine whether women should begin hormone replacement therapy at menopause, how long it should be continued, and whether it will reduce the incidence of heart disease and osteoporosis.

Prevention strategies are aimed at identification of risk factors and avoiding or stopping risky behaviors that can be changed. Avoiding or stopping risky behavior, such as smoking, drinking, overeating, and a sedentary lifestyle, can reduce the risk of chronic disease and mortality in this age range. Smoking has been linked with lung cancer, coronary artery disease, cerebrovascular disease, peripheral vascular disease, cervical cancer, hypertension, osteoporosis, and respiratory diseases. High-fat diets may contribute to colon cancer, obesity, coronary artery disease, and possibly breast cancer. Excessive alcohol use may cause cirrhosis of the liver, alcoholism, accidents and injuries, suicides, homicides, hypertension, obesity, anemia, malnutrition, and gastrointestinal hemorrhage. The moderate intake of alcohol and its possible protective effects against cardiovascular disease remain controversial.

Research topics recommended by NIH regarding women of childbearing and middle age include contraception, infertility, osteoporosis, chronic pain, and cancer as well as the effects of ethnicity, culture, sexual orientation, socioeconomic status, and disability. Research in the effects of access to screening, fitness and health education, contraception, infertility, low birth weight babies, infant mortality rates, premature labor, infectious diseases and STDs, premenstrual syndrome, substance abuse, mental health, pharmacodynamics of drugs in women, postpartum depression, violence, endometriosis, in different racial and ethnic groups is recommended. In addition, research

on poverty, health of urban women, and women with disabilities are priorities (NIH, 1999).

Mature Years

While many women aged 65 and over lead full and productive lives, statistics show that women in this age group die at a rate that is almost seven times higher than women 45 to 64 years of age. Death of women aged 65 and over accounts for 8 of 10 female deaths annually. Heart disease is the major killer of both men and women, followed by cancer, stroke, COPD, pneumonia, diabetes, accidents, nephritis, Alzheimer's disease, and septicemia (Table 9-10).

Older women experience a significant number of chronic illnesses, including hypertension, diabetes, arthritis, digestive disorders, thyroid diseases, neurologic degenerative diseases, dementia, osteoporosis, and incontinence. Frequently, older women have multiple health problems that can be compounded by social and psychological problems including loneliness, isolation, and loss of independence (Figure 9-11). Research topics recommended by NIH regarding women in the postmenopausal years are summarized in Table 9-11.

NIH research recommendations concerning the older woman include the effects of chronic diseases and disability on quality of life; longitudinal multigenerational effects of diethylstilbestrol; action and side effects of drug in relation to age, race, and ethnic group, and gender of client; the interactions of food, alcohol, tobacco, and other substances with drugs; impact of estrogen on immune, endocrine, and cardiovascular systems and on cognitive and affective

processes; impact of oral health on quality of life; evaluation of effectiveness, benefits, risks and costs of alternative and complementary medicine; multisensory impairment; relationship between self-efficacy and positive self-image; functional independence and self-care; influences of spirituality on health outcomes in diverse groups; causes, consequences, and interventions related to physical and emotional violence, abuse, and traumatic stress; influence of age, culture, and socioeconomic status on health practices and receptivity to lifestyle interventions; effectiveness of health behavior interventions in different population groups; impact of living arrangements (independent, group, familial, or institutional) and health care decisions; effectiveness of interventions for incontinence, falls, depression, anxiety, cognitive impairment, insomnia, and violence; medication use and polypharmacy; patterns of alcohol and drug abuse of subpopulations across the sociocultural spectrum; models of providing care and caregivers; interactions among women and caregivers of different culture, age, socioeconomic status, and racial and ethnic group; barriers to care of the homebound and disabled; inclusion of the oldest old and institutionalized clients in studies; attitudes toward death as a function of ethnicity, culture, and age; end-of-life decisions, including end-of-life care; cultural and ethnic backgrounds and their influences on end-of-life decisions; managing death and ethnic and cultural differences regarding pain management, family support, place of death, dignity, and assisted dying; and quality of dying and ways to improve the end of life for women and caregivers (NIH, 1999).

Nursing Tip

NIH RECOMMENDATIONS FOR RESEARCH CONCERNING WOMEN IN THE POSTMENOPAUSAL YEARS

- Health status of special populations
- Environmental exposures
- Epidemiology on risk factors & diseases
- Characteristics influencing health status & behaviors
- Health outcome differences in racial subgroups
- Quality of life with chronic disease
- Factors effecting breast cancer risk
- Role of menopause in aging
- Gender differences in surgical & pharmacologic treatments
- Risk factors for stroke
- Differences in prevalence of diabetes subgroups of women
- Screening tests & follow up in minority & underserved women
- Action of natural hormones in post menopausal women
- Drug use and misuse
- Gender differences in pain threshold tolerance and sensitive
- Gender & age differences in mental health effects of racism on health

HEALTH PROMOTION AND DISEASE PREVENTION

In recent years, health promotion has become a major goal for the U.S. and many other countries of the world. The World Health Organization defines **health promotion** as a process, action, program, or endeavor to obtain the goal of complete physical, mental, and social well-being. Other definitions have included concepts of self-care, health-promoting behaviors, empowerment, development of healthy lifestyles, maintenance or enhancement of well-being, and healthy environments.

Not only are there many definitions of health promotion and disease prevention, there are differing sets of preventive services recommended by government agencies, professional organizations, voluntary associations, and academic experts. However, in spite of this, there seems to

be basic agreement among authorities on recommendations for the major types of preventive care. The U.S. Preventive Services Task Force (1996) published its report in the *Guide to Clinical Services*, which is widely regarded as the premiere reference source on the effectiveness of clinical preventive services, including screening tests for early detection of disease, immunizations to prevent infections, and counseling for risk reduction (U.S. Preventive Services Task Force, 1996). Recommendations of the major U.S. authorities are also summarized (USPHS, 1994). The following is a summary of the major findings and recommendations contained within the report.

Delivery of Preventive Services

Even for those services in which there is agreement that the services are necessary among all major U.S. authorities, the delivery of preventive services is less than satisfactory. In some cases, the rate of delivery of services is less than 20%. Some of the reasons for these poor rates include lack of clinician time, inadequate reimbursement, lack of clinician interest and knowledge, lack of client involvement and knowledge, and lack of office or clinic systems to promote preventive care. Effective delivery of clinical preventive services includes establishment of a preventive care protocol and implementation plan.

Types of Preventive Services

The three major types of preventive services include screening, immunization, and counseling.

Screening

Screening is the process of completing a test or examination to detect the most characteristic sign or signs of a disorder or disease that may require further investigation. Screening sensitivity and specificity and positive predictive value must be considered when evaluating and selecting screening tests. There is little value in performing screening tests without close tracking of results and the necessary follow-up testing. Analysis of screening tests must adhere to national standards for accuracy in testing and reporting of results. Clients should be clearly informed of the potential cost and side effects of necessary follow-up testing and treatment as appropriate.

Immunizations

Immunizations can prevent or postpone serious disorders. The National Vaccine Advisory Committee has set standards for childhood immunization practices, and the National Coalition for Adult Immunization has developed standards for adult immunization practices.

Counseling

The third method to implement preventive care is counseling. The U.S. Preventive Services Task Force described 10 principles for client education and counseling with which all health care professionals should be familiar. These principles include:

1. Develop a therapeutic alliance
2. Counsel all clients
3. Insure that clients understand the relationship between behavior and health
4. Work with clients to assess barriers to behavioral change
5. Gain commitment from clients to change
6. Involve clients in selecting risk factors to change
7. Use a combination of strategies
8. Design a behavior modification plan
9. Monitor progress through follow-up contact
10. Involve office staff

In addition, the counseling should be culturally appropriate. Information and services should be presented in a style and format that is sensitive to the culture, values, and traditions of the client. The services should be provided at a level of comprehension consistent with the age and learning skills of the client.

The following are recommendations for development of preventive services.

- Preventive services must become an integral part of all health services, including nursing
- Protocols for prevention must continue to be developed

Web Activities

- Visit some of the websites listed in the Resources section, such as the American Cancer Society and the American Heart Association. Using the health promotion guidelines that they post, develop a teaching plan for a woman at risk for cervical cancer and cardiovascular disease.
- Search the CDC's website for statistics on various conditions discussed in this chapter. Is geographic information also included?

- Screening must be useful, i.e. have the ability to detect conditions that are treatable, and be completed at the right time
- Screening must be acceptable to the client
- Prevalence of a condition must be sufficient to justify the cost of the screening
- Immunizations can prevent or postpone serious disorders
- Counseling is an integral component of prevention
- Nurses must continue to strive for excellence and sensitivity in providing prevention education, counseling, and screening
- Counseling must be culturally appropriate

Key Concepts

- Historically, health care research has used male subjects with little attention to health issues or conditions that affect postmenopausal women.
- Because of technologic advances and more effective prophylactic treatment for acute and chronic diseases, both women and men will live longer in the next century.
- The leading cause for mortality in women is heart disease, followed by cancer and stroke, which account for two-thirds of all deaths among women.
- Factors that put women at increased risk of mortality and morbidity are smoking, obesity, and sedentary lifestyle. Prevention strategies to minimize these factors are essential.

Review Questions and Activities

1. Women's health relates to all of the following except:
 - a. Reproductive conditions of women
 - b. Diseases and conditions unique to women or more prevalent, more serious, or differently expressed in women than in men
 - c. Prevention, risk assessment, health promotion, early diagnosis, treatment based on genetics, culture, biology, economics, and psychological development of women
 - d. Socioeconomic status of men

The correct answer is d.
2. The Office of Research and Women's Health has as its mission all of the following except:
 - a. Promotion of healthy behavior in women
 - b. Improvement of health of minority women
 - c. Recruitment of women for legislative positions
 - d. Provision of greater access to health services for women

The correct answer is c.
3. The Women's Health Initiative is a:
 - a. 10-year study of breast cancer
 - b. Clinical trial to study cardiovascular drugs in women
 - c. Longitudinal study of nurses
 - d. 15-year study of major diseases and conditions of postmenopausal women

The correct answer is d.
4. Life expectancy in the U.S. is:
 - a. Decreasing faster in the last 10 years than ever before
 - b. Longer for men than women
 - c. Longer for women than men
 - d. Higher for African American women than Caucasian women

The correct answer is c.
5. Birth rates in the United States are:
 - a. Increasing in married adolescents
 - b. Increasing since 1950
 - c. Increasing in women over 30 years of age
 - d. Similar for African American and Caucasian women

The correct answer is c.
6. The highest birth rates are occurring in:
 - a. African Americans
 - b. Caucasians
 - c. Hispanics
 - d. Asians

The correct answer is c.
7. The two leading causes of death for both sexes are:
 - a. Heart disease and stroke
 - b. Cancer and stroke
 - c. Heart disease and cancer
 - d. Heart disease and accidents

The correct answer is c.

8. Heart disease in women:
- Occurs more frequently than in men at all ages
 - Decreases slightly after age 65
 - Increases after menopause, with an incidence similar to that in men by age 75
 - Occurs more frequently in Caucasian women than African American women

The correct answer is c.

9. Knowledge about cardiovascular disease in women is deficient because:
- Most studies on heart disease were completed in the 1960s and 1970s
 - Lipid levels in women have never been standardized
 - Women refused to participate in drug studies
 - Most studies have been conducted on middle-aged men

The correct answer is d.

10. Accidents are the leading cause of death in women in all of these age groups except:
- 5 to 14 years
 - 15 to 24 years
 - 25 to 44 years
 - 45 to 64 years

The correct answer is d.

11. Cancer deaths in the United States are:
- Increasing in men and decreasing in women
 - Decreasing in men and increasing in women
 - Increasing in both men and women
 - Decreasing in both men and women

The correct answer is d.

12. The leading cause of cancer deaths in women is:
- Lung
 - Cervical
 - Ovarian
 - Breast

The correct answer is a.

13. Lung cancer in women is:
- Decreasing because of a decrease in smoking habits of women
 - Increasing because of an increase in smoking habits of women
 - Difficult to treat, but easy to detect
 - Less important as a cause of death in women than breast cancer

The correct answer is b.

14. Risk factors for breast cancer include:
- Family history
 - History of HPV infection
 - Early menopause

- Low-fat diet

The correct answer is a.

15. Most women with breast cancer are all of the following except:
- Over the age of 50
 - Likely to have no known risk factors
 - Likely to have a good prognosis if the cancer is detected early
 - Likely to have another type of cancer before the diagnosis of breast cancer

The correct answer is d.

16. Ovarian cancer is:
- Common among young African American women
 - Easy to detect with the pap smear
 - Likely to carry a good prognosis once it is detected
 - Frequently detected late in its course

The correct answer is d.

17. Cancer prevention programs for women include all of the following except:
- Smoking cessation
 - Periodic screening
 - Bone density index measurement
 - Elimination of unopposed estrogen use for menopause

The correct answer is c.

18. Chronic diseases that women experience more frequently than men are:
- Diabetes, osteoporosis, arthritis
 - HIV infection, homicide, pneumonia
 - Alcoholism, cirrhosis, COPD
 - Asthma, ulcers, bronchitis

The correct answer is a.

19. The following statements are true regarding osteoporosis *except*:
- It affects one-third to one-half of postmenopausal women
 - It increases as women age
 - It puts women at high risk for hip fractures
 - It occurs as a result of arthritis

The correct answer is d.

20. Depression in women:
- Occurs less frequently than in men
 - Tends to be treated in only about 75% of women with the condition
 - Is twice as likely to occur in women than men
 - Is easy to treat with psychotropic drugs developed in research on women

The correct answer is c.

Common Conditions of the Reproductive System

Working with women who have conditions affecting the reproductive system is both challenging and rewarding. The process is challenging because creative solutions to daily health care concerns are required, and rewarding because helping women focus on individual health promotion activities enables families to focus on health promotion. To get the most out of each encounter with a woman in your care, you should gauge the awareness of her home environment, gauge your comfort level with her decision making regarding her health care, and be content to work on one condition or concern at a time. You may find the following questions helpful in determining your feelings and values regarding these conditions:

- *How do you feel toward a woman who repeatedly has sexually transmitted infections?*
- *What is your reaction toward a woman who chooses to purchase cigarettes instead of an annual "Pap" smear or healthy food?*
- *How will you provide high-quality care to a woman who is a single mother with several children, all of whom have a different father?*
- *Are you willing to facilitate health promotion for a woman who does not make the same choices for her health as you would?*
- *How would you react toward a woman who says she must ask her husband or partner if she can undertake a prescribed therapy?*
- *What is your reaction toward a woman who repeatedly comes into the health care facility with the same modifiable health problem, such as a vaginal infection, because of poor hygiene habits?*

Key Terms

Amenorrhea	False discharge	Nipple discharge	Premature ovarian failure
Cervical cancer	Fibroadenoma	Osteoporosis	Premenstrual syndrome
Cervical infection	Fibrocystic changes	Ovarian cancer	(PMS)
Dysfunctional uterine bleeding (DUB)	Fibroid tumor	Pathologic discharge	Primary amenorrhea
Dysmenorrhea	Invasive breast cancer	Pelvic inflammatory disease (PID)	Primary dysmenorrhea
Endometrial cancer	Lactational discharge	Pelvic relaxation	Secondary amenorrhea
Endometriosis	Localized breast cancer	Physiologic discharge	Secondary dysmenorrhea
Estrogen deficiency	Mastectomy	Polycystic ovarian syndrome	Vaginal infection
vulvovaginitis	Menopause		
	Metastatic breast cancer		

Competencies

Upon completion of this chapter, the reader should be able to:

1. Define each woman's reproductive health issue as addressed in the chapter.
2. Describe subjective and objective data, laboratory test results, and procedure result data for women's reproductive health conditions.
3. Discuss usual therapeutic interventions for women's reproductive health conditions.
4. Identify risk factors for women's reproductive health conditions.
5. Discuss the nursing process steps appropriate for each women's reproductive health condition.

Women are living longer now than ever before. Thus, a woman can expect to experience a variety of health conditions resulting from the aging process, as well as the normal physiologic “wear and tear” that occurs on a daily basis. Women can realistically expect to live into their 80's, and they want to have a high quality of life throughout their life span. Women traditionally have been the “keepers” of health for themselves and family members. Although women may have tended to ignore personal health conditions in the past, more women are now recognizing the need to attend to personal health, especially if conditions prevent them from maintaining their quality of life or from being able to meet the responsibilities of caring for loved ones. Nurses can facilitate the achievement of women's goals for quality of life by assessing their clients' health conditions and developing an individualized plan to reduce the adverse effects of disease. Conditions of the female reproductive system can be classified as common deviations from the usual pattern and occur from puberty to beyond menopause. Conditions addressed in this chapter include menstrual, mammary, pelvic, and menopausal conditions.

MENSTRUAL CYCLE ABNORMALITIES

In general, abnormal conditions of the menstrual cycle are deviations from what is normal for an individual woman. The condition may occur in the frequency or length of the cycle, volume or length of menstrual flow, or the total number of years of menstruation.

Menstrual cycle conditions are a readily noticeable concern. Common conditions may be classified as amenorrhea, dysfunctional or abnormal uterine bleeding, dysmenorrhea, endometriosis, or premenstrual syndrome. Refer to Table 10-1 for a list of menstrual cycle conditions and to Table 10-2 for therapeutic interventions for menstrual cycle conditions. Box 10-1 lists additional alterations in menstrual cycle function.

Amenorrhea

Amenorrhea is the absence or lack of menses during the reproductive years. Normal causes of amenorrhea include pregnancy, lactation, and menopause. Other causes can be pathologic and may include stress, excessive exercise, eating disorders, weight loss, a low body mass index (BMI),

Table 10-1 Menstrual Cycle Conditions

Condition	Data		
	Subjective	Objective	Laboratory or Procedure
Amenorrhea			
Primary amenorrhea	No menarche	Secondary sex characteristics Reproductive tract anomalies	Thyroid function tests Blood glucose level Karyotype (Turner syndrome) Laparoscopy (ovarian pathology)
Secondary amenorrhea	3 or more missed menstrual periods Menstrual pattern	Previous gynecologic procedures or problems Weight gain or loss Major life events Exercise level Thyroid size Exophthalmia Moon facies Hirsutism Delayed deep tendon reflexes Breast atrophy Thinning hair Temporal baldness	Decreased thyroid function tests Increased Blood glucose level Increased Serum prolactin level Laporoscopy to detect polycystic ovary syndrome Ultrasound to detect ovarian cysts
Abnormal or Dysfunctional Uterine Bleeding			
Bleeding between menstrual periods	Possible uterine abnormality Irregular bleeding Heavy bleeding Prolonged bleeding Light bleeding Short or long cycles	Anemia	Low thyroid function, pituitary function (FSH or LH) hCG studies (for anovulation) Increased prolactin level Pregnancy test CBC, Complete Blood Count for anemia or infection Ultrasound Endometrial biopsy to rule out endometrial cancer
Dysmenorrhea			
Primary dysmenorrhea	Mild to severe cramping, lasting from 2–4 days before menses to third day of menses GI symptoms: bloating, nausea, vomiting Back, thigh, and headache pain Family history	Nulliparity Age (adolescence to early 20s) Normal results on physical examination	Ultrasound
Secondary dysmenorrhea	Increasingly painful menses Dyspareunia Painful defecation Rectal pressure Heavy or irregular bleeding	Third or fourth decade of life Endometriosis PID, STD Increased uterine size Endometritis Salpingitis Leiomyomata	Elevated WBC count if STD or PID is present Cultures for Gonorrhea and Chlamydia Ultrasound Laparoscopy (endometriosis)

(continued)

Table 10-1 Menstrual Cycle Conditions (continued)

Condition	Data		
	Subjective	Objective	Laboratory or Procedure
Endometriosis			
Dysmenorrhea	Infertility Cyclic dyspareunia Dyschezia GI symptoms Pelvic heaviness Chronic pelvic pain (may radiate to thighs) Abnormal bleeding	Uterus may be fixed Possible adenexal mass(es) Pelvic tenderness	Ultrasound monitoring of implants Laparoscopy
Premenstrual syndrome			
Cluster of symptoms at luteal phase	Depressed mood Mood swings Irritability Difficulty in concentration or coping Fatigue Edema Breast tenderness Headache (premenstrual) Sleep disturbances Abdominal bloating Increased appetite Weight gain Food cravings Acne Heart palpitations Anxiety Hostility	Signs of stress Emotional lability	None

or other potentially life-threatening disorders. Amenorrhea can be classified as primary or secondary.

Primary Amenorrhea

Primary amenorrhea is the absence of menarche until age 16 or the absence of the development of secondary sex characteristics and menarche until age 14 (Keene, 1999). Causes of primary amenorrhea may involve hypothalamic, pituitary, enzymatic, or chromosomal abnormalities; genitourinary tract abnormalities; or drug therapy. The primary symptom is failure to experience menarche when there has been development of secondary sex characteristics or without such development as in Turner syndrome. Therapeutic intervention depends on the cause of primary amenorrhea and usually includes estrogen replacement therapy (ERT) to prevent osteoporosis or to stimulate development of secondary sexual characteristics.

Secondary Amenorrhea

Secondary amenorrhea is the absence of menses for at least 6 months or for three cycles after menarche (Keene, 1999; McGee, 1997). Secondary amenorrhea is more common than primary amenorrhea and is often caused by physiologic responses to pregnancy, lactation, or anovulation. (Keene, 1999). In addition to absence of menses, the woman may have diseases related to endocrine dysfunction that are causing the secondary amenorrhea, such as hypothyroidism, hyperthyroidism, adrenal disease, chronic hepatic disease, chronic renal disease, or polycystic ovary syndrome. Women athletes who train vigorously or women with anorexia often experience secondary amenorrhea because of the affects of the relationship of height and weight, percentage of body fat, and malnutrition on the hypothalamic-pituitary-ovarian axis. Therapeutic intervention for secondary amenorrhea includes cyclic proges-

Table 10-2 Management of Menstrual Conditions

Condition	Usual Therapeutic Interventions
Amenorrhea	
Primary amenorrhea	Hymenectomy for imperforate hymen Nutritional correction of low BMI
Secondary amenorrhea	Hormone replacement for endocrine dysfunctions Nutritional correction for high or low BMI Estrogen and/or progesterone replacement therapy Thyroid hormone replacement therapy
Dysfunctional or abnormal uterine bleeding	
	Hormone replacement therapy (OCPs, combined estrogen and progestin therapy, progestin therapy alone) Iron supplements for anemia Possible laser ablation of endometrium
Dysmenorrhea	
Primary dysmenorrhea	NSAIDs or prostaglandin synthetase inhibitors OCPs
Secondary dysmenorrhea	Antibiotics for infection Treatment specific to underlying cause
Endometriosis	
	NSAIDs Surgical removal or ablation of endometrial implants GnRH agonists Medroxyprogesterone (Provera) Continuous OCP therapy
Premenstrual syndrome	
	Education regarding syndrome Stress reduction techniques Regular exercise Smoking cessation Regular sleep habits Support groups Regular, balanced meals with low intake of sodium and caffeine Diuretic agent at time of symptoms NSAIDs Prostaglandin synthetase inhibitors Selective serotonin reuptake inhibitors (SSRIs) OCPs GnRH agonist (extremely severe symptoms)

terone, when the cause is anovulation; oral contraceptives, for the woman who desires contraception; bromocriptine, when the woman is experiencing hyperprolactinemia; gonadotropin-releasing hormone (GnRH), when the cause is hypothalamic failure; and thyroid hormone replacement therapy, when the cause is hypothyroidism. In addition, the woman who is hypoestrogenic is given calcium and ERT to prevent development of osteoporosis.

Dysfunctional Uterine Bleeding

Dysfunctional uterine bleeding (DUB) is “any significant deviation from the usual menstrual pattern” (Keene, 1999, p. 75). DUB occurs more often in adolescents and perimenopausal women. An estimated 20% of women seek therapeutic intervention at some point in their lives for

Box 10-1 Menstrual Cycle Alterations

- **Hypermenorrhea or menorrhagia:** Excessive menstrual bleeding, either in duration or amount, during regularly occurring menstrual cycles
- **Hypomenorrhea:** Decreased menstrual bleeding, either in duration or amount, occurring at regular intervals
- **Intermenstrual bleeding:** Irregular vaginal bleeding, usually not caused by menses and not excessive in amounts, occurring between regular menstrual cycles
- **Menometrorrhagia:** A combination of menorrhagia and metrorrhagia. Irregular, frequent, possibly excessive, or prolonged vaginal bleeding, which may or may not be menstrual.
- **Oligomenorrhea:** Light menstrual bleeding or infrequent menses, which occur in cycles at least 35 days apart
- **Polymenorrhea:** Frequent menses that occur in cycles no more than 21 days apart

DUB (Smith, 1998). The differences from the usual bleeding pattern may include hypermenorrhea and menorrhagia, intermenstrual bleeding and metrorrhagia, menometrorrhagia, oligomenorrhea, polymenorrhea, or hypomenorrhea.

Causes of DUB include hormonal abnormalities, such as anovulation; pregnancy-associated events; pelvic inflammatory disease (PID); trauma; neoplasm; endometriosis; and anatomic or systemic disease.

A woman may report characteristics of oligomenorrhea when she experiences a scant amount of menstrual bleeding or cycles more than 35 days apart. Therapeutic interventions include:

- ✦ Oral contraceptives for menstrual cycle control
- ✦ Administration of high doses of estrogen and progesterone to produce therapy withdrawal bleeding (pharmaceutical dilation and curettage)
- ✦ Cyclic progesterone therapy for chronic anovulatory bleeding
- ✦ Nonsteroidal anti-inflammatory drugs (NSAIDs) to reduce the amount of menstrual bleeding
- ✦ Endometrial ablation to decrease or eliminate menstrual bleeding by eliminating the tissue sloughing
- ✦ Hysterectomy, when abnormal uterine bleeding cannot be corrected by more conservative methods

Dysmenorrhea

Dysmenorrhea is painful menses or cramping during menstruation. Typically dysmenorrhea begins up to 48

hours before onset of menses and resolves within 2 to 4 days of onset or by the end of the menstrual period (Ugarriza, Klinger, & O'Brien, 1998). Dysmenorrhea can be classified as primary or secondary.

Primary Dysmenorrhea

Primary dysmenorrhea is painful menses with a uterine cause, but without pelvic pathology, and usually occurs within 1 to 3 years of menarche (Ugarriza et al., 1998). Painful uterine contractions stimulated by prostaglandin produced by the endometrium during menses are most often identified as the cause for primary dysmenorrhea. Symptoms of primary dysmenorrhea may include sharp, intermittent suprapubic pain radiating to the back or thighs; headache; fatigue; backache; flushing; dizziness; and syncope. Typically, adolescents do not experience dysmenorrhea until menstrual cycles become ovulatory. Women often experience reduction in dysmenorrhea after pregnancy. Therapeutic intervention for primary dysmenorrhea are directed toward reduction of symptoms and include NSAIDs started 1 to 3 days before the onset of menstrual flow (to decrease prostaglandin production) and oral contraceptives, to decrease endometrial proliferation and, therefore, the amount of prostaglandin produced by the endometrium.

Secondary Dysmenorrhea

Secondary dysmenorrhea is painful menses resulting from a pathologic process, such as pressure from outside the uterus, tissue ischemia, cervical stenosis, congenital abnormality (imperforate hymen), endometriosis, ovarian cysts, PID, or uterine fibroid tumors (Ugarriza et al., 1998). Symptoms may begin earlier in the cycle and last longer than the symptoms of primary dysmenorrhea, with specific symptoms other than pain. These symptoms can include breast tenderness and a change in bowel habits. Therapeutic intervention usually involves correction of the cause.

Endometriosis

Endometriosis is a chronic disorder resulting from the implantation of endometrial tissue outside the uterus. Pelvic sites of endometrial tissue implantation include the cervix, cul-de-sac, ovaries, fallopian tubes, pelvic peritoneum, uterine broad ligaments, and bowel (Figure 10-1) (Corwin, 1997). Distant sites of endometrial tissue implantation occur less commonly and can include the abdominal wall, kidneys, spleen, gallbladder, diaphragm, lung, stomach, or breasts. Each of these sites will bleed during the menstrual cycle. The disorder affects nearly one in seven women of childbearing age. Endometrial tissue, regardless of location, responds to cyclic ovarian hormone fluctuations. However, there is no place for the endometrial tissue to be sloughed off; blood shed from the endometrial tissue implants accu-

Figure 10-1 Common sites of endometriosis.

multate locally during menses. Often, women experience short menstrual cycles (less than 28 days), increased duration of bleeding (7 days or more), excessive bleeding (for at least 5 days), and significant cramping (Corwin, 1997). The woman experiences symptoms of pain, inflammation, or pelvic heaviness, depending on the duration of the disorder, location of endometrial tissue implants, and the phases of the menstrual cycle. The intensity and duration of symptoms seem to be greater in women with more advanced disease. Such women may experience chronic pelvic pain, frequent low back pain and heaviness, dyspareunia, cyclic painful defecation or rectal bleeding, cyclic diarrhea, cyclic flank pain, or cyclic hematuria or dysuria.

Therapeutic intervention is focused on stopping the progressive destruction of pelvic organs caused by the progression of endometrial implants and preserving fertility options for the woman. Endometrial implants are removed surgically or ablated with laser or electrocautery to preserve childbearing capability. NSAIDs aid in pain control by reducing prostaglandin production by the endometrial implants during menses. In addition, temporary relief can be

achieved by continuous administration of gonadotropin-releasing hormone (GnRH) to prevent release of luteinizing hormone (LH) and thus cause temporary cessation of menstruation. If suppression of menstrual cycles lasts longer than 6 months, low-dose ERT or estrogen and progesterone replacement therapy is usually begun to prevent bone loss and alleviate symptoms of menopause.

Premenstrual Syndrome

Premenstrual syndrome (PMS) is a cyclic cluster of behavioral, emotional, and physical symptoms that occur during the luteal phase of the menstrual cycle. The symptoms must be sufficiently severe to interrupt normal activity before the diagnosis can be made (Ugarriza et al., 1998). The cause is unknown but is thought to be related to hormonal changes. Since 1987, PMS has been recognized as a mental disorder (Ugarriza et al., 1998). For most women with PMS, symptoms are noticed from 2 to 12 days before the onset of menses and resolve within 24 hours of the onset of menses and vary in severity. An estimated

30% to 40% of women of childbearing age are believed to experience PMS to some degree (Ugarriza et al., 1998).

Women may experience one or more of the recognized symptoms, which can be classified as affective, autonomic, behavioral, neurologic, cognitive, dermatologic, a result of fluid or electrolyte imbalances, neurovegetative, or algetic. Affective symptoms include sadness, anxiety, anger, irritability, and mood swings. Cognitive symptoms manifest as decreased concentration, indecision, paranoia, rejection sensitivity, and suicidal ideation. Autonomic symptoms include nausea, diarrhea, palpitations, and perspiration. Behavioral symptoms are demonstrated by decreased motivation, poor impulse control, decreased efficiency, and social isolation. Clumsiness, seizures, dizziness, paresthesias (numbness or tingling), and tremors are the neurologic symptoms. Dermatologic symptoms are acne or greasy or dry hair. Fluid or electrolyte imbalances may cause bloating, weight gain, oliguria, or edema. Neurovegetative symptoms include insomnia, hypersomnia, anorexia, fatigue, lethargy, agitation, and libido change. Pain experienced by women with PMS can manifest as headaches, breast tenderness, and joint and muscle pain.

Therapeutic interventions for PMS are designed to achieve alleviation of symptoms, since PMS is not a disease. No single treatment has been effective. Women are taught to modify diet, increase exercise, alleviate stress, and change activities of daily living to reduce the intensity of symptoms, reduce fatigue, enhance the ability to sleep, and reduce stress.

Nursing Implications

Nursing assessment for menstrual conditions involves careful medical and gynecologic history taking, assessment of symptoms, and assessment for specific suspected conditions. The interview should begin with a discussion of medical and gynecologic history and lifestyle behaviors, which permit establishment of rapport before asking more personal questions specific to characteristics of the menstrual cycle. The physical assessment focuses on collection of data regarding the suspected menstrual cycle abnormality, including collection of laboratory test samples and specimens.

The nursing diagnosis can be formulated once the condition is identified. Nursing diagnoses are individualized for the client and her condition. Applicable nursing diagnoses may include:

- ✿ Pain related to a specific menstrual condition
- ✿ Fear related to the medical diagnosis
- ✿ Anxiety related to unknown outcomes
- ✿ Deficient knowledge related to limited experience (or information) regarding (specific menstrual cycle condition)

Planning includes specific actions the woman should complete to achieve the highest level of wellness. There is a greater guarantee of compliance when plans are designed in collaboration with the client. Collaborative planning increases the woman's self-esteem and supports her sense of control. Sample planning goals may include:

- ✿ Consume correct proportions of foods recommended in the food pyramid, as evidenced by a 24-hour diet recall.
- ✿ Exercise by walking 30 minutes each day.
- ✿ Take any prescriptive medications as written.
- ✿ Understand instructions regarding prescriptive medications.
- ✿ Return to the health care facility as scheduled for follow-up visits.
- ✿ Call the health care provider if adverse effects of prescriptive medications occur.
- ✿ Call the health care provider if symptoms do not improve.
- ✿ Have questions answered to satisfy need for information.
- ✿ Understand health promotion counseling.

Nursing interventions involve educating the woman regarding the specific condition and its consequences, therapeutic intervention choices and recommendations, specific procedures, prescription medications ordered, and outcomes; emotional support; reduction of fear, anxiety, stresses, and concerns; and relief of pain, if it accompanies the condition. Nursing actions are based on knowledge of the usual symptoms, consequences, outcomes, therapeutic interventions, counseling needs, and responses of women diagnosed with the condition.

Women diagnosed with endometriosis may experience loss of self-esteem because of being unable to fulfill various role expectations (e.g., work, family, social) during cyclical periods of intense pain. In addition, such women may be concerned about retaining childbearing capabilities. Educating women with endometriosis about coping strategies, such as guided imagery, relaxation and breathing exercises, massage therapy, and exercise can improve their sense of control and self-esteem (Corwin, 1997) and reduce intensity of symptoms.

Women with PMS can be counseled to keep a calendar to identify the timing of symptoms, so that they can plan to reduce other stresses during PMS, implement strategies to reduce severity of symptoms, and develop positive coping mechanisms. Some strategies that are beneficial can include dietary changes, such as reducing intake of salt, refined sugar, chocolate, and red meat; increasing intake of complex carbohydrates (fruit and vegetables); increasing aerobic exercise (walking, aero-

Case Study/Care Plan

CLIENT WITH ENDOMETRIOSIS

A 21-year-old undergraduate student comes to the health service with the chief complaint of painful menstrual periods that require bed rest at least 1 to 2 days each cycle. The client states, "When I have my period, it hurts so bad I have to go to bed for 1 or 2 days. I can't think straight or move. I have to finish school before I can have a baby, but I don't want to wait too late to have one." Following a physical examination, she is referred for laparoscopy. The diagnosis of endometriosis is established by the laparoscopic results. The client indicates the desire for childbearing in the future.

Assessment

Nulliparity, dyspareunia, dyschezia (painful or difficult bowel movements), and irregular bleeding; laparoscopy findings show extrauterine endometrial implants.

Nursing Diagnosis

Chronic pain, related to physiologic response, secondary to endometriosis.

Expected Outcomes Client will describe the physiologic source of pain.
 Client will identify days of cycle when pain begins and ends or is most intense.
 Client will discuss the impact of the disease process on her life.
 Client will discuss therapeutic options.

Planning

Assist client in outlining care measures that will be accommodated by her life-style.

Nursing Interventions

Rationales

- | | |
|---|--|
| 1. Explain endometriosis in simple terms. | 1. Simple terms are less likely to confuse the client. More complex terms can be added later based on her knowledge. |
| 2. Assist client in recording the intensity and timing of pain (e.g., continuous, cyclical, dull, sharp, mild, moderate, excruciating). | 2. Planning must be individualized to the client to be useful and must include the client in the process. |
| 3. Encourage discussion of the effects of the disease process on her life (class attendance, full time employment, daily activities). | 3. Determining the severity of the pain facilitates useful planning and improves compliance. |
| 4. Explain effects, side effects, indications, and outcomes of usual medications (NSAIDS, GnRH agonists, progestin, OCPs), and surgical interventions (surgical removal of implants, laser ablation of implants). | 4. The nurse is responsible for providing information for the client's decision making process. |

Evaluation

- Client understands that endometrial implants respond to ovarian hormones like uterine endometrium.
- Client knows to expect continuous heaviness and most intense pain during menses and for 2 days following menses.
- Client expresses frustration, nonacceptability of pain as excuse for class absence, timing of most intense pain on inconvenient days (e.g., on examination day), desire to delay childbearing until career established.
- Client states that her first treatment choice is continuous oral contraceptives and second choice is surgical removal of implants.

Client Education

Women's Health Problems

For the client to successfully achieve her outcome goals, she must know the following:

1. Expected, unexpected, and adverse effects of her medication.
2. Correct scheduling of medication according to her daily schedule.
3. Convenient reminders for taking medication (i.e., when she brushes her teeth or some other routine activity).
4. Rationale for change in lifestyle behaviors as they affect her treatment regimen.
5. Effects, outcomes, and physical sensations for all assessment procedures and treatment procedures.
6. Rationale for and recommended schedule for followup assessments.
7. Reinforcement that all medication must be taken, leftover medication must be discarded, primary provider must be informed when medication is discontinued before scheduled end of therapy, and medication must not be shared among family members or friends.

bics, jogging, bicycling, or swimming for 45 to 60 minutes three or four times per week); and restricting tobacco, caffeine, and alcohol intake (Ugarriza et al., 1998).

Women experiencing primary or secondary amenorrhea are at risk for premature development of osteoporosis at a time when they should be enhancing bone development for protection against postmenopausal osteoporosis. Thus, assessment of the lifestyle choices contributing to amenorrhea and subsequent counseling regarding calcium intake are essential nursing actions. Women can be taught creative ways of adding calcium to their diet while avoiding increased intake of fats. For example, skim milk, tofu, and reduced-fat or fat-free cheeses can be added to a variety of dishes, and nonfat powdered milk can be added to food (even to skim milk). Fat-free yogurt is an excellent source of calcium as well as a healthy snack.

All women can benefit from counseling regarding:

- Nutritional intake based on the food pyramid
- Exercise for cardiovascular health
- Osteoporosis prevention and maintenance of normal BMI

- Positive coping strategies for stressful situations
- Lifestyle choices to prevent disease and promote health
- Enhancement of knowledge regarding choices for therapeutic interventions

Nurses are in the ideal position to provide counseling each time a client seeks care.

Women may feel that the interventions and counseling are more personalized when the nurse takes the time to write a brief note that gives instructions specific to that woman's needs. She is more likely to read and follow those instructions.

BREAST CONDITIONS

Women's breast conditions are intimately connected with personal and social images of women. Thus, breast conditions have the potential to generate significant emotional and physiologic effects. Breast conditions tend to cause intense fear and anxiety. Some women even refuse to practice monthly breast self-examination (BSE) because of the fear of "finding something." Breast conditions can be categorized as benign or malignant. Table 10-3 lists data related to breast conditions and Table 10-4 lists therapeutic interventions.

Benign Breast Conditions

Benign breast conditions are noncancerous changes in the breast and account for the majority of breast conditions.

Client Education

Women's Health Promotion

For the client to achieve an optimal health outcome, she must be instructed regarding the following:

1. Breast self-examination (BSE), vulvar self-examination (VSE) and skin examination monthly.
2. The best time for her to perform BSE, based on her menstrual cycle status.
3. Rationale for performing BSE, VSE, and skin examinations (for skin cancer).
4. Convenient reminders to perform these examinations.
5. Strategies to protect skin from sun damage.
6. Rationale for avoiding tanning beds.

Table 10-3 Common Conditions of the Breast

Condition	Data		
	Subjective	Objective	Laboratory or Procedure
Benign Conditions			
Fibrocystic changes	Lump(s) Pain Tenderness Bilateral	Palpable, movable, rubbery, firm, smooth, distinct mass(es) Bilateral	Mammogram Ultrasound examination Fine-needle aspiration for biopsy Possibly excisional biopsy
Fibroadenoma	Lump(s) Nontender	Firm, smooth, discrete mass(es) Often bilateral	Mammogram Ultrasound examination Possibly excisional biopsy
Nipple discharge	Unilateral or bilateral discharge Pain (duct ectasia) Spontaneous discharge most often from one nipple only (intraductal) Papilloma (if multiple papillomas, discharge can be bilateral) Bilateral milky discharge (galactorrhea)	Multicolored or gray, thin-to-thick discharge (must be expressed) Nipple fixation Discharge from multiple ducts Serosanguinous discharge Usually one duct (unless multiple papillomas) Milky color From multiple ducts Possibly signs of hypothyroidism or pituitary enlargement	Cytologic examination of discharge Hemostix (blood detection strip) Cytologic examination of discharge Hemostix Surgical biopsy Visual field testing Pituitary MRI Hemostix
Malignant Conditions			
Localized cancer	Lump(s) Possibly unilateral nipple discharge	Palpable, nondiscrete, movable or fixed mass(es) Abnormal results on mammogram Nipple discharge that is bloody, serous, serosanguinous, or watery	Mammogram Ultrasound examination Biopsy Hemostix Cytologic examination of discharge
Invasive cancer	Lump(s) Possible nipple discharge May also include: nipple skin change, such as itching, burning, "weeping," bleeding ulceration (Paget's disease)	Hard, nondiscrete, fixed mass(es) Dimpling Nipple flattening or deviation (unilateral) Nipple discharge Peau d'orange (Figure 10-2) appearance Nipple skin changes Venous prominence (unilateral) Swelling (unilateral)	Mammogram Ultrasound examination Biopsy with cytologic examination Hemostix and cytology (for any discharge) Mammogram Ultrasound examination Biopsy Cytologic examination of discharge Hemostix
Metastatic cancer	Lump(s) Skin changes Arthralgia Bone pain Shortness of breath Possible spontaneous nipple discharge	Masses of varying size Hard, fixed lymph nodes Dimpling the skin Skin erythema Bloody, serous, serosanguinous, or watery discharge from single duct	Biopsy Bone scan Chest x-ray film Hemostix Cytologic studies

Figure 10-2 Peau d'orange
(Courtesy of Dr. S. Eva Singletary, University of Texas, M.D. Anderson Cancer Center)

Table 10-4 Management of Conditions of the Breast

Condition	Usual Therapeutic Interventions
Benign Conditions	
Fibrocystic changes	Consider avoiding methylxanthine (caffeine) Avoid tobacco Wear well-fitting bra Diuretic agent for premenstrual symptoms Clinical breast examination annually (every 6 months if there is a familial risk for breast cancer) Baseline mammogram at age 35, every 1 to 2 years from age 40 to age 50, annually after age 50
Fibroadenoma	Excisional biopsy for solid lumps not clearly identified as benign by other methods Follow-up clinical breast examinations and mammograms (see fibrocystic changes)
Nipple discharge	Evaluation for possible malignancy Follow-up clinical breast examinations and mammograms (see fibrocystic changes) Bromocriptine (Parlodel) for galactorrhea Surgery (depending on cause)
Malignant Conditions	
Localized cancer	Radiation Lumpectomy (breast-conserving surgery)
Invasive cancer	Surgery Combination therapy: chemotherapy, hormone therapy, radiotherapy
Metastatic cancer	Combination therapy: chemotherapy, hormone therapy, radiotherapy Possibly autologous marrow transplant Consider thoracentesis and paracentesis, if shortness of breath is a symptom

For the most part, benign breast conditions are related to physiologic changes and include fibrocystic changes, fibroadenoma, and nipple discharge. Evaluation and characteristics of breast masses are outlined in Tables 10-5 and 10-6.

Fibrocystic Changes

Fibrocystic changes are age-related changes most commonly involving cyst formation and thickening of breast tissue: the result is “lumpy” breasts. The “lumps” may be tender or painful. The tenderness may be present throughout the cycle or episodic. Women who report fibrocystic changes often experience cyclic, bilateral nodularity, usually in the upper outer quadrant of the breast or in the axillia, and increased tenderness or pain before the onset of menses (Baron & Walsh, 1995). The nodularity feels like fibrous thickening or lumpiness without a clear outline and may disappear after the menstrual period. The changes are thought to be caused by estrogen and progestin changes, imbalances, or fluctuations and occur in premenopausal women or chronically in women aged 35 to 50. When the changes result from atypical hyperplasia, the woman’s risk for development of breast cancer increases (White, Griffith, Nenstiel, & Dyess, 1996). There does not seem to be an association between fibrocystic nodularity and in-

creased risk of breast cancer. Therapeutic interventions are limited to differentiating between fibrocystic changes and breast cancer. Screening interventions include clinical breast examination, mammography, and ultrasonography. Contents of fluid-filled cysts are aspirated and evaluated to determine if neoplastic cells are present. Aspiration of the cyst often eliminates the cyst, but the cyst may reform.

Fibroadenoma

Fibroadenoma is a painless solid breast mass or tumor, which has well-defined borders, is mobile, often feels oval-shaped, frequently feels “rubbery,” tends to reach a size of 1 of 3 centimeters, and does not change in response to cycling hormone levels (Brucker & Scharbo-DeHaan, 1991). The woman may report a discrete, mobile, seed-sized, or marble-sized “lump” (with no nipple discharge) in one or both breasts. The cause of fibroadenoma is an overgrowth of breast tissue, which occurs most often between the ages of 20 and 40; however, it may not be discovered until the perimenopausal or postmenopausal period (Brucker & Scharbo-DeHaan, 1991). Therapeutic interventions are focused on establishing the benign diagnosis. Screening techniques include mammogram and ultrasound. The mass may be evaluated using fine-needle aspiration biopsy or excision biopsy.

Table 10-5 Evaluation of Breast Mass Characteristics

If a breast mass is noted during palpation, the following information should be obtained regarding the mass. Always note if one or both breasts are involved.

LOCATION

Identify the quadrant involved or visualize the breast with the face of a clock superimposed on it. The nipple represents the center of the clock. Note where the mass lies in relation to the nipple, e.g., 3 cm from the nipple in the 3 o'clock position.

SIZE

Determine size in centimeters in all three planes (height, width, and depth).

SHAPE

Qualify the mass as round, ovoid, matted, or irregular.

NUMBER

Note if lesions are singular or multiple. Note if one or both breasts are involved.

CONSISTENCY

Qualify the mass as firm, hard, soft, fluid, or cystic.

DEFINITION

Note if the mass borders are discrete or irregular.

MOBILITY

Determine if the mass is fixed or freely mobile in relation to the chest wall.

TENDERNESS

Note if palpation elicits pain.

ERYTHEMA

Note any redness over involved area (Figure 10-3).

DIMPLING OR RETRACTION

Observe for dimpling (Figure 10-4) or retraction (Figure 10-5) as the client raises arms overhead and presses her hands into her hips.

Figure 10-3 Erythema with Abnormal Vascular Pattern Secondary to Inflammatory Breast Cancer (Courtesy of Dr. S. Eva Singletary, University of Texas, M.D. Anderson Cancer Center)

Figure 10-4 Dimpling of Left Breast Tissue (Courtesy of Dr. S. Eva Singletary, University of Texas, M.D. Anderson Cancer Center)

Figure 10-5 Nipple Retraction on Left Breast (Courtesy of Steven M. Lynch, M.D.)

Table 10-6 Characteristics of Common Breast Masses

	Gross Cyst	Fibroadenoma	Carcinoma
Age	30-60; diminishes after menopause	puberty to menopause	most common after 50 years
Shape	round	round, lobular, or ovoid	irregular, stellate, or crab-like
Consistency	soft to firm	usually firm	firm to hard
Discreteness	well defined	well defined	not clearly defined
Number	single or grouped	most often single	usually single
Mobility	mobile	very mobile	may be mobile or fixed to skin, underlying tissue or chest wall
Tenderness	tender	nontender	usually nontender
Erythema	no erythema	no erythema	may be present
Retraction/dimpling	not present	not present	often present

Nipple Discharge

Nipple discharge is fluid produced by and accumulating within a secretory unit of the breast and exiting through the nipple (Arnold & Neiheisel, 1997). The woman may notice nipple discharge on her bra or night clothing. Nipple discharge can be categorized as lactation, physiologic, pathologic, or false discharge.

Lactation Discharge

Lactation discharge is any secretory discharge occurring as a physiologic response to the normal hormonal stimulation of pregnancy, postpartum, or the period following weaning of the infant (Arnold & Neiheisel, 1997). The discharge is usually thin and white and discharged from both breasts. With continued stimulation, the woman may continue to experience lactation discharge for several weeks to years after weaning the infant. The lactation discharge is

not harmful. Therapeutic interventions involve education regarding the cause of the discharge and the recommendation to limit or avoid stimulation of the breasts.

Physiologic Discharge

Physiologic discharge is the result of physiologic conditions affecting all breast tissue equally (i.e., bilaterally), involving secretory tissue in each breast, and resulting in milky-white or multicolored (yellow, green, or gray) fluid. Usually milky, nonlactation nipple discharge is referred to as galactorrhea. Occurrences or practices that are characteristic of galactorrhea include hyperprolactinemia (an elevated serum prolactin level); menarche or menopause; intake of exogenous estrogens or progestins, dopamine antagonist medications, or opiates; sexual or mechanical nipple stimulation; and traumatic anterior thoracic nerve stimulation. Thus, the discharge is not part of a disease process. Therapeutic interventions include reassurance and counseling.

Research Highlight

The Breast Cancer Prevention Trial: Evaluating Tamoxifen's Efficacy in Preventing Breast Cancer

Purpose

To review literature regarding tamoxifen and breast cancer with a focus on the Breast Cancer Prevention Trial (BCPT).

Methods

A sample of 16,000 women who were at least 35 years of age and were considered to be at risk for breast cancer were recruited to participate in a randomized, prospective, double-blind, placebo-controlled clinical investigation. Women who were pregnant, who had a history of breast cancer or a history of clinical depression, were taking oral contraceptives, ERT, HRT, or Warfarin (Coumadin) were excluded from the investigation. Women in the experimental group took 20 mg of tamoxifen once a day, and women in the control group took a placebo once a day. Each woman is seen for follow-up visits, initially at 3 months and then every 6 months for at least 7 years. The treatment continues for at least 5 years.

Findings

Preliminary findings after 4 years of study were reported McKeon (1998) showing 45% fewer diagnoses of invasive breast cancer in subjects who were randomly assigned to the experimental group (daily intake of 20 mg of tamoxifen) than in the subjects randomly assigned to the control (placebo) group. There were 85 women diagnosed with invasive cancer in the experimental group versus 154 in the control group. In addition, only 31 women in the experimental group were diagnosed with noninvasive cancer, while 59 were diagnosed with noninvasive cancer in the control group. Only 47 bone fractures occurred in women in the experimental group compared with 71 in the control group.

Nursing Implications

The findings can be used to gain knowledge regarding the effectiveness of tamoxifen in preventing breast cancer in women at risk. Additional studies should be conducted to provide information regarding prevention for women who are not at risk for breast cancer.

Note: McKeon, V.A. (1997). The Breast Cancer Prevention Trial: Evaluating tamoxifen's efficacy in preventing breast cancer, *Journal of Obstetric, Gynecologic, and Neonatal Nursing*, 26(1), 79–90.

Pathologic Discharge

Pathologic discharge is the result of pathologic conditions affecting the hypothalamic-pituitary axis, prolactin levels, or breast diseases, and, thus, may affect both breasts (Arnold & Neiheisel, 1997). Pathologic conditions that cause hyperprolactinemia include tumor of the pituitary gland, Addison's disease, and hypothyroidism. The nipple discharge associated with such conditions is thin and milky (Arnold & Neiheisel). Most of the causes of pathologic galactorrhea are benign and include intraductal papilloma (benign epithelial neoplasm), duct ectasia (inflammatory response to stagnation of breast duct secre-

tions), and breast infections. Nipple discharge caused by intraductal papillomas tends to be serous or bloody and may be secreted from only one breast, unless one or more intraductal papillomas are present in each breast. The color of the nipple discharge caused by ductal ectasia can be bloody, brown, cream-colored, gray, green, purulent, or white and can vary from thin to extremely thick. Breast infections usually result in purulent nipple discharge. Therapeutic interventions involve individualization of treatment to the cause of the discharge. Lactogenic medications can be eliminated or the dose reduced, antibiotics are administered for infectious processes, exercise habits

Nursing Alert

EXAMINING NIPPLE DISCHARGE

If a client is found to have abnormal nipple discharge:

1. Don gloves before proceeding with the assessment.
2. Note the following: color, consistency, amount of discharge, unilateral or bilateral, spontaneous, or provoked.
3. With a sterile, cotton-tipped swab, obtain a sample of the discharge so that a culture and sensitivity testing and Gram stain may be done.
4. Follow your institution's guidelines for sample preparation.

causing the discharge can be altered, and referral for biopsy for suspected malignant discharge establishes the cause of the discharge (Arnold & Neiheisel, 1997).

Of greatest concern is diagnosis of the pathologic discharge accompanying breast cancer. Fortunately, the majority of pathologic nipple discharges are caused by benign pathologic processes, but occasionally, pathologic nipple discharge is caused by breast cancer (Arnold & Neiheisel, 1997). In such cases, the discharge is most often spontaneous, associated with a breast mass, and a “classically unilateral, single-duct discharge” (Arnold & Neiheisel, 1997, p. 109). Usually, the discharge associated with breast cancer is bloody, serous, and watery: the bloody discharge ranges from bright red to black and the serous discharge is thin, sticky, and yellow to light orange (Arnold & Neiheisel, 1997).

False Discharge

False discharge refers to fluid appearing on the nipple or areolar surface that is not secreted by breast tissue (Arnold & Neiheisel, 1997). Conditions associated with false nipple discharge include any dermatologic disease (eczema, bacterial or viral dermatitis), nipple trauma, or Paget's disease (inflammatory, malignant neoplasm). The fluid appearing on the nipple or areola may be bloody, clear, colored, purulent, serous, or viscous. Management includes treatment of the disease causing the discharge (e.g., antibiotics, topical dermatologic medication).

Malignant Breast Conditions

Malignant breast conditions are life-threatening and life-altering, both emotionally and physically. The cancer most

Critical Thinking

Unaffordable Health Care

How do you feel about caring for a woman who comes into your facility for a well-woman “checkup” only “when she can get off work” and “when she has the money to pay for it,” even though she is at risk for breast cancer or cervical cancer? What if she can come only every 5 or 6 years instead of annually? What if she makes too much money to qualify for Medicare and works for a small business that does not provide health care for employees?

frightening to many women is breast cancer. In 2000, Johnson predicted, “An estimated 175,000 new cases of breast cancer among women will be diagnosed (in 2000), and 43,000 women will die of this disease”. The primary risks for development of breast cancer are female gender and increasing age (Thomas & Greirzu, 2000). Risk factors have been categorized as major (age and genetic factors), minor (reproductive status and lifestyle), and suspected, based on research studies (White, Griffith, Nienstiel, Dyess, 1996).

Hereditary breast cancer tends to occur before age 45, accounts for only 5% to 10% of all breast cancer development, and is thought to be related to a variety of lifestyle, environmental, and genetic factors (McCance & Jorde, 1998). Thus, most women who have breast cancer do not have familial risk factors. All people (male and female) the breast cancer genes, *BRCA-1* and *BRCA-2*. Familial premenopausal breast cancer risk is increased when a woman inherits mutations of the genes. Inheritance of “normal” *BRCA-1* and *BRCA-2* genes means the woman has a reduced risk for familial breast cancer and the same risk for breast cancer caused by other factors as other women. Some mutations of the *BRCA-1* and *BRCA-2* genes result in an increased risk for breast cancer, and other mutations increase the risk for ovarian cancer (McCance & Jorde). Women can inherit mutations of *BRCA-1* and *BRCA-2* genes from either parent. A man who inherits a mutation of the *BRCA-2* gene has a higher risk for development of breast cancer than other men in the general population, and a man who inherits mutations in the *BRCA-1* gene has an increased risk for prostate cancer (McCance & Jorde, 1998).

Malignant breast conditions arise from genetic (*BRCA-1* and *BRCA-2*) mutations or spontaneous abnormal epithelial cell growth and most often occur in ductal or lobular epithelial cells. In the presence of abnormal epithelial cell growth (atypical hyperplasia), the woman is at risk for development of ductal or lobular carcinoma. Malignant breast

Critical Thinking

Oral Contraceptives and Cancer Risk

There have been recent studies indicating a correlation between estrogen-based oral contraceptive use and breast cancer, with a two- to fourfold increased risk noted for some populations. During the breast assessment, the client asks you about the association between oral contraceptives and increased breast cancer risk because she is considering switching from oral contraceptives to another method of birth control. How would you respond?

conditions can be categorized as localized (ductal or lobular), invasive (ductal or lobular), or metastatic.

Localized Breast Cancer

Localized breast cancer has not metastasized, is usually less than 2 centimeters in size, is considered noninvasive beyond the breast, and has potential for the best client outcome. The lower the stage of breast cancer at diagnosis, the better the outcome. According to the tumor, nodal involvement, and metastasis (TNM) method of staging cancer, localized ductal or lobular breast cancer meets the criteria for TNM stage 0 or stage 1. Stage 0 criteria include cancer *in situ*, confined to the milk duct or the lobe, and with no occurrence of metastases and stage 1 criteria include size less than 2 centimeters, infiltration to surrounding breast tissue, and no lymph node involvement (Thomas & Greifzu, 2000).

Management of localized breast cancer, where the cancer is confined to one area, can include lumpectomy (to remove the tumor and a small amount of surrounding tissue) and adjunctive radiation therapy. Adjacent lymph nodes may be removed. The woman is not a candidate for lumpectomy if she has more than one tumor, tumors in more than one quadrant of the breast, or diffuse calcifications; has had previous radiation therapy to the area; has large breasts; has a tumor located under the nipple; or has small breasts with a large tumor mass-to-breast mass ratio (Thomas & Greifzu, 2000).

Invasive Breast Cancer

Invasive breast cancer has extended beyond the local epithelium and has the potential to spread (metastasize) from the breast to other parts of the body. Invasive breast cancer meets TNM criteria for stages II and III. TNM stage II criteria are size between 2 and 5 centimeters and tumor

Nursing Alert

RISK FACTORS FOR BREAST CANCER

Age and Genetic Risk Factors

- Over age (50)
- Female
- Personal history of breast cancer
- Personal history of ovarian or endometrial cancer
- Personal history of breast hyperplasia
- History of two or more first-degree relatives (mother, sister, daughter) with breast cancer
- History of a first-degree relative with bilateral cancer before age 50

Reproductive Status and Lifestyle Behavior Risk Factors

- Delayed childbirth (age 30 or older first completed pregnancy)
- Early menarche (age 11 or younger) and late natural menopause (age 55 or older)
- Nulliparity
- Exposure to ionizing radiation (before age 40)

Factors Needing More Research to Establish Risk

- Obesity (postmenopausal)
- Magnetic field exposure
- Environmental exposure to pesticides
- Excessive alcohol intake (nine or more drinks per week)
- Smoking
- High-fat diet

cells that have spread to adjacent axillary lymph nodes; stage 3A criteria include size less than 5 centimeters and fixed (attached to each other or to surrounding tissue) adjacent axillary lymph nodes; and stage 3B criteria include tumor of any size; spread to the skin, chest wall, or mammary lymph nodes; and no metastases to distant organs (Thomas & Greifzu, 2000).

Management depends on the size of the tumor, involvement of lymph nodes, and type of tumor cells (positive or negative estrogen receptors). The usual treatment includes mastectomy, radiation, chemotherapy, or a combination of these (Thomas & Greifzu, 2000). Adjuvant hormone therapy may be added to the treatment plan.

Case Study/Care Plan

CLIENT WITH BREAST CANCER

A 51-year-old, single, mildly retarded woman visits a community women's health clinic with a chief complaint of a lump in her left breast. Client states, "I am afraid of cancer. I am afraid I will die." The woman wrings her hands, eyes dart back and forth and she looks toward her sister as if for help.

Physical examination reveals a 3-cm solid mass with an irregular, dimpled surface in the inner quadrant of the left breast in the 10 o'clock position. Mammography indicates a potentially malignant mass, and she is referred for biopsy. Biopsy reveals the mass is malignant, and a mastectomy is scheduled.

Assessment

Nulliparity, sporadic practice of BSE, and sporadic use of the health care system.

Mammography results indicate malignant breast cancer.

Biopsy results document diagnosis of malignant breast neoplasm.

Nursing Diagnosis

Fear related to breast cancer diagnosis.

Expected Outcomes Client will:

1. Identify emotional feelings related to diagnosis of breast cancer.
2. Relate understanding of usual medical and surgical treatments for breast cancer.
3. Discuss perception of effect of mastectomy, radiotherapy, and chemotherapy on her life.
4. List coping strategies for incisional pain, radiation discomfort, and chemotherapy side effects.

Planning

The nurse must ensure that all information is presented at the client's level of understanding, with involvement of family and support persons as needed or appropriate.

(continued)

Metastatic Breast Cancer

Metastatic breast cancer is breast cancer that has spread to other parts of the body. It meets the criterion for TNM stage 4, which is metastasized tumors of any size (Thomas & Greifzu, 2000). Once metastases occur, there is no cure and life expectancy is short. Thus, therapeutic intervention is primarily futile.

Nursing Implications

Nursing assessment for breast conditions involves careful medical and gynecologic history taking, with special emphasis on breast history, including results of and frequency of BSE (e.g., several times per day versus once per month), breast trauma, breast stimulation, and assessment for symptoms of specifically suspected breast conditions. Physical assessment focuses on the collection of data regarding the suspected breast condition, including necessary laboratory test and collection of biopsy specimens.

Nursing diagnoses may include the following:

- Pain related to screening, diagnostic procedures, surgical procedures
- Fear related to medical condition and selected therapeutic intervention
- Grief, related to body image change or prognosis
- Deficient knowledge related to specific breast condition, screening, diagnosis, or intervention procedures

Nursing plans include specific actions that the client completes to achieve the highest level of wellness possible or to achieve peace regarding prognosis. Sample goals include the following:

- Consume food portions according to the daily recommendations in the food pyramid or as required on the basis of medical diagnosis from 24-hour diet recall; intention to consume suggested foods and intention to modify detrimental food intake.

Nursing Interventions**Rationales**

- | | |
|---|--|
| <ol style="list-style-type: none"> 1. Discuss client's emotional feelings regarding breast cancer diagnosis.
Facilitate client's use of support system.
Refer client to local breast cancer support group. 2. Explain the anticipated level of discomfort, physical sensations, anticipatory grieving, procedures, and outcome for mastectomy (loss of breast, removal of lymph nodes), radiotherapy (fatigue, itching or peeling skin). 3. Discuss client's perception of the effect of mastectomy, radiotherapy, and chemotherapy on her life (e.g., job, family, friends). 4. Describe potential coping strategies for incisional pain (pain medication, relaxation techniques), radiation effects (sunscreen, protective cotton clothing to decrease additional skin irritation), and chemotherapy effects (antiemetic medication, cap to decrease hair loss, balanced nutrition to decrease fatigue). Provide client with choices for coping strategies. | <ol style="list-style-type: none"> 1. Acknowledging client's feelings is supportive of her emotional response and demonstrates caring and a concerned attitude.
Diagnosis of breast cancer is a shock, and she will need a support system to help her cope. The local breast cancer support group has volunteers who have experienced breast cancer and support clients through all stages of the grieving, treatment, and recovery phases. 2. Information facilitates understanding and acceptance of condition; anticipatory guidance reduces fear. 3. Women's perception affects planning and compliance. 4. Anticipatory guidance decreases fear and increases compliance. Providing woman with choices increases sense of control and enhances self-esteem. |
|---|--|

Evaluation

- Client states that she can expect to have her breast and lymph nodes under her arm removed.
- Client states that she will need to come for radiation treatments after surgery each day for 5 to 6 weeks.
- Client states that she may have skin irritation and will have chemotherapy, possibly for 3 to 8 months, depending on the schedule chosen by her oncologist.
- Client states that she may have some nausea, vomiting, fatigue, and hair loss, and she will be given medication to control her nausea.
- Client states that she will not be able to work as a dishwasher at the café while she is recovering and undergoing radiation and chemotherapy.
- Client states that she will move in with her sister while she is recovering and taking radiation and chemotherapy treatments.
- Client states that she can take medication for pain and nausea.

- Complete daily exercise (walking 30 minutes per day, any prescribed exercise required for restoration of function after surgery).
- Understand instructions regarding prescriptive medications.
- Return to the health care facility for scheduled follow-up visits.

- Call the health care provider regarding adverse effects of prescriptive medications as instructed.
- Call health care provider regarding any adverse symptoms of breast condition as instructed.
- Have all questions answered to her satisfaction.
- Understand health promotion counseling.

THE CLIENT AFTER MASTECTOMY

There are four types of **mastectomy** (excision of the breast). In a simple mastectomy, only the breast is removed. In a modified radical procedure, the breast and lymph nodes from the axilla are removed (Figure 10-6). In a radical mastectomy, the breast, lymph nodes from the axilla, and pectoral muscles are removed (Figure 10-7). This procedure is rarely performed. In a subcutaneous mastectomy, the skin and nipple are left intact, but the underlying breast tissue and lymph nodes are removed. The client who has undergone a simple, modified radical, or radical mastectomy has had the breast amputated from the chest wall.

Reconstruction techniques include synthetic implants, tissue expansion techniques (in which a temporary device is placed in a subpectoralis-subserratus position between the anterior chest wall and skin and is then inflated with saline over a period of weeks), and latissimus dorsi myocutaneous flap breast reconstruction. A myocutaneous flap reconstruction involves transferring skin from the back or the abdomen to the anterior chest wall.

Assessment of the client who has had a mastectomy is guided by the type of mastectomy and the presence or absence of reconstructive surgery. Follow the standard assessment procedures and modify your technique to suit the amount of breast tissue and the presence, if any, of a nipple. Always begin the assessment on the unaffected breast. Mastectomy clients should continue to perform monthly breast self-examinations to determine if masses have returned to the excised area. Annual clinical evaluations and mammograms are also recommended.

Nursing interventions involve educating the woman regarding the diagnosis, consequences, interventions, specific procedures; her choices; counseling regarding expected outcomes; emotional support; reduction of fears, anxiety, stresses, and concerns; advocacy; and relief of current or future pain.

Women who seek care for breast conditions are demonstrating concern and are usually ready to learn about protecting the health of their breasts. Breast and general health promotion and disease prevention strategies include recommendations for regular exercise and for diet from the food pyramid to maintain normal BMI; avoiding or stopping smoking; performing self-assessments; and scheduling provider assessments and screenings as necessary. The nurse can use such interventional moments to assess the woman's practice of BSE, including the frequency, technique, and related concerns. Most women are concerned about being able to "tell the difference" between cancer and "normal" changes. Thus, the nurse needs to assure the woman that the purpose of the monthly BSE is not to determine whether or not she has breast cancer but to determine whether or not she feels anything different in her breast than she felt in the previous monthly BSE. The key is for her to identify anything she has not felt before and make an appointment with her provider for a clinical breast examination and screening. Caution her that most of the "differences" noted on BSE and clinical breast examinations are normal physiologic changes, and the reason for practicing BSE is to notice any problematic changes early. Diagnosis of breast cancer is facilitated best by the combination of attention to changes during the BSE, annual clinical breast examinations, followup screening (i.e., mammogram, ultrasound), and diagnostic procedures.

To ensure the woman can differentiate normal changes related to hormonal fluctuations, she should perform her BSE on the same day of her menstrual cycle each month, about a week after her menses. To help her remember, she can perform BSE on the day after her last day of menstrual flow.

Figure 10-6 Modified Radical Mastectomy. (Courtesy of Steven M. Lynch, M.D.)

Figure 10-7 Radical Mastectomy. (Courtesy of Steven M. Lynch, M.D.)

Women who seek care for breast conditions tend to be frightened and anxious. They are fearful of both the diagnosis and treatment. Thus, initial nursing actions are focused on reducing fear and anxiety. Acknowledgement of concerns and a careful history can begin to reduce the fear and anxiety.

Once the medical diagnosis is made, the nurse assesses the woman's understanding and the affect of the diagnosis on her life and support system. Nursing actions must include clarification, explanation, and education.

If the woman requires surgery, she needs to be educated regarding pain reduction interventions, anticipated appearance of the surgical wound, wound care, nutrition, postoperative exercises, recovery, and health promotion. She may need to be taught when to take medication, expected side effects of the medication, and adverse effects. If therapy involves radiation, she needs instruction on skin appearance and sensation after radiation therapy, how to reduce trauma to the site (i.e., wearing loose-fitting cotton clothing, avoiding additional trauma to the area, such as shaving, sun exposure), use of mild soap with lukewarm water, and avoidance of creams or lotions containing alcohol or oil (Thomas & Greifzu, 2000).

PELVIC CONDITIONS

Pelvic conditions can be categorized as infectious, benign, or malignant conditions. Infectious conditions include vaginal, cervical, and pelvic inflammatory infections. Benign conditions may affect the cervix, uterus, and ovaries. Malignant conditions can be cervical, uterine, or ovarian. Table 10-7 lists criteria for pelvic conditions, and Table 10-8 lists usual therapeutic interventions for pelvic conditions.

Infectious Conditions

Infectious conditions of the pelvis include vaginal infections, cervical infections, and PID. Infections may be caused by bacterial, viral, fungal, or protozoal organisms.

Vaginal and Cervical Infection

A **vaginal infection** is inflammation of the vagina, and a **cervical infection** is inflammation of the cervix. Many of the infectious organisms are sexually transmitted (chlamydia, gonorrhea, trichomoniasis, herpes simplex infection, human papilloma virus infection), while others are overgrowth of organisms normally or frequently found in the vagina (yeast, Döderlein's bacillus, beta-hemolytic streptococci). Postmenopausal women who are not receiving ERT or hormonal replacement therapy may experience atrophic vaginitis caused by the response of the vaginal environment to decreased estrogen levels. Bacterial vaginosis (inflammation caused by an overgrowth of anaerobic bac-

teria) accounts for 40% to 50% of vaginitis, vulvovaginal candidiasis (yeast infection) accounts for 20% to 25%, and vaginal trichomoniasis (a sexually transmitted protozoal infection) accounts for 15% to 20% (Cullins, Dominguez, Guberski, Secor, & Wysocki, 1999).

Women who come for treatment of vaginal infection typically relate symptoms of vaginal discharge (amount, odor, and color); pruritus; local irritation; dysuria; and dyspareunia. If the woman has bacterial vaginosis, she often complains of a "fishy" odor of the vaginal discharge, especially after sexual intercourse. If the vaginitis is caused by *Candida* species, pruritus, dysuria, and vulvovaginal irritation tend to be the primary complaints. The woman who has trichomoniasis usually complains of copious yellowish or greenish discharge with a foul odor, pruritus, vulvovaginal irritation, and dysuria. Table 10-9 contains a description of vaginal discharges. Women should be taught how to perform a self-inspection of the external genitalia (Figure 10-8).

Based on the Centers for Disease Control and Prevention (CDC) recommendations, therapeutic intervention for bacterial vaginosis is intravaginal metronidazole or clindamycin cream (Cullins, et al., 1999). CDC recommendations for vulvovaginal candidiasis are intravaginal terconazole cream or suppositories. Oral metronidazole is the CDC recommendation for treatment of trichomoniasis (Cullins et al., 1999). Since trichomoniasis is considered a sexually transmitted disease (STD), the woman's partner must be treated simultaneously and she must avoid sexual intercourse until the disease is cured.

Pelvic Inflammatory Disease

PID is inflammation of the uterus, fallopian tubes, or ovaries, or a combination, caused by ascent of vaginal flora or bacteria. At least 1 million women, 70% of whom are younger than age 25, are estimated to have PID annually (Mott, 1998). The majority of PID infections are caused by STD organisms, especially chlamydia and gonorrhea, ascending from the vagina. High-risk women are age 25 or younger, single or divorced, have multiple sex partners without barrier protection, who douche, and use intrauterine devices. PID is often undiagnosed and the treatment is delayed, which increases the risk for infertility, ectopic pregnancy, and chronic pelvic pain. The CDC criteria for diagnosis of PID are at least three symptoms of lower abdominal tenderness, adnexal tenderness, cervical motion tenderness, an oral body temperature of 38.3°C (101°F), abnormal vaginal or cervical discharge, elevated erythrocyte sedimentation rate, elevated C-reactive protein levels, and laboratory evidence of chlamydial or gonorrheal infection (Mott, 1998). Therapeutic intervention includes cefoxitin and doxycycline or clindamycin and gentamycin, if the woman is hospitalized, and cefoxitin or ceftriaxone and doxycycline or ofloxacin and metronidazole, for outpatient treatment.

Table 10-7 Pelvic Conditions

Condition	Data		
	Subjective	Objective	Laboratory or Procedure
Infections			
Cervicitis	Spotting (especially after sexual intercourse) Increase in vaginal discharge May be asymptomatic	Yellowish-white discharge Red, edematous, friable cervix Cervical motion Tenderness Grayish-green discharge, with cervix having strawberry-like appearance (trichomoniasis)	Wet mount for WBCs count, trichomonads Cultures for <i>C. trachomatis</i> , <i>N. gonorrhoeae</i> HSV Numerous white blood cells
Bacterial vulvovaginitis	Increased vaginal discharge Odor after sexual intercourse	Homogenous gray-white discharge Musty or fishy odor	pH of discharge using pH sensitive strips Wet mount (clue cells) Positive amine test
Monilial vulvovaginitis	Itching, burning Discharge Dyspareunia	Thick, curd-like vaginal discharge Vulvar or vaginal erythema Edematous cervix Possibly friable cervix	Wet mount (budding hyphae, leukocytes)
Atrophic vulvovaginitis	Vaginal dryness Vaginal irritation and burning Itching Postcoital spotting	Vulvar and vaginal atrophy Pale, thin, friable vaginal mucosa Sparse pubic hair	No lab test is reliable. A maturation index can be done with the pap smear to provide some data
Pelvic inflammatory disease	Lower abdominal pain or tenderness Chills and fever Nausea and vomiting Increased vaginal discharge Irregular bleeding Malaise Dysmenorrhea Dyspareunia Postcoital spotting Dysuria	Lower abdominal rebound tenderness Cervical motion tenderness Hypoactive bowel sounds Adenexal fullness, tenderness Mucopurulent cervical discharge Cervical friability Body temperature of over 100.4°F	C-reactive protein Erythrocyte sedimentation rate Positive Gonorrhea and chlamydia cultures Ultrasound for fluid in cul-de-sac or pelvic mass or abscess Wet mount
Benign Conditions			
Pelvic relaxation			
Uterine prolapse	Backache Pelvic pressure or heaviness	Cervix descended into vagina or through introitus	Bimanual pelvic exam
Cystocele	Urinary frequency, urgency, incontinence Dyspareunia Vaginal pressure Urinary tract infections Incomplete bladder emptying	Bulging of anterior vaginal wall	Postvoid urinary retention Postvoid analysis of urinary retention determines the severity of the condition
Rectocele	Difficult defecation Vaginal pressure Rectal fullness	Bulging of posterior vaginal wall	Rectal exam reveals the severity of rectocele
Enterocoele	Vaginal pressure Abdominal pain Loose stools	Bulging of cul-de-sac or posterior vaginal wall	

(continued)

Table 10-7 Pelvic Conditions (continued)

Condition	Data		
	Subjective	Objective	Laboratory or Procedure
Functional Conditions			
Polycystic ovary syndrome	Often asymptomatic		
	Amenorrhea or oligomenorrhea		
	Dysfunctional uterine bleeding	Obesity	Elevated LH Level
	Infertility	Hirsutism	Ultrasound examination of ovarian size and follicles
	Irregular menstrual cycles	Acne	Endometrial biopsy for hyperplasia
		Enlarged ovaries	Hyperinsulinemia
		Enlarged clitoris	Serum glucose
Voice changes		Serum Prolactin level	
Premature ovarian failure	Amenorrhea	Alopecia	Testosterone level
	Hot flashes		↑FSH and LH levels
	Night sweats	Vaginal atrophy	↓Thyroid function tests
	Vaginal dryness	Vulvar atrophy	↑Prolactin level
	Dyspareunia	Uterine atrophy	
Structural Conditions			
Fibroid Tumors	Most are asymptomatic		
	Possible pressure discomfort		
	Possible hypermenorrhea	Abnormal results on pelvic examination	Ultrasound examination
	Pain if tumor is twisted	Anemia from hypermenorrhea	Pelvic magnetic resonance imaging (MRI)
	Pelvic pressure	Palpation of painless, mobile, smooth uterine mass or nodule	These tests identify the location and size of fibroids
	Deep pelvic pain		
	Dyspareunia		
Malignant Conditions			
Cervical cancer	Blood-tinged, watery vaginal discharge		
	Abnormal vaginal bleeding	Enlarged cervix	Pap smear
	Postcoital spotting or bleeding	Foul smelling discharge	Colposcopy, cervical, and endocervical sampling for cytology
	Dyspareunia	Anemia	
	Abdominal, back, or flank pain	Leg edema	
Endometrial cancer	Metrorrhagia (premenopausal)		
	Pelvic pain or bloating (advanced disease)	Uterus may be an abnormal palpation	Endometrial biopsy for cytology
	Postmenopausal bleeding		
Ovarian cancer	Changes in bowel or bladder function		
	Abdominal fullness, discomfort	Ascites	Blood level of CA-125
	Dyspareunia	Possible pelvic mass	Vaginal ultrasound
	Irregular bleeding	Weight loss	Ba Enema
	Fatigue		MRI or CT scan with contrast
	Back pain		Laparotomy
	Shortness of breath		
Pelvic pressure			

Nursing Implications

Nursing assessment for infections includes assessment for risk, symptoms, medical history, gynecologic history, and lifestyle behaviors. Physical assessment focuses on data and specimen collection to aid diagnosis of the specific infection (Table 10-7).

Nursing diagnoses are formulated after diagnosis of infection. Applicable nursing diagnosis may include the following:

- ✿ Pain related to infection.
- ✿ Fear related to the diagnosis.

Table 10-8 Management of Pelvic Conditions

Condition	Usual Therapeutic Interventions
Structural Conditions	
Fibroid Tumors	Iron and progestins (small tumors and minimal symptoms) Surgery (myomectomy, hysterectomy) GnRH agonists (short-term therapy only) Annual pelvic ultrasound to monitor size of tumors
Pelvic Relaxation	
Uterine prolapse	Kegel exercises, ERT, vaginal pessaries (mild prolapse) Hysterectomy
Cystocele	Kegel exercises, vaginal pessaries for uterine prolapse, ERT Surgical repair
Enterocele	Weight reduction Vaginal pessary Surgical repair
Rectocele	High-fiber diet Regular bowel habits Increased fluid intake Stool softeners Vaginal pessary Surgical repair
Functional Conditions	
Polycystic ovary syndrome	Diet modification (obesity) Weight reduction Stress management (decrease excess androgen) Hair removal (hirsutism) Medroxyprogesterone for cyclic withdrawal bleeding Clomiphene for ovulation induction ERT or oral contraceptives (for hyperandrogenism) Possible ovarian wedge resection
Premature ovarian failure	Hormone replacement therapy

(continued)

- Deficient knowledge related to limited experience regarding the disorder.

Nursing plans include specific actions the client completes to achieve the highest level of wellness possible. Sample goals may include the following:

- Take prescriptive medication as written.
- Understand instructions regarding prescriptive medication(s).
- Return to health care provider as scheduled for follow-up assessment of infection status.
- Notify health care provider of adverse effects of prescribed medication(s).
- Notify health care provider of failure of symptoms to improve as expected.
- Adopt recommended change in lifestyle behavior to prevent recurrence of infection.
- Have questions answered to her satisfaction.
- Understand health promotion counseling.

Nursing interventions involve teaching, counseling for prevention, and explaining prescribed medications. Women with multiple sexual partners should be counseled about:

- The risks for infection
- Recommendations for annual screening for chlamydial and gonorrheal infections
- Testing for chlamydial and gonorrheal infections 3 to 6 months after starting a relationship with a new sexual partner

Table 10-8 Management of Pelvic Conditions (continued)

Condition	Usual Therapeutic Interventions
Infection	
Cervicitis	Medication specific to the causative organism (metronidazole for trichomoniasis, acyclovir for herpes simplex virus, ceftriaxone for gonorrhea, doxycycline for chlamydia)
Vaginitis	
Bacterial vulvovaginitis	Metronidazole, clindamycin
Monilial vulvovaginitis	Terconazole
Trichomoniasis	Metronidazole
Pelvic inflammatory disease	Cefoxitin or cefotetan and doxycycline; or clindamycin and ofloxacin; or clindamycin and gentamicin
	ERT or hormone replacement therapy
	Vaginal lubricant (K-Y Jelly, Replens)
	Atrophic Vaginitis
Malignant Conditions	
Endometrial cancer	Surgery: total abdominal hysterectomy and bilateral salpingo-oophorectomy (TAH-BSO) or TAH-BSO followed by radiotherapy or intrauterine radiation followed by TAH-BSO (depends on stage of cancer)
Cervical cancer	Chemotherapy and/or progestin therapy for distant metastases Cryosurgery, loop electrosurgical excision procedure (LEEP), cone biopsy, laser surgery, or hysterectomy for pre-invasive dysplasia Total vaginal hysterectomy TAH, radical hysterectomy with lymph node dissection (depending on size of lesion) Radiation (advanced disease)
Ovarian cancer	Surgery (from unilateral oophorectomy to TAH-BSO) and/or node excision (depends on stage of cancer) Radiotherapy Chemotherapy

Table 10-9 Description of Vaginal Discharges

Characteristic	Normal	Nonspecific Vaginitis	Trichomonal	Candidal	Gonococcal
Color	White	Gray	Grayish yellow	White	Greenish yellow
Odor	Absent	Fishy	Fishy	Absent	Absent
Consistency	Nonhomogenous	Homogenous	Purulent, often with bubbles	Cottage cheese-like	Mucopurulent
Location	Dependent	Adherent to walls	Often pooled in fornix	Adherent to walls	Adherent to walls
Anatomic Appearance					
Vulva	Normal	Normal	Edematous	Erythematous	Erythematous
Vaginal mucosa	Normal	Normal	Usually normal	Erythematous	Normal
Cervix	Normal	Normal	May show red spots	Patches of discharge	Pus in os

Reproduced with permission, from Estes, M.E.Z. (2002). *Health Assessment & Physical Examination*, 2nd ed. Albany, N.Y.: Delmar.

Women should be encouraged to examine their external genitalia once a month, following these steps:

1. Position yourself comfortably either sitting or squatting, so the genitalia are exposed. Use a mirror to better view the area.

2. Inspect for symmetry, moles, growth, changes in skin color, inflammation, irritated areas, and infestations.

3. Using the index and middle fingers, gently spread the labia to inspect the clitoris and inner sides of the labia.

4. Using the finger pads, gently palpate the vulvar region, noting any lumps, nodules, irregularities, or tenderness.

5. Using the index and middle fingers, spread the vaginal opening slightly and palpate the tissue for moistness, elasticity, lumps, nodules, irregularities, or tenderness.

6. Insert the thumb inside the labia and gently compress the tissue between the thumb and index finger, noting any lumps, lesions, or tenderness.

Figure 10-8 Steps to follow to perform vulvar self-examination.

- The need for sexual partners to be treated each time chlamydial and gonorrheal infections occur
- Eliminating douching, because such practices destroy the lactobacilli residing in the vagina and may force bacteria from the vagina into the uterus
- Distinguishing between normal vaginal discharge and discharge characteristic of vaginal infection

Educational nursing intervention includes explaining the dangers of self-diagnosis of vaginal infection and use of over-the-counter or herbal therapies instead of seeking early diagnosis and therapeutic intervention at the first sign of a vaginal infection. Nurses should provide emotional support and therapeutic communication to over-

come a client's embarrassment regarding vaginal infections and to help clients understand that the delicate balance of the vaginal ecosystem can be disturbed by a variety of factors (Cullins, 1999).

When a woman presents with a pelvic infection, the nurse can use such a moment to explain the vulvar self-examination to her. The woman can be encouraged to perform the vulvar examination at the same time of the month as she performs BSE. To perform the vulvar examination, she lies down, spreads and flexes her knees, and prepares to palpate the inguinal area and vulva with the flat surface of her hand to detect enlarged lymph nodes. Then, using a mirror, she inspects the entire vulvar surface (the area between her legs from the top of her pubic hair to the rec-

tum), looking for any growths or discolorations. She inspects surfaces of both the labia majora and labia minora. Then she spreads the labia with her index and middle fingers, looking for growths or discolorations. Lastly, she looks for discharge and, if present, evaluates for odor, amount, and color.

Benign Pelvic Conditions

Benign pelvic conditions can be categorized as structural or functional. Common structural conditions include pelvic relaxation and uterine fibroid tumors. Common functional conditions include polycystic ovary syndrome and premature ovarian failure.

Structural Conditions

Structural conditions are changes in the size or position of the pelvic organs, including the bladder, uterus, ovaries, and rectum. Common structural changes involving the pelvic organs are known collectively as pelvic relaxation.

Pelvic Relaxation

Pelvic relaxation is the loss of pelvic muscle support of the pelvic organs, which may result in development of a cystocele (bulging of the posterior wall of the bladder into the anterior vaginal wall), enterocele (bulging of the bowel into the posterior cul-de-sac and vaginal wall), rectocele (bulging of the anterior wall of the rectum into the posterior vaginal wall), or uterine prolapse (protrusion of the uterus into the vaginal canal). The causes of pelvic relaxation include permanent damage to connective tissue or muscular structure during the stretching and trauma of vaginal birth, chronically increased intraabdominal pressure (from heavy lifting, obesity, straining with constipation, ascites, coughing with obstructive respiratory disease), aging-related muscle atrophy (estrogen deficiency), and congenitally weak connective-tissue strength (elasticity). The woman may experience urinary incontinence, urgency, or frequency; constipation or difficult defecation; pelvic pressure; dyspareunia; walking or sitting discomfort; or protrusion of an organ through the introitus (Lucas, 1999).

Therapeutic interventions for pelvic relaxation depend on the stage of relaxation. First-degree prolapse consists of descent of the cervix into the lower third of the vagina; second-degree is descent of the cervix to the introitus or less than 1 centimeter through the introitus; third-degree is descent of the cervix 1 centimeter beyond the introitus; and fourth-degree is descent or prolapse of the uterus and cervix through the introitus (Lucas, 1999). Women with first- or second-degree stages may increase muscle support for the pelvic organs by performing Kegel exercises several times per day or using a vaginal pessary to provide support for the pelvic organs. For the woman with a third-

or fourth-degree prolapse, weakness of the pelvic musculature is irreversible and hysterectomy is usually the treatment of choice (Lucas, 1999).

Fibroid Tumors

Fibroid tumors (leiomyomas) are benign tumors arising in the myometrium, which can protrude into the uterine cavity (submucous leiomyomas), bulge through the outer uterine layer (subserous leiomyomas), or grow within the myometrium (intramural leiomyomas). The cause is proliferation of smooth-muscle cells. The tumors usually do not grow more than 1 to 2 centimeters per year; thus, the tumor growth can be watched until the uterus reaches a 4- to 5-month gestation size as a result of tumor growth (Lucas, 1999). By the time the uterus reaches this size, the woman may be experiencing excessive urination, backache, pelvic pressure, abdominal discomfort, hypermenorrhea, anemia, or pressure on the ureters (Lucas, 1999). The tumors are dependent on estrogen for growth and, thus, grow more rapidly during pregnancy. The tumors are found more often during the fourth or fifth decades of life, affect 1 out of 5 Caucasian women, affect 1 of 3 African American women, and occur more often in nulliparous, nonsmoking women who take oral contraceptive pills (Grabo, Fahs, Nataupsky, & Reich, 1999). Anovulatory menstrual cycles (unopposed estrogen) are thought to be the cause of fibroid tumor growth during the perimenopausal period (Grabo et al., 1999). The resulting distortion of uterine shape and size contributes to interference with conception, pregnancy maintenance, and fetal growth and development (Grabo et al., 1999).

Therapeutic intervention depends on the woman's desire for future childbearing. If she does not desire future pregnancies and the tumors are large (at least 4-months' gestation size), she may choose to have a hysterectomy (Lucas, 1999). If she desires future childbearing, she may have a myomectomy to remove submucosal tumors before conception. GnRH agonists may be used for short-term intervention to decrease the size of the fibroid tumors (Lucas). However, the woman will experience menopausal symptoms and is at risk for osteoporosis if the intervention is continued for more than 6 months (Lucas, 1999).

Functional Conditions

Functional conditions include changes in function of the pelvic organs, such as polycystic ovary syndrome and premature ovarian failure.

Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) is "a complex endocrine disorder associated with long-term anovulation and an excess of androgens circulating in the blood . . . [and] characterized by formation of cysts in the ovaries, a

REFLECTIONS FROM A NEWLEYWED

"I was vacationing at the beach with my new husband. The first day, we went for a long walk on the beach and I developed a little pain and stiffness in my lower back, which I attributed to the car ride, sleeping on a thin mattress, and walking in soft sand. About 3 AM the next morning, I was awakened by cramping and nonspecific pain in my lower pelvis. Thinking it was gas, I got up to go to the bathroom and could barely stand upright. After another half hour, the pain was no better—even a little worse. I was sweating and then was chilled and had a loose bowel movement. We called the ambulance, having no idea where the nearest hospital was. On the way, I vomited, my pulse was erratic, and I was generally miserable. When we arrived at the hospital, they drew blood, took a urine sample, and gave me a Cat scan. After considering everything from gas to kidney stones to appendicitis, they discovered through ultrasound that I had an ovarian cyst that had swollen and caused the ovary to twist around. Laparoscopic surgery proved that ovarian torsion was present, causing the cessation of blood flow that basically killed the ovary. I also had a cyst on the other ovary, but the doctor was pretty sure that was a "functional" cyst, which is pretty normal. During the surgery they removed the cyst, the ovary, and the fallopian tube.

I was 33, newly married, and had just stopped taking oral contraceptives and was looking forward to starting a family. I had always had an annual pelvic examination and Pap smear and had never before experienced any irregularity or cysts. We were very concerned about how having only one ovary would affect our ability to conceive, but we've been reassured it should be no problem."

process related to the failure of the ovary to release an ovum" (Marantides, 1997). PCOS is the leading cause of amenorrhea in premenopausal women. It is the cause for amenorrhea in 30% of all women, oligomenorrhea in 75% of women, and hirsutism in 87% of women. Causes of PCOS are the results of anovulation, such as ovarian failure, hypothalamic or pituitary suppression, and adrenal enzyme dysfunction. The syndrome begins with an imbalance of LH and follicle-stimulating hormone (FSH), with LH levels elevated and FSH levels low-to-normal. The result of the imbalance of LH and FSH is continued follicular development, elevated estrogen levels, anovulation, and formation of multiple ovarian cysts. Endocrine involvement results in hyperestrogenemia, adrenal androgen excess, ovarian abnormalities, hyperprolactinemia, and hyperinsulinemia. Women typically seek health care for amenorrhea or irregular menstrual cycles, infertility, hirsutism (excessive hair growth), acne, or obesity.

Medical management for PCOS is targeted to the woman's primary concern (e.g., amenorrhea, hirsutism, infertility, obesity) (Marantides, 1997). Combination oral contraceptives or GnRH agonists can be used for hyperandrogenic effects (e.g., male-pattern hair growth and acne). A weight-loss program must be established, or symptoms will return when medication is discontinued. Amenorrhea and anovulation associated with PCOS place the woman at increased risk for endometrial cancer at a young age and for postmenopausal breast cancer. Medroxyprogesterone (Provera) can be used for treatment of the PCOS amenorrhea.

Premature Ovarian Failure

Premature ovarian failure is failure of ovarian estrogen production and ovulation after the menarche and before age 40, in which the woman experiences the symptoms of menopause. The cause can be an endocrine imbalance (gonadal failure, hypothalamic-pituitary-ovarian disorder, Cushing's syndrome, Addison's disease, rigorous physical stress or training). Common causes of secondary amenorrhea are investigated. Medical management includes treatment for any causes of secondary amenorrhea identified or hormone replacement therapy.

Malignant Pelvic Conditions

Malignant pelvic conditions are considered collectively as gynecologic cancers. The most common gynecologic cancers are cervical, endometrial, and ovarian. In this group, only cervical cancer can be screened for early detection.

Cervical Cancer

Cervical cancer is a neoplasm of the uterine cervix. Because of the introduction of the Papanicolaou (Pap) smear in 1942 by Dr. George Nicholas Papanicolaou and Herbert Traut, the annual number of deaths of women resulting

Nursing Alert

RISK FACTORS FOR CANCER OF THE FEMALE GENITALIA

Evaluate each client for risk factors, and counsel the client regarding diminishing risk factors that are behavior dependent. Suspected carcinoma of the female genitalia requires an immediate referral.

Cervical Cancer

- Early age at first intercourse
- Multiple sex partners
- Prior history of human papillomavirus
- Tobacco use
- Family history

Endometrial Cancer

- Early or late menarche (before age 11 or after age 16)
- History of infertility
- Failure to ovulate
- Unopposed estrogen therapy
- Use of tamoxifen
- Obesity
- Family history

Ovarian Cancer

- Advancing age
- Nulliparity
- History of breast cancer
- Family history of ovarian cancer

Vaginal Cancer

- Daughters of women who ingested diethylstilbestrol during pregnancy

Source: Reproduced, with permission, from Estes, M.E.Z. (2002). *Health Assessment & Physical Examination*, 2nd ed. Albany: Delmar.

from cervical cancer have dropped significantly. However, invasive cervical cancer affects 16,000 women per year, and 5,000 women die of this cancer annually (Klingman, 1999). Cervical cancer is most prevalent in women aged 40 to 55 (Bristow and Montz, 2000). If detected early, cervical cancer is curable. Thus, screening by Pap smear is an essential health care assessment for every woman who is sexually active or age 18 or older.

The Pap smear is a screening device for cervical cancer; the results identify women at risk. Cervical cancer is detected by evaluating a biopsy specimen of abnormal

cervical epithelium. Risk factors for cervical cancer include initiation of sexual activity before age 18 years; multiple sexual partners; sexual partners who have had multiple sexual partners; history of STDs, including human papilloma virus (HPV); smoking; failure to use a barrier method of contraception; and exposure to diethylstilbesterol in utero (Foulks, 1998).

The cause of abnormal Pap smear results in approximately 25% of women is HPV infection; 80% of cervical cancers occur in the presence of HPV infection; and 50% of women are thought to be infected with HPV by age 30 (Klingman, 1999; Higgins, 1997). There are more than 100 HPV types. However, not all types of HPV have been seen in conjunction with development of cervical cancer. HPV types 6 and 11 cause genital warts, and types 16, 18, 31, and 33 are seen in conjunction with cancerous cervical lesions (Carson, 1999).

Medical management for abnormal cervical cell development or cervical cancer includes local excision, cryotherapy, electrocoagulation, or carbon dioxide laser therapy to destroy the abnormal cells (Bristow & Montz, 2000). Surgery, radiotherapy, or radiotherapy and chemotherapy combined are the usual therapeutic interventions when cervical conditions have progressed to invasive cervical cancer (Carson, 1999).

Endometrial Cancer

Endometrial cancer is a malignant neoplasm of the uterine lining. Endometrial cancer occurs most often in women aged 60 to 74; comprises 13% of all cancers in women in the United States, with 35,000 new cases found annually; and 25% of these cases have progressed to invasive cancer at the time of diagnosis (Carson, 1999). There is no screening method to identify women with atypical cellular changes before development of endometrial cancer. The Pap smear does not screen for this type of cancer. Risk factors for endometrial cancer include age over 50, postmenopausal status, irregular menses (because of potential anovulation caused by unopposed estrogen stimulation of the endometrium), polycystic ovary disease, diabetes mellitus, hypertension, and unopposed ERT with an intact uterus (Bristow & Montz, 2000). Endometrial cancer occurs most often in the perimenopausal or postmenopausal woman and tends to grow slowly.

Medical management for endometrial cancer includes endocervical curettage in a postmenopausal woman with vaginal bleeding or in a perimenopausal woman with heavy menses. The type of intervention depends on the stage of the cancer development and may include surgery, radiotherapy, chemotherapy, or hormone therapy.

Ovarian Cancer

Ovarian cancer is a malignant neoplasm of the ovary. Over 30 types of ovarian neoplasms have been identified,

involving the epithelium, germ cells, or stromal cells, with epithelial ovarian tumors accounting for 80% of ovarian cancers (Shurpin, 1997). Because there is no screening method for identification of early cellular changes, the cancer has usually spread beyond the ovary to the peritoneum by the time of diagnosis in 75% of cases. Only 20% to 25% of affected women survive longer than 5 years. Ovarian cancer is considered to be the “silent killer”. In addition, the first symptoms the woman may notice are vague (abdominal discomfort or fullness, pelvic pressure, urinary frequency, constipation, and dyspepsia as the tumor grows). Many women associate these symptoms with midlife changes or responses to stress rather than a “serious” disease process. Ovarian cancer occurs most often in women aged 40 to 70, is diagnosed in 24,000 women in the United States each year, and 13,600 women die of the disease each year (Averette & Nguglen, 1995).

Risk factors for ovarian cancer include family history (especially a first-degree relative); personal history of breast, colon, or endometrial cancer; ovulation for more than 40 years; and presence of an abnormal *BRCA-1* gene, which is considered responsible for 80% of inherited ovarian cancers. In high-risk women, transvaginal ultrasonography can detect ovarian enlargement and color Doppler ultrasonography can differentiate malignant and benign growths.

Medical management includes surgery, followed by radiotherapy or chemotherapy, or a combination of the two (Carson, 1999). Continued monitoring of blood levels of the tumor marker CA 125 and regular follow-up pelvic examinations are required after therapeutic interventions.

If woman is undergoing chemotherapy, recommend eating small, frequent, low-fiber, high-calorie, high-protein meals to reduce nausea, vomiting, anorexia, and diarrhea and to prevent malnutrition. In addition, taking an antiemetic before meals may enhance the ability to keep food down. Skin exposed to radiotherapy can be protected by avoiding the use of cosmetics, powder, soap, and sun (or infrared lamps) on the affected areas; wearing loose cotton clothing next to the skin of the affected area; avoiding shaving the affected area; carefully patting affected skin dry after bathing; and avoiding exposure of affected skin to extremes of heat and cold (Campbell & Pruitt, 1996).

Nursing Implications

Nursing assessment for pelvic conditions involve assessing risk factors for benign and malignant pelvic conditions, current symptoms, and medical and gynecologic history. Physical assessment focuses on the collection of data to rule out or confirm a benign pelvic condition and identification of the need to collect specimens for laboratory tests and for additional diagnostic procedures (Table 10-7).

Nursing diagnoses are formulated after the pelvic condition is identified. The diagnoses are individualized for the client and based on the identified pelvic condition. Applicable nursing diagnoses may include the following:

- ✿ Pain related to pelvic conditions
- ✿ Fear related to procedures and treatment
- ✿ Anxiety related to effects of condition or treatment on future childbearing
- ✿ Deficient knowledge regarding (specific pelvic condition)

Nursing plans include specific actions that the client will complete to achieve the highest level of wellness possible. Sample goals may include the following:

- ✿ Develop strategies for coping with pain.
- ✿ Consume recommended foods, based on the food pyramid, daily.
- ✿ Reduce stress and promote wellness by exercising at least 30 minutes daily (e.g., walking, swimming, biking).
- ✿ Take prescriptive medication as written.
- ✿ Understand instructions regarding prescriptive medication(s).
- ✿ Return to health care provider for follow-up visits as scheduled.
- ✿ Notify health care provider of adverse effects of medications.
- ✿ Notify health care provider of failure of symptoms to improve.
- ✿ Answer questions to her satisfaction.
- ✿ Become informed about choices for medical management.
- ✿ Understand expected outcomes of therapy.
- ✿ Understand health promotion activities.

Nursing intervention involves education, consequences and prevention of the condition (if possible), specific procedures in and the outcomes of the therapeutic intervention plan, prescription medications, and consequences of “doing nothing,” assisting the woman with informed decision making and serving as client advocate. Nurses must provide emotional support for each woman, especially the woman who is embarrassed.

Pain assessment includes rating the severity of pain (such as on a scale of 1 to 10, with 1 being no pain and 10 being the most excruciating pain possible), factors that relieve or reduce the pain, and factors that intensify the pain. The pain must be treated before it becomes severe. The nurse should avoid negating the woman’s perception of pain and help the woman select pain control options appropriate for her, her family, and her environment. The

Case Study/Care Plan

CLIENT WITH BACTERIAL VULVOVAGINOSIS

A 19-year-old with a complaint of “another vaginal infection” is being examined in the nurse practitioner clinic at the city health department. Client states, “I’ve got another infection. There’s lots of discharge on my pants and it smells bad when I have sex.” Her latest Pap smear (after a period of 2 years of failure to keep her scheduled appointments) reveals an abnormal result, suggestive of HPV infection. Her history indicates that she is single, never married; gravida 4, para 4 (each child has a different father); has had multiple sex partners; delivered her first baby at age 14; has been treated numerous times in the STD clinic; and has smoked 1 to 2 packs of cigarettes daily since age 10. On examination, copious, homogenous, gray, malodorous discharge is observed. A wet-mount examination of the discharge shows clue cells and the “whiff” test is positive for amine odor. The diagnosis is bacterial vulvovaginitis.

Assessment

- Positive results on “whiff” test.
- Wet-mount examination reveals copious clue cells (epithelial cells covered with bacteria), no lactobacilli present, and WBCs too numerous to count.

Nursing Diagnosis

Ineffective health maintenance related to risk-taking behaviors, as evidenced by chief complaint and subjective, objective, and laboratory data.

Expected Outcomes Client will:

1. Describe risk factors for cervical cancer.
2. Identify cervical cancer risk factors specific to herself.
3. Relate strategies she is willing to use to reduce her personal cervical cancer risk.

Planning

The nurse should take into account the client's developmental maturity and target education and materials to a level the client understands.

Nursing Interventions

1. Discuss cervical cancer risk factors (cigarette smoking, early age at first sexual intercourse, first childbirth before age 20, history of STDs (especially HPV infection), multiple sexual partners.
2. Assist client in relating risk factors to herself.
3. Discuss potential strategies to decrease risk for cervical cancer (i.e., stop smoking, “safe sex”). Facilitate implementation of cervical cancer reduction strategies.

Rationales

1. Teaching is more effective when it builds on a woman's existing knowledge base. Official list of risk factors may help late adolescent accept reality of vulnerability to cancer.
2. Awareness of the reality of risk increases the likelihood that the woman will change lifestyle behaviors.
3. Information permits informed decision making. Verification of woman's understanding permits correction of misinformation. Her involvement in planning increases compliance.

Evaluation

- Client is able to state cervical cancer risk factors in her own words.
- Client identifies cigarette smoking, young age at first sexual intercourse and first childbirth, multiple sexual partners, frequent STDs and HPV infection, abnormal Pap smear results.

Client Education

Kegel Exercises

Every woman should be taught to use Kegel exercises every day to prevent or improve urinary incontinence. Kegel exercises contract the pubococcygeus muscle (the muscle supporting the pelvic organs) by alternately contracting and relaxing the muscle controlling the rectum. The client is instructed to first relax the muscle as she would for defecation. She may visualize the process better if she conceptualizes her pelvic floor muscle as an elevator. When the elevator is in the basement, the muscle is relaxed. She contracts (or squeezes) the muscle enough to raise the elevator to the first floor, then contracts the muscle a little more to raise the elevator to the second floor, and contracts the muscle a little more to raise the elevator to the third floor, where she holds it for 3 seconds at first and gradually increases the time each week by 2 to 3 seconds, until she sustains the contraction for 10 seconds. She then relaxes the muscle by descending the elevator to the second, then first, and finally the basement floor. She maintains relaxation for 3 seconds (increasing the relaxation time as she increases the contraction time) and repeats the process 10 times. She is instructed to complete 6 to 8 sets of 10 repetitions per day. She can use a variety of triggers to remind her to complete a set of Kegel exercises. Some events used as triggers include a stop at a red light or stop sign while driving, the ringing of the telephone, or a commercial while watching television.

nurse should teach nonpharmacologic methods of coping, such as guided imagery, breathing and relaxation techniques, massage, cold or hot baths, and diversional activities. Assist the client in controlling as many factors regarding her care and pain control as possible by providing support and advocacy for the client's choices. Reduce the woman's fears by providing sufficient information in a form that she can understand to make informed choices.

MENOPAUSE

Menopause is the result of the decline in ovarian function (estrogen production). **Menopause** refers to the end of menses, just as menarche refers to the beginning of men-

strus. Menopause is determined when the woman experiences no menstrual periods for 12 months. At the beginning of the 1990s, there were approximately 1.3 million women who had reached the age of 50, making about one-third of the United States' female population menopausal (Moore & Noonan, 1996). Because many women today live well into their 80s, and if they experience natural menopause in their early 50s, they can expect to live a large portion of their lives after menopause.

If she lives long enough, every woman will experience menopause at some point in her life, most often at about ages 49 to 51, and thus, experience the physiologic effects of estrogen deficiency in tissues containing estrogen receptors. Even though the severity of symptoms varies from woman to woman, most women experience menopausal symptoms, with some of these symptoms persisting for decades. Typical menopausal symptoms are related to vasomotor instability, urogenital atrophy, psychological discomforts, and long-term effects, such as development of cardiovascular disease and osteoporosis (DeMasters, 2000).

Vasomotor Instability

Vasomotor instability is commonly known as "hot flashes" or "hot flushes." The hot flash is uncontrollable, unpredictable, uncomfortable, and embarrassing and prompts many women to seek relief. Women experience the hot flash as an intense heat sensation, beginning in the upper chest or neck, progressing to the head, and demonstrated by a reddening of the skin. It occurs either occasionally (one or two a day) or frequently (several in an hour) (LeBoeuf & Carter, 1996). For many women, hot flashes are more severe at night, resulting in night sweats and contributing to insomnia. In addition, women report the increased occurrence of hot flashes during periods of stress.

The cause of hot flashes is unknown and the response of the brain to surges of LH levels is not well understood. A hot flash is known to coincide with an LH level surge, including a measurable increase in body surface temperature with a measurable drop in core body temperature. There is speculation that the fluctuating estrogen levels may alter the balance between norepinephrine and dopamine; thus creating the hot flash. Other professionals speculate that the low estrogen levels result in a malfunction of the temperature control system in the brain and cause an overproduction of heat in general or that a drop in body temperature may stimulate the body to readjust its temperature (Crandall, 1997).

Intervention for vasomotor instability responses most often includes ERT. An additional nonprescription intervention may include vitamin E therapy (DeMasters, 2000). Nursing interventions frequently include recommendations

to wear nonsynthetic fabrics (cotton or silk) and loose clothing, dress in layers for easy removal of clothing during a hot flash, place two sets of cotton sheets on the bed for easy removal of damp sheets during the night, maintain normal blood glucose levels (small, frequent, nutritious meals), drink at least 6 to 8 glasses of water per day to maintain fluid balance, and avoid intake of substances associated with hot flashes (such as spicy foods, alcohol, and caffeine) (Crandall, 1997).

Urogenital Atrophy

Urogenital atrophy is the response of the estrogen receptor tissues to loss of estrogen. Such responses typically include a thinning and decreased elasticity of the vaginal epithelium and walls; change in color of vaginal epithelium to pale, almost whitish-pink; vaginal narrowing and shortening; progressive decrease in vaginal rugae and vaginal secretions; increased vaginal pH; vaginal dryness and itching; dyspareunia; and lower urinary tract symptoms (LeBoeuf & Cartz, 1996). With loss of estrogen, the genitourinary tract epithelium loses peripheral blood flow, resulting in loss of tone and development of urinary incontinence and a shortened urethra. This loss of tone may result in development of cystocele and rectocele (Crandall, 1997). In addition, cystocele increases urinary incontinence and rectocele increases constipation. Vaginal dryness results in dyspareunia, a risk for tearing the vagina during sexual intercourse, and development of atrophic vulvovaginitis (inflammation of the vulva or vaginal epithelium).

ERT as a therapeutic intervention successfully reverses the physiologic responses of the urogenital tissues to loss of estrogen (DeMasters, 2000). Since oral or transdermal ERT can take several weeks to reverse urogenital atrophy, some providers prescribe topical estrogen for the woman to apply for a short time, along with oral or transdermal ERT.

Nonprescriptive nursing interventions often include recommendations to increase vaginal moisture by using a lubricant (K-Y Jelly, Replens), continue sexual activity to increase blood flow to the genitourinary tissues, spend more time in foreplay to increase vaginal lubrication, and try to find a position during sexual intercourse that decreases the discomfort of dyspareunia (Crandall, 1997). Performing six to eight sets of 10 repetitions of Kegel exercises daily can reduce episodes of urinary incontinence and increase structural support to pelvic organs. In addition, eliminating substances known to cause frequent urination and bladder irritation, such as caffeine, artificial sweeteners, and even some fruit juices, may decrease episodes of urinary incontinence. Increasing water and fresh vegetable intake and walking for exercise can decrease constipation.

Psychological Conditions

Psychological disturbances of menopause include the mood swings, irritability and changes in short-term memory thought to be related to declining estrogen levels. Decreases in circulating estrogen directly affects neurotransmitters responsible for regulating mood, appetite, sleep, and pain perception (Wasaha, & Angelopoulos, 1996; Crandall, 1997). The changes in mood are responses similar to the psychological and emotional responses of premenstrual syndrome and postpartum blues, conditions related to the decrease in hormone levels. In addition, the menopausal woman is usually experiencing the role and lifestyle changes (retirement, widowhood, caring for sick parents, caring for grandchildren, beginning a career or second career) characteristic of the aging process, along with the accompanying insomnia. Thus, the combination of such changes and the decline in circulating estrogen can intensify psychological and emotional responses to both processes.

Alzheimer's disease is a chronic, progressive disease of mental deterioration and disability, the incidence of which increases from 5% of women over age 65 to 25% to 50% of women over age 85 (Cotter, 1997). ERT has demonstrated an effect of delaying the onset of Alzheimer's disease (Cotter, 1997).

Long-Term Considerations

Long-term effects of menopause are linked to estrogen loss and, if progression is undetected, may cause irreparable damage (Crandall, 1997). These effects include cardiovascular disease and osteoporosis. Estrogen fosters new bone growth and helps prevent cardiovascular disease.

Cardiovascular Disease

Cardiovascular diseases are collectively known as heart disease. Cardiovascular disease is the leading cause of death in the United States. Men have three times more risk for death than women at age 50 or younger, but women have an equal risk for death by age 65 (LeBoeuf, 1996). The increased cardiovascular disease risk for women is related to pathologic increases in cholesterol and triglyceride levels because of estrogen loss after menopause. Thus, after menopause, cardiovascular disease becomes the leading cause of disability and death in postmenopausal women (Crandall, 1997). More than 500,000 women die annually of cardiovascular disease (DeMasters, 2000). Although women are more frightened of dying of breast cancer, only 1 postmenopausal woman in 28 dies of breast cancer annually, while 1 in 2 dies of cardiovascular disease. Other factors related to cardiovascular disease development include smoking, diabetes mellitus, excess weight, and genetic factors.

Therapeutic interventions for postmenopausal cardiovascular disease include medication, lifestyle changes, and ERT. The Postmenopausal Estrogen/Progestin Interventions (PEPI) trial has demonstrated the cardioprotectiveness of ERT and hormone replacement therapy (HRT) for women with and without existing cardiovascular disease. The PEPI findings reveal an *increased* number of cardiac events in women *with* existing cardiovascular disease (Byyny and Speroff, 1996) when they begin ERT or HRT in comparison to women without existing cardiovascular disease; these women require closer evaluation by their clinicians.

Osteoporosis

Osteoporosis includes the progressive bone loss, increased bone fragility, and increased risk for bone fractures that occur in postmenopausal women. Symptoms (atraumatic skeletal fractures, height loss, spinal deformity) do not occur until significant bone loss has occurred. One in 10 Caucasian women will experience an osteoporotic fracture; 400,000 people are admitted to hospitals and 44 million to nursing homes as a result of osteoporosis at an annual cost of approximately \$14 billion; 20% of hip fractures and hip fracture-related complications result in death, killing more women than breast cancer (DeMasters, 2000). Osteoporosis has been diagnosed in approximately 28 million people in the United States, and the number is expected to continue to increase (Kessenich, 2000).

Risk factors for osteoporosis include the following (Licata, 1999; McClung, 1999):

- Caucasian ancestry (Northern European)
- Family history of osteoporosis (especially maternal family)
- Sedentary lifestyle
- Low intake of dietary calcium
- Small-boned frame
- Low body weight
- Excessive alcohol intake
- Smoking
- Late menarche and early menopause
- History of amenorrhea
- Excessive intake of certain medications (glucocorticoids, thyroid hormone, tetracyclines)
- Chronic illness (kidney, bowel, or liver disease; Cushing's syndrome; hyperthyroidism, hyperparathyroidism; hyperprolactinemia; hypogonadism)

Women achieve peak bone mass in the third decade of life and then begin losing 1% to 1.5% of bone mass per year until menopause, when the loss is accelerated up to

5% during the first 5 menopausal years as a result of estrogen loss (Crandall, 1997). Thus, women can lose approximately 40% to 50% of their bone mass after the third decade of life. Throughout life, bone tissue is remodeled on a cyclic basis by osteoblasts (bone cells that cause bone growth) and osteoclasts (bone cells that cause bone breakdown and resorption) (Kessenich, 2000). After menopause, the remodeling process is altered: osteoclast activity (bone breakdown) exceeds osteoblast activity (bone growth).

Therapeutic interventions for osteoporosis prevention and treatment include adequate calcium and vitamin D intake, weightbearing exercise, and consideration of ERT or HRT (DeMasters, 2000). In addition, bisphosphonates—etidronate (Didronel), alendronate (Fosamax), risedronate (Actonel) act to inhibit osteoclast activity. Studies document the benefit of bisphosphonates in the treatment and prevention of osteoporosis.

Nursing interventions include emphasizing the need for girls and women to consume at least 1000 mg of dietary calcium daily until age 50 and to increase the consumption after age 50 to 1500 mg daily (Crandall, 1997). Calcium-rich foods include dairy products, green leafy vegetables, and calcium-fortified foods such as cereal and orange juice). If the woman is unable to consume sufficient calcium from food, she can take calcium supplements in divided doses (1250 mg of calcium carbonate provides 500 mg of absorbable calcium; 1500 mg of calcium citrate provides 315 mg of absorbable calcium) (Crandall, 1997). Calcium is absorbed more readily when stomach acidity is increased and adequate vitamin D (400 IU daily) is available. Nurses need to remind women that smoking and caffeine and alcohol intake interfere with osteoblast cell activity and that weightbearing exercise (such as walking, cycling, tennis, dancing, weightlifting, or low-impact aerobics) increases osteoblast cell activity.

Nursing Implications

Nursing assessment for menopausal conditions involves careful personal and family history taking, and assessment for personal and familial risk factors, symptoms, and how the client has been coping with the symptoms. Physical assessment is focused on data collection for a diagnosis of the menopausal condition. Identification of necessary laboratory tests and diagnostic procedures also must be done.

Nursing diagnoses are individualized to each woman and her specific menopausal condition. Applicable diagnoses may include the following:

- Pain (mild or moderate) related to (specific menopausal condition)
- Grief related to mid to late life losses

- ✿ Deficient knowledge related to limited experience (or information) regarding (specific menopausal condition)
- ✿ Ineffective coping related to lack of acceptance of prognosis for (specific menopausal condition)

Nursing plans include specific actions the woman and her family will complete to achieve the highest possible level of wellness. Sample goals may include the following:

- ✿ Consume recommended foods based on the food pyramid in serving sizes to meet body requirements, including intake of calcium from foods or supplements.
- ✿ Exercise 30 minutes per day at least 3 to 4 times per week.
- ✿ Take prescriptive medication(s) as written.
- ✿ Understand instructions regarding prescriptive medication(s).
- ✿ Understand therapeutic intervention plan.
- ✿ Notify health care provider of adverse effects of medication(s).
- ✿ Notify health care provider of failure of symptoms to improve.
- ✿ Return to health care provider for scheduled follow-up visits.
- ✿ Have questions answered to her satisfaction.
- ✿ Understand health promotion counseling.

Nursing interventions for menopausal conditions include education regarding reduction of risk factors for

Client Education

Hormone Replacement Therapy

The client who is at risk for osteoporosis should be taught the following:

1. Perform weight bearing exercise at least 5 days per week.
2. Consume 1200 mg of calcium with 400 IU of vitamin D per day if premenopausal.
3. Consume 1500 mg of calcium with 400 to 800 IU of vitamin D per day if postmenopausal and not on hormone replacement therapy.
4. Consume 1200 mg of calcium with 400 to 800 IU of vitamin D per day if postmenopausal and on hormone replacement therapy.
5. Consider hormone replacement therapy if she is postmenopausal. (Note: The client who has not had a hysterectomy must take both estrogen and progesterone to prevent an increased risk for endometrial cancer caused by unopposed estrogen therapy.)
6. Avoid smoking.

each woman, emphasizing prevention strategies, and explaining therapeutic interventions to ensure successful compliance. Nursing interventions for each menopausal condition described must be explained, encouraged, and evaluated. In addition, education should focus on health-promoting nutrition, maintenance of appropriate weight for height (BMI), and exercise: these can prevent many osteoporotic conditions.

Many women are frightened to take ERT or HRT because of conflicting news reports of research findings. Nurses can help women evaluate the research studies and recommend the benefits of ERT or HRT in comparison to the adverse potential of each woman's risk for each menopausal condition. For example, is a particular woman's risk of death from cardiovascular disease greater than her risk for death from breast cancer? In addition, the woman can be reminded that the increased risk of developing breast cancer from taking HRT must be weighed against post menopause breast cancer that occurs postmenopausally, which is less aggressive, typically takes longer to develop than aggressive cancer, responds to early diagnosis and treatment, and carries a better survival rate among HRT users than those not taking HRT (DeMasters, 2000). Women without a uterus who use ERT seem to have a lower risk of developing postmenopausal breast

Critical Thinking

ERT and Cancer Risk

Research has been completed that focuses on the relationship of ERT and the risk for breast cancer. Some of the research identifies a slightly increased risk for clients on long-term ERT. Others do not support this finding.

Your client is an 84-year-old woman with severe osteoporosis (bilateral hip fractures, vertebral fractures, microfractures of the bones in the feet). After her second hip replacement, she began taking estradiol. She now has a suspicious result on her mammogram and is scheduled for a biopsy. She asks you if she should continue to take her estradiol. How would you respond?

cancer than women who use estrogen plus progestin (HRT) (DeMasters, 2000).

Research has shown the risk for endometrial cancer is almost eliminated by adding progestin to estrogen (DeMasters, 2000). Some research findings indicate women who use HRT may have a lower endometrial cancer risk than women who do not. Other research findings seem to indicate that ERT and HRT are protective against colorectal cancer, delay Alzheimer's disease, and may help prevent osteoporosis and cardiovascular disease. Several long-term research studies in the woman's health initiative, will be completed in the next few years that may provide answers to many of the questions and concerns of women and, most likely, create new questions.

Web Activities

- Visit the American Cancer Society's website. What are the 5-, 10-, and 20-year survival rates for the cancers discussed in this chapter?
- Search for information on some of the disorders in this chapter, such as endometriosis. Are there websites available? Do they offer "healthy-living" guidelines? Can you volunteer to be part of a clinical trial if you have some of these conditions?

Key Concepts

- Menstrual cycle alterations relate to frequency and length of cycle, amount of flow, and number of years cycles are experienced.
- Endometriosis is a chronic disorder caused by implantation of endometrial tissue outside the uterus; it affects 1 in 7 women of childbearing age.
- Premenstrual syndrome affects 30% to 40% of women of childbearing age and is characterized by behavioral, emotional, and physical symptoms.
- Common benign breast conditions include fibrocystic changes, fibroadenoma, and nipple discharge.
- Risk factors for breast cancer include age over 50, female gender, history of ovarian or endometrial cancer, and history of first-degree relatives with breast cancer.
- Infections in the pelvic area include vaginal, cervical, and pelvic inflammatory diseases, which may be caused by bacteria, viruses, fungi, or protozoa.
- Benign pelvic conditions affect the vagina, cervix, uterus, and ovaries.
- Cancers of the pelvic region include cervical, endometrial, and ovarian.
- Menopause may be accompanied by hot flashes, urogenital atrophy, mood swings, irritability, and estrogen loss, which may increase the risk of cardiovascular disease and osteoporosis.

Review Questions and Activities

1. You are counseling a perimenopausal client regarding prevention of osteoporosis. You recommend that she increase her dietary intake of which of the following?
 - a. Milk and iron
 - b. Calcium and vitamin D
 - c. Magnesium and vitamin C
 - d. Magnesium and phosphorus
 The correct answer is b.
2. You are explaining the intervention strategies for PMS to a 28-year-old client. You recommend that during the latter part of her cycle she limit which of the following?
 - a. Exercise
 - b. Fluid intake
 - c. Fruits and vegetables
 - d. Salt and caffeine intake
 The correct answer is d.

3. You are completing the chief complaint interview for a 17-year-old with dysmenorrhea. You will assess for which of the following symptoms:

- a. Food cravings
- b. Heart palpitations
- c. Abnormal bleeding
- d. Duration of her pain

The correct answer is d.

4. You are counseling a 40-year-old who has come to the clinic because she found a “lump” in her breast last night. She is frantic because she believes she has cancer. The clinical breast examination reveals firm, smooth, discrete masses in both breasts. You reinforce the physician’s impression that what she is feeling is most likely a noncancerous “lump” and that she should have which of the following evaluation procedures first:

- a. Lumpectomy
- b. Mammogram
- c. Excisional biopsy
- d. Stereotactic biopsy

The correct answer is b.

5. You are collecting data from a 37-year-old client who you suspect may have fibroid tumors. You expect her subjective data to include which of the following symptoms:

- a. Urinary urgency
- b. Difficult defecation
- c. Cyclic migraine headaches
- d. Deep pelvic pain dyspareunia

The correct answer is d.

6. You are completing the chief complaint interview with a client who states that she has a continuous blood-tinged, watery discharge; postcoital bleeding; and dyspareunia. Based on her subjective data, you suspect which of the following medical diagnoses:

- a. Cervical cancer
- b. Hypermenorrhea
- c. Pelvic relaxation
- d. Polycystic ovary disease

The correct answer is a.

7. The chief complaint interview on a client reveals vaginal discharge with itching and burning. The client also reveals she experiences dyspareunia. If her diagnosis is monilial vulvovaginitis, you would expect the wet mount slide to contain which of the following:

- a. Bacteria
- b. Clue cells
- c. Trichomonads
- d. Budding hyphae

The correct answer is d.

8. You are conducting the discharge teaching session for a client with bacterial vulvovaginitis. You instruct her regarding which of the following medications:

- a. Cefoxitin
- b. Gentamicin
- c. Doxycycline
- d. Metronidazole

The correct answer is d.

Violence and Abuse

Nurses who work with clients who are abused may experience strong personal emotions because providing supportive counseling to these clients is often difficult. The following questions are designed to help caregivers of these women and children clarify their personal feelings and increase their awareness of the far-reaching consequences of physical and emotional abuse.

- *How do I feel when I see a woman in the emergency department or office with injuries such as bruises or broken bones sustained from a beating by her husband?*
- *Have I personally experienced emotional, physical, or sexual abuse?*
- *Am I emotionally distressed when I interview and care for children or older persons who are abused?*
- *What are my feelings about women who return to their abusers after a severe beating?*
- *What do I believe about sexual harassment, date rape, and forced sex? Do I believe that women are responsible for bringing these acts on themselves, or do I think they are victims of a crime?*
- *Have I ever seen a woman with a gunshot or knife wound? How did I feel when caring for her? How did I react when she was discharged from the hospital? How did I react when one of these women died?*

Key Terms

Acquaintance rape
Adult maltreatment
syndrome
Assault

Child abuse
Date rape
Femicide
Incest

Neglect
Perpetrator
Rape
Stalking

Stranger rape
Supine hypotension
syndrome
Wife rape

Competencies

Upon completion of this chapter, the reader should be able to:

1. Identify factors that may support a system in which abuse of adults, children, or older persons occurs.
2. Define categories of violence: physical and psychological violence, sexual abuse, and neglect.
3. Identify risk factors for abuse or neglect of adults, children, and older persons.
4. Describe the legal responsibilities of the nurse involved with mandatory reporting and documentation of abuse.
5. Describe the cycle of abuse of an intimate partner.
6. Utilize community resources to aid in the prevention and treatment of persons in abusive relationships.

Violence against women in the United States is a serious threat to their health and welfare (Paluzzi & Houde-Quimby, 1996). This chapter focuses on interpersonal violence and abuse against women of all ages and their children.

INTIMATE PARTNER VIOLENCE

Intimate partner violence is sometimes referred to as *intimate partner abuse*, *domestic violence*, *domestic abuse*, *spouse abuse*, or *wife battering*, all of which describe intentional violent or controlling behavior by a current or former intimate partner. In 1996, some 840,000 women experienced aggravated **assault** (the intentional act of inflicting physical injury on another person), rape, and assaultative victimization by their current or former spouses, boyfriends, or girlfriends (Greenfield et al., 1998). On average, each year from 1992 to 1996, 8 of every 1,000 women received nonfatal injuries from willful or intentional abusive acts by their intimate partners. In addition, women are eight times more likely than are men to be assaulted by intimate partners (Greenfield et al., 1998). Each abusive interaction has the potential to be deadly. From 1976 through 1996, 29.7% of women victims of murder were killed by husbands, ex-husbands, and nonmarital partners compared with 5.9% of male victims (Greenfield

et al., 1998). Among murder victims for every age group, females are much more likely than are males to have been murdered by intimate partners (Cooper & Eaves, 1996). Thousands of deaths occur as a result of repeated assaults over many years (Hodges, 1993). Coercive behaviors of the **perpetrator** (the person accused of a criminal offense), such as belittlement, physical assaults, and stalking, can escalate to **femicide** (murder of a female). Of murders attributed to intimate partners, 75% were female victims. Femicide is the major cause of death for African American women aged 15 to 34 years and the seventh leading cause of premature death for all women in the United States (Hambleton, Clark, Symaya, Weissman, & Horner, 1997). According to the Federal Bureau of Investigation, in 1996, 30% of all women victims of murder were slain by husbands or boyfriends (Uniform Crime Reports for the United States, 1996).

Sexual Assault

Rape is defined as sexual penetration of another by force or threat of force, without consent. Abuse by an intimate partner accounts for half of all rapes of women over 30 years old (Jones, 1994). In one study, Murdoch and Nicholand (1993) found that one in four women in the military under the age of 50 had been physically abused within the past year. Of enlisted women, 31% had been forced to have nonconsensual sex.

REFLECTIONS FROM NURSES

In 1990, the first silent witnesses were produced (see Resources for information on the Silent Witness National Initiative). The silent witnesses are free-standing life-size wooden figures painted red (Figure 11-1). They bear the name and story of a woman murdered in domestic violence, honoring her life and memory. Each figure is carried by two persons in a demonstration march, or the figure is placed on a stand for display. In 1997, Washington, DC, was the site of the Silent Witness National Initiative, where representatives from all 50 states and several countries brought their witnesses for a silent march to Capitol Hill.

During this rally one of the speakers, Laura Katzif, shared her story. Her husband attacked her and cut her face, requiring 17 stitches. As she lay on the gurney in the emergency room thinking to herself, “What did I do to deserve this?,” an attending nurse came up to her, leaned toward her head, and whispered in her ear, “You don’t deserve this. No one does.” Hearing the nurse’s poignant words of validation helped her to make changes to leave this dangerous situation.

Figure 11-1 The Silent Witness National Initiative demonstration in Washington, DC, in 1997 has focused national attention on the many women who have lost their lives as a result of abuse.

Two major categories of rape exist: acquaintance rape and stranger rape. **Acquaintance rape** occurs when a perpetrator with whom the victim has had a previous non-violent relationship uses deceit and coercion to obtain sex. Two types of acquaintance rape are wife rape and date rape. **Wife rape** is a forced sexual experience with a common-law or legally married spouse; **date rape** is rape that occurs between a dating couple without consent of one of the participants. **Stranger rape** is a nonconsensual sexual experience between a victim and an assailant who are strangers. Stranger rape is sudden and often involves weapons (Marx, Wie & Gross, 1996). By 1993, all 50 states had passed laws making marital rape a crime. Studies have estimated that 14% to 25% of wives are forced by their spouses to have sexual intercourse against their will at some time during the course of their marital relationship (Resnick, Kilpatrick, Walsh, & Vernonen, 1991; Russell, 1990).

To assess and provide care to a person who experiences rape, nurses must first understand the psychological effect of rape trauma syndrome. This syndrome is characterized as a response to the extreme stress and profound fear of death, which most survivors experience (Figure 11-2). Rape trauma syndrome begins with an acute or immediate phase of disorganization followed by a long-term process of reorganization that occurs as a result of attempted or forcible sexual assault. The majority of women report symptoms of avoidance and denial, which may prevent them from seeking help and participating in legal prosecution (Kramer & Green, 1991). Nurses may use information on the prevalence of symptoms of post-traumatic stress disorder (PTSD) to help in identification and provision of anticipatory guidance to survivors of sexual assault. PTSD is discussed later in this chapter.

Critical Thinking

Risks of Being Raped

- What would you say to a woman who asks if it is possible to contract AIDS or gonorrhea as an outcome of being raped?
- What are her options for sexually transmitted disease testing?
- What are her options for preventing conception?

Figure 11-2 Caring for a woman who has survived an assault requires compassion and sensitivity during both the interview and physical examination.

Nursing Tip

HELPING SURVIVORS OF RAPE

What you can say to a survivor of intimate partner violence or rape:

- I am afraid for the safety of you and your children.
- Violence only gets worse over time.
- You know when it would be safest to leave, and we are here for you when you are ready.
- You do not deserve to be hit.
- It is not your fault.
- Let me help you figure out a safety plan for you and your children.

Violence During Pregnancy

Abuse during pregnancy occurs at rates of 9% to 20% (Paluzzi & HoudeQuimby, 1996; Rodriguez, Quiroga, & Bauer, 1996). McFarlane, Parker, Soeken, and Bullock (1992) reported a 60% recurrence rate of abuse among pregnant women who are battered. Abuse is associated with the following complications of pregnancy: low weight gain, anemia, infections, increased incidence of first and second trimester bleeding, and increased rates of maternal depression and attempted suicide. Abuse also is

associated with increased use of tobacco, alcohol, and illicit drugs during pregnancy.

The normal physiologic changes of pregnancy can mask the severity of battering and thus the extent of injury to the mother and fetus. Therefore, the nursing assessment for the traumatized client who is pregnant must include an understanding of a woman's altered body systems (i.e., cardiovascular, respiratory, and gastrointestinal systems) during pregnancy. As cardiac output increases, the hormone progesterone lowers systemic vascular resistance. This lowered resistance can cause a hypervolemic state that could mask hypovolemic shock until nearly a 30% blood loss has occurred. At that point the uterus would not have adequate uteroplacental perfusion, and decreased fetal oxygenation would result. The enlarging uterus may further compromise perfusion by compressing the vena cava, decreasing venous blood return to the heart. This phenomenon is referred to as **supine hypotension syndrome**. Severe shock can occur when blood loss is coupled with supine hypotension syndrome.

During pregnancy, respiratory function creates a state of chronic respiratory alkalosis to provide adequate fetal oxygenation. Lower levels of arterial carbon dioxide pressure and serum bicarbonate decrease the buffering capacity of the woman's body and allow for hypoxic tissue damage to occur more rapidly in the traumatized client. Gastric motility is encumbered by the size of the uterus, and the hormones of pregnancy relax the gastroesophageal sphincter. These normal changes make the woman more likely to aspirate food and liquids, and bowel sounds are less audible. Because it is displaced anteriorly by the developing fetus, the urinary bladder is at greater risk for injury.

The abdomen and trunk areas are frequent targets of assaultive blows. A leading cause of fetal death from blunt abdominal trauma is placenta abruption, which is most likely to occur within 48 hours of an assault. Separation of the placenta can be complete (total dislodgment) or incomplete (partial separation). Hemorrhage caused by the abruption will be either concealed (confined within the uterine cavity) or, more frequently, external. If external, blood will drain through the cervix. Women experiencing placental abruption will have unremitting uterine or back pain, a tender and irritable uterus, and visible or concealed hemorrhage. Signs

of fetal distress, disseminated intravascular coagulation, and hypovolemic shock may or may not occur. Placental separation may be detected early by fetal monitoring. Monitoring will show increased uterine tonus, contractions, and a rapid fetal heart rate. The fetus has a better prognosis if the abdominal trauma occurs late in the third trimester and results in only a small, partial separation of the placenta.

Maternal and fetal morbidity risks increase with each additional episode of battering. Campbell (1995b) has found that as the severity of battering increases, so does the woman's risk of death.

Research Highlight

Nurses Assessing for Domestic Violence at Prenatal Visits

Purpose

To determine the extent of violence during pregnancy experienced by Hispanic women receiving prenatal care at an urban public health department.

Methods

During the routine prenatal intake interview the clinic nurse screened all prenatal clients for abuse at the first visit to the maternity clinic. Abuse screening procedures were based on the March of Dimes protocol and included administration of the Abuse Screen questionnaire, developed by Judith McFarland, PhD. If the women had been abused in the year before or during the current pregnancy by their current or former male partners, the women were referred to the on-site abuse counselor. The counselor obtained consent and administered the Severity of Violence Against Women Scale (SVAWS) (Marshall, 1992).

Findings

During a 12-month period, 329 Hispanic women were identified as having been abused. SVAWS scores were high: 30% of women had been threatened with death, 18% had been threatened with a knife or gun, 40% had been punched, 33% had been kicked, and over 20% had been coerced or forced into having sexual relations. Of these women, 80% had been shaken or roughly handled, 71% had been pushed or shoved, and 64% had been slapped on the face and head. Hispanic women who were abused during pregnancy experienced violence of sufficient severity to pose a risk to maternal and fetal health.

Nursing Implications

This study demonstrates the importance of screening healthy women regularly for abuse and if abuse is present, for injury to the unborn child. Nurses should always ask these four prenatal abuse screening questions:

1. During any pregnancy were you ever pushed, shoved, slapped, hit, kicked, or otherwise physically hurt by anyone?
2. During this pregnancy have you been pushed, shoved, slapped, hit, kicked, or otherwise physically hurt by anyone?
3. Before you were pregnant had anyone ever forced you to engage in sexual activity?
4. Since this pregnancy began has anyone forced you to engage in sexual activity?

Wiist, W. H., & McFarlane, J. (1998). Severity of spousal and intimate partner abuse to pregnant Hispanic women. *Journal of Health Care for the Poor and Underserved*, 9, 248–261.

Emergency Department Visits

Bureau of Justice Statistics (1997) show that of 243,000 American women who were abused, 199,260 (82%) were treated in hospital emergency departments for injuries sustained as a result of intimate partner violence and 32% of the women who went to the police did not seek medical treatment. Between 22% and 35% of women seeking medical treatment at an emergency department received their injuries from partners in an ongoing abusive relationship (Anderson & Taliaferro, 1997). These data show that the injuries caused by intimate partner violence are not merely

minor bruises, contusions, or excoriations. Of all women needing emergency surgery, research shows that 20% were battered (Jones, 1994).

The self-report study by Straus and Gelles (1986) has estimated that about 16% of women experienced violence at the hands of intimate partners, which included punching, kicking, and attacks with an object or weapon. Another national survey by Greenfield and co-workers (1998) has shown that 51% of abused women reported their injuries to the police. One in five of these women sought professional medical treatment, with 7% going to an emergency department, and 32% were not treated (Greenfield et al., 1998). Serious injuries (4%) included broken bones,

Research Highlight

Physical Abuse During Pregnancy

Purpose

To determine the prevalence of physical abuse among an ethnically stratified group of pregnant women experiencing vaginal bleeding and reporting to an emergency department.

Methods

This study was a cross-sectional survey using two screening tools: the Abuse Assessment Screen (Stark et al., 1981) and the Danger Assessment (Campbell, 1986). The study sample consisted of 261 African American, Hispanic, and Caucasian pregnant women seen for vaginal bleeding in private and public emergency departments in a large metropolitan area. The women were interviewed in private rooms and were informed about community resources regarding domestic violence. Pregnancy status was determined by urine or serum beta human chorionic gonadotropin tests. A discharge diagnosis was obtained from emergency department records.

Findings

Of the 261 pregnant women interviewed, 33% reported abuse: of these, 27% were African American women; 25% were Hispanic; and 58% were Caucasian. Overall, Caucasian women reported significantly more abuse than did non-Caucasian women. No differences were found among diagnostic groups, and no significant differences among ethnicities were seen.

Nursing Implications

Pregnant women who are abused commonly report to an emergency department and can be readily identified using the following two-question 5-minute screening process:

1. Have you ever been hit, slapped, kicked, or otherwise physically hurt by your partner?
2. Have you ever been forced to engage in sexual activity by your partner?

A “yes” response to either question identifies the need for further abuse assessment. The Danger Assessment (Campbell, 1986, 1995b) is one such tool that can be used to identify whether the woman is at high risk for escalating violence that might be life-threatening.

Greenberg, E. M., McFarlane, J., & Watson, M. G. (1997). Vaginal bleeding and abuse: Assessing pregnant women in the emergency department. *Maternal Child Nursing*, 22, 182–186.

internal injuries, loss of consciousness, and any other injury requiring 2 or more days' hospitalization; other injuries (41%) consisted of bruises, black eyes, lacerations, chipped teeth, and injuries requiring less than 2 days' hospitalization. Of injuries reported to the police, 6% resulted from rape or sexual assault, whereas 0.05% resulted from gunshot or knife wounds (Greenfield et al., 1998).

Recognizing the importance of health care providers in the care of persons experiencing domestic violence, the Joint Commission for the Accreditation of Healthcare Organizations (JCAHO, 1997) requires accredited emergency departments to have policies, procedures, and staff education on the treatment of adults who are battered. Utilization of the ICD-9 diagnostic code of **adult maltreatment syndrome** (995.81) for all clients who have a current history of abuse greatly aids in the monitoring for both JCAHO site review and the prevalence and recidivism of violence by clients using the facility. Some states require nurses to have received continuing education on the topic of domestic violence to renew their nursing license. Use of nationally prepared training materials and programs are helpful in meeting these requirements. Much progress has been made in identifying abuse and implementing interventions to ensure the safety of the client and her family.

Primary Care of Abused Women

Neufeld (1996) reported that 23% of women seen in a family practice setting had experienced domestic violence within the past 12 months. Other researchers showed abuse rates from 14% to 32% in ambulatory care practices (Cohen, DeVos, & Newberger, 1997; Rodriguez, Quiroga, & Bauer, 1996). All this violence by intimate partners adds up to 100,000 days in the hospital, 30,000 emergency department visits, and 40,000 health care visits each year (Felder, 1996).

Forensic nursing is a specialty area of practice that advocates for abused clients by providing clear, precise, detailed descriptions of the abuse. This documentation can be used legally to help obtain a protective or restraining order or assist in the prosecution for assault or murder. Included in the forensic nursing process is an assessment of the client's immediate danger and the creation of a safety plan. These steps are the responsibility of every nurse. Sexual assault examinations involve collecting oral, vaginal, and anal swabs; performing external and internal genital examinations (speculum and colposcopic or endoscopic procedures); combing pubic hairs; and inspecting the skin surfaces of the body for sperm using Wood's light (ultraviolet light) (Figure 11-3). The clinician collects and preserves the integrity of the evidence. While providing examinations to obtain legal evidence, the trained clinician

Figure 11-3 A sexual assault evidence collection kit contains detailed instructions on paper evidence collection and labeling.

always must be aware that these invasive procedures are highly traumatic to the survivor. Some survivors have even referred to the process as a “second rape.” Nonjudgmental support, therapeutic listening, and an individualized safety plan can help the client to take steps toward ending the cycle of abuse.

Safety Planning

Minimum components of a safety plan include preparatory steps for ensuring safety during violent episodes, or details

about how the woman who is being abused will leave the relationship. Community resources (e.g., women’s shelters, the police, the district attorney’s office, women’s centers, and hotline phone numbers) are reviewed, and referrals are offered or made at the time of the visit. The nurse should assess the client’s risk of danger privately, maintaining confidentiality, and must maintain a nonjudgmental demeanor. Each encounter with a client can foster disclosure of the extent of intimate partner violence and empower the client to develop strategies that increase her safety. The nurse should discuss methods of limiting the

Research Highlight

Retaliation after Reporting Abuse

Purpose

To describe the amount of violence experienced by women after they have sought help from the police for violence committed by intimate partners.

Methods

Nurse researchers interviewed 90 consecutive women at a family violence unit of an urban police department after the women sought to file assault charges. Threats of violence, physical assault, stalking, and danger for homicide were measured by interview questionnaires on the day charges were filed and again 3 and 6 months after filing. The women were assigned a counselor and then a police officer who counseled them on the legal process, the cycle of violence, safety planning, and community resources.

Findings

Of these women, 33% had enough evidence to file assault charges, 15% did not, and 11% dropped charges previously accepted by criminal justice officials. Of the perpetrators, 37% were arrested, and 4% were fugitives. Mean violence scores for each outcome were calculated for each time frame using one-way analysis of variance. Only one group was statistically different. The danger of homicide at 3 months was higher in women who had insufficient evidence to file assault charges. The act of attempting to file assault charges by the women, whether or not the charges were accepted or the abusers were arrested, resulted in equally lower levels of future violence.

Nursing Implications

During safety planning, two fears commonly arise: retaliation by the perpetrator because the woman has sought police assistance and inability of the police to provide safety for the woman being abused. In this study, some women reported that the perpetrator knew she had gone to the police. This action demonstrated that she intended to put a stop to the violence and that she had legal support to make it happen. The perpetrators were deterred by the criminal justice system and the prospects of “going to jail” for their crimes. In addition to experiencing less violence after partnering with the criminal justice system, women being abused gained knowledge of their legal rights and how to use the legal system for their protection.

McFarlane, J., Willson, P., Lemmey, D., & Malecha, A. (2000). Women filing assault charges on an intimate partner: Criminal justice outcome and future violence experienced. *Violence Against Women*, 6 (4), 396–408.

Nursing Alert

SAFETY PLANNING

Help a client plan for safety or escape by considering the following:

- Is it safe for the woman and her children to go home?
- Are there weapons in the home?
- Has there been an increase in the frequency or severity of the violence?
- Has the woman been hospitalized in the past as a result of the intimate partner violence?
- Has the abuser threatened to kill the woman or himself?
- Has the woman thought of committing or tried to commit suicide?
- Does the abuser hurt the children?
- Has the woman attempted or is she planning to leave the relationship?

danger, such as removing guns from the house and attempting to avoid arguments in high-risk rooms, such as the kitchen, garage, or any room with objects that are potential weapons. The nurse should help the client prepare a decisive escape plan. First, the client should consider how she will exit the house, for example, by which door or window. Second, the client needs to plan what to take with her when leaving: purse, car keys, cash, and important papers. The client should know to keep these items nearby. She should gather together important documents and be sure they are secure and easy to access. Personal

documents she will need include birth certificates, social security cards, and her driver's license; medical documents include health insurance identification cards and policies; and financial information includes bank account numbers.

A safety plan includes seeking out supportive family members or friends who will assist the woman in leaving the relationship, provide shelter, and call the police when violence is suspected. Integral to all safety planning is referral to community agencies that assist women who are abused. It is important to discuss the woman's concerns about using community agency resources. Fear of physical retaliation after reporting the abuse to the police is a common concern. Does filing assault charges against one's partner stop the abusive behaviors or just make them worse? Some research findings indicate that police intervention is associated with decreased levels of abuse. Research-based clinical practice can assist the nurse in helping the abused woman overcome her fears by building on knowledge and dispelling myths.

Threats of abuse, physical assaults, and the increased risk of homicide experienced by women who are abused affect their health and carry a tremendous amount of morbidity. Campbell and Lewandowski (1997) identified multiple violence-associated illnesses that ranged from minor difficulty with mental concentration and headaches to irritable bowel syndrome and PTSD.

Post-Traumatic Stress Disorder

Post-traumatic stress disorder may develop when an event outside the range of normal human experience occurs that produces marked distress in the person. Violence-related events that may result in PTSD in women include rape, sexual molestation, attempted sexual assault, and witnessing such events. Most typically the triggering event is either aggravated assault with or without a weapon (physical attacks or threats made with the intent to injure) or simple assault, such as pushing, shoving, hitting, kicking, or punching. This traumatic event (or events) coupled with characteristic symptoms that may include intrusive thoughts, nightmares, and flashbacks are frequently and persistently relived by survivors. They experience intense psychological or physiologic distress, or both, when they are re-exposed to environmental stimuli that resemble aspects of their traumatic event. Hence, clients with PTSD try to avoid stimuli that are painful or that cause anxiety by avoiding thoughts or conversations associated with the trauma; avoiding persons, places, or activities that remind them of the trauma; or blocking out memories of the trauma. Women experiencing PTSD from abuse may have a combination of panic disorder and major depression.

Nursing Tip

SEQUELAE OF ABUSE

Abuse of women is likely to be the precursor of chronic disease, substance abuse, and mental health problems, which affect women of all ethnic backgrounds and socioeconomic classes (Grisso & Ness, 1996). All those who experience or witness abuse suffer psychological consequences; some are so traumatized they develop PTSD (Bohn & Holz, 1996).

Cultural Influences

No ethnic or socioeconomic group of women is immune to domestic violence. The National Victims Survey found no significant difference in the rates of severe abuse among Caucasian, African American, or Hispanic American women (Campbell, Masaki, & Torres, 1997). Unfortunately, women belonging to minority groups often face racism and anti-immigrant sentiment that create additional barriers to ending the abuse. Male batterers may use culture and immigration status to control their partners (e.g., claiming that battering is an acceptable cultural practice or threatening to report the woman for deportation if she does not do as told). Fewer services and less information are available to battered women of color, primarily because of economic restraints. Awareness of cultural influences on the abusive ex-

Client Education

Culturally Appropriate Solutions

For clients experiencing violence, refer to the following:

- Bilingual and bicultural programs within the community.
- Support groups that meet in predominantly local areas (e.g., shelters and churches), which provide shared experiences for persons of the same race.
- National African American Women's Health Project, which uses model community-based self-help programs, community-based health centers, films, and publications.
- Immigrant and Refugee Women, Immigrant Assistance Line: English and Spanish, 415-554-2444; Cantonese, Mandarin, and Vietnamese, 415-554-2454.
- Native Americans, Women of Nations: 612-222-5830.
- Additional sources, which can be found by looking in the blue or white pages of your local telephone directory under Domestic Abuse Information and Treatment Centers, Social Service Organizations, Human Service Organizations, Shelters, Women's Organizations, or Family Services.

Nursing Tip

OVERCOMING CULTURAL BIASES

Culturally astute nurses are aware of their own biases and how they may affect their perceptions and relationships with clients from other cultures. You should seek information about other cultures through interactions with clients and community experts, and through reading.

perience can assist nurses in approaching and individualizing services for the client in a more caring manner.

Research studies suggest that African American women are more likely than are Caucasian women to report abuse and other violent crimes to the police (Bachman & Coker, 1995; Hutchison, Hirschel, & Pesackis, 1994).

Stalking

Stalking is repeated harassing or threatening behavior, such as following a person, appearing at a person's home or workplace, making harassing phone calls, leaving written messages or objects, or vandalizing personal property. Stalking includes behavior that would cause fear in a reasonable person: repeated occasions of visual or physical proximity; nonconsensual communication; or verbal, written, or implied threats (Tjaden & Thoennes, 1998). Like sexual assault, stalking is almost exclusively a crime against women and often is perpetrated by ex-husbands or ex-boyfriends (DeBecker, 1997; Jordan, 1995; Patton, 1994; Tjaden & Thoennes, 1998). The National Violence Against Women Survey (Tjaden & Thoennes, 1998) collected information from 8,000 men and women on violence and found that 8% of women and 2% of men had been stalked at some time in their lives. Tjaden and Thoennes found that 1.4 million Americans are stalked yearly and that women are four times more likely to be victims of stalking and twice as likely to be stalked by intimate partners. Stalking affects the health of victims by causing fear and anxiety, which stimulates 30% of women to seek help through counseling and 55% to seek police protection (Tjaden & Thoennes, 1998).

The Bureau of Justice (National Criminal Justice Association, 1996; Greenfield et al., 1998) proposed the following three broad classifications for stalkers based on their relationship to victims: (1) intimate or former intimate persons, (2) acquaintances, or (3) strangers (frequently involving celebrities). By far the most common category of stalking is by intimate partners, and it is the most likely to

QUESTIONS TO ASK ABOUT STALKING

- Are you being followed or spied on by your intimate partner (or previous partner)?
- Does your intimate partner wait outside or show up unexpectedly at your home, school, or workplace?
- Do you receive unwanted phone calls from your intimate partner, or are you receiving many hang-up calls?
- Has your intimate partner sent or left you unwanted notes, letters, or other items of communication that frighten you?
- Has your intimate partner threatened to harm you, the children, or family members?
- Has your intimate partner caused damage to your personal property, for example, cut up your clothing, torn up photographs, slashed your car tires, tried to break down your door, or killed a pet?

have a serious or fatal outcome (DeBecker, 1997; Lingg, 1993; Meloy, 1997).

Interpersonal violence and stalking often are interrelated and may indicate an increased risk of severe violence or fatal outcome (Lingg, 1993; Perez, 1993; Sanford, 1993). A national survey found that 81% of stalked women also were assaulted physically by the same partner (Tjaden & Thoennes, 1998). This finding confirms results of other studies that report a stalker is more likely to be violent if there has been an intimate relationship with the victim (Coleman, 1997; Meloy, 1998). When stalking occurs in conjunction with intimate partner violence, it is likely to end in severe violence and possibly murder (DeBecker, 1997; Perez, 1993). Experts believe that most (70%) women murdered by intimate partners had been stalked by the murderers (DeBecker, 1997; Lingg, 1993; Meloy, 1997; Perez, 1993).

California enacted the first anti-stalking law in 1990, and today comprehensive stalking laws modeled after the Model Stalking Code (National Institute of Justice, (1993) have been adopted by other states (Wallace, 1999; Westrup, 1998). The effect that anti-stalking laws have had and will have on the health and safety of women and children will remain unknown until evaluative studies have been conducted. Most states stipulate that to be classified as an offense the following must have occurred:

- ✦ *Course of Conduct.* The person must commit an act on more than one occasion (the acts included vary from state to state).
- ✦ *Threat Requirement.* The person must commit actions that would cause a reasonable person to be fearful (the threat need not be written or verbal to instill fear).
- ✦ *Intent of the Stalker.* Most states require that the perpetrator know the conduct will cause the other person to perceive said behavior to be threatening (National Criminal Justice Association, 1996). Many states do not require proof of intent to cause fear, rather, merely the intent to commit the act is sufficient.

Impact in the Workplace

Workplace violence is a growing concern in the United States. The employment setting is often the site of an attack by an intimate partner. Several surveys of women who are abused report that high percentages of women experienced harassment or stalking while at work (Riger, et al., 1998; Shepard & Pence, 1988). The workplace is the leading site for homicide of employed women. Most working women are killed in the course of a robbery or other crime. However, Department of Labor statistics show that from 1992 to 1994, 17% of alleged murderers of women in the workplace were current or former husbands or boyfriends. For African American women, the figure was 28%; for Hispanic women, it was 20% (U.S. Department of Labor, 1996).

The effects of domestic violence impact employment productivity. Working women who are being abused at home reported being harassed by their abusive partners in person or by telephone while at work. These women reported being late for work, having to leave work early, and missing work because of the abuse. Some women reported having their cars vandalized by their abuser so that they would have no way of getting to work. In addition, women reported being reprimanded by their employers for problems associated with the behavior of the abusers (Shepard & Pence, 1988). These women also reported losing at least one job because of the violence in their lives. In an attempt to escape or cover up the abuse, women may be compelled to frequently change jobs or accept low-salary positions.

In a study conducted by EDK Associates (1997), 37% of women who had experienced domestic violence reported that the abuse had an impact on their work performance. One in four (24%) victims of domestic violence said the abuse caused them to arrive late for work or to miss days of work. Of these women, 15% had a difficult time keeping a job, 20% said the abuse affected their

Nursing Alert

WARNING SIGNS FOR POSSIBLE WORKPLACE VIOLENCE

The following are indicators of possible violent behavior in a co-worker:

- Keeping away from others.
- Failing to take responsibility for personal actions.
- Behaving in a rigid and controlling manner.
- Acting out anger, or seeing only one point of view.
- Talking one way and acting another.
- Engaging in addictive behavior, which is used to escape reality.
- Acting out of character, which is done to shock others.

ability to advance their careers, and 12% reported that a current or former intimate partner harassed them at work.

Employers have begun to recognize that domestic violence is a threat to employee safety and productivity. Companies now are actively implementing policies and procedures that support a “no tolerance” attitude toward domestic violence.

Domestic Violence in the Workplace

The cost of domestic violence to businesses is enormous. Statistics show that the yearly medical costs of domestic violence total \$3 to \$5 billion (Bureau of National Affairs, 1990). Businesses forfeit another \$100 million owing to lost wages from sick leave and absenteeism and to the costs of nonproductivity, turnover, and retraining (Colorado Domestic Violence Coalition, 1991). Domestic violence has negatively impacted many aspects of employee performance, most notably psychological well-being (56%), productivity (49%), and attendance (47%) (Roper Starch Worldwide, 1994). It is clear that physical abuse, harassment, and stalking by intimate partners affect quality of work and even the ability to be employed.

Portrait of an Abuser

Chronic alcohol use and illicit drug use are among the most prevalent risk factors for being an abuser (Fagan, Barnett, & Patton, 1988; Greenfield et al., 1998; Hotaling & Sugarman, 1986; Kantor & Straus, 1989; Ptacek, 1998). Roberts (1988) found that at the time of the assault, 70% of perpetrators were under the influence of drugs, alcohol, or

both; 32% used only drugs, 17% used only alcohol, and 22% used both. Even higher rates of drug and alcohol use were seen in a study by Brookoff (1997): 92% of perpetrators used illicit drugs or alcohol on the day of the assault, and 45% had been intoxicated daily for the past month. Coleman and Strauss (1983) reported rates of violence almost 15 times higher for husbands who were “often” versus “never” drunk in the past year. Men’s drinking patterns, especially binge drinking, are associated with marital violence across all ethnic groups and social classes (Kantor, 1993).

Battering is more than an isolated case of the person “blowing up.” It is a process of deliberate intimidation intended to coerce the person being abused (i.e., girlfriend or boyfriend, spouse, significant other, child, or older person) into doing the will of the abuser. It is enacting behavior that shows an established set of control skills. In reality the man who abuses his wife and children is not “out of control,” rather, he is very much “in control.” The perpetrator enforces control in a way that compares to brainwashing. Coercive techniques are used to set up a regulating situation for domestic violence. These techniques include isolation, monopolization of perception, induced debility and exhaustion, threats, occasional indulgences, demonstration of the abuser’s omnipotence, degradation,

Client Education

Business Interventions Against Intimate Partner Violence

- Provide safety training sessions on the telltale signs of domestic abuse to aid in recognizing abuse and providing help for employees who are being abused.
- Post hotline numbers for violence prevention information in rest rooms where they can be written down discreetly.
- Provide cellular phones to employees who are being abused for rapid access to emergency police intervention.
- Assign parking spaces close to front doors to employees who are being abused to allow them to avoid isolated parking areas.
- Alter the workplace or work pattern of employees who are being abused by temporarily reassigning them to a different branch of the company or by initiating a flexible time schedule.

Research Highlight

Indicators of Intimate Partner Domestic Violence in Women's Employment

Purpose

To better understand the effects of violence committed by an intimate partner on employee productivity.

Methods

Nurse researchers surveyed 90 consecutive women applying for protection orders against intimate partners (current or former) at the district attorney's office of a large county.

Findings

The researchers found that 87% of women interviewed had been employed at one time and 89% had experienced harassment by intimate partners related to their work. The most common outcome (65%) of work-related harassment was being late for work or leaving work early as a result of abuse. Lost productivity and reduced performance also were indicated by findings that these women missed work (58%), lost a job (21%), or were prevented from working (47%) because of intimate partner violence. When these women were asked how the abusers prevented them from working, almost half (44%) stated the abusers left them without transportation to work by disabling the car or hiding the car keys.

Nursing Implications

This study shows the need for nursing intervention in intimate partner violence in the workplace. Nurses should help women who are abused to develop personal safety plans, which include safety issues at the workplace. Nurses should also develop community interventions through corporate and business public education projects by working collaboratively with occupational health nurses, company safety committees, and concerned employees.

McFarlane, J., Malecha, A., Gist, J., Schultz, P., Willson, P., & Fredland, N. (2000). Indicators of intimate partner violence in women's employment: Implications for workplace action. *Journal of Occupational Health Nursing*.

and enforcement of trivial demands (Jones, 1994; Willson, 1998). Perpetrators of abuse use these same techniques over a broad spectrum of victims (i.e., intimate partners; older persons; special populations, such as persons who are disabled or homeless and immigrant persons; and children).

- ✱ Isolation of the person being abused from support systems makes that person solely dependent on the person committing the abuse. For example, women frequently say, "He moved me away from my friends, he didn't want me to go anywhere unless he was with me, or he would eavesdrop on my telephone conversations."
- ✱ Monopolization of perception is the total perceptual concentration of the person being abused on not upsetting the person committing the abuse. For exam-

ple, this technique is expressed by the comment, "I was always scared the abuser would blow up." This technique causes the victim to concentrate on the immediate situation, be introspective, and decrease competing input that frustrates (or eliminates) all actions that are not in compliance with the wishes of the controller (Jones, 1994; Willson, 1998).

- ✱ Induced debility and exhaustion occurs when the person committing the abuse physically or emotionally debilitates the victim and acts to create a state of exhaustion in that person. Examples of this technique are keeping the victim awake at night by starting a fight and not allowing access to a health care provider for injuries the victim receives from battering or other types of abuse. The exhaustion or debilitated physical condition weakens the victim's ability to resist the will of the controller.

- Threats also are used to induce anxiety and despair. For example, the person committing the abuse may threaten to take away something of great value to the victim (e.g., children from a mother; a car or home from an older person; an ambulatory aid, such as a wheelchair, from a person with a disability; or a special pet, toy, or person from a child). Perpetrators also exact their control by making threats such as “I’ll find you wherever you go.”
- Occasional indulgences (e.g., flowers; a vacation; special gifts; or treats, such as dining out, going to a movie, or visiting a friend) are positive motivators for compliance with the controller’s wishes. Because the victim is very isolated, these occasional indulgences may be the only signs of kindness or love she receives (Jones, 1994; Willson, 1998).
- Demonstration of omnipotence often is manifested in physical signs of abuse and seems to prove to the victim the total futility of resistance (Jones, 1994; Willson, 1998). For example, the abuser often beats the victim or withholds food, assistance with personal care regimens, or mobility (e.g., transportation; or if the victim is a person with a disability, a wheelchair, braces, or ambulatory assistance).
- Degradation is another tactic used by the controller (Jones, 1994; Willson, 1998). Degrading words and actions beat down the victim’s spirit and self-confidence. Victims are left with an eroded sense of self-worth and no belief in their own capabilities.
- Enforcement of trivial demands (e.g., “You’ll wear your hair long or else!”) by the controller is used to develop the habit of compliance in the victim. A behavioral pattern of obedience occurs because every victim knows what “or else” means in their relationship with an abuser.

By using the behavior clues listed previously, abusers succeed in turning victims into obedient isolated persons with low self-esteem. Victims are restricted emotionally and often socially and financially. Victims are fearful of leaving because the threats made by the person committing the abuse may be carried against them and possibly their loved ones. Victims fear for their lives!

Nursing Implications

Women who are abused seek health care interventions at emergency departments; prenatal clinics; general medicine practices; and social support agencies, such as women’s shelters (Klein, Campbell, Soler, & Ghez, 1997). When the abusive relationship becomes eminently violent, women most often seek help and protection from legal enforcement agencies (McFarlane, Soeken, Reel, Parker, & Silva,

Nursing Alert

ABUSE ASSESSMENT SCREENING

Questions that help you screen for abuse:

- Has anyone ever hit, slapped, restrained, or hurt you physically or emotionally?
- Are you afraid of your partner at times? Of your previous partner?*
- Have you ever felt unsafe in your home situation?*
- Does your partner* like to boss you around?
- If your partner does not get his own way, how does he act?
- Have you been forced to have sexual relations or engage in sexual activities that you are uncomfortable doing?
- When arguing with your partner, does he threaten to hurt you or the children?
- Has your partner ever stopped you from leaving home, visiting family or friends, or going to work or school?
- Do you have a say in how to spend money?
- Are any of these things occurring now?

*Partner, spouse, boyfriend, ex-husband, or ex-boyfriend.

**Quick screening questions.

Figure 11-4 In addition to physical and emotional support, nurses can share literature and make referrals for clients who have experienced violence.

1997). In large urban police departments, specialty units have been established to facilitate services for domestic violence victims (Berry, 1998).

Violence against women creates a public health dilemma that mandates nurses to implement preventive strategies. Nurse clinicians are called on to assess the dangerousness of abusive relationships for their clients in a variety of settings and to offer care, resources, and referrals as appropriate (Figure 11-4). These assessments frequently are based on a history of abuse, the nurse clinician's intuition, and the clinician's knowledge of risk factors for homicide (Campbell, 1995b; Gondolf, 1998). Nurse clinicians refer or are mandated to report women who are abused to the criminal justice system, that is, the police or the district attorney's office.

THE CYCLE OF VIOLENCE

The cycle of violence was first described by Walker in 1962 (Paluzzi & Houde-Quimby, 1996). Walker (1984) identified family violence patterns as consisting of three phases: the tension-building phase, the acute battering phase, and the honeymoon phase. The cyclic behavior begins with a time of tension-building arguments, progresses to violence, and settles into a making-up or calm period. The time between the acute battering and honeymoon phases was identified by Curnow (1997) as the open-window phase, when the battered victim is most receptive to receiving help. With time, this cycle of violence increases in frequency and severity as it is repeated over and over again.

The traditional view of a woman who is battered is that of a dependent victim, one psychologically unable to take steps to stop the abuse (Campbell & Fishwick, 1993; Gondolf, 1998; Gondolf & Fisher, 1988). This traditional perspective fails to see the potential present in these women that enables them to survive. These women will seek help; and it behooves nurses to understand when that will occur, learn effective interventions, and provide empirical information as to the impact of those interventions.

Understanding Walker's cycle of violence can assist nurses in identifying the process and timing of interventions for women who are stalked and abused. In phase one, the tension-building phase, the perpetrator becomes irritated easily and increases demands and efforts to control the woman. She, in turn, increases her attempts to placate the abuser and denies awareness of impending danger. This phase may last for hours, day, weeks, or even years.

In phase two, the acute battering phase, perpetrators hit, slap, kick, or perform other acts of violence against the intimate partners. This phase also may last for hours or

days, and women are powerless to affect the outcome. Women who are battered initially may not perceive the reality of their situations and therefore ignore their intuition, cognitively minimize the danger and severity of the violence, or blame themselves (DeBecker, 1997; Graham et al., 1995). These women believe no alternatives to the violence exist and thus focus their attention on survival (Curnow, 1997; Landenburger, 1989; Walker, 1984). Women who are severely abused experience a loss of self and often become zombielike or numb (Graham et al., 1995; Vitanza, Vogel, & Marshall, 1995).

In phase three, the honeymoon phase (calm period), the perpetrator expresses sorrow and promises the abuse will never happen again. Denial permeates the cycle; the woman denies her partner is a batterer, denies being injured, and denies there are alternatives. She also defends herself by appealing to high loyalties, such as religion, marriage, and family values (Curnow, 1997). The denial of reality prevents her from seeking help during this phase.

A phenomenon observed in women who are severely abused is that they appear to lose their "observing self" and question their own perceptions (Gondolf & Fisher, 1988). It is the loss of self or an awareness of the reality of her situation that prevents a woman who is abused from seeking help. However, during the open-window phase the woman is most likely to see the reality of her situation, that is, she is a victim and is not able to stop the violence (Curnow, 1997). That is not to deny the fact that persons who are abused have innate strength, will work to change or improve their situation, and will seek help as the violence escalates (Gondolf & Fisher, 1988). Another perspective is that once the costs of living in a violent relationship (e.g., injuries) outweigh the benefits (e.g., loving contriteness), the woman will seek help if she perceives effective help is available (Walker, 1984).

Helpseeking in women who are abused may offer a narrow window of opportunity for nursing interventions to occur. Various actions indicate helpseeking: calling police; going to the emergency department or a clinic; contacting a lawyer; seeing her clergy; confiding in someone; talking about suicide, retaliation against the violence, and leaving the abuser (Curnow, 1997; Gondolf & Fisher, 1988; Greenfield et al., 1998). According to Curnow the open-window phase is the opportune time for nurses to intervene and educate these women as to the reality of their situation (Figure 11-5). Curnow (1997, p. 132) states that during this phase women make reality statements such as "I realized I couldn't take it anymore" or "I just woke up." When the woman seeks help, she is in less denial and open to validation of her current perceptions (Curnow, 1997). Nursing knowledge concerning abusive behaviors at the time of helpseeking and abusiveness after helpseeking can provide empirical knowledge to facilitate interventions at the most opportune time and may save the woman's life. It is

Figure 11-5 Nurses need to be skilled in recognizing when a client who is battered is most receptive to help and most likely to accept the reality of the abusive situation.

essential that nurses attain information to identify and strengthen protective mechanisms used by women who are abused (Woods & Campbell, 1993). This information is vital because researchers have indicated that the abused woman's continued helpseeking depends on the response she receives and the impact that response has on the violence (Dobash, Dobash, & Cavanagh, 1985).

VIOLENCE AGAINST CHILDREN

Children who are in an environment in which violence is occurring among adults are far more likely to be abused than are other children. Even if they are not abused, young children may receive serious injuries such as broken bones or loss of consciousness when objects are thrown, slammed, or overturned. Older children may sustain injuries while trying to intervene to end the assault. The witnessing of their mothers being assaulted by their partners—emotionally, physically, or sexually—causes children to live in fear and a state of instability. Children who witness battering often suffer from guilt, anger, depression, anxiety, and shyness; they have nightmares, are irritable, and have problems getting along with others. Frequently they “act-out,” that is, they mimic aggressive and violent behaviors they have seen (e.g., slapping a younger sister, like Dad does Mom; or telling their mother to “shut up or I’ll kill you”).

A major modifier of human behavior is experience—not genetics—and it results in the critical neurobiologic factors associated with violence (Perry, 1997, p. 125). Family relationships during infancy and childhood determine how the neurologic pathways of the person are organized. In a study by Perry, Pollard, Blakley, and Baker (1995),

175 young children who were severely traumatized demonstrated both mental and physical adaptive responses that included hyperarousal and dissociation. These researchers theorized that the trauma of violence on the developing child disrupts the normal sequential order of brain development, leading to major abnormalities in neurodevelopment (Perry et al., 1995). For example, the child experiencing severe abuse may develop atypical or abnormal patterns of neuronal activity, such as an overactive “fight and flight” response that can be expressed as hypervigilance, difficulty sitting still or concentrating, and learning problems. Preschoolers from violent homes may develop aggressive behavior or PTSD.

Children who witness violence may internalize their stress. They frequently blame themselves for the violence. Considerable amounts of their energy are spent trying to figure out how to prevent their parents from fighting. Both physical and intellectual growth can be affected. These children routinely have been found to have higher blood pressure readings and higher pulse rates than children who do not witness violence. Children from violent homes experience more colds, sore throats, sleepless nights, and bed-wetting than do other children. In psychological development the child must first obtain a sense of safety before progressing to the higher developmental stages of self-esteem or self-actualization. Children reared in violent homes have difficulty expressing empathy. Typically the child's method of conflict resolution is learned from parental modeling; in a violent home this modeling consists of either passive (submissive) or aggressive (abusive) methods to resolve problems.

It can be difficult for health care workers to distinguish the normal injuries of childhood from those resulting from abuse. Children routinely sustain scratches, scrapes, cuts, bumps, and broken bones. Some of these injuries are serious enough for medical attention in a physician's office, a clinic, or hospital. However, some of these children with

Critical Thinking

Evaluating the Risks and Benefits of Leaving an Abusive Spouse because of the Children

- Is it better for a woman to leave an abusive spouse and rear the children in a single-parent home?
- What if the single parent has financial difficulties?
- What are the benefits and risks of keeping the family together “for the children's sake”?

injuries are victims of abuse. As a nurse, you will be on the front line in caring for these injured children. You must sort through the historical and physical data to implement a nursing care plan that ensures optimal health and safety for the young patient.

Child Abuse

Child abuse is any physical or mental injury, sexual abuse, exploitation, negligent treatment, or maltreatment of a child who is of the age designated by the particular state as being a child (usually 18 years old or younger). Mental abuse can damage a child's psychological, social, and intellectual well-being. Behavioral signs and symptoms include anxiety, depression, aggression, and withdrawal. Often, one or more behaviors are exhibited by a change in the child's behavior (e.g., the child drops out of extramural school activities), emotional response (e.g., the child behaves aggressively, or cognition (e.g., a sudden drop in the child's grades is seen). **Neglect** of a child occurs when the parent or guardian fails to provide adequate food, clothing, shelter or medical care expected within the family's financial means. The negligent acts endanger

REFLECTIONS FROM A NURSE

"The year was 1975. A neighbor boy's very tired stepfather came home from his auto repair shop one hot summer afternoon. He drank several beers as he rested while mom left to mind the shop. The 9-year-old boy did not jump to do something the stepfather instructed, so he took off his 2-inch leather belt and lashed the boy's back and even left a buckle mark by his ear. Some of the welts were bloody when the boy appeared on my doorstep for first aid, and I called the chief of police. The stepfather was arrested, went to trial, paid a fine, and was released. As a neighbor, nurse, and parent myself, I was shocked and angry that a 9-year-old child would be subjugated to such violence."

Nursing Alert

WARNING SIGNS OF CHILD ABUSE

- Bruises and welts that resemble the shape of the object that inflicted the injury, such as a belt buckle
- Cigarette burns on the soles of the feet, palms of the hands, back, or buttocks
- Immersion burns, that is, doughnut-shaped burns on the buttocks, or stocking or glovelike patterns without splash burns on the extremities
- Rope burns
- Lacerations or abrasions of the mouth, gums, lips, eyes, ears, or external genitalia
- Broken bones
- Abdominal injuries, that is, bruises, intestinal perforation, ruptured liver or spleen, renal or urinary bladder injury, pancreatic injury, or intramural hematoma of the bowel
- Subdural hematoma, subarachnoid hemorrhage, or cerebral infarction
- Retinal hemorrhage and other symptoms of suffocation
- Chemical abuse

the child's health. Physical abuse can be recognized by the nurse's assessment of subtle or obvious signs and symptoms.

The long-term physical and mental consequences of *corporal punishment* (use of physical force to discipline) are well documented in the literature and support the position of the scientific community on nonviolent discipline (Hemenway, Solnick, & Carter, 1994). These authors indicate that verbal abuse may have even more severe outcomes than does physical abuse. Verbal intimidation is the root of low self-esteem, poor conflict resolution skills, and lower intelligence.

Physical assaults, such as hitting the back of the hands with a ruler or strap, can cause permanent orthopedic deformities of the hands and subsequent loss of function (Chicarilli et al., 1997). Children can suffer PTSD from their abusive experiences. Spanking to the buttock invokes sexual physiologic responses. Johnson (1996) has indicated that the sexual nature of the buttocks is understandable by the close proximity to the genitals as well as the high concentration of nerve endings. When the buttock is spanked, blood flow to the genitals increases. This physiologic change coupled with the desire for intimacy with the parent can link an association of fulfillment of longing with the pain of spanking.

A common sense rule of moral code is “Do not injure.” This rule would support preventing physical, sexual, and psychological injury to a child. Another, common sense rule is “Prevent an innocent person from being harmed.” Class disruption and a poor learning environment may result in greater harm to more students than would a spanking to one child, especially if the corporal punishment was given in a timely manner, consistently, and without emotion. Societal rules for corporal punishment are in a state of flux and are weighted on the side of nonuse of corporal punishment. Nurses should offer other choices to parents to achieve nonviolent outcomes, such as a system that reinforces positive behavior (e.g., the parent gives the child praise for favorable behavior). Discipline need not be punitive to be effective. One common type of noncorporal punishment is “time-out” whereby the child’s behavior causes the consequence of being made to “sit in a chair” or “go to bed” for a few minutes instead of receiving a “spanking.” Nurses should discuss with parents different forms of discipline and help parents form clear discipline guidelines that aid in reinforcing their child’s positive behavior. Parents must be comfortable with the guidelines they set forth for their children or the guidelines will be difficult to reinforce consistently.

Child Sexual Abuse

For decades child sexual abuse had been thought to be rare; however, growing research indicates the contrary. Salter (1992) reviewed child abuse studies from the 1920s through the 1980s and found that child sexual abuse was a substantial social problem. All the studies she analyzed reported sexual abuse prevalence rates of at least 20%. Child abuse often occurs in the form of *incest*, or sexual relations between blood relatives or surrogate family members.

The number of substantiated child sexual abuse cases in the United States was 126,095 per year (U.S. Bureau of Census, 1997). One national telephone survey of 1,042 boys and 958 girls aged 10 to 16 years revealed that 15.3% of girls and 5.9% of boys interviewed had experienced some form of sexual abuse (Finkelhor & Dzuiba-Leatherman, 1994). These reports demonstrate the need for vigorous investigation of child sexual abuse as a public health problem. Sexual abuse occurred more frequently than did acquired immunodeficiency syndrome (71,547 cases), hepatitis A (31,582 cases), hepatitis B (10,805 cases), Lyme disease (11,700 cases), salmonellosis (45,970 cases), shigellosis (32,080 cases), primary and secondary syphilis (16,500 cases), and tuberculosis (22,860 cases) (Centers for Disease Control and Prevention, 1998).

When a sexually transmitted disease (e.g., gonorrhea, syphilis, or chlamydia) is diagnosed in a child after the neonatal period, sexual abuse must be considered in de-

termining the cause. Nurses are ethically and legally obligated to report suspected child abuse, including sexual abuse.

Some indicators of child sexual abuse are:

- ✱ Sexually transmitted diseases (STDs). STDs among children presenting for care after the neonatal period almost always indicate sexual abuse (Eng & Butler, 1997, p. 80).
- ✱ Anogenital injuries. Anogenital injuries often are absent in children who are sexually abused because these elastic tissues can return to their normal appearance after injury, bruises may take more than 24 hours to appear, and lubricants may have been used to prevent injury. It also is possible that penetration may not have occurred. Gross injury is seen in 25% to 40% of children who are sexually abused (De Jong, 1992). Colposcopy, tissue stains, and photographic evidence may aid in detection of anogenital injuries. Some of the injuries reported are labial agglutination, external injuries to the labia minora, posterior fourchette (indicative of penile penetration), irregular hymenal scarring, and swelling or bruising of the perineum (Bachman, Moeller, & Benett, 1988; De Jong, 1992). Indicators of anal trauma are anal sphincter relaxation, swelling, and bruising; anal fissures; loss of perianal fat; and venous engorgement after 2 minutes in a knee-chest position (De Jong, 1992; McCann, Voris, Simon, & Wells, 1990). The increased vascularity in the anal region may last from weeks to years.
- ✱ Other physical injuries. Other physical indicators of sexual abuse in children are enuresis, encopresis, sleep disturbances, eating disorders, and increased oral behavior, such as nail biting and thumb sucking (De Jong, 1992).

Children Witnessing Violence

Children witness violence on television, in sports, on the playground, in the classroom, on the streets, and in the home. Every year 3 to 10 million children observe their mothers being physically assaulted (e.g., punched, slapped, stabbed, shot, or burned) by their intimate partners (Humphreys, 1997; Jaffe, Wolfe, & Wilson, 1990). Children are more traumatized by witnessing such violence in their own homes than by witnessing violence that occurs outside the home, such as street fighting or gang violence (Groves, 1995; Groves, Zuckerman, Marans, & Cohen, 1993). Kalmuss (1984) has studied children who experienced physical violence and compared them with those who only witnessed violence within their family. Children who witnessed violence in their home were more likely to commit spousal abuse as adults than were those

who did not. Intergenerational learned abuse is supported by an almost societal tolerance of violence—outbursts of fighting by sports celebrities, songs about abuse and killing of abusers, computer games emphasizing violence.

Children who exhibit violent behavior during their preschool years or who have learning disabilities, language delays, or attention deficit–hyperactivity disorder are at increased risk for conduct disorders when they are older. Youngsters who are physically aggressive before the age of 15 years have the strongest propensity for being perpetrators of violence.

Unfortunately, spousal and child abuse often occur together. Stark and Flitcraft (1988) reviewed the charts of children suspected of being abused or neglected and found that 45% of the mothers of these children were abused. A somewhat higher estimate was obtained in Straus and Gelles' 1985 national survey of over 8,000 American families (Straus & Smith, 1995). In a home in which the husband hit his wife, child abuse was 150% more likely to occur than in a home in which the husband did not do so (Straus & Gelles, 1996). Not only are children at risk for injury, they also are at risk for death. Felix and McCarthy (1994) examined 67 child fatalities in families identified by the Massachusetts Department of Social Services and found that 29 (43%) of these deaths occurred in families in which the mother of the child also was beaten.

Child abuse sequelae are most often exhibited by the child's physical behavior (aggression and conduct problems) and the child's emotional behavior (withdrawal, anxiety, or fearfulness) (Kolbo, Blakely, & Engleman,

Critical Thinking

Questions on Corporal Punishment

Is corporal punishment ever justified?

Who should decide?

Who should administer it?

What does it teach children?

1996). Aggression has a common pattern of problematic behaviors (aggressive, antisocial, and oppositional actions), particularly among boys. Holden and Ritchie (1995) have found that children of women who are battered showed significantly more physical aggression toward their mothers than did children of women who were not battered. Role modeling may account for the high aggression rates among boys who observe their fathers hitting their mothers. Straus, Gelles, and Seimetz (1980) found that boys who observed their fathers hitting their mothers were 1000% more likely to abuse their wives than were sons who did not witness this type of abuse.

Holden, Geffner, and Jouriles (1998) found that many children of women who are abused experience learning difficulties, PTSD, and social behavior problems. Exposure to domestic violence has negative mental health effects on children, with higher levels of conflict resulting in more severe dysfunction (Campbell & Lewandowski, 1997). Whereas even young children are sensitive to parental verbal aggression, it is the actual acts of abuse that have the most harmful effects (Kilpatrick & Williams, 1997; Laumakis, Margolin, & John, 1998).

Jaffe, Wolfe, and Wilson (1990) have suggested that the school problems of children who witness abuse may be due to anxiety surrounding imminent violence. These researchers noted that these children spend much of the school hours distracted and inattentive to classroom activity.

Client Education

Recommendations of the American Academy of Pediatrics

The American Academy of Pediatrics (AAP) recommends that parents be taught:

- That homes without handguns reduce accidental and intentional injury or suicide.
- That they should monitor television content to avoid violence and limit viewing time to 2 hours daily (no TV before 2 years of age).
- That they should set limits for children, without spanking or hitting them.

Conference News Update: American Academy of Pediatrics 1999 Annual Meeting. Washington, DC. (2000). *Clinician Reviews*, 10(1), 154–156.

Nursing Implications

Children living in abusive homes are at developmental risks as well as being at risk for physical abuse and ultimately death. Yet these children are difficult to identify because their symptoms can mirror behavioral problems unless viewed in the context of the conflict at home. For example, it may be abnormal for children to be concerned about the safety of their parents unless it is viewed in the context of the violence that the parent is experiencing in the home. Another reason it may be difficult to identify

these children by their symptomatology is that the aberrant behaviors, such as sleeping disorders, may be labeled as pathological conduct (Hughes & Barad, 1982). Identification of children living in abusive homes may also be difficult because these children are asymptomatic at the time. Therefore, nurses must remain cognizant that children being seen for health care may be living in a violent home and may need nursing intervention.

In school, these children may exhibit vision, hearing, learning, and developmental problems. Regression symptomatology in a child could trigger the school nurse to consider psychological testing or psychiatric referral for stress, trauma, alcohol or drug dependency, or depressed

mood states. Indeed, these are important differential diagnoses; however, for the child witnessing violence in the home, health interventions may not ameliorate the problem. The child's situation can only be resolved by resolving the violence in the home.

Child health visits are perfect opportunities for nurses to detect and intervene for the entire family (Barkan & Gary, 1996). A woman who is battered may not seek health care for herself but will take her young children for routine preventive health care and for identified childhood issues such as encopresis, enuresis, or night terrors. Therefore, many professionals have encouraged routine screening of women who are battered within the pediatric setting

Nursing Tip

NURSING CARE OF THE CHILDREN OF WOMEN WHO ARE BATTERED

Indicators of Abuse in Children

- Difficulty sleeping, night terrors
- *Enuresis* (involuntary release of urine after the age of bladder control)
- *Encopresis* (watery colonic contents that bypass a hard stool)
- School problems: drop in grades, truancy, or dropping out of school
- Aggressiveness: hitting a parent or fighting with siblings or peers
- Unexplained weight loss or gain
- Loss of appetite lasting more than a month

Indicators of Abuse in Mothers

- Lack of eye contact
- Low tone of voice
- Inappropriate affect for the situation
- Visible injuries
- Expression of feelings of hopelessness or of being trapped
- Few support systems

Questions to Ask the Mother

- We all have conflict in our homes. How is conflict handled in your home?
- Are you being slapped, hit, punched, kicked, or beaten by your partner?
- Has your child witnessed this violence?

Plan of Action

- Develop a protocol for a plan of action before assessment.
- Advise the mother that no one deserves to be abused.
- Discuss the cycle of violence to diminish the mother's minimization of the problem.
- Encourage the mother to develop a safety plan: Have her find family and friends who will help her get out of the dangerous situation. She should
 - Hide a suitcase packed with clothes, any insurance policies, her marriage license, her driver's license, and any bank account numbers.
 - Hide money.
 - Hide an extra set of house keys and car keys.
 - Establish a secret code with her family and friends.
 - Initiate role-playing about the secret code with her children.
- Offer to keep a photocopy of the children's social security cards, birth certificates, and immunization records in the chart for the mother.
- Address the presence of guns in the home; if present, encourage the mother to try to ensure the guns are not loaded.
- Refer the mother to the appropriate community services.
- Refer the mother to the social services department.

(American Academy of Pediatrics' Committee on Child Abuse and Neglect, 1998; Barkan & Gary, 1996; Wright, Wright, & Isaac, 1998).

Routine screening of battered women at all well-child visits allows mothers the opportunity to talk about this problem and gives advanced practice nurses the opportunity to educate families. Health care workers should interview women alone; ask questions such as "We all have disagreements at home—what happens when you and your partner disagree?"; provide information on community resources; and educate women about the dangerousness of domestic violence (American Academy of Pediatrics' Committee on Child Abuse and Neglect, 1998). Tested clinical nursing protocols exist for assessment and intervention (McFarlane & Gondolf, 1998; McFarlane & Parker, 1998) (Table 11-1). A unique form of child abuse called Munchausen Syndrome by Proxy is discussed in Box 11-1.

Current interventions are focused primarily on safety. Another concern is prevention of intergenerational transmission of aggressive behaviors, which can be accomplished by focusing on the safety of the victim and children.

Box 11-1 Munchausen Syndrome By Proxy

Munchausen syndrome by proxy is a form of child abuse that can cause illness, disease, or even the death of a child. This syndrome is defined as the deliberate induction of symptoms of illness or reporting of physical symptoms in a child by the caregiver (often the mother) to solve some personal conflict. For these caregivers, their personal history of illness or family members' illness has taught them that sickness brings attention and love. This syndrome has four components:

- The caregiver first simulates the symptoms of illness in the child (e.g., bleeding, seizures, central nervous system dysfunction, apnea, diarrhea, vomiting, fever, or rashes) (Rosenberg & Fenley, 1991).
- The caregiver may stimulate symptoms by suffocating or poisoning the child or by contaminating laboratory specimens. Children are repeatedly brought for medical care, whereby the child is subjected to multiple diagnostic procedures in search of the cause of the illness.
- The caregiver appears as caring and overprotective; however, when the child and caregiver are separated, the child's symptomatology ends.
- The caregiver denies causing the symptoms that have stopped. In light of the caregiver's protective behavior, it is often a difficult diagnosis for the health care team to make.

VIOLENCE AGAINST OLDER PERSONS

Older persons usually are defined as those over 65 years of age; however, this definition may include persons aged 60 and older. This population often is further classified into two groups: the young-old, 65 to 75 years of age, and the old-old, over 75 years of age. The percentage of older persons in the population is increasing rapidly because of declining birth rates and increased life expectancy. Unfortunately, an alarming number of older persons are being abused or neglected. Domestic abuse of older persons remains a hidden and underreported crime. The National Center for Elder Abuse (NCEA, 1997) estimates that only 1 of 14 abuse incidents in this population is reported to adult protective agencies or the police. The U.S. national incidence and prevalence of abuse in older persons is unknown; estimated figures range from 820,000 to 2.5 million persons.

Characteristics

Most (67%) older persons who are abused and neglected are women, with a median age of 77.9 years for both men and women (NCEA, 1997). Of abused older persons, 66% are Caucasian, 19% are African American, and 10% are Hispanic. Ethnic groups with the lowest rate of abuse are Asian–Pacific Islanders and Native Americans. In addition, older persons who are abused often come from families with a pattern of violence for several generations or in which stress levels are high for a caregiver ill-prepared to fulfill the complex needs of an older person. No stereotypical set of characteristics exists for those who commit abuse against older persons: The perpetrators may be spouses, adult children, close friends, family members, guardians, or neighbors.

Signs

Abuse of older persons falls into five categories: neglect, physical abuse, psychological (emotional) abuse, financial abuse, and sexual abuse. Neglect is the most common form of abuse in older persons and results when the caregiver fails to provide adequate care. Neglect may be a

willful act or the result of inadequate knowledge on the part of the caregiver; the latter is known as nonwillful failure to provide adequate care of the older person. Self-neglect is failure of older persons to care for themselves. Some indicators of neglect are poor personal hygiene, soiled clothing, misuse of medications, malnutrition, and isolation (being left alone).

Physical and psychological (emotional) abuse are the next most frequent types of abuse in this population. Physical abuse of older persons is like that in any age group: hitting, slapping, tripping, beating with an object (e.g., a belt or paddle), pushing or shoving, deliberate food or medicine deprivation (or overmedicating, overfeeding), or deliberate withdrawal of providing adequate personal hygiene. Psychological (emotional) abuse is withholding attention, inducing sensory deprivation, deliberately frightening the person by action or words, annoying the person by action or words (e.g., playing music known to irritate the person or making hateful remarks and threats), or abandoning the person for long periods of time without adequate provision of care.

Financial abuse or financial exploitation consists of misuse or misappropriation of assets. The crime may include theft or conversion of money or property by using force, misrepresentation, or other illegal acts that take advantage of the older person's partial or total lack of legal competency. Because many older persons have a fixed income, even minimal monetary loss could leave the person unable to afford the essentials of daily living, that is, adequate food, medications, or rent.

Sexual abuse of older persons is the least frequent category of reported abuse. Sexually transmitted diseases or

any pain, itching, bleeding, or bruising in the genital area should raise the suspicion of sexual abuse.

Nursing Implications

State laws mandate that doctors, nurses, social workers, police officers, fire fighters, and home care agency personnel report suspected abuse of older persons. State laws also designate which agency is to receive and investigate reports of abuse, neglect, and exploitation of older persons. The most frequently designated reporting agencies are state Adult Protective Service agencies, (APS) human service agencies, and law enforcement agencies. If an incident is witnessed the police or a law enforcement agency would be the most appropriate choice for a referral. A 24-hour hotline has been established through the Department of Elder Affairs, Department on Aging, or Commission on Aging for each state and depending on which state you are in, and this department receives reports from health professionals and citizens alike. In 1996, 64% of all suspected abuse reports were substantiated. In the 10 years from 1986 to 1996, a steady increase in abuse of older persons occurred, accounting for a 150% increase in abusive incidences reported (NCEA, 1997).

Protective service agencies initiate the following process once a report is received:

- ✿ Investigate allegations of abuse.
- ✿ Determine the severity and cause of the abuse.
- ✿ Initiate steps to alleviate the abuse.
- ✿ Arrange home care to relieve some of the burden on the caregiver(s).
- ✿ Assist the older person to obtain a restraining or protective order.
- ✿ Refer the case to the district attorney's office.

SPECIAL CASE: FEMALE CIRCUMCISION

Female circumcision is a practice steeped in cultural traditions but that often is viewed as a form of abuse by those of different cultural backgrounds. The statement of the Director-General to the World Health Organization's (WHO) Global Commission on Women's Health (1994) points out the lack of knowledge between the cultural norm in societies practicing female circumcision, sometimes referred to as female genital mutilation, and future outcomes for the young women subjected to this practice (WHO, 1996):

Experience shows for example that many people in the societies concerned do not naturally see the link between genital mutilation suffered by a woman in her childhood and the pain, infections

Nursing Tip

ASSESSING FOR ABUSE AND NEGLECT AMONG OLDER PERSONS

Some examples of questions you should ask to assess for abuse or neglect of the older person are

1. Does anyone hit you?
2. Are you afraid of anyone at home?
3. Does anyone take things that belong to you without asking?
4. Has anyone ever touched you without your consent?
5. Are you alone a lot?
6. Does anyone yell at you or threaten you?

and health problems she may suffer in her later years. Our first task must be to document this link, and then to inform people very simply and clearly about it.

The Council on Scientific Affairs of the American Medical Association (1995, p. 1714) defined **female genital mutilation** as “the medically unnecessary modification of female genitals.” This procedure falls into four types of mutilation (Barstow, 1999):

1. Sunna, which is removal of the prepuce of the clitoris.
2. Clitoridectomy, which is removal of the prepuce and the clitoris.
3. Excision, which is removal of the prepuce, clitoris, upper labia minora, and some of labia majora.
4. Infibulation, which is removal of the prepuce, clitoris, labia minora, and labia majora.

Female circumcision is an ancient custom that has been practiced worldwide for 2,500 years (Barstow, 1999; Dire & Lindmark, 1991). Today, 100 to 130 million women in 40 countries have undergone female circumcision

(Burstyn, 1995). Central Africa is the main area where different forms of female circumcision are performed, with the most severe forms in Sudan and Ethiopia (Kun, 1997). Various rationale are given for performing this surgery, from religious practice claimed to be endorsed in the Koran and the Bible, assurance of marriageability, cleanliness, enhanced sexual faithfulness, to protection from temptations by the devil, and protection from forcible rape and abortion (Barstow, 1999).

The surgery usually is carried out by a lay midwife, who uses a razor blade or broken glass and no anesthesia; the conditions often are unsanitary (Barstow, 1999; Odoi, Body, & Elkins, 1997). Infibulation involves the complete removal of the clitoris, labia minora, and inner surface of the labia majora. The two sides of the vulva are stitched together with either thorns or sutures made of silk or catgut. When the remaining skin of the labia majora heals, it forms a bridge of scar tissue over the vagina (WHO, 1996). A small opening is maintained by the insertion of a foreign body until the site heals to permit the passage of urine and menstrual blood. The girl's legs usually are bound closely together for several weeks until scar tissue forms over the wound (WHO, 1996).

Research Highlight

Prevalence of Female Circumcision

Purpose

To examine the prevalence of and motivation for female circumcision among an Egyptian village population.

Methods

A survey was conducted of all 819 households in a village in Upper Egypt near Assiut. The mothers of 1,732 girls under 20 years of age were interviewed to obtain information about their daughters' genital procedures.

Findings

Sixty-two percent of mothers said that their daughters had undergone female circumcision, most often at 5 to 9 years of age; 36.6% of mothers were planning for their daughter to undergo this procedure; and 1.1% of mothers had no plans for their daughters to have this procedure. The most prevalent (77%) reason given for female circumcision was that it followed customs and traditions.

Nursing Implications

The study raises a number of questions about the motivation for maintaining the practice of female circumcision and the kinds of interventions needed. Community health education and individualized counseling about the risks and complications may help change the prevalence of this practice.

Sayed, G. H., El-Aty, M. A. A., & Fadel, K. A. (1996). The practice of female genital mutilation in Upper Egypt. *International Journal of Gynecology & Obstetrics*, 55, 207–335.

The procedure of female circumcision became restricted in the United States on March 30, 1997, with enactment of the U.S. Federal Prohibition of Female Genital Mutilation Act of 1995. This practice is punishable by law, with prison sentences of up to 5 years for a person who “circumcises, excises, or infibulates the whole or any part of the labia majora or labia minora or clitoris of another person who has not attained the age of 18” (Robinson, 1998, p. 1).

Thousands of women who have had various forms of circumcision immigrate to the United States each year from countries in which this surgery is routinely performed (Feminist Majority Foundations, 1998). In order to acknowledge the cultural and religious diversity of these women and to meet their special health care needs, it is important that nurses know how to provide sensitive non-judgmental care both for the woman and her spouse (Barstow, 1999). Culturally sensitive nursing care may include having the spouse be present at all his wife’s procedures and having only female nurses participate in her care.

Circumcision can impact young girls both physically and psychologically. Immediate physical complications seen after this procedure include shock, hemorrhage, urinary retention, infection, tetanus, and death (Odoi, Body, and Elkins, 1997). Delayed complications may include chronic urinary tract infections, vulvar dermal cysts, vaginal stenosis, dysmenorrhea, and chronic pelvic inflammatory disease (Odoi, Body, and Elkins, 1997).

During labor and delivery the vaginal closure needs to be deinfibulated, or opened (Barstow, 1999). In the women’s native country the closure would be reinfibulated

after delivery, and this process would be repeated with each subsequent delivery. Multiparous women may have thick scarring and little redundant skin. Multiple complications of labor and delivery are seen in women with female circumcision: higher than normal incidences of maternal and neonatal mortality and morbidity, prolonged second stage of labor, more frequent postpartum hemorrhage, and a higher rate of episiotomies in primiparas (De Silva, 1989).

Web Activities

- Search the web for sites addressing abuse, violence, and rape. Do these sites offer information on the different types of assault (e.g., acquaintance rape versus date rape)? Are there resources for families as well as health care providers?
- Check the sites of some of the major nursing and health care organizations, such as NANDA, the National League for Nursing (NLN), and DSM (APA). Do these sites include information on abuse, violence, and rape?
- Search government web sites for support groups for survivors of violence and self-help programs for abusers. Are research studies available on-line?

Key Concepts

- Domestic violence is a public health problem with great consequences, including the physical, mental, and emotional pain of the victim.
- The economic cost of violence and abuse is felt by the health care industry, the legal system, and business communities.
- Health economists calculate that violent crime costs the United States \$192 billion per year (Gladwell, 1997).
- The nurse is an essential provider of domestic violence prevention, screening, and referral to community resources.
- Children who witness violence are more likely to become abusers themselves.
- The implementation of an interdisciplinary community plan for prevention of domestic violence needs nursing leaders, educators, researchers, and practitioners to help design, develop, and implement it.
- Minimum components of a safety plan include a private interview, preparatory steps for ensuring safety or for leaving the relationship, and a listing of community resources.
- Subsequent client encounters are opportunities for nurses to re-question the client about abuse and her safety.

Review Questions and Activities

1. Outline appropriate nursing care for a rape survivor.
2. Which physical signs would you expect to find in a pregnant woman who is abused?
3. Suggest approaches to ensure that the physical examination of a woman who has experienced rape does not feel to her like a “second rape.”
4. Develop an escape plan for a wife who is battered and has two school-age children.
5. Outline the different types of abuse experienced by older persons.

UNIT III

Human Sexuality Across the Life Span

Sexual and Reproductive Function

Topics dealing with bodily functions and sexuality continue to be shrouded in secrecy and embarrassment. Often, health care providers and those seeking assistance find they are uncomfortable exploring issues that may affect reproductive functioning. Terms as diverse as the “monthlies” or the “curse” are used to refer to the menstrual cycle. These terms may indicate being uncomfortable with more specific technical terms or a negative attitude toward menses. Alternatively, these terms may merely have been acquired from the cultural milieu and are not indicative of a person’s attitude toward menses. Terms dealing with menstruation and sexuality often are value-laden. The following questions can be used to explore personal knowledge, values, and beliefs that may affect your ability to care for women and their partners:

- ❖ *Do I understand the interrelationship of menstruation and ovarian function? Can I explain the relationship clearly to clients of various ages and educational levels?*
- ❖ *How do I feel about men or women whose choices, such as drug use or sexual activity, may have affected their fertility?*
- ❖ *How do I feel about pregnancy, the decision to have children, and the decision not to have children?*
- ❖ *Which terms do I use to describe menses, sexuality, and body parts? Are these terms value-laden? Are they appropriate to the client’s level of education and understanding? Which issues affect the use of certain terms?*
- ❖ *Do my attitudes toward sexuality influence my delivery of health care?*

Key Terms

Anovulatory	Gonadotropin-releasing hormone (Gn-RH)	Menarche	Puberty
Corpus luteum	Graafian follicle	Menopause	Refractory period
Desire phase	Hydrocele	Menses	Resolution phase
Dyspareunia	Hypothalamic-pituitary-gonadal axis	Menstrual phase	Secretory phase
Endometriosis	Human chorionic gonadotropin	Mittelschmerz	Seminiferous tubules
Endometrium	Impotence	Neurohormonal	Serial monogamy
Estrogen	Infertility	Orgasmic phase	Sexual dysfunction
Excitement phase	Leydig cells	Ovulation	Spermatogenesis
Follicular phase	Libido	Perimenopause	Spermatozoa
Follicle-stimulating hormone (FSH)	Luteal phase	Plateau phase	Spinnbarkeit
Galactorrhea	Luteinizing hormone	Precocious	Testosterone
Germ cells		Progesterone	Vaginismus
Gonadal		Proliferative phase	Varicocele
		Prostaglandins	

Competencies

Upon completion of this chapter, the reader should be able to:

1. Explain the menstrual cycle in terms of the ovarian, endometrial, and neurohormonal components.
2. Identify the normal ages of onset and cessation of menses and factors related to normal variations.
3. Describe normal menstruation in terms of length of cycle, flow, and quantity.
4. Describe spermatogenesis.
5. Discuss factors related to male and female infertility.
6. List key components of an infertility examination and a rationale for their inclusion.
7. Discuss the emotional impact of infertility.
8. Describe regimens to treat infertility, including assisted reproductive technology.

Considering the coordination of the complex body systems required for reproductive functioning, it is amazing that conception and birth occur. Yet within that complexity, finely ordered events produce cyclic changes that can be predicted. In women the most evident result of this neurohormonal interplay, the menstrual cycle, provides a basis for understanding the physiology of reproduction. (The term **neurohormonal** pertains to hormones formed by secretory cells and liberated by nerve impulses.) To grasp the usually predictable events, which are driven by the functioning of the ovary, it is helpful to start at the beginning of human sexual development. In men the physiology is not quite as complex; however, a number of organs and systems are involved with reproduction.

This chapter describes the physiology of the female and male reproductive systems. Normal parameters for

functioning are provided as guidelines for assessment. Sexuality and sexual dysfunction are discussed. Finally, infertility is discussed. Its emotional impact and clinical guidelines for assessment and treatment are presented.

NORMAL SEXUAL DIFFERENTIATION

In human embryos, sexual development is a product of genetic and hormonal influences, which determine the differentiation of the internal systems and formation of external genitalia. **Gonadal** (referring to the ovaries in the female and the testes in the male) development begins at 5 to 6 weeks' gestation, with testicular differentiation at 7 weeks' gestation. At this time the production of **testosterone**, a potent, naturally occurring androgen (male) hor-

none, begins. Testosterone regulates the development of the penis, testes, scrotum, seminal vesicles, prostate gland, and genital duct system.

Without the activity of the Y chromosome, ovarian development occurs 2 weeks later. In the female ovary, 5 to 7 million **germ cells**, the precursors of ova, are evident by 20 weeks' gestation. By birth, this number has already decreased to 1 to 2 million cells. By puberty, the number of germ cells is approximately 300,000. This decrease continues until menopause when only thousands are left. The ovaries provide varying amounts of **estrogen** (female sex hormone) and **progesterone** (antiestrogenic hormone) needed for the production of eggs (**oocytes**) from these germ cells. The ovaries coordinate the development and sloughing of the **endometrium** (lining of the uterus), resulting in the menstrual cycle. Thus, these two events, the ovarian and the endometrial cycles, occur at the same time and produce **ovulation** (release of a mature ovum) and **menses** (monthly bleeding from the lining of the uterus).

Client Education

Adolescence and Puberty

Puberty, the development of secondary sex characteristics and the ability to reproduce, can be a tumultuous time for parents and teens. It is quite common for the mother of an adolescent girl to have questions about when certain developmental events can be expected in her daughter's life. The nurse may be the person who is first approached to provide this information. The following is a synopsis of the range of normal events:

- The average age of menarche in the United States is 12.8 years.
- Menarche usually is a mid to late event in puberty and usually occurs after the development of pubic and axillary hair, breast buds, and genital changes.
- A young girl who has not developed secondary sex characteristics by the age of 14 years should be evaluated by a physician.
- A young girl who develops secondary sex characteristics but does not begin menses also should be evaluated by a physician.

Female Reproductive Function

The onset of menstrual bleeding, or **menarche**, usually occurs between 9 and 16 years of age (Speroff, Glass, & Kase, 1999). The average age of menarche in the United States is 12.8 years. Several factors may affect the age of onset of menses including family history, geographic location, general health, and nutrition. Current information supports the importance of body weight in determining the time of menarche (Speroff, Glass, & Kase, 1999). Moderately overweight girls begin menstruation earlier than do those of normal weight. Girls with very low body fat, such as those having anorexia and girls who participate in strenuous athletics, may have delayed menarche.

For 12 to 18 months after menarche, menses may be irregular, often do not produce ovulation (**anovulatory**), and may be very heavy or very light. It is important to be aware that pregnancy can result during this time, and appropriate education should be provided. Parents may seek evaluation with concerns that their daughter may be experiencing early (**precocious**) puberty (Smith & Hornberger, 1997), irregular or heavy menses, or delayed menses. Often, explaining the wide range of what is considered to be normal is all that is required. Conversely, the child under 8 years of age who has pubertal changes, such as menarche, requires further evaluation because there may exist important growth implications or another underlying disease. Likewise, with delayed menses, a girl over the age of 17 years could have a genetic, hormonal, or hypothalamic-pituitary disorder. Anatomic defects of the uterus and vagina also must be ruled out.

A menstrual cycle refers to the time that passes from the first day of one menstrual period to the first day of the next menstrual period. The normal cycle length can range from 21 to 36 days, although 95% of women have cycles between 25 to 32 days. A working number used to describe a so-called normal cycle is 28 days. Timing the cycle

Nursing Tip

IRON AND MENSTRUATION

Blood loss from menstruation results in approximately 0.5 mg of iron being lost with each milliliter of blood, explaining why women tend to have lower hemoglobin levels than do men, especially women with heavy menses. These iron deficits can be overcome through dietary means by eating liver and other foods rich in iron or by taking a multivitamin with iron.

MENOPAUSE

It is important to realize that the diagnosis of menopause, and the end of reproductive functioning, is not made until 1 year after the last menses (Speroff, Glass, & Kase, 1999). Thus, it is wise to counsel women to continue contraception throughout the perimenopausal years.

begins on the first day of bleeding, day 1 of the cycle. Bleeding usually continues for 3 to 5 days, with 1 to 8 days considered to be within normal limits. The amount of blood lost averages 30 mL (1 oz) per cycle but ranges from 20 to 80 mL (0.67 to 2.67 oz). Blood loss usually is greater during the first 3 days of the cycle because the precise hormonal events leading to menses affect the entire **endometrium** (cellular lining of the uterus that is shed monthly at the time of menses) at the same time, resulting in generalized sloughing of the endometrial tissue.

Normally, menstruation continues until **menopause** (cessation of menses), which occurs between the ages of 35 and 60 years (Byyny & Speroff, 1996). Menopause is determined to be present when a woman has completed 1 year without menses. For as many as 15 years before the cessation of menses, women may experience changes in their cycle, such as heavier or lighter bleeding and changes in the length or duration of menses. This time is described as the **perimenopause** and is a result of changes in ovarian function. In the United States, 51 years of age is the average time of menopause (Speroff, Glass, & Kase, 1999).

Endometrial Activity

The activity of the endometrium during the menstrual cycle can be described as the menstrual, proliferative, and secretory phases. The endometrium is prepared for implantation of a fertilized ovum by the ovarian hormones. When implantation does not occur the tissue sloughs and new tissue begins to build for the next cycle. This cycle of growth and regression occurs approximately 300 to 400 times in the human adult. Specific changes in the endometrium occur in the various phases of the menstrual cycle.

The **menstrual phase** is the time during which the woman experiences vaginal bleeding. It begins with day 1 of the menses and continues for about 5 days, during which time almost two thirds of the endometrial tissue is lost. The lost tissue has been described as having evidence of necrosis and white cell infiltration as well as fragmentation of vessels and glands.

The **proliferative phase** describes the endometrium from the end of menses through ovulation, which occurs on or about day 14 of the normal 28-day cycle. The growth of the glands of the endometrium is associated with increased estrogen levels produced by the ovary. The tissue of the endometrium has changed and grown from being dense and approximately 0.5 mm thick to being spongy and 3.5 to 5.0 mm thick, an increase of 7 to 10 times in size.

The **secretory phase** continues from the time of ovulation (days 14 to 28) under the combined effects of estrogen and progesterone. The endometrium stops growing but increases in vascularity and the glycogen-producing glands occur. With the increased blood and glycogen, the tissue is ready for implantation. Without fertilization and implantation, estrogen and progesterone levels decrease, leading to decreased blood supply to the tissue. As blood vessels constrict and relax, leading to separation of the prepared endometrial layer, necrosis of the tissue results in menstruation. Even during menses, increasing estrogen levels produced by the ovary begin the healing process, and the endometrium begins to regenerate and prepare for the next cycle.

Ovarian Regulation

In the reproductive aspect of a woman's life there are baselines of all sex hormones. Fluctuations also occur that establish the menstrual cycle. The main organs of regulation are the hypothalamus and pituitary in the brain and the ovaries in the pelvis (Speroff, Glass, & Kase, 1999). These structures are termed the hypothalamic-pituitary-gonadal axis and form a feedback loop that controls hormone production. Although a delicate interplay and regulation between the brain and ovaries exist, the ovaries actually drive the process of ovulation. Two phases can be used to describe the functioning of the ovary as it regulates the menstrual cycle and the development of an egg, the follicular and the luteal phases.

The **follicular phase** refers to maturation of the follicle leading to the production of an egg and ovulation. The **luteal phase** refers to the secretion of hormones from the corpus luteum, which is formed from the follicle that produced the egg. The corpus luteum continues to secrete estrogen and progesterone. These hormones prepare and maintain the endometrium for implantation of the fertilized ovum. Again, it is important to remember that the menstrual cycle is driven or regulated by these ovarian hormones. Thus, the visible evidence of the hormone fluctuations and ovarian functioning is menses. When a woman's cycle is regular and predictable, without the aid of hormone therapy, she probably is ovulating.

As well as producing the steroid hormones estradiol and progesterone and small amounts of testosterone, the

ovaries produce oocytes or eggs. At 4 to 6 days before menses, ovarian follicles begin to grow independent of hormonal stimulation. For most follicles, growth is limited, and they never reach maturity. Under the influence of hormones, a single follicle is chosen to reach maturity by day 5 to 7 in the cycle. Termed the *preantral* or *primary follicle*, the selected follicle continues to enlarge. It is surrounded by a membrane, the *zona pellucida*. The size and number of layers of the cells increase under the influence of estrogen, and follicular fluid begins to increase. The maturing follicle or **graafian follicle** continues growing until ovulation occurs. Typically, in a 28-day cycle, ovulation would be on day 14; however, the day of ovulation varies according to the number of days needed for maturation of the follicle. The follicular phase may vary in length from 7 to 22 days and determines the length of the cycle. That is, the follicular phase may vary in length but the luteal phase is consistently 14 days. Thus, menses will begin 14 days after ovulation.

Ovulation

Although not always considered a phase of the ovarian cycle, multiple important events occur at the time of ovulation that warrant special note. Physical and hormonal events take place to enhance the possibility of fertilization (Speroff, Glass, & Kase, 1999). The increased estrogen levels at this time have prepared the endometrium for implantation but also change the characteristics of the cervi-

cal mucus. The role of cervical mucus is to facilitate sperm transport into the uterus. Before ovulation, cervical mucus threads are 1 to 2 cm long, increasing to 12 to 24 cm and becoming thin, clear, and copious when ovulation occurs. The increased elasticity is called **spinnbarkeit** and facilitates sperm transport into the uterus (Figure 12-1). The cervix becomes softer and the os opens. Some women can determine the time of ovulation because they experience pain in the lower abdomen called **mittelschmerz**.

Hormonal events include an increase in androgen levels. Androgens are hormones derived from testosterone that increase libido and prepare the follicle for ovulation. **Prostaglandins** are chemicals produced by many bodily systems, including those of the female reproductive system. Prostaglandins increase and, although the exact action is not known, may act to thin the follicle wall and contract smooth muscle in the cell wall to facilitate release of the oocyte.

The luteal phase begins with ovulation as the cells of the ovary that produced the egg increase in size and accumulate lutein. Lutein is a yellow pigment that gives the name to the **corpus luteum** or *yellow body*. The corpus luteum continues to produce estrogen and progesterone. Progesterone levels increase rapidly for nearly 8 days as this hormone suppresses the growth of new follicles. The corpus luteum begins to degenerate on days 9 to 11 when not sustained by the hormone of early pregnancy, **human chorionic gonadotropin (hCG)**. When pregnancy occurs, hCG prevents regression of the corpus luteum, which

A.

B.

Figure 12-1 Spinnbarkeit test. A. Before ovulation, cervical mucus is thick, preventing transport of sperm. B. At ovulation, secretions become thinner and elastic, facilitating sperm transport.

continues to produce hormones until 9 or 10 weeks gestation. By this time the placenta has assumed production of the needed steroidal hormones estrogen and progesterone.

When pregnancy does not occur the corpus luteum begins to degenerate and the levels of estrogen and progesterone decrease, stimulating the start of a new cycle. This continuing cycle of events, although controlled by the follicle, which will ovulate, are under the direction of the anterior pituitary and hypothalamus. The **hypothalamic-pituitary-gonadal axis** is a triad of the hypothalamus, pituitary, and ovaries that regulates the hormones of reproduction and that must function in synchrony for conception to occur.

Hormonal Regulation

The hypothalamus functions similarly to a thermostat, sensing hormone levels in the blood (Speroff, Glass, & Kase, 1999). Depending on the set levels, the hypothalamus sends a message to the anterior pituitary to either increase or decrease the amounts of the specific hormone needed. As well as regulating the ovaries, the hypothalamus also plays a regulatory function in growth hormone, thyroid-stimulating hormone (TSH), and the adrenal hormones.

The hypothalamic hormone that controls the gonadotropins is called **gonadotropin-releasing hormone (Gn-RH)**. When the hypothalamus senses a decrease in the level of hormones produced by the ovary Gn-RH is released into the blood. The hypophyseal portal system provides a mechanism by which the hypothalamus and anterior pituitary communicate. The anterior pituitary receives the message that more or fewer hormones are needed and either stimulates or suppresses the release of hormones.

The hormones produced by the pituitary are **follicle-stimulating hormone (FSH)**, which stimulates the ovary to prepare a mature ovum for release, and **luteinizing hormone (LH)**, which is responsible for the release of the ovum. The anterior pituitary also produces the hormone prolactin, which regulates milk production. With the release of FSH and LH, events in the ovary are regulated to produce the hormones needed to support the development of the oocyte and for ovulation. As the ovary is preparing an egg for ovulation, the endometrium is being prepared to support the implantation and growth of the fertilized egg. Preparation of the endometrium is primarily under the influence of estrogen. Estrogen is the hormone responsible for the secondary sex characteristics of the female.

During the second phase of the cycle the corpus luteum produces progesterone, which stimulates the secretory phase and supports the continued growth of the endometrium. When fertilization does not occur 8 to 10 days after ovulation, the corpus luteum degenerates and prog-

esterone levels rapidly decrease. This rapid decrease results in progesterone levels below those needed to sustain the endometrium, and menstruation begins. With the decrease in progesterone levels the hypothalamus is stimulated to increase secretion of Gn-RH, and the cycle begins again (Speroff, Glass, & Kase, 1999).

An understanding of the complexity and interrelatedness of the hypothalamic-pituitary-gonadal axis provides a basis for understanding and treating many of the problems related to the reproductive system. The diagnosis of problems such as dysfunctional uterine bleeding, amenorrhea, and infertility and the appropriate treatment can be determined based on this knowledge.

Male Reproductive Function

The genetic sex of the fetus is determined at conception. The male and female reproductive systems, however, are similar until differentiation begins at 5 to 6 weeks' gestation and testicular development occurs by 7 weeks' gestation. In utero, the fetal gonads are active and secrete either estrogen or testosterone. As noted previously, in the male the hormone testosterone regulates development of the penis, testes, scrotum, seminal vesicles, prostate gland, and genital duct system. During childhood, hormones are inhibited. During puberty, however, the hypothalamus begins to produce increased levels of Gn-RH, which stimulate the anterior pituitary to produce FSH and LH. Hormones produced in the hypothalamus, pituitary, and testes are responsible for **spermatogenesis**, or development of sperm cells. This system is analogous to the hypothalamic-pituitary-ovarian axis in the female, which produces an ovum.

Follicle-stimulating hormone stimulates the production of primary spermatocytes in the **seminiferous tubules**, which are the tubes that carry semen from the testes. Concurrently, LH stimulates the **Leydig cells** in the testes to produce testosterone. Testosterone encourages maturation of the **spermatozoa**, or sperm.

Testosterone is essential for spermatogenesis and also stimulates the production of seminal fluid. Testosterone is responsible for secondary sexual characteristics such as the distribution of body hair, increased muscle mass, and enlargement of the vocal cords. The sexual drive is thought to be controlled by testosterone. The action of testosterone continues throughout life, including the development of sperm. Levels of this hormone decrease as men age, however, resulting in decreased hair distribution, reduced body mass, and decreased sexual activity. This decrease in testosterone has led to the suggestion that men have a series of physical and emotional changes comparable with those that occur during menopause in women.

Development of sperm in the testes takes approximately 70 days. After leaving the testes the sperm remains

in the epididymis for 12 to 26 days, during which time they mature. The semen, which forms the ejaculate, contains sperm and secretions from the prostate, vas deferens, and seminal vesicles. Being a complex system, it is apparent that many factors can affect male fertility, even events that occurred days to months before the sperm is developed. Some of the factors that affect male fertility can be as simple as wearing tight-fitting underwear, excessive use of hot tubs, or use of marijuana. A combination of events also may affect male fertility, including infection, a varicocele, and injury.

Once ejaculated, sperm can live from 2 to 3 days in the female genital tract but with decreasing activity after 24 hours, whereas an ovum is fertile only for 24 hours. The relative long life of sperm enhances the capacity for fertilization of an ovum.

In addition to the purely physiologic processes in men and women that regulate fertility, there are behaviors involved in procreation that society has termed *sexuality*.

SEXUALITY

Sex, sexual behavior, and sexuality are terms that often are used synonymously. In reality, they are different but related concepts. Sex is one of four primary drives, including thirst, hunger, and avoidance of pain. Sexual behavior refers to those practices involving sexual intercourse and other behaviors involving stimulation of the genitalia and other erogenous zones for the purpose of procreation or gratification. Sexuality is a complex concept that deals with the quality of being sexual, sexual activity, and sexual receptivity or interest. Sexuality encompasses issues related to human sexual response; sexual orientation; and beliefs, attitudes, and social and cultural patterns related to sexual matters. The expression of sexuality is influenced by ethical, spiritual, cultural, and moral factors.

Sexuality and sexual function are important to a woman's health and well-being. The nurse plays a significant role in assisting women to understand their sexual health, sexual development, and sexuality (Figure 12-2). In fact, the holistic framework requires that the nurse be able to assist clients with concerns related to sexuality. Nurses, like other health care providers, can be uncomfortable discussing such personal topics with their clients. This unease may stem from vulnerability related to inadequate experience in dealing with clients with sexual difficulty, lack of information, or misinformation on the part of the nurse. Sexual awareness is required on the part of the client; however, cultural influences may inhibit conversation about such matters.

Many women have questions about their sexuality or sexual function. In fact, it has been estimated that as many as 60% of women have questions related to their sexuality (Baram, 1996). Many times women are hesitant to discuss these personal problems with anyone. Women may be

Figure 12-2 Nurses play an important role in helping clients understand their sexual health and development.

most uncomfortable asking questions related to sexuality when cared for by someone of the opposite sex. Because of the awkwardness of discussing personal issues with providers, there is a tendency to seek information from other women or from the lay press. Occasionally, this practice leads to myth and misinformation. The tendency to obtain partial information and misinformation makes it very important for the nurse to assess the client's perception of her situation before institution of a plan of care.

Sexual dysfunction can produce multifaceted and severe alterations in a woman's physical and mental health. Even if the question is one of health promotion, the nurse is in an excellent position to help women voice their questions and to dispel myths. Before these things can happen, the nurse must have an adequate understanding of the complexity of sexuality and the interaction of its components. Typically, this information is not high priority in educational programs and may not be discussed. In fact, it has been the practice at some institutions to relegate the study of sexuality to prenursing courses. The resulting general lack of information decreases the likelihood that the nurse will feel comfortable with this subject matter. Providing information about sexuality requires that the

BEING NONJUDGMENTAL

In the United States, body piercing and tattooing currently are trends. It is common to see piercing of navels, nipples, tongues, and the clitoris. These practices have roots in sexuality and sexual mores. You have the duty to accept the client's practices even when they differ from your own values.

nurses have a nonjudgmental accepting attitude to allow women who have been enculturated never to discuss sex to do so in a public setting. Some women may not even have the vocabulary to voice their questions and concerns. The nurse may have to teach some women the names of body parts and their functions before being able to assist in answering questions or solving problems. Assistance may take many forms. A woman who has been sexually abused, for example, may have great difficulty tolerating a simple vaginal examination. A woman who is a lesbian may not participate in routine gynecologic care because she does not want her health care providers to know about her lifestyle. The young adolescent may not understand how to insert a tampon and may be very uncomfortable about seeking such information.

The nurse may be required to closely examine personal values through self-reflection and rely on cultural competence to assist women with their sexual concerns (Figure 12-3). It is important that the nurse does not inject personal biases and other factors into the nurse-client interaction that will produce negative outcomes.

Figure 12-3 During the health history and interview, the nurse must remain nonjudgmental when discussing clients' practices and lifestyle choices.

Human Sexual Response

Masters & Johnson (1966) are renowned for their study of human sexual response. They conceptualized the human sexual response consisting of four phases: excitement, plateau, orgasmic, and resolution. These phases occur in men and women and are associated with a number of physiologic changes. Contemporary sources include a fifth phase, which has been identified as the desire phase. The **desire phase** is conceptualized as being present before the other four phases. The desire phase has been described as the motivation or inclination to be sexual. Baram (1996) indicates that internal cues, such as fantasies, or external cues, such as an interested partner, may trigger sexual desire. Baram further states that desire also depends on proper neuroendocrine function. Other influences include sexual orientation, sexual preferences, mind set, and the environment. All of these factors affect an individual's libido.

The **excitement phase** occurs as a result of internal or external cues. During this phase the woman experiences increased vaginal lubrication, engorgement of the blood vessels of the breast and pelvis, and a sense of muscular tension. She also experiences increased heart rate, respiratory rate, and blood pressure. Besides the increase in muscular tension, many women experience flushing of the skin over the chest, neck, and face known as *sexual flushing*. These skin changes are the result of surface vasodilation, which produces congestion of the vessels with blood. The woman's nipples also become erect. Because of pelvic vasocongestion, the clitoris and labia become swollen. The vagina becomes distended and elongated, and the vaginal opening constricts forming what is called an orgasmic platform (Kohn & Kaplan, 2000).

The man's response during the excitement phase includes changes in the scrotum, penis, and breasts. The scrotal sac becomes thickened and is elevated against the body owing to shortening of the spermatic cord. The penis becomes engorged with blood, which increases its circumference and length. This penile state is called an erection. As in the woman, the man's nipples become erect and he may experience the same sexual flushing of the chest, neck, and face.

The **plateau phase** of sexual response follows the excitement phase. During the plateau phase, women experience the most heightened sense of sexual tension. The labia become congested with blood to the extent that they may have a bluish hue. The change in color may be more difficult to recognize in dark skin types. There is full vaginal expansion as well as elevation of the uterus out of the pelvis in preparation for entry of the penis. By this phase, 75% of women experience sexual flushing. Tachycardia and hyperventilation occur as does a modest increase in

blood pressure of 20 to 60 mm Hg (Cohen, Kenner, & Hollingsworth, 1991).

The man's response during the plateau phase includes an increase in coronal circumference of the penis with continued erection. The testicles increase in size and are elevated against the body. As in the woman, there is generalized muscular tension that increases in intensity as orgasm approaches. The man also experiences tachycardia, hyperventilation, and increased blood pressure. The systolic pressure increases by 20 to 80 mm Hg, and the diastolic pressure increases by 20 to 40 mm Hg (Cohen, Kenner, & Hollingsworth, 1991).

In the **orgasmic phase** the woman experiences elongation of the vaginal canal. There is an intense desire for sexual release as a result of blood vessel congestion. This sensation builds until the woman reaches orgasm. During this time the woman experiences an increase in blood pressure, tachycardia, and hyperventilation.

As the man enters the orgasmic phase, he experiences muscular contractions of the accessory reproductive organs, including the vas deferens, seminal vesicles, and ejaculatory duct. The sphincters of the bladder relax, and contractions of the urethra and perirectal muscles occur. Ejaculation occurs as the man achieves orgasm. As in the woman, the man experiences further tachycardia, hyperventilation, and blood pressure elevation.

During the **resolution phase** release of muscular tension occurs. The woman experiences a feeling of warmth and relaxation. Physiologic changes that took place in the previous phases of the response are reversed within 5 to 10 minutes (Baram, 1996). Resolution is slower when orgasm has not been achieved. Findings by Masters and Johnson suggest that women actually may experience a very short **refractory period**, that is, time before they are interested in experiencing intercourse again. Women are capable of multiple orgasms.

The man experiences a longer resolution phase. Immediate decrease in penile erection occurs after ejaculation, with partial decrease in vasocongestion. Over a few minutes after ejaculation, complete remission of erection occurs. There is a refractory period in which the man cannot achieve another erection. The time of the refractory period is somewhat variable; however, it is unusual for men to achieve multiple orgasms as do women.

Saks (1999) indicated there is a physiologic difference in the brains of men and women after orgasm. There is a hippocampal neurologic discharge in the brain that makes men sleepy. In women, there is no such discharge. Women may experience a spurt of energy after orgasm.

American Sexual Practices

The public image of sex in America bears very little resemblance to what occurs in reality. Television portrays

men and women as sexual beings who must be thin, beautiful, and young. The results of these myths are false expectations, deficits in self-esteem, broken relationships, and perhaps even a decline in physical health. When one tries to untangle the reality of sexuality, however, it becomes apparent that a realistic picture is almost impossible to ascertain. Masters and Johnson spent their entire careers scientifically analyzing the human sexual response, and many questions still remain unanswered.

In the late 1960s and 1970s, federal agencies studied sexuality, sexual practices, and homosexuality in an attempt to uncover the truth about sexuality in America (Michael, Gagnon, Laumann, & Kolata, 1994). Many of these studies were flawed and biased, and therefore, myths sometimes were perpetuated.

In 1994, Michael, Gagnon, Laumann, & Kolata undertook a survey to study sexuality that was designed to eliminate some of the flaws in previous research. The survey consisted of a sample of 3432 Americans. Responses of the participants were compared with U.S. census data on the variables of gender, age, education, marital status, and race and ethnicity. The study group was found to represent 97.1% of American adults from 18 to 49 years of age. The following is a description of findings from the survey and may assist the nurse in making decisions about so-called normal sexuality.

When asked how many sexual partners they had had in the past 12 months, participants responded as follows: 11.1% of men and 13.7% of women denied having sexual partners, 67.6% and 75.5% had one partner, 9.6% and 6.3% had two partners, and 11% and 4.5% had three or more partners, respectively. These data support the notion that most American men and women participate in monogamous relationships. These data, however, do not address the concept of serial monogamy as a sexual practice.

Serial monogamy is a term used to describe the practice of having one sexual partner at a time but several partners during a lifetime. There has been speculation that a factor in the exceedingly high divorce rate in the United States is the great value Americans have placed on monogamy (Michael, Gagnon, Laumann, & Kolata, 1995). It is speculated that when a person become sexually dissatisfied with a relationship with a spouse, divorce enables that person to leave the relationship and still maintain the value of monogamy. This is a characteristic of serial monogamy. In reality, divorce is a much more complex phenomenon.

Sexual Preferences

The next question addressed by the survey (Michael, Gagnon, Laumann, & Kolata, 1994) related to gender preference. The question was "Have your sex partners in the past 12 months been exclusively male, male and female,

or exclusively female?” In answer to this question, 98.3% of women and 96.3% of men reported heterosexual relationships; 1.0% of men and 0.5% of women reported bisexual relationships; and 2.6% of men and 1.2% of women reported homosexual relationships.

Frequency of intercourse is a factor that is commonly discussed among couples concerning what is normal and was addressed in the survey. Frequency of intercourse was analyzed based on gender, age, marital status, education, religion, and race and ethnicity. The norm for frequency of intercourse was several times monthly: 37% of men and 36% of women reported having intercourse several times monthly; 26% of men and 30% of women reported having intercourse 2 to 3 times weekly; and only 8% of men and 7% of women reported engaging in intercourse four or more times weekly. These findings suggest there is a wide range of what is considered normal behavior concerning frequency of intercourse. Frequency of intercourse becomes a problem for couples when expectations are different between the two members of the sexual dyad.

Age is a factor in frequency of participation in intercourse. Men under the age of 30 years reported engaging in intercourse more frequently (2 to 3 times per week). Men over 40 years of age more commonly (43%) reported engaging in intercourse several times per month. Women in all age categories most commonly reported intercourse several times per month. Similar findings were obtained concerning marital status, education, religion, and race and ethnicity. This group of variables can have immeasurable influence on one's sexuality and sexual behavior.

This study also examined sexual practices and preferences. Vaginal intercourse had the widest appeal for men and women. The least preferred sexual practice was forcing a partner to have sex or being forced to have sex of any type.

Masturbation was another sexual practice studied. Findings suggested that masturbation is not rare. It is a practice preferred by men more than women but common in both genders. In this study, fewer than 6 out of 10 (60%) of men in the 18- to 24-year-old age group and 7 out of 10 (70%) of all men reported masturbating in the past year. Fewer than 4 out of 10 (40%) of women in the 18- to 24-year-old age group and 3 out of 10 (30%) of women over 54 years of age masturbated. Nearly half of women in their 30s reported masturbating. It has been speculated that masturbation is not as common as once thought among young men because it is perceived by them to be an activity indicating immaturity. It also has been suggested that masturbation is controlled by social factors and cultural influences (Michael, Gagnon, Laumann, & Kolata, 1995).

Among the group of most sexually active persons, approximately 85% of men and 45% of women living with a sexual partner reported masturbating in the past year. Married persons were more likely to masturbate than were

those living alone. These findings led the researchers to conclude that masturbation is not a substitute for other sexual practices but is an activity that stimulates and is stimulated by other sexual activity.

A change has occurred in American culture involving the meaning and place of sexuality (D'Emilio & Freedman, 1997). The view that sex is a family-centered process with the aim of reproduction, as was conceptualized in the colonial era, has changed to the view that sex is for personal pleasure. In the 19th century, sexuality was focused more on intimacy and romance. In contemporary times the attitude exists that sexuality is linked to personal identity, individual desire, and personal fulfillment. The focus is away from procreation and continually is being reshaped by the nature of the economy, the family, and politics. For example, the availability of abortion for the woman with limited means may change depending on politics because funding for abortion may be decreased by the federal government in an administration having antiabortion sentiment.

One of the factors that has contributed greatly to the contemporary view of sexuality is contraception (Figure 12-4). In the 1920s and 1930s there was much resistance to the idea of contraception. When oral contraceptives became available in the 1960s, the social and sexual cultures had changed to the extent that contraceptive practices became acceptable. Sexual abstinence was less likely as marriage and childbearing were more likely to occur later in life after completion of education. It was considered more socially acceptable for couples to live together; however, childbearing was more likely to be delayed until marriage. Unintended pregnancy is sometimes the precipitating event that leads to marriage in cohabiting couples. In sex-

Figure 12-4 An important element in sex education and counseling is sharing information on contraceptive options.

ual relationships, contraception and conception may be the key to the relationship, especially when partners do not agree about sexual matters. In fact, some believe that women do not control their destiny until they control their fertility (D'Emilio & Freedman, 1997).

Media and advertising have contributed greatly to how women view their sexuality. For example, advertisements offer suggestions about clothing and a vast array of personal grooming products to make women feel more attractive sexually. The media has greatly influenced our sexuality, and increasingly so in the past few decades.

As sexuality has changed, so have attitudes about sexual preference. During the era of World War II, homosexuality was considered a psychiatric problem. In the decades since then, homosexuality has been viewed as sexual deviance and most recently as an alternative lifestyle. Even though homosexuality is not the predominant sexual preference in the United States, evidence exists that it is becoming more widely accepted culturally. Evidence of this acceptance can be seen in the laws that have changed to enable marriage and adoption of children by couples of the same gender. Even the rigid structure of the military is exhibiting some flexibility by no longer questioning service people about their sexual preference.

Pregnancy and Sexuality

Pregnancy is a time when sexual issues may come to the forefront. Couples may express concerns about maintaining a sexual relationship throughout their pregnancy. Certain changes may take place in normal sexual response that are related to the physiologic changes of pregnancy (Alteneder & Hartzell, 1997). In fact, there may be changes in each trimester. In the first trimester, the woman may be less interested in sex because of fatigue, nausea, or adaptation to pregnancy. In the second trimester, her interest may increase. As she nears term however, she may experience some discomfort unless there are position changes to allow for the increase in her abdominal size. Education and support may assist the couple in maintaining a positive sexual relationship.

Women who are sexually abused in childhood may develop gender and sexual identities that emphasize self-worth based on sexuality (American College of Obstetricians and Gynecologists, 2000). These women are likely to have particular problems with sexual issues during pregnancy.

Sexuality and Aging

There is not an abundance of evidence related to sexuality and aging. There are physiologic changes that occur with aging, as well as attitudinal factors, physical illnesses, and social factors that can affect sexuality as a woman ages. Two physiologic changes in women are likely to affect a

Figure 12-5 Sexual expression and intimacy are elements of partnerships throughout the life cycle.

woman's sexuality as she grows older. Decreases in the rate of production and volume of vaginal lubrication can lead to vaginal dryness and a sense of tightness, irritation, or burning after intercourse (Byyny & Speroff, 1996). Some loss of elasticity of the vaginal muscles also occurs that limits the woman's ability to tolerate deep or prolonged thrusting. These changes can result in postcoital spotting and soreness. These atrophic symptoms can be relieved or eliminated by the use of lubricants, a change in coital position, or hormone replacement therapy.

Even after menopause women have sexual desire. Women in their 60s and 70s may continue to be sexually active depending on their health and social circumstances (Figure 12-5). Many times older women have outlived their husbands and thus their opportunity for sexual expression is limited.

Byyny & Speroff (1996) suggest that younger people and health care providers underrate the interest older people have in sex. These authors submit that the two most important factors influencing interest in sex are strength of the relationship and health of both partners. They further suggest that sexual activity among the aging is more influenced by culture and attitude than by nature and physiology.

SEXUAL DYSFUNCTION

Sexual dysfunction is the disturbance of one or more of the phases of human sexual response. The diagnosis is based on clinical judgment and must be evaluated in the biopsychosocial context in which it occurs (Vermillion & Holmes, 1997). In other words, sexual dysfunction may be biologic, psychologic, or social in nature or the result of a

combination of any of these variables. Because the disturbance is so complex, a thorough assessment must be undertaken to determine the cause.

Epidemiologic data concerning sexual dysfunction are sparse and reflect the hesitancy to discuss such matters by clients and some health care providers. Sexual dysfunction can affect males and females; however, it is unclear statistically which gender is more greatly affected.

Female Sexual Dysfunction

Problems with female sexual dysfunction are not rare; however, precise data are not available concerning the incidence of specific disorders. Sarwer and Durlak (1996) suggest there is a lifetime prevalence of adult female sexual dysfunction that may be as high as 35%. Berman, Berman, & Goldstein (1998) submit the incidence may be as high as 76%. Hypoactive (significantly diminished) desire is considered the most prevalent sexual dysfunction and may affect as many as one in five women. It has been estimated that 5% to 10% of women experience inhibited orgasm (O'Donahue, Dopke, & Swingen, 1997). It also has been reported that 10% to 15% of women identify painful intercourse as a presenting complaint when seeking medical treatment (Meana, Binik, Khalife, & Cohen, 1997). An interaction of physical, psychologic, and relationship factors determine sexual responsiveness (Heiman & Meston, 1997).

Four types of female sexual disorders have been identified, including desire disorders, pain disorders, orgasmic disorders, and disorders related to other conditions. These disorders are described and discussed.

Desire Disorders

Desire disorders may be of two types. If the woman has a persistent deficiency or absence of sexual feelings and desire for sexual activity that is not accounted for by a psychiatric problem, it is classified as an hypoactive disorder. Hypoactive desire may be further classified as primary or secondary based on whether the disinterest has always existed or whether it is a new phenomenon. This disorder may result from physical or psychologic causes. Common organic causes of the disorder include decreased testosterone levels, use of medications, substance abuse, chronic disease, pregnancy, and malnutrition (Vermillion & Holmes, 1997). Psychogenic factors include relationship problems, loss of personal attractiveness, and situational disturbances such as personal tragedy, illness, and stress.

Sexual aversion disorder is the second type of sexual desire disorder. It is characterized by persistent or recurrent aversion to or avoidance of contact with a partner, not accounted for by other major psychiatric disorder (Vermillion & Holmes, 1997). This disorder is much rarer than are

hypoactive sexual desire disorders. It is characterized by low sexual desire and occasionally vaginismus or dyspareunia. Women with this disorder exhibit inadequate lubrication and vasocongestion during the excitement phase. Sexual aversion disorder is common among women with a history of physical or sexual abuse. Extensive relationship problems may exist. Physical factors rarely are involved; however, significant related anxiety occurs.

Pain Disorders

Sexual pain disorders include vaginismus and dyspareunia. **Vaginismus** is painful spasm of the muscles of the introitus that can prevent penetration. When a woman experiences **dyspareunia**, that is, painful sexual intercourse, she has genital or pelvic pain before, during, or after intercourse. Its cause may be physical, psychologic, or a result of a combination of factors. Some physical factors that have been associated with dyspareunia are vaginitis, cystitis, hormone deficiency, endometriosis, uterine prolapse, cystocele, rectocele, pelvic cancer, pelvic inflammatory disease, gastrointestinal disease, and renal disease (Vermillion & Holmes, 1997). The most commonly cited characteristic in women with chronic pelvic pain is a history of sexual trauma (Holland & Finger, 1999).

Certain psychologic factors also have been associated with dyspareunia (Meana, Binik, Khalife, & Cohen, 1998). Predominant factors identified are phobic anxiety, negative attitudes toward sexuality, relationship conflicts, and childhood sexual abuse (Sarwer & Durlak, 1996).

Whatever the cause of dyspareunia, women with this problem tend to require a great deal of support when undergoing the childbirth experience or even when attaining routine gynecologic health care. These women may experience avoidance behavior or an anxiety attack linked to simple procedures such as obtaining a Pap smear and having a bimanual pelvic examination. Postmenopausal women may experience dyspareunia secondary to decreased lubrication.

Vaginismus is a pain disorder in which the woman experiences discomfort related to involuntary spasms of the muscles of the outer third of the vagina. These muscle spasms either interfere with or prevent penetration. Vaginismus is classified as primary or secondary dependent on timing of onset. Primary vaginismus usually manifests itself by an unconsummated marriage (Renshaw, 1994). Secondary or acquired vaginismus may arise from sources such as a conditioned response to vaginitis, a healing episiotomy, problems with the sexual experience, or adverse past sexual experiences.

Orgasmic Disorders

Women with orgasmic disorders experience delayed orgasm, or cannot experience orgasm. The woman may be

unable to achieve orgasm with intercourse but may be able to achieve orgasm with a partner using noncoital methods. This disorder is found most commonly among young, less sexually experienced women and is often situational. The cause usually is psychological and may be related to discomfort or use of medications, especially selective serotonin reuptake inhibitors or other antidepressants.

Disorders Related to Other Conditions

Chronic medical conditions can affect sexual function. Many times this effect is associated with medications that are taken to treat the chronic condition. For example, anti-hypertensives, antiseizure medications, digoxin, diuretics, methyldopa, psychoactive drugs, sleeping pills, and tranquilizers can affect sexual response (Ringel, 1999). In fact, it has been suggested that many times noncompliance with medication regimens is related to the sexual side effects of drugs.

Substance abuse has been associated with sexual dysfunction. Alcohol can affect sexual desire. Cocaine has been associated with sexual promiscuity and sexually transmitted diseases. Other drugs have been linked to diminished sexual response, including antidepressants, anti-hypertensives, anti-inflammatory drugs, antiparkinsonian drugs, antiseizure medications, beta-blockers, cimetidine, digoxin, diuretics, methyldopa, psychoactive drugs, sleeping pills, and tranquilizers (Ringel, 1999).

Another factor associated with sexual dysfunction among women is sexual abuse in childhood. Sarwer & Durlak (1996) reported studying 359 married women who sought sex therapy with their spouses. In this study, 75% to 94% of women could be identified as having been victims of previous sexual abuse.

Male Sexual Dysfunction

The most common sexual dysfunction in men is erectile dysfunction, also called **impotence**. Until recently, this condition was not discussed publicly because there was no effective treatment (Bachman, Coleman, Driscoll, & Renshaw, 1999). It is estimated that 30 million men in the United States are affected by erectile dysfunction. The condition increases in incidence with aging, even in the absence of illness. Use of medications, chronic illnesses, and use of alcohol also have been implicated as causative agents. It has been estimated that half of cases of erectile dysfunction are related to atherosclerotic changes in men over the age of 50 years (Bachman et. al., 1999).

With the release of the drug Viagra (sildenafil) in 1998, it became apparent how pervasive the problem of erectile dysfunction is in the United States. The drug was adver-

tised as a cure for impotence. In the first 8 months on the market, 50 million prescriptions were written for sildenafil. It proved so popular and effective in men that women began taking it to see if it would improve their sexual function. There is no known benefit to women, and the Food and Drug Administration had not approved the drug for use in women. The popularity of sildenafil has stimulated discussion about how sexual response differs between men and women (Leiblum, 2000). Several deaths reportedly have been linked to the use of sildenafil.

Premature ejaculation is another form of sexual dysfunction in men. Commonly, this disorder is seen in very young men and men who have abstained from sex for long periods of time. It also is seen in men with chronic illnesses and multiple sclerosis (Bachman, Coleman, Driscoll, & Renshaw, 1999). If it persists, premature ejaculation can lead to other sexual problems, such as erectile dysfunction.

Priapism is a condition in which erection is sustained for several hours. This disorder may be associated with certain chronic diseases and with abuse of substances, such as cocaine. This situation is dangerous because persistent engorgement of the penile vessels causes cell death and fibrosis. Treatment of priapism usually consists of removal of blood from or injection of phenylephrine into the corpora cavernosa (Bachman, Coleman, Driscoll, & Renshaw, 1999).

Evaluation of Sexual Dysfunction

The nurse can make a major contribution to the care of couples with sexual dysfunction by providing an atmosphere that allows discussion of personal, highly emotional topics. The nurse often is the person with whom individuals share their feelings. Evaluation of sexual problems begins with taking a sexual history from both parties in the relationship (Van Sickle & Rosenstock, 1999). Although it is not the nurse's role to treat sexual dysfunction, the practitioner should have enough knowledge to discuss normal compared with dysfunctional behavior and make appropriate referrals.

The PLISSIT model has been identified as a useful one in general care settings for discussing sexual concerns (Katz, 2000). PLISSIT is an acronym for permission, limited information, specific suggestions, and intensive therapy. The PLISSIT model also has been used successfully to address sexual concerns during pregnancy (Alteneder & Hartzell, 1997).

Permission

When taking a sexual history, the nurse should ask open-ended, nonjudgmental questions that identify what the woman considers to be her normal sexual activity. This ap-

Research Highlight

Impact of Hysterectomy on Sexual Functioning

Purpose

To examine changes in sexual functioning after hysterectomy.

Method

Of 1,299 women interviewed before hysterectomy, 1,101 (84.8%) completed the study with follow-up at 6, 12, 18, and 24 months postoperatively. The main outcome measures were frequency of sexual activity, dyspareunia, orgasm, vaginal dryness, and sexual desire.

Findings

Finding	Preoperatively (%)	12 mo Postoperatively (%)	24 mo Postoperatively (%)
Engaging in sexual activity	70.5	77.6	76.7
Decreased dyspareunia	18.6	4.5	3.6
Anorgasmia	7.6	5.2	4.9
Decreased libido	10.4	6.3	6.2
Vaginal dryness	37.3	46.8	46.7

Each of the outcome measures improved after surgery.

Nursing Implications

Many times nurses are asked questions about how hysterectomy will affect sexual function. This study lends support to teaching clients that many sexual factors may actually improve after surgery.

Rhodes, J.C., Kjerulff, K.H., Lagenberg, P.W., & Guzinski, G.M. (1999). Hysterectomy and sexual functioning. *Journal of the American Medical Association* 282, (20), 1934–1941.

proach gives the woman permission to express concerns and ask questions.

Limited Information

The nurse should be familiar with sexual terms and sexual norms and should be able to determine which limited information is needed to assist the woman with her problem. Many times information is all that is necessary to resolve the problem.

Specific Suggestions

The nurse should have enough knowledge to make suggestions for alleviation of client concerns. In pregnancy, for

example, women may have dreams that they find unacceptable. It may be sufficient to let them know that many pregnant women experience emotionally charged dreams. If this information is not sufficient, however, the nurse can make a suggestion for referral to another health care provider who has expertise in dealing with such problems.

Intensive Therapy

The nurse should know her limitations concerning time and expertise and should make referrals for complex or time-consuming cases. In making the referral, it is wise for the nurse to suggest that the client needs someone with more skill rather than insinuate there is something abnormal about the client's problem.

INFERTILITY

As noted previously, when one considers the complex physical and hormonal sequence of events required for conception and pregnancy, it is amazing that normal births ever occur. For pregnancy to occur the female ovary must produce a mature egg, capable of being fertilized, which must be transported through the fallopian tube into the uterus where the hormonally prepared endometrium supports implantation. The male testes must produce an adequate quantity of mature, motile sperm, capable of surviving the arduous trip through his reproductive system, into the vagina, through the cervical mucus, uterus, and fallopian tube to join with the ovum. With each normal ovulatory cycle, there is about a 25% chance of pregnancy resulting. For normal couples, pregnancy may not occur for 6 months to 1 year with unprotected intercourse.

Clearly, many factors affect fertility. The ability to have children, however, is considered a normal expectation of adult life. **Infertility** is defined as the inability to conceive after 1 year with appropriately timed coitus without the use of contraception. Infertility affects almost 15% of couples (Silverberg, 2000), with the risk increasing for women after 35 years of age. After this age, nearly one third of women desiring a child are unable to conceive (Wallach, Garcia, Rosenwaks, & Seifer, 1998). For those who have difficulty or are unable to conceive, infertility can be devastating.

It is estimated that there were 4.5 million women who reported infertility in 1982 (Stephen & Chandra, 1998) as compared with 4.8 million in 1988 and 6.2 million in 1995. This increase is thought to be multifactorial. Proposed factors include delayed childbearing by a number of baby-boomers in society, the decreased popularity of permanent sterilization as a means of contraception, and an advance in age limits beyond 35 years as a criterion to qualify for infertility treatment. The result has been that many couples wait until later in life to attempt a first pregnancy.

The financial and psychological costs of infertility can be immense (Jerka, Schuett, & Foxhall, 1996). Estimates of the financial costs of infertility treatment vary according to the technology used. However, Van Voorhis (1998) noted that "In 1992, the overall cost per delivery was \$30,252." Psychologic sequelae described include depression, guilt, stress, loss, grief, disturbances of self-esteem, relationship problems, and even divorce. Estimates of financial costs often are inexact but include direct medical costs, such as drugs, ovulation prediction kits, physician fees, laboratory tests, hospitalizations, and radiologic examinations. Indirect costs may include expenses related to food and transportation when seeking care, lost wages, and extended care of children while the parents are undergoing testing. Other elusive costs may

be incurred related to pain and grief or psychologic counseling.

Factors Affecting Fertility

Because of the complexity of determining the cause of infertility and its expense, it is important that both partners be involved in the process from the beginning. A thorough assessment, which can be time-consuming, expensive and emotionally burdensome, may be required to produce a live birth. For the infertile couple the evaluation and treatment may be positive experiences because they offer hope.

Female Factors

Approximately 40% of the time female factors are the cause of infertility. Within this group of women, for 40% the major reason is failure to ovulate (Rosenthal, 1997). Another 40% have either tubal or pelvic problems. The remaining 20% have unusual problems or unexplained infertility.

Perhaps the single most important factor in female infertility is aging (Sauer, 1998). Although the causes of infertility are many, the decision to delay childbearing may result in difficulty in achieving a pregnancy. The decline in fertility with age has several components. With increasing age, there is higher risk of spontaneous abortion. The incidence of pelvic or tubal problems increases. Finally, the endocrine changes that begin 10 to 15 years before menopause lead to decreased fertility. Factors related to infertility are presented subsequently and then a systematic method for evaluation is presented.

Problems of Ovulation

For most women (95% to 98%) the presence of monthly menstrual cycles with premenstrual symptoms indicates an ovulatory cycle. Although its value has become more controversial with more sophisticated test measures (Illions & Thompson, 1997), taking the basal body temperature (BBT) can be a helpful and inexpensive indicator of ovulation for the woman experiencing monthly menses. The BBT should be evaluated after two menstrual cycles. A biphasic temperature pattern suggests ovulation.

The woman who is having irregular or infrequent menses or who is not having menses should be evaluated for ovulatory dysfunction (Kaplan, 1996). Common signs of problems of ovulation other than alterations in menses are **galactorrhea** (nipple discharge); signs of androgen excess, such as facial hair or male pattern hair growth; alterations in thyroid or adrenal functioning; and weight changes.

Ovarian Abnormalities. Anovulation may be a result of ovarian abnormalities such as hypogonadism (Turner's

syndrome), a genetic disorder, or external causes such as radiation or chemotherapy (Seaman, Telich-Vidal, & Sable, 1997). A cause that occasionally is overlooked is the use of oral contraceptives, which were initially prescribed to regulate menses or for the treatment of acne. Ovarian tumors or polycystic ovaries may prevent ovulation owing to changes in the feedback mechanism regulating ovarian function.

Hormonal Abnormalities. Abnormalities of hormonal functioning or ovarian failure may result in anovulation (Prior, 1997; Anasti, 1998). Irregularities in any of the sectors of the hypothalamus-pituitary-ovarian axis may alter the hormonal balance needed for ovulation. Appropriate levels of the adrenal, thyroid, and pituitary hormones also are needed. General poor health, inadequate nutrition, stress, and excessive exercise affect ovarian function.

Tubal Structural Problems

Fertilization usually occurs in the outer portion of the fallopian tube, which also provides transport for the embryo into the uterus for implantation. Obstruction or narrowing of the tube can lead to the inability to conceive or tubal pregnancies. Blockages may be a result of congenital defects or endometriosis (Spielvogel, Shwayden, & Coddington, 2000). Infection is the most common cause of scarring, however, and can result from organisms such as *Neisseria gonorrhoeae*, *Chlamydia trachomatis*, *Mycoplasma*, and *Mycobacterium tuberculosis*. Seemingly minor surgery such as appendectomy or laparoscopy also may cause infection or adhesions, with resultant infertility.

Structural Problems of the Uterus

Infertility related to uterine problems also usually of structural origin. Although fibroid tumors (leiomyomata) themselves usually are not a cause of infertility, they may obstruct the fallopian tubes or interfere with implantation. Although somewhat rare, congenital malformations may interfere with implantation or the ability to carry a fetus to term. An inadequate endometrium also may impede fertility because implantation may not be successful. An inadequate endometrium can result from Asherman's syndrome, a thinning of the uterine lining after surgical procedures, or inadequate hormonal preparation.

Endometriosis has gained the reputation for being the cause of many cases of infertility (Berube, Marcoux, Langenum, & Maheux, 1998). **Endometriosis** is the implantation of uterine endometrium outside the uterus. The exact mechanism is not known but a reflux through the tubes at the time of menses is thought to explain the unusual implantation sites. Although the most common sites for endometriosis are in the lower pelvis and bowel, it has been

seen on the diaphragm, lungs, and brain. Again, it is difficult to correlate the severity of the endometriosis with infertility because a woman with very few visible implants may be unable to conceive, whereas a woman with a severe case may have no problem conceiving. The exact reason for the resultant infertility also is not known. The infertility may be merely from obstructing implantation or adhesions, or it may be a result of a much more complex problem involving the body's response to foreign tissue (Seltzer & Pearse, 1995).

Structural Problems of the Vagina and Cervix

As the vagina and cervix are developing, a variety of congenital structural abnormalities may occur that could interfere with the transport, implantation, or growth of the embryo. There may be two vaginal vaults, two cervices, imperforate hymen, irregularly shaped uterus or tubes, or the cavities within either may be misshapen. Although these structural problems may be determined by physical examination, other diagnostic tests such as ultrasonography may be needed.

In addition, infections may change the cervical mucus and vaginal secretions that aid sperm motility and viability. Historically, cervical mucus and vaginal secretions were of greater concern. The use of intrauterine insemination, however, has lowered the incidence of these problems.

Male Factors

Male factors account for 35% to 40% of infertility. The incidence of male reasons for infertility is summarized in Box 12-1.

A semen analysis, a simple noninvasive screening test, should be an early if not first step in assessing a couple experiencing infertility. It is important that the specimen be collected and analyzed properly. After at least 48 hours of abstinence, a specimen obtained by masturbation should be collected in a clean container. The specimen should remain at body temperature and be delivered to the laboratory in 30 to 45 minutes. Because of the variability between specimens, it is suggested that the test be repeated

Box 12-1 MALE FACTORS ASSOCIATED WITH INFERTILITY

- Idiopathic, 70%–75%
- Testicular disorders (surgery, trauma), 10%–13%
- Genital tract obstructions, 8%–10%
- Sperm autoimmunity, 4%–6%
- Hormonal disorders, 1%
- Ejaculation, sexual dysfunction, 1%

Table 12-1 Normal Semen Analysis

Element	Quantity or Quality
Volume	2.0 mL or more
Sperm concentration	20 million/mL or more
Motility	50% or more with forward progression, or 25% or more with rapid progression within 60 min of ejaculation
Morphology	30% or more normal forms
Leukocytes	Fewer than 1 million/mL
Immunobead test	Fewer than 20% with adherent particles
SpermMar test	Fewer than 10% with adherent particles

in 2 to 4 weeks. Findings in a normal semen analysis are provided in Table 12-1.

Even the parameters in Table 12-1 are not necessarily predictive of fertility because there are many possibilities for error, including laboratory error, error in the way in which the specimen was collected, or events that occurred 3 months before the test that may have affected spermatogenesis, such as an illness or injury.

Many factors should be considered when the cause of a low sperm count seems to be idiopathic (Bigelow, et al., 1998). Increased scrotal heat owing to activities, such as frequent hot tub or sauna use, chronic infections causing increased body temperature, and sitting at a desk or in a car or bike riding for long periods, can cause a decreased sperm count. Sons of mothers who took diethylstilbestrol (DES) while pregnant have been shown to have reduced sperm counts. Trauma to the testes and surgery also can affect sperm production or cause adhesions resulting in obstructions (Silber, 2000). The use of drugs or alcohol is a factor that may cause low sperm count. Environmental factors such as exposure to toxic drugs, chemicals, and anesthetic gases also have been implicated in low sperm counts.

Testicular disorders account for approximately 10% to 13% of male infertility (Illions & Thompson, 1997). These disorders include cryptorchidism (undescended testes) and other congenital abnormalities. Obstructions of the genital tract (8% to 10%) can result from congenital abnormalities, trauma or surgery, and genital infections. Abnormalities in hormonal functioning, including the thyroid, pancreas, and pituitary, can impair fertility. Ejaculation or sexual dysfunction, which may be physical or psychologic, also may result in an inability to reproduce. Even when sperm count and mobility seem adequate, an immune response to the sperm in the male or female may decrease fertility.

Unexplained Infertility

For approximately 10% of infertile couples no specific causative problem can be identified. Possibly, each partner has minor problems that alone cannot explain the infertility but in combination prevent fertility (Guzick, 2000). For couples such as these, assisted reproductive technology may be of benefit. Often, however, these couples will require support and encouragement to seek other alternatives, such as adoption.

Assessment of the Infertile Couple

When a couple presents with concerns about infertility, it is important to understand that men and women possibly are very concerned and emotionally fragile. Many couples have read and tried many of the common folklore remedies to achieve pregnancy. Depending on their own values, or those of their culture, the ability to bear children can be very important. Entering a medical setting for evaluation is in itself, for some, an admission of failure. In addition, much concern can center on which partner is at fault. Before even beginning the medical aspects of care, it is important to understand and assist the couple to understand their motivation for pregnancy and be prepared to offer support. The couple should understand that the evaluation and treatment for infertility will be stressful and will involve both partners throughout the process. It is important to meet with the couple together. Some time also should be spent alone with each individual because there may be issues the person would prefer not to discuss in the presence of his or her partner.

The first and perhaps most valuable step in the evaluation for infertility is taking a detailed medical history from each partner. An outline for this history is shown in Box 12-2.

Client Education

Sperm Count

Several habits can reduce sperm count:

- Frequency of ejaculation
- Wearing tight-fitting clothing
- Overuse of saunas and hot tubs
- Marijuana use

Box 12-2 EVALUATION OF INFERTILITY**Female History**

1. Age
2. Fertility history
 - How long the pregnancy has been sought
 - Prior pregnancies: age at conception, outcome of each pregnancy
 - Prior contraception: method, complications, length of time without contraception
 - Use of an intrauterine device
 - Abortions: number, type
3. Menstrual history
 - Date of last menstrual cycle
 - Age of menarche
 - Characteristics of menses: interval, duration, regularity, predictability (breast tenderness, bloating), dysmenorrhea
 - Awareness of ovulation, change in cervical mucus, mittelschmerz (midcycle pelvic pain), midcycle spotting
 - Polycystic ovaries, ovarian cysts
4. Medical history
 - Major diseases: diabetes, tuberculosis, tumors
 - Treatments for disease, including medications and chemotherapy
 - Sexually transmitted infections: gonorrhea, syphilis, chlamydia, herpes
 - Hormonal irregularities: adrenal, thyroid, pituitary (hyperprolactinemia)
5. Surgical history
 - Laparoscopy or other reproductive surgery
 - Appendectomy
 - Endometriosis
 - Any abdominal surgery
 - Dilation and curettage
6. Medications
 - In utero exposure to DES
 - Hormones, including oral contraceptives
 - Antibiotics
 - Tretinoin (Retin-A)
7. Occupation
 - Exposure to radiation, toxic drugs, chemicals, anesthetic gases
8. Personal and sexual habits
 - Alcohol or drug use (cocaine, marijuana, inhalants, and so on)

Smoking
 Extremes of weight gain or loss
 Douching
 Frequency of intercourse; use of lubricants
 Timing of intercourse for optimum conception
 Pregnancy with other partners
 Number of other partners (risk of sexually transmitted infections and antibody reaction to sperm)

Male History

1. Fertility history
 - Age
 - Previous children
 - Frequency of intercourse; difficulties associated with function, including erection and ejaculation
2. Medical history
 - Major diseases: diabetes; tuberculosis; renal, thyroid, or adrenal diseases; other hormonal imbalances
 - Mumps after childhood
 - Abnormality or disease of the genital tract, tumors, epididymitis, prostatitis
 - Acute illness in past 3 months
 - Sexually transmitted infections and treatment
3. Surgical history
 - Genital surgery, including hernia repair, retroperitoneal surgery, and prostate surgery
4. Medications
 - List all drugs being taken, both prescription and over the counter (some may affect spermatogenesis, others function)
5. Occupation (sitting for long periods affects spermatogenesis)
 - Exposure to radiation, toxic drugs, chemicals, anesthetic gases
6. Personal and sexual habits
 - Alcohol or street drug use (cocaine, marijuana, inhalants, and so on)
 - Smoking
 - Wearing of tight underwear or biking shorts (elevates temperature)
 - Use of hot tubs (temperature)
 - Use of personal lubricants; condom use
 - Frequency of intercourse (very frequent ejaculation can reduce sperm count)

Physical Assessment and Diagnostic Tools

In many infertility practices the medical history is completed by the nurse. Often the physician or nurse practitioner will complete the physical examination, with the nurse providing assistance and much of the education. An overview of tools commonly used in infertility assessment is given in Table 12-2. Typically, the woman's examination is done in the office of the infertility practice; however, the man may be referred to a urologist for evaluation. In the man's examination, the presence of secondary sexual characteristics and genital abnormalities should be noted. Key evaluations include undescended testes and absence of the vas deferens. Attention should be paid to the presence of a **varicocele**, or abnormal blood vessels in the scrotum. A varicocele and the presence of a **hydrocele**, fluid in the scrotum, may be related to infertility.

In the woman, attention is paid to secondary sexual characteristics, such as breast development, pattern of facial and genital hair distribution, and the presence of acne. These characteristics are indicators of sexual maturity and therefore the ability to conceive. The thyroid should be palpated carefully for enlargement or nodules. The breasts should be evaluated for normal development and the presence of discharge. Surgical scars may indicate abdominal surgery, with resultant adhesions affecting reproductive function. A complete pelvic examination, including inspection of the external genitalia, should be performed to rule out anatomic abnormalities and infection. With the pelvic examination, cultures should be taken and a Pap smear performed. The first visit is an ideal time to offer preconceptional counseling, including testing for blood type, Rh antibodies, and immunity to measles. Vaccines should be given as needed for measles, hepatitis B, and

BASAL BODY TEMPERATURE

The basal body temperature (BBT) test has become less popular since the advent of the ovulation prediction kits because the BBT is less accurate.

REFLECTIONS FROM AN INFERTILE COUPLE

"We wanted to have a child very badly, but after 3 years of marriage and unprotected regular intercourse we had no pregnancy. After a long discussion with my husband, we decided to seek medical advice. We decided the best way to proceed was for me to visit my gynecologist.

We had no idea how impersonal and cold the whole process would be. You are asked to distance yourself from the emotional aspects of sexuality and focus on the mechanics of conception. My husband remembers the semen analysis as being the most challenging. He was given a sterile container, shown to a room, and told to produce a semen specimen. No further instructions were given. My most embarrassing time was when we had a postcoital test scheduled. The physician wanted me to be seen in his office within 2 hours after intercourse to examine my vaginal secretions under the microscope. On a bad traffic day, it can take 2 hours to travel from our home to his office. We had to rent a motel room near my husband's workplace and have intercourse during his lunch hour because we both had missed so much work. I'm not sure health care providers understand how stressful some of these tests can be."

UNDERSTANDING THE MENSTRUAL CYCLE

Many couples do not understand when the fertile time of the menstrual cycle occurs. Before considering an infertility workup, it is important to explore basic knowledge about sexuality and timing of intercourse. Helping the woman to be more aware of how her body functions, when ovulation occurs, and midcycle changes in the cervical mucus can assist couples in achieving conception.

Table 12-2 Tools Used to Assess Infertility

Test	Instructions	Findings
Semen analysis	<p>Semen should be collected by masturbation after 2–3 days' abstinence.</p> <p>Collect in a clean, dry container.</p> <p>Be sure to collect entire ejaculate; do not use withdrawal or condoms for collection. Special sheaths can be used, if required.</p> <p>Specimen should be kept warm and delivered to the laboratory in 30–60 min.</p> <p>Two or three specimens may be collected over several months because spermatogenesis takes 2.5 months.</p>	<p>Normal values:</p> <p>Volume, 2–6 mL</p> <p>Viscosity, liquid within 30 min</p> <p>pH, 7–8</p> <p>Count, more than 20 million/mL</p> <p>Motility, more than 40% moving</p> <p>Morphology, more than 50% mature and normal</p>
Basal body temperature (BBT)	<p>Used to confirm ovulation and time intercourse.</p> <p>Temperature can be taken orally or rectally with a regular thermometer, but special BBT thermometers or newer digital ones may be easier to read.</p> <p>Temperature must be taken on awakening, before any activity.</p> <p>The chart should be started on day 1 of the cycle. All events, such as intercourse, variations in normal activity, and illness, should be recorded.</p>	<p>Typically, the temperature decreases slightly (0.2 F) 24–36 h before ovulation and increases (0.4–0.8°F) 24–72 h after. Temperature stays elevated for 11–16 d. This biphasic pattern indicates ovulation. The most most fertile time is 3–4 d before ovulation and 1–2 d after. Coitus every other day during this time is suggested.</p>
Postcoital test	<p>Evaluates cervical mucus to determine adequacy of mucus and the ability of sperm to transverse it.</p> <p>Intercourse should occur after 48 hours of abstinence within 24–48 h of ovulation.</p> <p>Cervical mucus is examined by obtaining a sample during pelvic examination 2–8 h. after coitus.</p>	<p>The mucus should be described in terms of quantity, clarity, viscosity, pH, spinnbarkeit, and sperm characteristics of number, motility, and forms.</p> <p>Normal findings are described as 5–10 morphologically normal sperm with linear motility in thin, clear, copious, acellular mucus with spinnbarkeit >8 cm.</p>
Ovulation predictor kit	<p>A urine test used to predict ovulation based on luteinizing hormone (LH) be measured in the urine.</p> <p>Available over the counter, the kits cost \$30–\$40/mo and include 5–10 tests. LH triggers ovulation, which occurs 20–48 h after the LH surge. LH can be detected in the urine 8–12 h after its peak levels.</p> <p>Urine should be tested at the same time each day.</p> <p>Some tests require first morning voiding. Be sure to read instructions in the kit.</p>	<p>False-positive results can be obtained owing to menopause, pregnancy, and polycystic ovaries. Instructions in the kit will describe the findings.</p>
Hysterosalpingogram	<p>An X-ray study to determine if the uterine cavity and fallopian tubes are open and healthy. Performed 2–5 d after the end of menses.</p> <p>Special evaluation and possible alternative treatment should be considered if a history of pelvic inflammatory disease, pelvic mass, or sensitivity to iodine exists.</p>	<p>Abnormalities of the structure of the uterus or tubes may be identified.</p> <p>Narrowing or occlusion of the tubes can be seen.</p>
Endometrial biopsy	<p>A sample of the endometrial tissue lining the uterus to determine the uterine response to hormonal stimulation.</p> <p>Performed 2–3 d before an expected menstrual period.</p> <p>Danger of pregnancy loss exists, and a pregnancy test should be performed before this biopsy.</p> <p>Usually done in the physician's office with the use of a pipelle, a thin catheter inserted into the uterine cavity.</p> <p>Taking ibuprofen decreases possible cramping and discomfort.</p> <p>Helpful in diagnosing a luteal phase defect.</p>	<p>The pathology report will describe the influence of hormones on the uterus.</p>

(continued)

Table 12-2 Continued

Test	Instructions	Findings
Ultrasonography	Sound waves used to evaluate the structure of the pelvic organs and monitor ovulation by identification of follicles and release of the ova. Used to evaluate the fetus during pregnancy. Identifies ectopic pregnancies, endometriosis, and submucosal fibroids. May be abdominal or vaginal.	Structural abnormalities can be identified. Size, development, and maturation of ovarian follicles can be monitored, and status for egg retrieval provided.
Laparoscopy	Surgical procedure using an endoscope to view the pelvic organs. Treatments may be performed as problems are identified. Uterine abnormalities such as fibroids, adhesions, and endometriosis may be identified and removed. Used to retrieve eggs for reproductive technology. May be abdominal or vaginal. Usually suggested when no other cause of infertility is found.	Depending on the findings, treatment usually is performed at the same time to correct abnormalities. Findings might include fibroids, endometriosis, adhesions, ovarian cysts, and tubal blockages.
Laboratory evaluations	Based on medical history and physical examination, additional blood or urine tests may be ordered to evaluate the function of ovaries, pituitary, adrenal, hypothalamus, thyroid, and other glands to determine the cause of infertility.	Test parameters vary and are determined by the laboratory. Abnormalities may require further testing or treatment.

other immunizations as recommended. Teaching should include the need to use contraception until the immunizations have been completed. This recommendation is not likely to be received positively by the couple who so desperately want to conceive a pregnancy.

Before any further evaluation is done, a semen analysis should be obtained. This is the easiest and least invasive test that can be performed and often is overlooked. The ordering of further diagnostic tests will depend on the findings of the medical history and physical examination.

After the first examination, couples who have not previously kept a BBT chart may be asked to keep this record for 1 or 2 months. With newer technology such as the ovulation predictor kit and hormonal assays, however, the BBT may not be required.

Management of Infertility

After the findings of the history, physical examinations, laboratory tests, and other diagnostic tests are reviewed, a therapeutic regimen to treat the underlying cause of the infertility is decided on with the couple. It is very important that the couple understand each treatment considered for their situation. In planning their care the health care provider also must take into consideration influences such as the ages of the partners, how long they have been try-

ing to conceive, health care insurance coverage or financial resources, and any cultural or religious concerns. Generally, less invasive and less complex treatments are tried first, moving progressively to more involved procedures or combinations of therapies (Angard, 1999). Treatment decisions will depend on the couple's desires. Because of the expense of infertility treatment, both financial and emotional, communication about the proposed treatments, possible side effects, and potential effectiveness is very important.

Laparoscopy

Laparoscopy is one of the most important diagnostic and therapeutic tools used in infertility. It allows direct visualization of peritoneal structures and definitive diagnosis of endometriosis, adhesions, and abnormalities in structure or function of the pelvic organs. During the procedure, treatment of adhesions, ablation of endometriosis, and restoration of patency of the fallopian tubes may be accomplished. Occasionally, a myoma or fibroid may interfere with fertility and may be removed during laparoscopy. A general anesthetic typically is used and carbon dioxide gas is used to distend the abdomen for better visualization. It is important to inform the woman that there may be some discomfort, such as cramping from manipulation of the pelvic organs and shoulder pain as a result of the gas used.

Nursing Tip

CANCER AND FERTILITY

As cure rates for cancer have improved, both men and women who have or have had cancer are considering the effects of the cancer and cancer treatments on their fertility. Although the cancer itself may affect the ability to conceive, treatment with surgery, chemotherapy, or radiation may damage reproductive capability. With increased awareness, more emphasis is being put on preserving reproductive function. Cryopreservation (freezing) of sperm, decreased toxicity of chemotherapy, and the use of shielding during radiation have been used. Hormonal suppression of gonadal activity has been suggested as a means of preserving gonadal function.

It is important to be aware of the implications of cancer on fertility and that couples may desire pregnancy after cancer therapy. Education, information, and emotional support can assist these clients in making treatment decisions.

Artificial Insemination

Artificial insemination, with either the partner's or donor's sperm, allows for semen to be placed in the vagina near the cervical os. This is most appropriate when infertility is a result of problems with sperm production or ejaculation. Intrauterine insemination provides a means to bypass cervical mucus problems when the tubes appear to be open, allowing for fertilization in the tubes. For this procedure, a washed sperm specimen is prepared and inserted high into the uterus at the appropriate time in the cycle.

The use of donor sperm presents health and ethical issues that should be discussed clearly with the person seeking insemination. Standards for testing, preparation, and storage of sperm have been established and reduce the possibility of infection with the human immunodeficiency and hepatitis viruses. The couple also has the option to describe criteria used for donor matching, such as ethnic and physical characteristics.

Hormonal Therapy

A disturbance in ovulation usually is treated with one or more hormones, depending on the cause of the problem. Many times medications are available to assist in the management of infertility (Table 12-3). Bromocriptine, clomi-

Table 12-3 Medications for Treatment of Ovarian Disorders

Drug	Purpose	Administration
Bromocriptine (Parlodel)	Inhibits prolactin secretion by the pituitary, which interferes with the secretion of gonadotropin-releasing hormone (Gn-RH). Used in the presence of galactorrhea or elevated prolactin levels.	2.5 mg, orally, twice daily (because of side effects, may start with 2.5 mg at bedtime increasing to twice daily).
Clomiphene (Clomid, Serophene, Milophene)	Induce ovulation. May produce multiple gestation. Incidence of twins may be slightly higher (Wolf, 2000).	50 mg, orally, starting day 5 of the cycle for 5 days. If no ovulation, increase dosage by 50 mg/mo to 200–250 mg. If no pregnancy by 3–4 mos, reevaluate.
Human menopausal gonadotropin or menotropins (Pergonal, Humegon, Repronex)	Stimulate follicle growth in the ovaries, often with multiple eggs. For women who fail to respond to clomiphene. Watch for hyperstimulation syndrome.	Made from equal amounts of follicle-stimulating hormone (FSH) and luteinizing hormone (LH). 75 or 150 IU injected intramuscularly daily starting day 3–5 for 7–14 d based on estrogen blood levels and ultrasound monitoring of follicles.
Gn-RH (Leuprolide, Lupron)	Reduces endometriosis of fibroids and suppresses LH surge.	May be given intravenously, intranasally, or subcutaneously; dose will vary according to method.
Purified FSH (Metrodin)	Induces ovulation in clomiphene-resistant women with higher levels of LH than FSH.	Daily intramuscular (IM) injections starting early in the cycle.
LGC (APL, Pregnyl, Profasi, Novarel)	Stimulates LH surge, and triggers ovulation. Used in conjunction with clomiphene, hMG, and FSH.	10,000 IU given IM.
Progesterone	For luteal phase defects.	Given as vaginal or rectal suppository.

Research Highlight

Efficacy of Intrauterine Insemination

Purpose

To examine the efficacy of intrauterine insemination and the baby take home rate in cases of infertility attributable to male factors with and without a woman's hormone factor.

Methods

A retrospective analysis was done of 78 long-standing involuntarily childless couples in Austria.

After the follicular phase, a Gn-RH analogue protocol with a menotropin (Pergonal) was undertaken to stimulate ovulation and a silica preparation (Percoll) and capacitation of the man's semen were completed. Intrauterine insemination was completed. Percoll is an isotonic fluid used to replace semen for intrauterine insemination.

Findings

Of 109 inseminations there were 53 pregnancies and 38 deliveries. Of these, 49 infants were live born and 47 remain alive.

When combined with ovarian stimulation, semen preparation, and sperm capacitation, intrauterine insemination is a feasible solution to male factor infertility.

Nursing Implications

Because of new technologic advances, such as those described in this study, more couples are able to conceive a pregnancy than would have been possible in the past.

Rammer, E., & Friedrich, F. (1998). The effectiveness of intrauterine insemination in couples with sterility due to male infertility with and without a woman's hormone factor. *Fertility and Sterility*, 69, (1), 31–36.

phene, human menopausal gonadotropins, Gn-RH, and purified FSH are used to induce ovulation. HCG stimulates ovulation. Progestins may be used to support the luteal phase of the cycle. Before these drugs are used, thyroid, pituitary, and adrenal disorder must be diagnosed and treated.

Assisted Reproductive Technology

Although many advances in the diagnosis and treatment of infertility have improved the chances of pregnancy, for some couples pregnancy would be impossible without the use of advanced technology. Assisted reproductive technology (ART) involves the use of in vitro fertilization (IVF), gamete intrafallopian transfer (GIFT), and embryo transfer (ET). Typically, ovulation is induced with the use of fertility drugs to produce several mature follicles from which eggs can be retrieved. In IVF and ET, the eggs are aspirated from the ovarian follicles and fertilized outside the woman's body. IVF is most appropriate when the tubes are absent or blocked. In this process the eggs are fertil-

ized, and after 48 hours the embryo is inserted into the uterus for implantation. In GIFT and ET, at least one tube must be open. In ET, the eggs are fertilized outside the body but placed in the tube and enter the uterus for implantation. In GIFT, the retrieved egg and prepared sperm are drawn into a catheter separately and injected into the tube so that fertilization can take place in the tube. These methods have been in use for almost 20 years and have been successful in many cases.

New technology has provided the means for retrieving sperm from the testes when ejaculation is not possible, injecting sperm into the ova (intracytoplasmic sperm injection, or ICSI), cryopreservation of embryos for future pregnancies, and surrogate pregnancies. Future advances may include cloning, chromosome manipulation, the transfer of cell components from one cell to another, and biochemically assisted hatching of the egg to improve the chances of fertilization (American Society for Reproductive Medicine, 1998). As technology has expanded, ethical and legal issues have emerged. The ethical issues that have arisen

include the use of technology for sex selection, pregnancies in much older women, and the use of donor eggs and embryos. Legal issues defining parenthood, the use of embryos and sperm after death or divorce of the spouse, and the disposal of embryos cause concern. Nurses need to be aware of these issues and help clients address them as possible outcomes.

The use of technology is not without cost. ART can be very expensive, and pregnancy is not guaranteed (Angard, 1999). Many couples have undergone numerous cycles without success. Insurance companies have varying policies as to what will be covered, and often very little is included in the policy. Clearly, the financial and emotional impact can be immense, and nurses may be in the position to help couples deal with giving up the hope of having a biologic child.

NURSING IMPLICATIONS

All nurses should be familiar with the terminology and substance of information concerning sexuality, sexual dysfunction, fertility, and infertility. This information is essential in dealing with clients in any clinical setting. The nurse is viewed by the public as someone who has this knowledge and is very capable of taking very technical material and relaying it in terms that almost anyone can understand. Every nurse should be equipped with information to take an accurate and adequate sexual medical history. Every nurse should be aware of the PLISSIT model and be familiar with its use in screening for sexual dysfunction.

Every nurse should be able to identify resources that couples could refer to if they are having problems with sexuality or fertility.

Some nurses choose to work in the field of sexual counseling or infertility. These nurses need more extensive education and training to develop expertise. Sometimes these nurses actually participate in teams who undertake the infertility workup or in surgery where the ART is undertaken.

Web Activities

- What support groups, chat rooms, or resources can you locate for infertile couples?
- Search the Internet under the key words “fertility,” “infertility,” and “artificial insemination.” What links can you find?
- Visit the website of a pharmaceutical company such as Glaxo or Mead Johnson. Do they offer information on their infertility drugs?
- Go to www.aasect.org. What three major sexual concerns can you identify using their on-line journal that are of importance to women?

Key Concepts

- Couples experiencing infertility or sexual dysfunction undergo a highly emotionally charged situation that also may be technically difficult.
- Many times a couple's problems with infertility or sexuality are multifactorial and may require prolonged interaction with the health care system for diagnosis and treatment.
- To some couples, conception is more important than most other things in their lives.
- With new advances in technology, conception is occurring in couples in whom it would not have been possible in the recent past.
- The new assisted reproductive technologies carry ethical considerations with which society must deal.

Review Questions and Activities

1. What is the most common male factor in infertility?
2. What is the most common female factor in infertility?
3. When fertility is in question, which factors must be evaluated and why?
4. Why is infertility sometimes difficult to diagnose and treat?
5. Which cultural practices do humans have related to fertility and sexuality?
6. Which components relate to the experience of sexual dysfunction?
7. What is serial monogamy, and how is it an important concept in American culture?

8. What are your ethical beliefs about freezing and storing fertilized ova?
9. How do you see the Human Genome Project relating to infertility?
10. With new information forthcoming, what reproductive technologies may be available in the coming century?

Genetics and Genetic Counseling

Genetic counseling has been defined as a specialized type of family counseling. A great portion of nursing education is dedicated to the teaching and application of mental health methodology. Even if you are not a practicing psychiatric-mental health nurse, you have been exposed to these techniques and approaches during your education. They are extremely helpful in a genetic counseling situation and, as a member of a genetic counseling team, you are contributing invaluable expertise and experience to this process. However, the nurse in a genetic counseling team is often confronted with ethical issues that may evoke past personal and professional experiences. They require some preparation on the part of the practitioner, and you may want to review, before the occasion, some of your personal and ethical value systems. For example:

- ❖ *How would you respond to the often-heard question: "Tell me what you would do in my place. Help me make this decision"?*
- ❖ *Could you maintain a strictly nondirective approach to counseling? Is it even desirable to be nondirective?*
- ❖ *Are you able to support the decision of a client (for example, not to have amniocentesis in a high-risk genetic situation) that goes against your moral values?*
- ❖ *How do you feel about giving a client referral information that may lead him or her to an outcome contrary to your beliefs?*

Key Terms

Allele	Dominant	Heterozygote	Mutation
Alpha-fetoprotein (AFP)	Euploid	Homologous	Nondisjunction
Amniocentesis	Gamete	Homozygote	Pedigree (Genogram)
Aneuploidy	Gametogenesis	Karyotype	Phenotype
Autosome	Gene	Meiosis	Polygenic
Chromosome	Genetic counseling	Mitosis	Proband
Clastogen	Genotype	Monosomy	Recessive
Cytogenetics	Haploid	Mosaicism	Translocation
Deletion	Hemizygous	Multifactorial	Trisomy
Diploid			

Competencies

Upon completion of this chapter, the reader should be able to:

1. Discuss the genetic etiology of human disease, emphasizing the difference between gene alterations and chromosomal abnormalities.
2. Discuss the numerical and structural features of chromosomes.
3. Compare and contrast the stages of gamete formation in oogenesis and spermatogenesis.
4. Define and characterize meiotic and mitotic chromosome nondisjunction.
5. Differentiate between euploidy and aneuploidy, and discuss mechanisms that lead to aneuploidies.
6. Discuss the normal function of structural genes and analyze their derangements in Tay-Sachs disease, phenylketonuria, and Lesch-Nyhan syndrome.
7. Differentiate between transmission of alleles in dominant and recessive patterns.
8. Compare characteristics of single-gene and multifactorial inheritance.
9. Describe the major clinical manifestations of selected autosomal and X-linked disorders. Analyze their significance in prenatal testing.
10. Describe the major features of selected disorders that result from numerical and structural chromosomal abnormalities and discuss their effects on women's health care.
11. Analyze the consequences of screening for genetic diseases.
12. Discuss the various elements of genetic counseling and their effect on the family.
13. Compare and contrast various procedures and methods used in prenatal diagnosis.

Medical genetics is a relatively new branch of an old science. Familial occurrences of specific traits have been cited in the literature for centuries. An early example of accurate genetic observation that illustrates the X-linked inheritance of hemophilia is provided in the Jewish Talmud. According to Jewish law, any newborn boy whose male maternal cousin had a bleeding disorder is exempted from circumcision.

However, it has been only since the turn of the 20th century, and especially after 1950, that formal knowledge about medical aspects of genetics has begun to flourish. The landmark work by Archibald Garrod (1902) on alkaptonuria introduced the concept of “inborn errors of metabolism” and established the grounds for the emerging science of biochemical genetics. Despite his limited knowledge of genetic mechanisms—the work of Gregor

Mendel was not yet widely disseminated—Garrod concluded that the existence of blood relatives among affected individuals in his study represented inherited human biochemical variations, a concept currently termed “polymorphism.” He accurately predicted that the lack or dysfunction of some mediators of metabolic pathways was responsible for the disorders studied.

In the early 40s, research by Beadle and Tatum (1941) established the relationship between genotype and phenotype (a concept initially known as “one gene-one enzyme”) and defined genes as the primary determinant in the control of protein synthesis. Their studies gave Garrod’s work immediate validation by identifying enzymes as Garrod’s missing mediators. The era of molecular genetics was marked by the discovery of a molecular defect in sickle cell disease, initially postulated by Linus Pauling in 1949 (Pauling, Itano, Singer, & Wells, 1949), and confirmed by Ingram in 1956. With these discoveries, the focus of genetic research was turned to identifying the protein (enzyme) products of specific genes and to relating them to disease process (Cox & Sinclair, 1997).

The field of **cytogenetics**, or the study of chromosomes with a special focus on chromosome abnormalities, was launched by the discovery of the first human chromosomal abnormality by Jerome Lejeune and coworkers in 1952, who identified trisomy 21 as the causative event in Down syndrome. Many other chromosomal disorders were subsequently defined, and cytogenetics was the standard working tool of geneticists for many years.

In the early 1960s, the technique of prenatal diagnosis was to be totally revolutionized by the development of genetic **amniocentesis**. In this technique, a sample of amniotic fluid is removed, and cells that were sloughed off by a developing fetus are studied, allowing geneticists to identify both biochemical defects and chromosome anomalies. The process of genetic counseling, which up to this point was based, at best, on statistical predictions and fixed-risk figures, now could be done on a personal level, as geneticists began to provide genetic information about a specific pregnancy. In the early 1970s, Sarah Lawrence University in New York began to offer the first master’s degree program in genetic counseling, with a curriculum based on a strong foundation of genetics and psychology. The modern approach to genetics is based on the concept of reverse genetics, whereby genes are mapped and cloned before the identification of their (protein) products. The addition of gene cloning to the armamentarium of medical genetics set the pace for genetic engineering and potential gene correction of hereditary diseases.

The purpose of this chapter is to provide the reader with baseline essentials of genetics and to awaken an interest in further reading. A thorough glossary of genetic terms can be found on the Internet (see Resources).

CHROMOSOMAL BASIS OF INHERITANCE

A **gene** is a segment of nucleic acid that contains genetic information necessary to control a certain function, such as the synthesis of a polypeptide. A **chromosome** is a filament-like nuclear structure consisting of chromatin that stores genetic information as base sequences in DNA, and whose number is constant in each species. When attempting to generate a list of human genetic disorders, one soon discovers that some are classified under gene alterations (e.g., sickle cell disease, galactosemia, cystic fibrosis), while others represent chromosomal abnormalities (e.g., Turner syndrome; Down syndrome; cri du chat, or cat’s cry syndrome). Although such numerical or structural chromosomal aberrations automatically affect large groups of genes, a small gene alteration does not alter chromosome structure and number. Alterations in single genes (single-gene disorders) or even in large groups of genes (polygenic disorders) may be a lesion too small to cause an alteration in chromosomal structure and cannot be identified by karyotype analysis. A **karyotype** is the chromosomal constitution of an individual, which is represented by a laboratory-made display, in which chromosomes are arranged by size and centromere position. This concept is easily understood when one considers that human somatic cells (nucleated cells, with the exception of ova and spermatozoa) contain approximately 100,000 genes, distributed in the form of tightly coiled DNA molecules along 46 **chromosomes**. If all chromosomes were the same size, each would carry approximately 2,300 genes. However, since human chromosomes vary in size, the larger the chromosome, the greater the number of genes carried. Therefore, the clinical manifestations of numerical chromosome alterations increase in severity in proportion to the increasing size of the involved chromosome. For example, a **trisomy** (a condition caused by the presence of an extra chromosome that is added to a given chromosome pair and results in a total number of 47 chromosomes per cell) in which the extra chromosome is one of the smallest size, group G (Down syndrome, or trisomy 21), produces malformations that are much more compatible with life than a trisomy involving a larger chromosome, group D (Patau syndrome, or trisomy 13).

Chromosome Number and Structure

When grouped in a karyotype (Figure 13-1) for cytogenetic analysis, somatic cell chromosomes, usually derived from small lymphocytes collected from circulating blood, are arranged according to size (groups A through G, in decreasing size) and position of the centromere (metacentric, submetacentric, and acrocentric chromosomes). Group A

Figure 13-1 Karyotype of a human female cell. Chromosomes obtained from a peripheral blood lymphocyte culture. (Courtesy of Dr. David Ledbetter, Department of Human Genetics, University of Chicago)

chromosomes consist of pairs 1 through 3, group B include pairs 4 and 5, and group C encompass pairs 6 through 12; groups D (pairs 13 to 15) and G (pairs 21 and 22) are the large and small acrocentric chromosomes, respectively; group E contain pairs 16 to 18; and group F include pairs 19 and 20. The X chromosome approximates the size and shape of a group C pair, and the Y chromosome is similar to a group G chromosome. Short chromosome arms are designated as *p* (for *petit*, or small in French), long arms as *q*. This nomenclature allows for quick recognition of chromosomal structural features or abnormalities. For example, the designation 46, XX, B(5)p[−] indicates a deletion (−) of a portion of the small arm (*p*) of chromosome pair number 5 of the B group, occurring in a female (XX) with a normal chromosome number (46). This is the typical chromosome pattern found in the cri du chat (cat's cry) syndrome. When stained with special techniques, each homologous chromosome pair displays a different, constant pattern of banding (e.g., Giemsa stain banding as depicted in Figure 13-1). Banding techniques, developed in the early 1970s, allow the exact classification of chromosomes in groups and the identification of alterations in chromosome structure, such as deletions and translocations. The term **deletion** refers to the loss of chromosomal material, and **translocation** is the misplacement of genetic material from one chromosome to another.

Patterns of Chromosome Anomalies

The normal structure of chromosomes is subject to alterations that result from breakage and rearrangement. Chromosome breakage has long been recognized as a significant source of genetic abnormalities. The term **clastogen** (i.e., chromosome-breaking agent, from *clastos*, to break, and the suffix, *gen*, an agent) was coined in the early 1970s to designate agents that could cause chromosome breakage. Many clastogens have been identified since then, including physical agents (e.g., ionizing radiation), chemical agents (e.g., chlorpromazine), and biologic agents (e.g., viral infections). However, the significance of clastogens as disease-causing agents has been questioned in many instances. For example, an infection with the influenza virus usually results in chromosome breakage in somatic cells (circulating small lymphocytes), but the chromosome structures return to normal in a few days. Chromosome breakage, therefore, becomes significant when: 1) it is permanent, or at best, long-lasting; and 2) these permanent changes, in addition to appearing in somatic cells, are also present in germ cells and thus have the potential of being transmitted to the offspring. Figure 13-2 depicts some of the possible consequences of chromosome breakage.

Chromosome breakage resulting in loss of the broken fragment is termed “chromosome deletion,” which may have significant clinical consequences, such as cri du chat syndrome. In addition, chromosome breakage may also result in unstable end points (“sticky ends”), which predisposes chromosomes to a variety of rearrangements of the resulting fragments. One such rearrangement is a translocation, by which a chromosomal fragment reunites with another nonhomologous chromosome. Two types of translocations have clinical significance: reciprocal and robertsonian. In a reciprocal translocation, breaks occur in two different chromosomes and the fragments are mutually exchanged, resulting in derivative chromosomes. Robertsonian translocations occur when the short arms of two acrocentric chromosomes (pairs 13 to 15 of group D, and pairs 21 and 22 of group G) are lost, and the remaining long arms fuse at the centromere, forming a “single chromosome.” Both types result in individuals who have the same amount of genetic information, although “rearranged,” and therefore no clinical manifestations are expected. These persons are termed “balanced translocation carriers.” However, if this person reproduces, there is a chance that the translocated chromosome will be present in the gamete that undergoes fertilization by a normal gamete. The resulting zygote will have a gene imbalance caused by the extra chromosomal (genetic) material, and the child will be at risk for physical and mental abnormalities.

Initial Configuration	Breaking Points	Outcomes
A 		
B 		
C 		
D 		

Figure 13-2 Examples of structural rearrangements after chromosomal breakage. Initial chromosome constitution, breaking points, and consequences of the breaks and rearrangements are shown. In panel A, a break occurs between markers *d* and *e*. Three consequences are: the resulting chromosomes, bearing markers *a* through *d* have undergone a deletion. The severed fragment may stay aligned with the rest (top example), the space being narrower than the length of the fragment: chromosome gap. Or it may be lost (bottom example): chromosome break. In panel B, the initial chromosome suffers two breaks (between markers *a* and *b* and between *d* and *e*). The center portion undergoes a pericentric inversion, resulting in a newly arranged chromosome, in which the markers are sequenced *a*, *d*, *c*, *b*, and *e*. Panel C depicts an exchange of genetic material between chromosomes bearing markers *a* through *e* and *f* through *j*. Since no genetic material was lost, only rearranged, this is termed a balanced translocation. Panel D represents a robertsonian translocation between two acrocentric chromosomes (one from group G, the small chromosome, the other from group D, the large chromosome). Loss of the short arms and fusion at the centromere results in a translocated chromosome. If no significant genetic material is lost, this is also a balanced translocation, causing no clinical manifestations.

Distribution of Chromosomes During Cell Division

Human somatic cells are **diploid** (a cell which contains two copies of each chromosome). Such a diploid chromosome number is represented by the notation $2n=46$. A **haploid** chromosome constitution ($n=23$) is found in germ cells, the male and female **gametes** (spermatozoa and ova). Somatic cell chromosomes are represented by 44 **autosomes** (the 22 pairs of chromosomes, which do not greatly influence sex determination at conception) and two sex chromosomes, XX in females and XY in males. As somatic cells multiply by **mitosis**, each daughter cell receives the same chromosome number as the initial cell. This equitable chromosome sharing results from a phenomenon termed “disjunction.” During anaphase, chro-

Figure 13-3 Consequences of chromosome nondisjunction occurring during mitosis, after a normal zygote was formed by fertilization of two normal gametes. (Only one chromosome pair is represented). Following the first mitosis, the upper cell originates a normal line of cells with the correct chromosome number. The bottom cell undergoes nondisjunction, resulting in a line of cells with one extra chromosome. (The monosomic cell is not viable and there are no further divisions.) The outcome is a mosaic individual with two cell lines, one containing the normal chromosome number, the other aneuploid.

matids of each chromosome separate and migrate to opposite poles of the cell, guided by microtubules of the mitotic spindle (Figure 13-3). Disruption of this orderly chromosome distribution occurs in **nondisjunction**. Through failure of homologous chromosomes or chromatids to separate properly during meiotic (meiosis I or II) or mitotic anaphase, daughter cells will have different chromosome numbers (e.g., 45 and 47, instead of 46 and 46). Cells that are **monosomic** (the aneuploid condition of having a chromosome represented by a single copy in a somatic cell) tend to degenerate and die, but those with the extra chromosome (trisomic) continue to divide and generate a complete line of trisomic cells.

Mitotic Nondisjunction and Mosaicism

When mitotic nondisjunction occurs during embryonic development, the trisomic cell line proliferates concomitantly with the normal cell line, and an individual with **mosaicism** for that particular chromosome results. Mosaicism, therefore, results in an individual (mosaic) with two or more genetically different cell populations. The chromosomal notation for a male with a mosaic type of Down syndrome, for example, is: $46, XY/47, XY, G(21)^+$. The slash (/) indicates a dual cell population, in which one has the normal chromosomal constitution (46, XY), while the other carries the extra G(21) chromosome (+) and has a total number of 47 chromosomes.

Oogenesis and Spermatogenesis

The halving of chromosome number that occurs in **gametogenesis** (a series of mitotic and meiotic divisions occurring in the gonads that leads to the production of gametes) takes place during the first division (meiosis I) of meiosis. **Meiosis** is a reductional type of cell division, in which the chromosome number is halved. The second division (meiosis II) is an equational, mitosis-like cell division. As somatic chromosomes are shared by the products of the first meiotic division, each daughter cell receives one member of each autosomal pair and one of the sex chromosomes (either the X or the Y). As a result, women can form only X-bearing ova, but men can produce X-bearing and Y-bearing spermatozoa.

Oogenesis

The process of oogenesis (Figure 13-4) begins during prenatal development and comprises three main phases: cell proliferation by mitosis, reduction of chromosome number and genetic recombination through meiosis, and maturation of oocytes. During fetal development, early germ cells divide by mitosis until the stages of oogonia and primary oocytes are reached. These cells still have a diploid chromosome number ($2n=46$). Primary oocytes then enter meiosis I and, at birth, they are found at an arrested stage, termed “dictyotene,” which persists until puberty. Starting at menarche, shortly before each ovulation, the primary oocyte resumes cell division and completes meiosis I, now with the number of chromosomes reduced to the haploid number ($n=23$). The outcome of meiosis I is one secondary oocyte and one first polar body. At ovulation, the nucleus of the secondary oocyte initiates meiosis II (the first polar body degenerates). At this point, if fertilization does

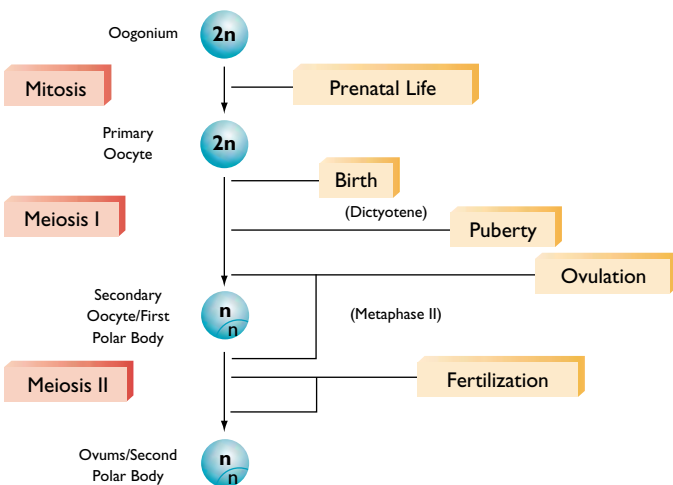

Figure 13-4 Oogenesis. Depicted here are the various types of cell division, the resulting cell types, and the time elapsed from primordial oogonium to mature ovum. First ovum is released at menarche, the last one immediately before menopause. Permanence of the latter in the ovary, approximately 52 years.

not occur, the secondary oocyte degenerates and dies without completing meiosis II. However, if fertilization occurs, the nucleus of the secondary oocyte resumes and completes meiosis II as the male pronucleus approaches it. The product of meiosis II is one ovum and one secondary polar body (which later degenerates). The female pronucleus contained in the ovum now fuses with the (haploid) male pronucleus and forms a diploid zygote, which evolves into the embryo, fetus, and newborn infant.

Of the approximately 2 million oocytes present at birth, only about 300,000 are present at puberty, and of these, only approximately 400 reach full maturity, which culminates in monthly ovulation during reproductive years. The remaining follicular units undergo progressive atresia, by apoptosis, a physiologic phenomenon that persists throughout those years. From a genetic perspective, the long duration of the first meiotic division, while the oocyte continues its metabolic functions, may be responsible, at least in part, for the occurrence of meiotic errors, such as nondisjunction. From a teratogenic viewpoint, an ovum fertilized at an advanced age has remained in the ovaries since birth and therefore has been exposed to a variety of environmental (internal and external) influences. This long-term exposure may account for the linear relationship between maternal age and birth defects discussed later.

Spermatogenesis

Unlike oogenesis, in which oocytes are produced prenatally, the process of sperm production only begins at puberty (Figure 13-5). As in oogenesis, three sequential steps can be identified in spermatogenesis: intense cell prolifer-

Figure 13-5 Spermatogenesis. Different cell divisions and resulting cells. Approximate time elapsed from spermatogonia to mature spermatozoa is 75 days, followed by a further 10 to 12 days of maturation in the epididymis.

ation by mitosis, the recombination and reduction events of meiosis, and spermiogenesis (maturation of spermatozoa). At puberty, testicular endocrine cells, called Leydig cells or interstitial cells, increase in number and begin to produce testosterone, which initiates spermatogenesis. The process of spermatogenesis is characterized by a series of mitotic divisions, followed by meiosis I and II. Reduction in the number of chromosomes occurs in meiosis I, between the stages of primary and secondary spermatocytes. Meiosis II converts secondary spermatocytes into spermatids. After this step, no further divisions occur, only a process of maturation (spermiogenesis), which results in mature spermatozoa. Unlike oogenesis, which produces only one viable gamete, each spermatogonium (early male germ cell) entering spermatogenesis produces four mature gametes. Spermatogenesis continues throughout a lifetime.

Meiotic Nondisjunction and Aneuploidy

Meiotic nondisjunction is a major cause of **aneuploidy**, an abnormal chromosome pattern in which the total number of chromosomes is not a multiple of the haploid number, $n=23$. Nondisjunction can occur during meiosis I and II, during both oogenesis and spermatogenesis, resulting in gametes with an aneuploid chromosome number (for example, 22 and 24, instead of 23 and 23) (Figure 13-6). As in the case of somatic cells, gametes lacking a chromosome are not likely to survive. The gametes with an extra chromosome are more viable, and on fertilization, a normal gamete will produce an aneuploid zygote. The most com-

Figure 13-6 Outcomes of meiotic chromosome nondisjunction occurring during meiosis I (left) and meiosis II (right). (Only one chromosome pair is represented). Nondisjunction at meiosis I results in one aneuploid and one monosomic cell (which does not survive). Meiosis II produces two aneuploid gametes, which, on fertilization by normal, euploid gametes, will produce trisomic zygotes. Likewise, nondisjunction at meiosis II also results in aneuploid gametes, and subsequently in trisomic zygotes.

mon aneuploidies in humans are trisomies. For example, as a result of meiotic nondisjunction, a spermatozoon carrying an extra G(21) chromosome, i.e., 24, X or Y, $G(21)^+$ may fertilize an ovum with a normal chromosomal constitution, 23, X. The result will be a zygote with 47 chromosomes, including the extra G(21), which will develop into an infant with Down syndrome, or G(21) trisomy. The chromosome notation for a female with free trisomy-type Down syndrome, for example, is 47, XX, $G(21)^+$. Unlike the mosaic case described, all somatic cells in this person contain the extra G(21) chromosome. The addition of one chromosome to one of the pairs (trisomy) creates a relatively small aneuploid alteration in the total chromosome number (46 to 47), which is usually quite compatible with life. However, the addition of one or more chromosomes to each pair (increments of the haploid number, 23) results in triploid cells with 69 chromosomes ($46+23$) or tetraploid cells with 92 chromosomes ($46+23+23$). The product of this uniform addition of chromosomes to all of the original pairs is termed euploidy, a **euploid** cell being one whose chromosome number is a multiple of 23. But even in the case of triploid individuals ($3n=69$) the genetic imbalance is of such magnitude that the few infants who are carried to term have severe multiple abnormalities that limit their life span to a few hours or days.

GENE STRUCTURE AND FUNCTION

Genes are sequences of DNA that determine a certain biologic function. Many are structural genes and carry the necessary information to promote the synthesis of proteins (polypeptides), others are regulatory and control the function of other genes or groups of genes. A **mutation** (alteration) of a structural gene may result in the synthesis of an abnormal protein (e.g., enzyme) with potential clinical consequences. The following four figures illustrate some mechanisms of gene-protein interaction. Figure 13-7 represents the normal metabolic conversion of a substance

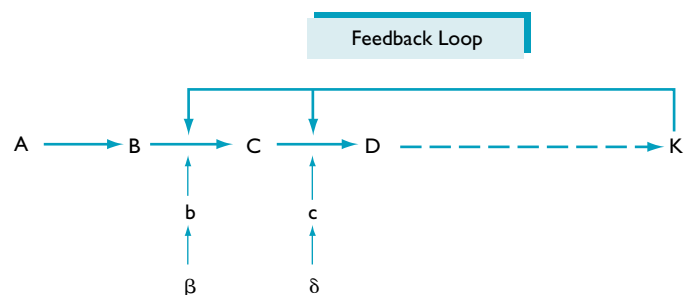

Figure 13-7 Normal sequence of events in the metabolic conversion of product A into end product K, mediated by enzymes b and c, which are encoded by genes β and δ respectively.

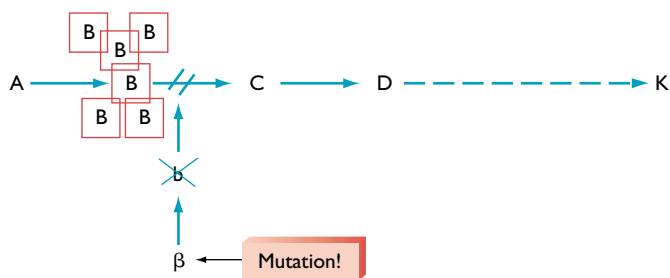

Figure 13-8 Consequences of a mutation in gene β , resulting in lack of enzyme b , interruption of the metabolic pathway, and accumulation of byproduct B . Prototype gene dysfunction in Tay-Sachs disease.

A into an end-product K , via byproducts B , C , D , and so on. Enzymes b and c , whose synthesis is controlled by genes β and δ , catalyze steps $B \Rightarrow C$, and $C \Rightarrow D$, respectively. A feedback loop ensures physiologic levels of K .

In Figure 13-8, a mutation has occurred in gene β , preventing normal (quantitative or qualitative) synthesis of enzyme b , and the consequent interruption of the pathway between B and C . Continuous uptake of A will produce two results: accumulation of B , and depletion of all products beyond the block. An example of this situation is Tay-Sachs disease (a GM_2 gangliosidosis): mutation of the Tay-Sachs gene (β) causes the lack of the enzyme hexosaminidase A (HexA), represented by (b) , and whose absence results in accumulation of ganglioside GM_2 (B) in nerve cells, producing all the clinical manifestations of this progressive neurologic disorder.

Figure 13-9 depicts a mutation in gene δ , blocking the synthesis of enzyme c , and interrupting the metabolic conversion of C into D . In this instance, an alternative pathway $C \Rightarrow E \Rightarrow F$ is opened. This event may have two out-

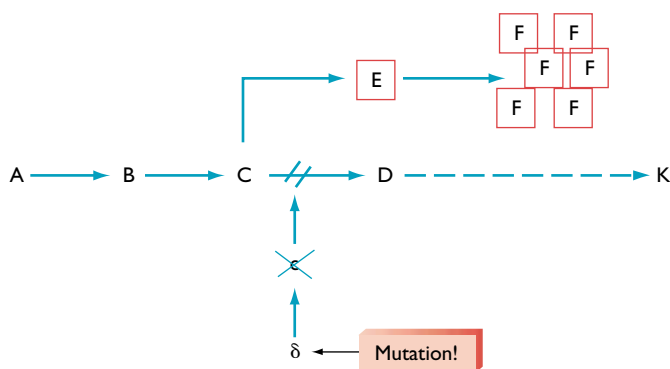

Figure 13-9 Consequences of a mutation in gene δ , resulting in lack of enzyme c , interruption of the metabolic pathway, and opening of an alternate pathway. The outcome is accumulation of byproduct F . Prototype gene dysfunction in phenylketonuria (PKU).

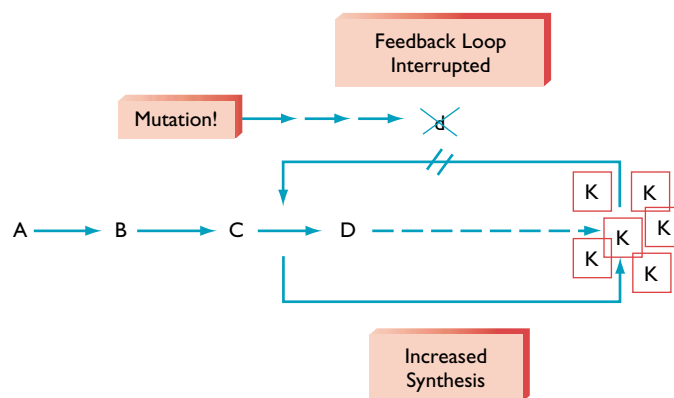

Figure 13-10 Consequences of a mutation in the gene encoding for enzyme d , which is involved in the feedback control loop for end-product K . As a result, increased synthesis of K is observed, eventually reaching toxic levels. Prototype gene dysfunction in Lesch-Nyhan syndrome.

comes: product F may eventually be converted into K , with no significant clinical consequences, or F may represent the end point to the alternative pathway and begin to accumulate until it reaches toxic levels. The example here is phenylketonuria (PKU), an inborn error of metabolism that creates an intolerance to the amino acid phenylalanine. The missing enzyme here (c), which results from mutation in the PKU gene (δ), is phenylalanine hydroxylase. The alternative pathway leads to the formation and accumulation of phenylketones (F), which, in combination with phenylalanine deficiency, prevents the postnatal completion of myelination of nerves and results in profound mental retardation.

Figure 13-10 represents a genetic alteration of the enzyme d , which mediates the feedback loop controlling ideal concentrations of K . As a result, K may accumulate to toxic levels. The prototype genetic disease here is Lesch-Nyhan syndrome, in which d is the enzyme hypoxanthine-guanine phosphoribosyl transferase (HGPRT) and K is uric acid. Accumulation of uric acid to extremely high levels, plus HGPRT deficiency, results in mental retardation and a tendency for self-mutilation in affected persons.

SINGLE GENE (MENDELIAN) INHERITANCE

The concept of gene, by definition, does not determine the expression of that gene. A gene is defined as a segment of nucleic acid that contains genetic information necessary to control a certain function, such as the synthesis of a polypeptide. For example, the gene for Tay-Sachs disease is a site on a chromosome that controls the synthesis of the enzyme HexA. The possible expressions of this gene would be $HexA^+$, indicating the command for synthesis of

HexA, or HexA⁻, indicating the lack of such command, resulting in the absence of the enzyme. Such alternate forms of gene expression are termed **alleles** of the gene HexA. The genetic constitution of an individual at any given locus is called **genotype**, whereas the expression of that gene's function in terms of measurable or observable features of the individual is termed **phenotype**. Whether or not a gene is expressed in the phenotype depends on the arrangement of its alleles and on the concepts of dominance and recessivity. A mutation in the original, or "wild-type" allele, in this case HexA⁺, may result in a different allele, such as HexA⁻.

Dominant Gene Inheritance Pattern

Consider a gene with two alleles, the normal ("wild-type") represented by (+), and the mutant allele represented by (-). Figure 13-11 illustrates the three possible arrangements for the alleles in persons carrying that gene. Represented here are pairs of somatic **homologous chromosomes** (chromosomes with matching genes) where that gene is located. The model may also be used to illustrate the X chromosome pair in women. The first individual (A) received from each parent a copy of the normal allele (+/+). The second person (B) received from one parent one copy of the normal allele and from the other, one copy of the mutated allele (+/-). The third person (C) received from each parent a copy of the mutated allele (-/-). These are the only possible mathematical combinations, given one gene with two alleles. Persons (A) and (C) are **homozygous** for either allele (+/+) or (-/-). A homozygous person, or homozygote, is an individual possessing a pair of identical alleles of a given gene. Person (B) is termed a **heterozygote**, that is, an individual who has two different alleles at a given locus (+/-).

Figure 13-11 Dominant inheritance pattern. Schematic of the three possible allelic arrangements of a dominant gene: genotypes and possible phenotypes. Note absence of carrier state.

Now, imagine determining by physical examination the phenotypes of these three individuals. Person (A) carries normal alleles and displays a normal phenotype. Person (C) has only mutant alleles and exhibits an affected phenotype. Person (B), the heterozygote, also displays an affected phenotype, but the clinical manifestations in person (C), the homozygote for the mutant alleles, are more severe. When this type of correlation between genotypes and observed phenotypes is obtained, the mode of inheritance is termed **dominant**. This term implies that in the heterozygote (person B) the expression of the mutant allele dominates over the expression of the normal allele. In other words, in the case of dominant genes, the presence of one copy of the mutant allele is sufficient to express the phenotype. And by extension, two copies of the mutant allele bring about a more accentuated expression of that characteristic. In summary, a dominant allele is one that is phenotypically expressed in single copy (heterozygote) and in double copy (homozygote).

In addition to the patterns of phenotypic expression described above, conditions exist that may cause a variation of expression. These include incomplete penetrance and variable expressivity.

A gene is said to have reduced or incomplete penetrance in a population when a proportion of persons who possess that gene do not express the phenotype. Usually, those who do express the affected phenotype have a complete expression of the phenotype, with all features of the syndrome present. A gene is said to have variable expressivity when individuals possessing that gene display the features of the syndrome in various degrees of expression, from mild to severe.

Vertical Transmission of Dominant Genes

A clear understanding of transmission patterns requires a few general guidelines. First of all, most genetic diseases are rare. The probability that two affected persons will produce offspring is very low for most diseases (exceptions to this rule are discussed later). Second, depending on the disease, if one parent is affected, he or she is much more likely to be heterozygous (+/-) than homozygous (-/-) for the mutant allele. Usually, an individual homozygous for the mutant allele experiences physical or mental abnormalities at a much more severe level. Those assumptions being accepted, two questions remain:

1. What are the chances for transmitting the mutant allele to the offspring?
2. What are the risks for the offspring being affected?

The outcomes of these matings are best expressed by the use of Punnett squares (Figure 13-12).

Dominant Inheritance: Punnett Squares

		Parent 1: $+/+$ [normal]		
		Parent 2: $-/-$ [affected]		
Outcomes:		100% $+/-$ [affected]		

		Parent 1: $+/-$ [affected]		
		Parent 2: $+/+$ [normal]		
Outcomes:		50% $+/-$ [affected]		
		50% $+/+$ [normal]		

Figure 13-12 Punnett squares depicting transmission of a dominant gene and resulting offspring's genotypes and phenotypes. Genotypes of the parents (top left cell), the possible gametes produced by each parent (single symbols), and the result of their random combination at fertilization. Possible outcomes in each pregnancy.

An individual who is homozygous for the mutant allele of a dominant gene ($-/-$) may contribute that allele ($-$) to all of his or her offspring. Since a single copy of the mutant allele is sufficient for the expression of the phenotype, all children will be affected, regardless of the genotype of the other parent. Panel 1 of Figure 13-12 illustrates the mating of such an affected homozygote with an unaffected partner. However, because of the often severe physical and mental manifestations found in an affected homozygote, the mating represented in panel 2 is more often encountered. Here, an affected heterozygote ($+/-$) will have equal chances of contributing the mutant allele ($-$) or the normal allele ($+$) to the offspring. (Random chromosome segregation during meiosis results in half of all gametes carrying the mutant allele and half carrying the normal allele.) Any time the mutant allele ($-$) of a dominant gene is transmitted to the offspring, the phenotype is expressed, regardless of the genotype of the other partner. Since most genetic disorders are rare, the mating illustrated in panel 2 of Figure 13-12, in which the other parent is unaffected ($+/+$), is representative of the majority of cases. In such mating, each pregnancy carries a 50% chance of being affected ($+/-$) and a 50% chance of being unaffected ($+/+$). These probability figures are fixed for each time conception occurs in the same set of parents, because each pregnancy is a statistically independent event.

However rare dominant diseases may be, in some circumstances the manifestations brought about by the condition serve to approximate affected individuals and increase their social interaction. One such example is achondroplasia. Because of their short stature, achondroplastic dwarfs tend to associate with persons who have the same syndrome. Here again the homozygote for the mutant allele ($-/-$) is often not carried to term or is born with severe malformations (e.g., hydrocephaly). Therefore,

even in the absence of genotype determination, it is more likely that two socially adept achondroplastic dwarfs are both heterozygotes ($+/-$). In such cases, each pregnancy produced by this couple has a 25% chance of being genotypically and phenotypically unaffected ($+/+$), a 50% chance of being affected with dwarfism like the parents ($+/-$), and a 25% chance of carrying the severe stigmata of the homozygote for the mutant allele ($-/-$).

As previously mentioned, the conceptual model for transmission of dominant genes applies to homologous autosome pairs and to the X chromosome pair in women (Box 13-1). The situation for sex chromosomes in men is different, since the X and the Y chromosomes contain extremely small areas of homology, so that they do not exhibit the side-by-side meiotic pairing observed with the autosomes and the X chromosome. Because of this, men are **hemizygous** for all genes on the X chromosome that do not have a homologous site on the Y, and their alleles are represented as single copies. Therefore, in the inheritance of an X-linked dominant gene, the single-copy presence of its normal or mutant allele results in the expression of the normal or mutant phenotype, respectively.

Recessive Gene Inheritance Pattern

The term **recessive** suggests the idea of “hidden” or “ocult.” In a genetic connotation, it reflects the behavior (expression) of the mutant allele in the heterozygote. A recessive allele is one whose phenotypic expression occurs in a homozygous or hemizygous condition; in the heterozygote, a recessive allele is masked by its dominant homologous counterpart. For example, Figure 13-13 illustrates the relationships between genotypic and phenotypic expression of a recessive gene with two alleles, ($+$) representing the normal or “wild-type” allele and ($-$) representing the mutated allele. Here again, the concepts apply to autosome pairs and the X chromosome pair in females. In the expression of a recessive gene, individuals (A) and (B) display both a normal (unaffected) phenotype, and only (C), who inherited two mutant alleles from both parents, is affected. This means that a recessive disease can only be phenotypically expressed when two copies of the mutant allele are present, and therefore, both parents must equally contribute to this outcome. In other words, in the heterozygote, the mutant allele is recessive (hidden), and the effect of the normal allele predominates (dominates), causing a normal phenotype to express. The difference between (A) and (B), however, is significant; whereas (A) can produce only gametes (ova or spermatozoa) with normal alleles, (B) carries the mutant allele and thus 50% of the gametes produced transmit this allele. This situation illustrates the concept of carriers for a genetic disease, that is, individuals who are clinically normal (or nearly normal), but who are potential transmitters of the disease.

Box 13-1 Characteristics of Dominant Inheritance

Autosomal Dominant Pattern*

1. A carrier state does not exist. A single dose of the mutant allele is sufficient to cause the phenotype to express.
2. The phenotype appears in consecutive generations. Affected persons tend to have an affected parent.
3. Children of an affected parent have a 50% chance of inheriting the mutant allele and being affected.
4. Phenotypically normal persons in a family pedigree are free of the mutant allele and do not transmit the phenotype to their offspring.
5. Both males and females are equally likely to be affected.
6. Homozygotes for the mutant allele are likely to be more severely affected.

X-Linked Dominant Pattern*

1. Both males and females can be affected, but women are usually less severely affected than men.
2. Affected males do not transmit the mutant allele to their sons.
3. All daughters of an affected male are affected and have a 50% chance of passing the mutant allele to their sons and daughters.

*Unless otherwise specified, affected persons' partners are unaffected.

Identification of such carriers is of paramount importance for genetic counseling. In the case of an unaffected couple who produce a child with a recessive disease, identification is easy. Because they each must contribute a mutant allele, they must be considered obligate carriers, even in the absence of specific carrier testing for that gene. Specific tests to detect heterozygous carriers of a variety of genetic diseases are available, but it would be impractical and certainly not cost-effective to screen all prospective parents without specific risk factors with all available tests. Genetic screening for carriers is usually limited to populations at risk, either because they belong to a high-risk group for a certain disorder (e.g., Ashkenazi Jews and Tay-Sachs disease), or because of a family history. Carriers for certain specific disorders can be identified by tests before conception (e.g., sickle cell disease), by means of routine screening, or after conception by means of prenatal diagnosis (e.g., Tay-Sachs disease).

Vertical Transmission of Recessive Genes

One of the most common situations in clinical practice is that of an asymptomatic couple who produce a child with a recessive disorder. Most people who seek genetic counseling fall into this category. The surprise element of this scenario is understandable if the following factors are considered:

1. Genetic disorders are rare, and therefore the chances that both parents will be heterozygous for the same gene are remote.
2. Many people remain childless for years, or they may have produced healthy children before the one affected and are unaware that they carry a deleterious gene.
3. Even when both parents are carriers, the transmission by each parent of the mutant allele (which results in an affected child) does not always occur.

Box 13-2 summarizes characteristics of recessive inheritance.

As with dominant inheritance, the best visualization of transmission of recessive genes is obtained through Punnett squares. Panel 1 of Figure 13-14 illustrates the example described previously. Both parents are asymptomatic heterozygous carriers ($+/-$) for a recessive gene. On forming gametes, each parent has a 50% chance of passing on the mutant allele ($-$). Random combination of these alleles during conception results, in each pregnancy, in a 25% chance of producing a child with a normal phenotype ($+/+$), a 50% chance of producing an asymptomatic carrier like themselves ($+/-$), and only a 25% chance of producing an affected child ($-/-$). Panel 2 of Figure 13-14 demonstrates that even when one of the parents is affected

Figure 13-13 Recessive Inheritance Pattern. Schematic of the three possible allelic arrangements of a recessive gene. Genotypes and possible phenotypes. Note the introduction of a heterozygous carrier (B).

Box 13-2 Characteristics of Recessive Inheritance

Autosomal Recessive Pattern*

1. A carrier state exists; both males and females can be carriers.
2. Both males and females are equally likely to be affected.
3. The disease appears to “skip a generation.” Members of that generation who have affected children are asymptomatic carriers.
4. Carrier parents have a 25% chance to produce an affected child in each pregnancy.
5. Parent consanguinity (mating between blood relatives) may be a factor when a child is affected with a *rare* recessive disease.

X-Linked Recessive Pattern*

1. Most affected persons are male; affected females are extremely rare.
2. Male-to-male transmission of the X-linked mutant allele does not occur. Males transmit their X chromosomes to their daughters.
3. All daughters of an affected male are (heterozygous) **carriers**, none are **affected** (homozygotes).
4. Sons of carrier females have a 50% chance of inheriting the mutant allele and being **affected** (hemizygotes). Daughters have a 50% risk of inheriting the mutant allele and being (heterozygous) **carriers**.

*Unless otherwise specified, all affected or carrier persons' partners are normal.

($-/-$), the other parent's genotypically normal ($+/+$) contribution ensures that they cannot produce an affected child ($-/-$). All their children will be carriers ($+/-$). However, in very common diseases, such as sickle cell disease among African Americans, it is possible that an affected person ($-/-$) and a heterozygous carrier ($+/-$) will produce an affected child ($-/-$). The risk for this event in every pregnancy is 50%, with another 50% probability of producing a carrier ($+/-$) i.e., 50% carrier/50% affected.

POLYGENIC AND MULTIFACTORIAL INHERITANCE

Risk calculation with single gene disorders, as discussed previously, follows strict Mendelian rules and is fairly straightforward. However, very few phenotypes are com-

pletely controlled by the action of a single gene. The majority of traits in the human body are controlled by several genes working in cooperation to produce the final effect: these are **polygenic** traits. When environmental factors also contribute to the expression of the phenotype, these are **multifactorial** traits. One of the primary characteristics of polygenic and multifactorial inheritance is the existence of a *continuous variation* in the trait, as opposed to an all-or-nothing distribution: for example, distribution of height in or the distribution of various body shapes. Box 13-3 summarizes characteristics of multifactorial inheritance.

Included in the many pathologic conditions that are polygenic and multifactorial in nature are coronary artery disease, diabetes mellitus, hypertension, obesity, and common psychiatric illnesses, such as schizophrenia and bipolar disorder. Even though an undeniable genetic predisposition to these conditions exists, they are heavily influenced by environmental factors, such as lifestyle, dietary habits, and stressful events.

Box 13-3 Characteristics of Multifactorial Inheritance

1. No clearly defined pattern of inheritance within a single family.
2. The recurrence risk increases when more than one family member has the trait.
3. The recurrence risk increases with increasing severity of the malformation.
4. The recurrence risk increases with consanguineous parents (mating between blood relatives).

Risk determination in polygenic and multifactorial inheritance is made on the basis of *empirical observation* of a large number of cases, followed by a specific statistical analysis for each trait. For several disorders, risk prediction and determination tables exist that take into consideration family history, number of cases in the family, and extent or severity of the malformations. By consulting these tables, the nurse and other clinicians can help clients understand the likelihood of genetic disorders occurring in future pregnancies.

SINGLE-GENE DISORDERS

By comparison with multifactorial inheritance, single-gene disorders are in the minority. However, precise molecular information has been developed using monogenic disorders as a framework. The work of Ingram (1956) on sickle cell disease is a clear example. McKusick's latest (2000) online cataloging of *Mendelian Inheritance in Man* (OMIM) lists 11,807 single-gene disorders, of which 11,072 are autosomal, 637 are X-linked, 38 are Y-linked, and the remaining 60 result from mitochondrial gene action (see Resources). Table 13-1 lists some examples of monogenic disorders, their mode of inheritance, and frequency of occurrence.

Autosomal Dominant Disorders

Selected autosomal dominant disorders are discussed in this section, including achondroplasia, Ehlers-Danlos syndrome, familial hypercholesterolemia, Marfan syndrome, neurofibromatosis (type 1), osteogenesis imperfecta, and polycystic kidney disease.

Achondroplasia

The most common form of dwarfism (adult stature, 48 to 52 inches) is achondroplasia, characterized by shortened limbs, especially proximally (rhizomelia), and a normal length torso. Common features include lordosis, prominent forehead with flattened nasal bridge, and short hands with stubby fingers. Life span and IQ are within normal limits among heterozygotes. One of the common complaints is backaches and there is an increased risk of spinal cord compression. Gynecologic problems include premature menarche, enlarged breasts, and premature menopause. Pregnancy often results in increased mechanical and locomotive burden. Skeletal malformations also affect the normal progress of pregnancy and delivery: because of a small chest cavity, adverse cardiorespiratory conditions

Table 13-1 Selected Single-Gene Disorders

Disorder	Classification	Frequency
Achondroplasia	Autosomal dominant	1:26,000
Albinism (oculocutaneous)	Autosomal recessive	1:10,000 to 1:12,000
Cystic fibrosis	Autosomal recessive	1:2,000 to 1:2,500 (all persons) 1:17,000 (African Americans)
Cystinuria	Autosomal recessive	1:10,000
Duchenne muscular dystrophy	X-linked recessive	1:3,000–5,000 (males)
Ehlers-Danlos syndrome	Autosomal dominant	1:150,000
Familial hypercholesterolemia	Autosomal dominant	1:200 to 1:500
G6PD deficiency	X-linked recessive	1:10 (African American males) 1:50 (African American females)
Hemophilia A (classic)	X-linked recessive	1:2,500 to 1:5,000 males
Hemophilia B (Christmas)	X-linked recessive	1:30,000 males
Huntington disease	Autosomal dominant	1:18,000 to 1:25,000 (US and UK) 1:333,000 (Japan)
Hypophosphatemic vitamin D-resistant rickets	X-linked dominant	1:20,000
Marfan syndrome	Autosomal dominant	1:10,000 to 1:20,000
Mucopolysaccharidoses	Autosomal recessive	1:20,000 (type III most common)
Neurofibromatosis type I	Autosomal dominant	1:4,000 to 1:5,000
Osteogenesis imperfecta	Autosomal dominant	1:20,000 (all types combined)
Phenylketonuria	Autosomal recessive	1:15,000
Polycystic kidney disease	Autosomal dominant	1:200 to 1:1,250
Sickle cell disease	Autosomal recessive	1:400 to 1:600 (African Americans)
Tay-Sachs disease	Autosomal recessive	1:3,600 (Ashkenazi Jews) 1:360,000 (all other groups)

may develop, and because of a contracted pelvis, delivery by cesarean section is often recommended. Increased paternal age may be a factor in producing a child with achondroplasia.

Ehlers-Danlos Syndrome

This genetic disease is an umbrella term for a group (with nine sub-types) of disorders of connective tissue that result in hyperelasticity of skin, hyperflexible joints, vascular fragility, and poor wound healing. Common complications include a tendency for bruising, hernias, and varicose veins, all of which are aggravated during pregnancy. Poor wound healing and a predisposition to hemorrhaging are risk factors during and after delivery (e.g., an episiotomy may be complicated by these factors). The life span may be limited by vascular events, such as aneurysms and rupture of large vessels. Even though the three most common variants are inherited as autosomal dominant traits, autosomal recessive and X-linked inheritance patterns have been reported. Prenatal diagnosis is possible in type V, since enzyme (lysyl oxidase) activity is present in normal amniotic cells.

Familial Hypercholesterolemia

Also called hyperlipoproteinemia IIa, this is one of various disorders of lipoproteins, along with abetalipoproteinemia and familial combined lipoproteinemia. Familial hypercholesterolemia (FH) is one of the most common single-gene disorders, in which the manifestations are sensitive to environmental (dietary) variations, to the point of being classified at times as a multifactorial disorder. However, individuals who are homozygous for this gene tend to develop severe and life-threatening conditions, such as early onset of atherosclerotic disease that affects the coronary, cerebral, and peripheral circulation. Postmortem examination of young children (ages 3 and 4) and young adults has revealed early arterial changes with lipid deposition and some plaque formation. Variants of the FH gene have been described, increasing the genetic complexity of this disease. Prenatal diagnosis has been accomplished by measurement of the hydroxymethylglutaryl coenzyme A (HMG CoA) reductase.

Marfan Syndrome

Marfan syndrome is another disorder of connective tissue, involving a triad of ocular, skeletal, and cardiovascular alterations. The most common ocular abnormality is a subluxation of the lens. Common skeletal findings include: tall stature, arachnodactylic ("spider-like") hands and feet, and scoliosis. Severe scoliosis may compromise respiratory function in pregnant women with Marfan syndrome. The major life-threatening risk, however, is the frequent occur-

rence of aortic fusiform or dissecting aneurysms. Fifty percent of aortic aneurysms in affected women under age 40 occur during pregnancy, with rupture most likely to occur in the third trimester (Godfrey, 1993). Aortic valve abnormalities found in Marfan syndrome also contribute to an increased mortality rate during pregnancy. As a point of curiosity, historians have suggested that President Abraham Lincoln had Marfan syndrome and may have died from a dissecting aneurysm if he had not been felled by the assassin's bullet. Average life span with Marfan syndrome is 40 to 50 years.

Neurofibromatosis

The hallmark of type I multiple neurofibromatosis (MNF I), or von Recklinghausen disease, is the development of multiple soft tumors of peripheral nerves, or neurofibromas, and an abnormal skin pigmentation. In early childhood, the disease presents with multiple brown (or café-au-lait) spots, usually on the torso, and then progresses, from adolescence onwards, in the form of neurofibromas. This progression has also been reported in association with pregnancy, with the possibility of some regression after delivery. An important finding is that apparently, affected infants born to affected mothers have a worse prognosis than those who had affected fathers and those without a family history (fresh mutations) (Simpson & Golbus, 1992). This fact emphasizes the importance of genetic and reproductive counseling for clients with MNF I. As many as 75% of patients with MNF I go through life without developing some of the complications of this disease: scoliosis, moderate to severe mental retardation, learning difficulties, hypertension, seizures, spinal cord or root compression, optic gliomas, pheochromocytomas, and malignant changes in the neurofibromas (Seashore & Wappner, 1996).

Osteogenesis Imperfecta Type I

All four types of osteogenesis imperfecta (OI) involve osteoporosis and recurrent fractures of long bones with minimal trauma. Type I disease is also characterized by blue sclera, conductive deafness (secondary to otosclerosis), and discolored teeth resulting from dentinogenesis defects. (Type II results in perinatal lethality with multiple fractures during gestation and birth). Life span of type I OI is usually normal in spite of the multiple fractures throughout life. Pregnancy in women with OI type I is complicated by respiratory difficulties among those with kyphoscoliosis and by cephalopelvic disproportions among those with previous pelvic fractures. Special precautions during delivery must also be observed for the safeguard of both mother and child (who may also have OI). In some cases, OI has been identified prenatally via sulfate incorporation test.

Polycystic Kidney Disease

This is a fairly common disorder that causes cysts in the kidneys, liver, pancreas, and spleen. Renal cysts may remain asymptomatic until the third or fourth decade of life, when the onset of renal failure or hypertension prompts a diagnosis of polycystic disease. Occasionally, an enlarged kidney is detected on X-ray studies before the onset of other manifestations, such as hematuria and proteinuria. Polycystic renal disease accounts for approximately 10% of all adult cases of chronic renal failure (Gabow, 1993). Since asymptomatic women have no related complications during pregnancy and the risk for an adverse outcome increases with progressing renal disease, it is important that reproductive counseling be provided to women with a family history of polycystic renal disease who want to have children. Prenatal diagnosis has been accomplished through linked polymorphism genetic tests.

Autosomal Recessive Disorders

The most common autosomal recessive disorders include cystic fibrosis, mucopolysaccharidoses, phenylketonuria, sickle-cell disease, and Tay-Sachs disease.

Cystic Fibrosis

Cystic fibrosis (CF) is the most common lethal genetic disease affecting Caucasians. Clinical manifestations include abnormal exocrine gland function with pancreatic insufficiency and malabsorption, chronic pulmonary disease, and excessive salt in sweat (sodium in excess of 60 mmol/L and chloride exceeding 70 mmol/L) (Pagana & Pagana, 1999). The pancreatic insufficiency results in pancreatic juice that lacks trypsin, an enzyme that must be exogenously replaced throughout life. Chronic lung disease is secondary to recurrent infections resulting from the inability of the ciliated epithelium to secrete excessive mucus. Pulmonary function progressively deteriorates and a large number of affected children die before age 10. Presently, over 50% of children with cystic fibrosis live beyond age 20, and survival depends on the extent of the disease and on additional involvement of body systems (Ferri, 1999). Other manifestations include: rectal prolapse, neonatal meconium ileus, cirrhosis of the liver, gall stones, and salivary gland obstruction. Pregnancy for women with cystic fibrosis obviously presents serious risks of increased morbidity and mortality. A classic national survey of cystic fibrosis reported the outcome of 97 pregnancies in women with cystic fibrosis (Cystic Fibrosis "GAP" Conference Report, 1975). According to this survey, the most detrimental factor to the success of a pregnancy was a decreasing vital lung capacity secondary to pulmonary disease. Prenatal diagnosis is available.

Mucopolysaccharidoses

This diverse group of mucopolysaccharide accumulation disorders (MPS) encompasses 6 different syndromes, whose primary types are: Hurler syndrome (type I), Hunter syndrome (type II), Sanfilippo's syndrome (type III), and Morquio syndrome (type IV). All but type II are inherited as autosomal recessive traits. Hunter syndrome is an X-linked recessive disorder.

Individuals with type I disease exhibit coarse facies in infancy, short stature, skeletal and joint deformities, deafness, corneal clouding, umbilical hernia, progressive mental retardation, and death in the second decade of life. Type II (X-linked) is similar to type I, except for later onset, clear corneas, and death in the third decade. Type III is the most common type, with normal facies, stature, and corneas, progressive mental retardation in early childhood, and death in the second decade. Type IV results in normal intelligence, facies, and corneas; short stature with scoliosis; and death in the third decade. Some types of mucopolysaccharidosis can be detected prenatally, since their defective enzymes (listed here in parentheses) have been identified: Hurler syndrome (α -L-iduronidase); Hunter syndrome (α -L-iduronic acid-2-sulfatase); Sanfilippo syndrome (type A: heparin sulfatase; type B: N-acetyl- α -D-glucosaminidase); Morquio's syndrome (chondroitin sulfate-N-acetylhexosamine sulfate sulfatase).

Phenylketonuria

One of the most fascinating genetic diseases, phenylketonuria (PKU) represents a success story in the management of a genetic disorder. As previously mentioned, PKU results from an enzyme (phenylalanine hydroxylase) deficiency, and the consequent accumulation of the amino acid phenylalanine and its byproducts cause mental retardation and other manifestations. Management for PKU consists of removing phenylalanine from the newborn's diet and maintaining a low dietary phenylalanine intake throughout life. If initiated within the first days of life, a low-phenylalanine diet ensures a normal development and life span. However, the offspring of "rescued" (treated) women with PKU are at risk for mental retardation, microcephaly, congenital heart disease, and intrauterine growth retardation. This is not a result of their genetic makeup, since children of homozygous mothers ($-/-$), except in the rare case of the father being a heterozygous carrier ($+/-$) for PKU, are unlikely to be homozygous for the mutant allele. Fetal damage is the result of intrauterine exposure to high levels of maternal phenylalanine and its metabolites, and the degree of damage is proportional to the maternal phenylalanine blood level. Placing a rescued woman with PKU on a

REFLECTIONS FROM A NURSE

"J.X. and S.T., a married couple, had just delivered their first child, after an uncomplicated pregnancy. The newborn girl weighed 3500 g at birth and began feeding well. However, 10 days after the delivery, results of biochemical tests indicated that the child had phenylketonuria (PKU). The baby's serum phenylalanine level was 30 mg/dL, the normal level is less than 2 mg/dL. On a subsequent office visit, I informed the parents that PKU is an inborn error of metabolism that prevents the use of an amino acid, phenylalanine, found in most foods. The disorder is inherited as an autosomal recessive trait, which indicates that both parents are heterozygous carriers for the PKU gene. I recommended that the baby be placed on a low-phenylalanine diet to prevent mental retardation and ensure a healthy life. I also told the parents that a low-phenylalanine diet must be observed throughout the child's life span, because an increase in dietary phenylalanine during childhood or adolescence may result in loss of cognitive function and in emotional disorders. While ac-

knowledging the difficulty of maintaining a child on such a strict diet, I also stressed the need for adherence and suggested referrals to counseling and support group activities. In addition, I told the parents that, on reaching child-bearing age, their 'PKU-rescued' daughter would need to be aware that increases in dietary phenylalanine may increase her chances of producing children with mental retardation.

As a nurse working with this family, I found that my ability to provide nursing care was greatly enhanced by a strong procedural knowledge and understanding of the condition and its implications. This prepared me to answer the parents' questions regarding:

- ✱ *Their risks for transmitting this condition to future offspring*
- ✱ *The consequences of this condition for normal life activities of this child*
- ✱ *The chances of this child passing on the condition to her offspring."*

low-phenylalanine diet before a pregnancy to maintain her blood levels at 120 to 480 $\mu\text{mol/L}$ produces good outcome. Unfortunately, the treatment is often initiated after conception, at times too late to prevent microcephaly and cardiac damage to the fetus. The possibility of preventing malformations and mental retardation among the offspring of rescued mothers with PKU is a strong argument in favor of early identification or disclosure of those women at risk. Initiated in the 1960s and now a legal requirement in all states, screening for PKU in newborns has made early initiation of treatment and the prevention of mental retardation possible in most cases. Prenatal diagnosis by means of measuring fetal phenylalanine hydroxylase has been accomplished.

Sickle Cell Disease

Sickle cell disease (SCD) is a serious, chronic hemolytic anemia that results from homozygosity for the mutant allele ($-/-$) of the *HbS* gene. As a consequence of this genetic imbalance, hemoglobin S (HbS), an abnormal hemoglobin, replaces the normal adult hemoglobin A. HbS has reduced oxygen-carrying capacity and red blood cells have a decreased life span. The affected red blood cells acquire a sickle-shaped appearance, a morphologic change that greatly contributes to obstruction of small vessels and further ischemia. Infarctions of the lungs, kidneys, spleen, and bones are common. The result is a lifelong series of sickle cell crises, with recurrent pneumococcal in-

fections and salmonella osteomyelitis, painful leg ulcers, dactylitis, priapism, and other manifestations. Renal failure is a common serious complication. The life span is significantly shortened, even with aggressive management.

The gynecologic and obstetric management of the woman with SCD requires special attention. Complications during pregnancy include aggravation of sickle cell crises and infections, development of other anemias, and toxemia. The prevalence of SCD is extremely high among African Americans and significant among people of Mediterranean extraction. The prevalence of homozygotes (—/—) among African Americans is approximately 1 in 400, with a heterozygote carrier frequency of 1 in 10.

Tay-Sachs Disease

Tay-Sachs disease (TSD) is a lipid storage disorder, with accumulation of GM₂ ganglioside in cells of the nervous system, resulting in a progressive neurologic disorder. The genetic defect results in decreased production of the enzyme β -hexosaminidase A (HexA), from a significant reduction in the heterozygote carrier (+/—) to total absence in the homozygote (—/—). During their short life, children with TSD experience a progressive and steady neurologic deterioration in a series of mental and motor deficits, which begin at approximately 6 months of age. Manifestations at various ages include loss of the developmental milestones acquired before the onset of the disease, along with deafness, blindness, seizure activity, and death by age 3 to 5. TSD is highly prevalent among the Ashkenazi Jews (Jews of Central and Eastern European origin), with a frequency of approximately 1:3,600 for homozygotes (—/—), 1:25 to 30 for heterozygote carriers (Jorde, Carey, Bamshad, & White, 1998). By comparison, among Sephardic Jews (Jews of Southern European, North African, and Middle-Eastern origin) and gentiles, the gene is 100 times rarer (1:360,000). Prenatal diagnosis by determination of fetal HexA levels is commonly performed.

X-Linked Disorders

Genetic disorders whose causative gene is located on the X chromosome include Duchenne muscular dystrophy, glucose-6-phosphate dehydrogenase deficiency, the hemophilias, and Lesch-Nyhan syndrome.

Duchenne's Muscular Dystrophy

One of two types of X-linked recessive muscular dystrophies (the other being Becker's muscular dystrophy), Duchenne muscular dystrophy (DMD) results in progressive muscle weakening, atrophy, and contractures, beginning in early childhood. In the majority of cases, the age of onset is less than 5 years and the disease is characterized

by delayed walking. A pseudo-hypertrophy of the calf (in which muscle is replaced by adipose tissue) may mask the disease to the inexperienced clinician. Affected children are usually unable to run, and 95% of affected children are using a wheelchair by age 12 (Korf, 1996). Mild mental retardation occurs in about 1 of 4 cases. Death, often from respiratory insufficiency, usually occurs in the second decade. Prenatal diagnosis is done by assessing for various mutations that lead to the deficiency of dystrophin, the deficient protein in various muscular dystrophies.

Glucose-6-Phosphate Dehydrogenase Deficiency

This common, self-limiting hemolytic anemia is often used as a prototype for genetic environmental interaction. Glucose-6-phosphate dehydrogenase (G6PD) deficiency is usually asymptomatic until the affected male is exposed to one of many environmental triggers, such as certain drugs (antimalarial agents, aspirin, sulphonamides) or certain foods (especially fava beans, from which the popular name "favism" originates). The hemolytic episode may also be precipitated by infections. In one disease subtype (B variant), affected males suffer from a chronic hemolytic anemia in the absence of environmental triggers. Carrier females (+/—) remain asymptomatic even when exposed to a trigger agent. Homozygote females (—/—) do exist, as progeny of a carrier female (+/—) and an affected hemizygous (—/—) male. Pregnancy in women with G6PD deficiency (homozygotes) presents several complications. Hemolytic episodes are more frequent; urinary infections, common in pregnancy, cannot be treated with sulphabased drugs; and exposure of a fetus with G6PD deficiency to maternally ingested trigger substances may result in fetal hemolysis, hydrops fetalis, and death. The incidence of anemia, hyperbilirubinemia, and kernicterus is also increased among newborns with G6PD deficiency.

Hemophilia A

Classic, or type A, hemophilia is a fairly common X-linked recessive disorder of coagulation, resulting from deficiency or defect in clotting factor VIIIc. In 10% of clients, the factor VIIIc level is normal, but its activity is reduced (Jorde, et al., 1998). Variable degrees of deficiencies are probably caused by genetic heterogeneity (different mutations). In the presence of severe factor VIIIc deficiency, massive hemorrhages after trauma and surgical procedures (including dental procedures) can occur. "Spontaneous" bleeding frequently occurs in areas subject to trauma (e.g., joints, resulting in hemarthroses). Petechiae and echymoses are usually absent. Prenatal diagnosis by measurement of factor VIII is possible.

Lesch-Nyhan Syndrome

Also known as HGPRT deficiency, Lesch-Nyhan syndrome is a rare X-linked recessive disease characterized by a tendency toward self-mutilation, mental retardation, choreo-athetosis, spasticity, and hyperuricemia. Prenatal diagnosis is made by determination of fetal levels of HGPRT.

CHROMOSOME ABNORMALITIES

Both the autosomes and the sex chromosomes can experience numerical and structural chromosomal abnormalities that have clinical consequences. Table 13-2 shows the prevalence of chromosomal abnormalities in newborns. Structural chromosomal abnormalities do not alter the total chromosome number, but in some cases, they can cause

clinical consequences as devastating as those resulting from numerical changes. As previously mentioned, numerical alterations resulting in hyperploidy (3n, 4n, and so on) produce a wide spectrum of malformations that render them incompatible with life. However, small variations around the normal diploid number (46), such as occurs in trisomies (total chromosome number 47), are often found in clinical practice. The only monosomy compatible with life is a missing X chromosome in persons with Turner’s syndrome.

Numerical Abnormalities of the Autosomes

Numerical alterations of the autosomes include some of the most common trisomies found in humans: trisomy 21 (Down syndrome), trisomy 18 (Edwards’ syndrome), and trisomy 13 (Patau syndrome).

Table 13-2 Incidence of Selected Chromosomal Abnormalities in Newborns	
Chromosome Abnormality	Incidence
Numerical, Autosomes	
Trisomy 21 (Down syndrome)	1 : 650 to 700 live births
Trisomy 16–18 (Edward syndrome)	1 : 8,000 live births
Trisomy 13–15 (Patau syndrome)	1 : 20,000 live births
Other autosomal anomalies	1 : 50,000 live births
Numerical, Sex Chromosomes	
47, XXY (Klinefelter syndrome)	1 : 1,000 male births
47, XYY (Jacobs syndrome)	1 : 1,000 male births
Other male anomalies	1 : 1,350 male births
45, XO (Turner syndrome)	1 : 10,000 female births
47, XXX (triple-X female)	1 : 1,000 female births
Other female anomalies	1 : 2,700 female births
Structural, Autosomes	
Balanced robertsonian, t(Dq/Dq)	1 : 1,500 live births
Balanced robertsonian, t(Dq/Gq)	1 : 5,000 live births
Reciprocal translocations	1 : 7,000 live births
46, XX or XY, B(5)p [−] cri du chat syndrome	1 : 20,000 live births
Total Chromosome Abnormalities	1 : 160 live births

Data adapted from Simpson and Golbus, 1992

Trisomy 21

Down syndrome is the most common aneuploidy compatible with development to full term with a reasonable quality of postnatal life. Physical and mental abnormalities vary enormously in spectrum (Jorde, et al., 1998). Mean IQ is 50, with a range of 25 to 70. Multiple physical anomalies include craniofacial abnormalities (brachycephaly, flat occiput, low-set ears, oblique palpebral fissures, epicanthal folds, Brushfield spots (on the iris), broad nasal bones and flattened profile, and open mouth with protruding tongue); skeletal abnormalities (broad, short fingers, clinodactyly of fifth finger); cardiac malformations (ventricular and atrial septal defects, patent ductus arteriosus); and various other abnormalities (hypotonia; increased susceptibility to respiratory infections and to acute leukemia; palmar simian crease; and abnormal dermatoglyphics, or fingerprint pattern). In spite of modern medical developments, life expectancy is still shortened, with 22% dying in the first decade and 50% by age 60, mostly from hematologic malignancies and cardiac defects. Males with Down syndrome are usually sterile, but a few females have reproduced. About one third of their offspring are also trisomic for chromosome 21.

The chromosomal constitution of Down syndrome is variable, with three possible configurations:

- 1. Free trisomy, 47, XX or XY, G(21)⁺, is the pattern in 95% of all cases of Down syndrome; the extra chromosome 21 is unattached and segregates freely during meiosis. This type of Down syndrome increases linearly in frequency with increasing maternal age (from 1 : 1,500 live births for mothers age 20, to 1 : 30 live births by age 45) (Korf, 1996).

2. Translocation Down syndrome, 46, XX or XY, $t(Gq/Dq)^+$ or $t(Gq/Gq)^+$, accounts for approximately 4% of all Down syndrome cases. The majority of cases are sporadic (without family history), but about 40% have one balanced-translocation carrier parent. When one such carrier and a normal partner reproduce, their chances of producing a child with Down syndrome range from 33% (for carriers of $t(Gq/Dq)$ and $t(21q/22q)$) to 100% (for carriers of $t(21q/21q)$). This latter situation is one of the rare examples in genetics in which an abnormality is passed on to *all* living progeny. The incidence of translocation Down syndrome is slightly elevated (9%) among mothers who are older than age 30 at conception (compare with 2% for mothers younger than age 30) (Gelehrter, Collins, & Ginsburg, 1998).
3. Mosaic Down syndrome, 46, XX or XY/47, XX or XY, $G(21)^+$. This rarer type of Down syndrome (about 1% of all cases) results from mitotic nondisjunction that occurs during early embryonic development of a normal zygote. Persons with this type have mixed cell populations, some with the normal karyotype, others with the extra chromosome. Contrary to what might be expected, children with Down syndrome mosaicism do not necessarily have a better developmental outcome than those with the free trisomy syndrome.

Trisomy 18

Edwards' syndrome is a fairly common trisomy affecting mostly chromosome 18. In addition to severe mental retardation, children with this defect present with severe craniofacial abnormalities (dolichocephaly with a prominent occiput, low-set and malformed ears, and micrognathia), skeletal abnormalities (clenched fist with overlapping fingers, flexion deformities, adducted hips, "rocker-bottom" feet), cardiac anomalies (ventricular and atrial septal defects, patent ductus arteriosus), and urogenital malformations ("horse-shoe" kidneys, hydronephrosis, cryptorchidism, prominent genitals). Hypotonia is also common. Although the life span is longer for females (10 months, average), females are more often affected. Mean survival for males is about 3 months. Overall, 30% of these children die in the first month, 50% die in the second month, and few survive 1 year (Simpson & Golbus, 1992).

Trisomy 13

Patau syndrome causes more severe malformations than the previous two trisomies discussed, which is consistent with the increased size of the extra chromosome and a greater gene imbalance. Craniofacial anomalies are much more pronounced: microcephaly, low-set and malformed

ears, microphthalmia or anophthalmia, coloboma of the iris, and cleft lip and palate. Skeletal abnormalities include polydactyly and syndactyly; overlapping, flexed fingers; and hypoplasia of the pelvis. Systemic anomalies include cardiac defects (ventricular and atrial septal defects, patent ductus arteriosus) and urogenital malformations (malformed kidneys, hydronephros, polycystic kidneys, cryptorchidism, bicornuate uterus). Mean life expectancy is 4 months, with 45% dying in the first month and fewer than 5% surviving 3 years (Simpson & Golbus, 1992).

Numerical Abnormalities of the Sex Chromosomes

Alterations in number may also involve the sex chromosomes. Some of the most common genetic disorders caused by sex chromosome aneuploidies are Klinefelter, Jacobs, Turner, and the triple-X female syndromes.

47, XXY

Klinefelter syndrome is characterized by multiple X chromosomes and one Y chromosome. The greater the total chromosome number, the more severe the anomalies that result from increased gene imbalance. Physical abnormalities include elements of decreased masculinization, such as gynecomastia; hypogonadism (with sterility caused by degeneration of seminiferous tubules); and increased pubis-to-sole length, reflecting elongated lower limbs. Mental development is normal in most cases; mental retardation, if it occurs, is in the IQ range of 50 to 85. Delayed language skills, however, are common. Chromosome mosaicism (46,XY/47,XXY) rarely occurs; when it does, it results in individuals with milder manifestations than their trisomic counterparts.

47, XYY

Jacobs syndrome was reported in the early 1960s by Patricia Jacobs, a Scottish cytogeneticist who detected a higher-than-expected frequency of double-Y males among inmates of penal institutions in Britain. In early reports, an extra Y chromosome was seen as responsible for an individual's increased tendency toward aggression against property (as opposed to aggression against humans). A detailed statistical analysis by Borgaonkar and Shah (1974), of more than 200 cases later revealed that the only correlates with an extra Y chromosome were tall stature (more than 6 feet) and skin disorders, such as persistent adult acne. Mental retardation and aggressive tendency correlations with XYY were not found to be significant in that large study, and the syndrome remains a scientific curiosity. A majority of children produced by XYY fathers have normal chromosomal constitution, probably reflecting a

selective advantage of normal haploid gametes over aneuploid ones.

45, XO

Turner syndrome, originally described clinically as ovarian dysgenesis (with gonads consisting of streaks of connective tissue and devoid of germ cells), is an example of a monosomy that is compatible with quasi-normal life. Clinical manifestations include: low birth weight and short adult stature (4'6" to 4'8"); low posterior hair line and webbing of the neck; shield-shaped chest with divergent nipples; short fourth metacarpals; cubitus valgus; coarctation of the aorta; urinary tract abnormalities; lymphedema of hands and feet in the newborn; and fetal cystic hygroma and hydrops. Intellectual development is normal, with verbal IQ exceeding performance IQ. Due to decreased secondary sexual characteristics, administration of female hormones at puberty is a common practice. However, it tends to further stunt growth and must be judiciously considered. Treatment for the reduced growth with growth hormone and anabolic steroids is also in practice. Mosaicism also occurs in Turner syndrome (46, XX/45, XO), resulting in milder expression of the phenotype.

47, XXX

Occasionally, triple-X females have been reported in textbooks under the unfortunate term "super females." Whereas this nomenclature is valid in fruit flies, where the extra X chromosome causes an exacerbation of female characteristics, the term is totally unjustified in humans. A relatively common condition (1:1000 live female births), triple-X females display a normal phenotype, with perhaps a slight decrease in mental capacity, when compared to their euploid sisters. Gynecologic complications include a delayed menarche and a premature menopause. As with XXY males, the offspring of XXX females are largely normal, indicative of a selective advantage of euploid gametes.

Structural Chromosomal Abnormalities

Structural abnormalities include a variety of chromosome defects (e.g., deletions, translocations) that do not alter the total chromosome number. They include the cri du chat (cat's cry) syndrome, fragile X syndrome, and several chromosome instability syndromes, in which the hallmark is chromosome breakage or rearrangement.

46, XX or XY, B(5)p

Cri du chat, or cat's cry, syndrome is a rare (1 in 50,000 live births) (Jorde et al., 1998) chromosome deletion syn-

drome resulting from loss of the small arm of chromosome B(5). In early infancy, this syndrome presents with a typical but nondistinctive facial appearance, often a "moon-shaped" face, with wide-spaced eyes (hypertelorism). As the child grows, this feature is progressively diluted, and by age 2, the child is undistinguishable from age-matched controls. Profound mental retardation persists throughout a short life; most affected children die in infancy from multiple genetic imbalances. Typical of this disease is a crying pattern that is abnormal and cat-like. At times, it sounds like an angry cat; at others, like a soft mewling sound. This is a result of laryngeal atrophy, which improves with age. By age 3, the crying pattern is still abnormal, but it acquires a normal pitch and loses its cat-like quality.

Fragile X Syndrome

Although listed here as a structural abnormality, fragile X syndrome acquired its name from the fact that in *in vitro* conditions, the X chromosome frequently displays breaks and gaps in its terminal portions. However, this is an X-linked dominant condition with increased prevalence among males (approximately 1 in 1,250 males and 1 in 2,500 females are affected). Clinical features include mental retardation and a typical facial appearance, including an elongated face and long, elf-like ears (Jorde et al., 1998).

Chromosome Instability Syndromes

This is a heterogeneous group of genetic disorders characterized by a high frequency of chromosome breakage that is observed *in vitro*. They include ataxia-telangiectasia (or Louis-Bar's syndrome), Fanconi anemia, and xeroderma pigmentosum. These syndromes are associated with decreased immune function and an increased incidence of cancer, mostly lymphomas and leukemias.

GENETIC SCREENING

Because of the complexity and magnitude of genetic damage, treatment for genetic disorders is rarely successful. The primary weapon against increases in the prevalence of genetic disease is an aggressive program of genetic screening and counseling. The first corollaries of any such intervention must be *voluntary participation*, *equal access to all*, and *confidentiality* (both in conducting the tests and in handling records and results). In addition, education and counseling about tests and procedures must be an integral part of any screening program. Attention must be paid to ensure quality control of all aspects of testing and laboratory procedures.

Purposes for genetic screening are threefold:

1. To provide early recognition of a disease for which effective intervention and therapy exist, before symptoms occur. Example: PKU.
2. To provide identification of carriers of a genetic disease for the purpose of maximizing parenthood planning options. Example: Tay-Sachs disease.
3. To obtain population data on frequency, spectrum, and natural history of a genetic disease. Examples: chromosomal abnormalities in newborns.

Screening for genetic disorders can occur during various times in a person's life:

- Screening of selected populations for heterozygous carriers (e.g., mass screening of African Americans for sickle cell disease, as it occurred in the 1970s in clinics sponsored by the Black Panther Party)
- Screening of relatives of a known carrier or affected individuals within a family, for the purpose of reproductive decision making
- Preconception screening for carriers (e.g., screening for Tay-Sachs disease among couples contemplating parenthood, as it occurred in synagogues in the U.S. after development of testing methods)
- Postconception (prenatal) testing (e.g., screening for Tay-Sachs disease in the product of a pregnancy by two heterozygous carriers)
- Newborn testing (e.g., testing for PKU in all newborns, as mandated by law in all U.S. states). The benefits of early detection of PKU and treatment initiation warrant mandatory testing.

An ideal genetic screening test must have high sensitivity (ability to detect true-positive results) and specificity (ability to detect false-negative results); it must yield rapid results and be safe and cost-effective; and it should cause minimum physical and emotional discomfort to all involved. Geneticists and other members of the genetics team must be prepared to weigh all favorable and unfavorable consequences of genetic screening before implementing a program or conducting a screening activity.

Among the potential benefits of screening for carriers is the removal of a stigma and restoration of self-esteem when the results do not reveal a carrier status. It also facilitates genetic counseling, and reproductive planning, and provides useful information to other potentially affected family members. Testing newborns for genetic defects provides for early detection and treatment initiation, maximizing quality of life.

Risks incurred in genetic screening include the potential for stigmatization of those identified as carriers or affected individuals and for the development of feelings of

inadequacy and guilt often seen in conjunction with genetic disease. A positive test result for one family member may result in the disclosure of genetic risks to other family members who did not seek or want to know the outcome of the tests.

GENETIC COUNSELING

In its narrower sense, genetic counseling consists of one or more encounters with the probands and their families with the objective of providing information about their genetic disease. A **proband** is a clinically identified person who displays the characteristics or features of the disease in question. This information includes risk figures, options, and provides a framework for a course of action to be taken by the individual or family. It should also include an assessment of psychosocial family dynamics, which are an integral part of a genetic disease, and an exploration of feelings and perceptions often elicited by the newly obtained knowledge. **Genetic counseling**, in its broader definition, refers to a series of procedures that include processing the initial referral, assessing the needs, deciding on the appropriate tests, interpreting the results, and finally, communicating these findings to the proband and family.

In the majority of families that request genetic counseling, the precipitating event is the birth of an affected child. In the case of dominant diseases, usually one of the parents is affected, and there is some degree of preparation for the possibility of an affected child. In recessive disorders, however, the parents are usually clinically normal, which precludes any warning of a potentially negative outcome.

The counseling process has been referred to as a specialized form of family counseling. However, two factors make genetic counseling a unique process. First, there is the total lack of preparation and anticipatory grief. Even with the knowledge of a potentially negative outcome, a certain amount of hope and denial usually prevails until the birth of the affected child brings the family back to reality. Second, the parents' knowledge that they are biologically responsible for their child's condition is a burden often too heavy to carry without emotional damage. The physical contact with that person, sometimes for a lifetime, is a constant reminder of what may be perceived as "reproductive failure" and "bad seed."

For these reasons, a strong medical-psychological-spiritual support system is essential. These forms of support are usually available to the client through diverse sources. Medical and client care issues are covered by the health care professionals, such as nurses and physicians. The nurse is often in a position to offer initial and ongoing support. Emotional support is provided by family members,

counselors, social workers, or even through question-and-answer columns in daily newspapers and on the Internet. Spiritual, religious, and ethical support may be received from a hospital chaplain or family clergy. Unfortunately, in many instances, the helping efforts of these three areas function independently from one another and in an uncoordinated manner. Efforts should be made to ensure effective communication among the services provided by professionals in these three areas. Since no health care provider alone can provide all needed services, the best approach to genetic counseling is a team approach. Members of the team should include a generalist

physician, geneticist, medical specialist, nurse, psychologist (psychiatrist, clinical social worker, or therapist), and clergy.

Typically, the genetic counseling process begins when a clinician refers a family in which a genetic disease has been identified. It is important at this point to have a conclusive diagnosis of the condition, as many errors in genetics counseling are a result of mistaken or incomplete diagnoses. Provided with this information, a member of the genetic counseling team (GCT) contacts the family and describes the process that is about to begin. The parents should be informed that they need to collect data about their family, such as previous disease cases, causes of death, degree of closeness of relationships (e.g., consanguinity), and how to secure medical records. In small communities, especially in traditional rural cultures, a family Bible is often a good source of information.

In the first personal interview, the GCT gathers pertinent information from family members. Once a detailed **pedigree chart** is generated, the GCT identifies the mode of inheritance and confirms the initial diagnosis. Testing of other family members, if recommended, is initiated at this time, and a second appointment is made. It is important in the first contact that the family members be made to feel at ease, and that ample time be allotted for answering all questions. In the second interview, with all the previous information processed, the GCT discusses with the family all the implications of the findings, presents options, and clarifies possible outcomes. Team members should be prepared to handle ethical and religious issues that often surface, such as the possibility of therapeutic abortion or sterilization, in a sensitive and caring manner. It is of paramount importance that genetic counseling remain a nondirective process, with the GCT members refraining from pressuring family members in any possible direction and remaining supportive but neutral about decisions that must be made. At times, this may present a challenge to a health care provider who feels that he or she has the correct answers and that the family is mistaken about the decision they have made. It must be remembered that the family members are the ones who will have to live with their decision, and therefore their decision, once made, must be respected and supported by all health care team members.

Prenatal Diagnosis

One of the commonly used tools in genetic counseling is prenatal diagnosis of genetic disorders. Several approaches for prenatal diagnosis have been developed: screening procedures include a trisomy profile test and a ultrasound-assisted nuchal translucence test. The two main diagnostic procedures are midtrimester amniocentesis and chorionic villi sampling (CVS). In addition, routine ultra-

Critical Thinking

So You Want to be Part of a Genetic Team?

Until the mid-70s, the field of medical genetics was exclusively in the hands of physicians who did not have a formal education in genetics. Most medical geneticists of the time were self-taught and came from a medical specialty: most were pediatricians (who saw several cases of the same genetic disorder and became interested experts), obstetricians (after observing a recurrent birth defect or fetal loss), endocrinologists (who may have been repeatedly consulted for delayed puberty), and family physicians. Medical genetics was taught in the medical curricula not in comprehensive courses, but as part of specific body systems.

In 1981, the American Society of Human Genetics instituted a Medical Genetics Board with certification in several specialties: M.D. clinical geneticist, Ph.D. medical geneticist, clinical cytogeneticist, or biochemical geneticist, all required clinical or research doctorates. Genetic counselor was the only entry point for a master's-degree prepared genetic counselor. Nurses, at first hesitant in undertaking an activity for which they were not originally trained, soon became invaluable members of medical genetics teams. Several programs in genetic counseling soon followed the pioneer efforts at Sarah Lawrence University.

If you want to know more about applying nursing skills and technology to medical genetics and genetic counseling, visit the Genetics Society of America/ American Association for Human Genetics WebPage or the University of Kansas Medical Center WebPage. Another excellent resource is the Creighton University's International Society of Nurses in Genetics (ISONG) website, which contains useful genetics-related hyperlinks (see Resources).

Critical Thinking

Genetic Counseling Situation

Mrs. B. presents to the emergency service with a broken tibia, the result of a fall. While taking a medical history, the nurse discovers that Mrs. B. is 12 weeks into her fifth pregnancy. The nurse finds out further that, of the previous children, three have osteogenesis imperfecta (OI), as has Mr. B. The nurse calls for an obstetric consult and places the hospital chaplain on alert. The obstetric resident discovers that Mrs. B. is well-informed about OI, its mode of inheritance, and the risk for this pregnancy. Apparently all of the children are in good shape, as is Mr. B., and the disease seems to present no major concerns to them. However, the resident feels that it is his duty to offer to Mrs. B. a therapeutic abortion and tubal ligation. Mrs. B. refuses both suggestions on the basis of her religious beliefs. The resident is convinced that Mrs. B. is making the wrong decision and presents forceful arguments, accompanied by color photographs of people with severe OI. Mrs. B. is unmoved. The hospital chaplain is called into consultation and, after a long interview, concurs that Mrs. B. is making a well-informed decision that is based on her strong religious convictions. Mrs. B. returns to her small rural community. The obstetrics department is later informed in a follow-up letter from the local physician that Mrs. B. has delivered her fifth child, the fourth to be born with OI.

Do you think that the obstetric resident should have been more forceful and tried to convince Mrs. B. to have an abortion and a tubal ligation? Would you be able to accept Mrs. B.'s decision, given the severity of this disease?

sonography provides invaluable information in a noninvasive manner.

Trisomy Profile Test

It has been known since 1984 that maternal serum **alpha-fetoprotein** (MSAFP) levels are, on the average, lower in pregnancies affected by Down syndrome compared with levels in a normal pregnancy. The accuracy of the test was later increased by taking into consideration maternal age. In 1987, it was discovered that maternal serum levels of human chorionic gonadotropin (hCG) were twice as high in Down syndrome pregnancies during the second trimester. In addition, unconjugated estrogen (uE₃) levels

in maternal serum were found to be 25% lower in the presence of a Down syndrome pregnancy. The trisomy profile maternal serum test presently includes maternal age, MSAFP, hCG, and uE₃ and has a high rate of identification of common chromosome disorders.

Nuchal Translucency on Intravaginal Ultrasonography

This high-resolution ultrasonography is being used more and more often to detect increased nuchal translucency, as an indicator of Down syndrome. An increased nuchal translucency or the presence of cystic hygromas (septated, fluid-filled sacs in the nuchal region) are common features of several fetal aneuploidy conditions, including the common trisomies 13, 18, and 21. The sensitivity of this test for these trisomies combined is approximately 62%, and for trisomy 21 alone, 54%. (Taipale, Hiilesmaa, Salonen, & Ylostalo, 1997) The procedure can be performed earlier in the pregnancy than serum screening, and it may decrease the need for future CVS or amniocentesis.

Midtrimester Amniocentesis

This method was applied for the first time for diagnosis of genetic disorders in the early 1960s and has been widely used since then. The procedure is commonly performed between the 14th and 16th weeks of gestation, under ultrasound guidance, and consists of transabdominally withdrawing approximately 20 mL of amniotic fluid for analysis of cells sloughed off by the developing embryo. The material obtained is then cultured to obtain a large number of cells. Two basic sets of tests are performed: chromosome analysis and biochemical analysis of the fluid (e.g., alpha-fetoprotein measurements for the assessment of neural tube defects) or cell products (e.g., hexosaminidase A determinations for the diagnosis of Tay-Sachs disease). The high accuracy of amniocentesis in detecting chromosomal and biochemical defects has been well-established. However, one serious concern still remains: since the test is run as late as the 16th (and sometimes the 17th) week of pregnancy, the results are often returned at a quite advanced phase of pregnancy, making the possibility of a late therapeutic abortion an issue of ethical and medical concern. Potential sources of error include the mistaken analysis of maternal cells (but only if the embryo is female) or when mosaicism masks the presence of aneuploid cells. However, if a sufficient number of cells is studied, the abnormal cells eventually are detected. The risks involved in this procedure are small but measurable, at approximately 0.5%, and include risks for the developing embryo (needle perforations and scratches), for the continuation of the pregnancy ("spontaneous" abortions), and for the mother (immunologic cross-reactions) (Jorde et al., 1998). However small the risk, this is an invasive procedure that

should be used only after careful consideration. Indications for amniocentesis include: maternal age above 35; previous history of chromosomal abnormalities; family history of genetic disorders that can be diagnosed by amniocentesis; and an increased risk of neural tube defect.

Chorionic Villi Sampling (CVS)

This recently developed prenatal diagnosis technique is rapidly replacing the traditional midtrimester amniocentesis, mostly because it can be performed at an earlier time (usually 9th to 12th week), yields results sooner, and its safety approaches that of the midtrimester test. The test is accurate in 99% of the cases, provided true chorionic villi material is obtained. One major disadvantage of CVS is that alpha-fetoprotein determination for detection of neural tube defects cannot be obtained and must be attempted at a later date, when the concentration of this substance increases.

NURSING IMPLICATIONS

One of the most important advances in biomedical science is the mapping of the human genome. This project has the potential to make dramatic changes in all health care and certainly will affect the care of women and infants. Apart from a few genetic disorders that have a direct expression in disease, the majority of genetic information is more complex and, in many cases, a genetic predisposition to a disease interacts with environmental conditions for expression. The latter has the most implications for nurses because of the need to teach environmental modification through lifestyle modification, risk avoidance, and health management.

The nurse is likely to interact with the client and family in a number of ways related to genetics. The involvement can vary depending on setting and level of education.

Web Activities

- Visit the University of Indiana biotechnology website at <http://biotech.chem.indiana.edu> for an excellent basic review of general principles of genetics and molecular biology.
- Visit the March of Dimes website at <http://modimes.org> and explore the various resources available to families and health care professionals about birth defects.
- Visit the Cytogenetics Gallery at the University of Washington (Seattle) website at <http://www.pathology.washington.edu/Cytogallery> and explore different karyotypes and their association with disease processes and clinical manifestations.
- Visit the Genetic Alliance website at <http://www.geneticalliance.org> and use this resource to guide a family with a genetic disorder.
- Visit the National Institutes of Health, Office of Rare Diseases, at <http://rarediseases.info.nih.gov/ord/patient-support.html> to connect with various resources that assist you in understanding the management of genetic disorders.
- Visit the National Human Genome Research Institute home page at <http://www.nhgri.nih.gov> and engage in a discussion on "How to Conquer a Genetic Disease."
- Visit the Human Genome Project Information website at <http://ornl.gov/hgmis> and participate in ethical, legal and social debates on applications of the Human Genome Project. Communicate with experts and peers in a chat room.
- Visit the Med Help International website at <http://medhelp.org> to retrieve a list of support organizations to assist families with genetic disorders.
- Visit the Journal of Gene Therapy website (England) at <http://www.wiley.co.uk/genetherapy/> for the latest information on various approaches to the treatment of genetic disease using gene therapy technology.
- Visit the Center for Bioethics, University of Pennsylvania website at <http://med.upenn.edu/~bioethic> to review articles on discrimination, privacy, and other ethical issues in genetic screening.

The staff nurse should have a general knowledge of genetics and genetic terminology to answer client questions and direct them to resources. There are major implications in supporting couples in reproductive decision making and in coping with potential genetic risks. Additionally, nurses may be in the position to provide education and support for risk management for clients who have their own genetic risk factors, such as breast cancer.

Nurses in advanced practice may function as genetic counselors, provided they have appropriate education in genetics and counseling. They may also work in birth-defect clinics and provide risk screening for normal prenatal or high-risk populations. Advanced practice nurses also are in a position to screen their clients for genetic conditions, even if the appropriate management would include referral to another member of the health care team.

All nurses need to have read and learned from current literature related to genetic information and to be able to provide information to clients about rapidly changing information and technology related to this field. Nurses in any area of practice are likely to be faced with ethical issues regarding the advancing knowledge of genetics. Each new discovery in genetics raises questions about who should have genetic information about individuals and families. Who should be treated for genetic conditions? When should treatment be given and what should be treated? What treatment is appropriate? These questions must be answered. As new treatments evolve, the cost concerns regarding distribution of scarce resources becomes an issue that must be addressed.

Key Concepts

- An alteration in a single gene may cause multiple physical and mental derangements without changing the gross structure of a chromosome, or altering the total chromosome number of an individual. Therefore, genetic disorders may be classified under gene disorders and chromosome abnormalities.
- Structural genes encode genetic information for the synthesis of enzymes. A mutation in one gene may result in the synthesis of an abnormal enzyme, thus interrupting a metabolic pathway and causing a genetic syndrome. Many genetic syndromes are single-gene (Mendelian) disorders.
- Many genes often cooperate to create or modify a given phenotype. Many human characteristics follow this polygenic inheritance pattern.
- Chromosomal abnormalities may result from alterations in individual chromosomes (structural abnormalities) or from alterations in the total number of chromosomes (numerical abnormalities). Either situation may cause significant phenotypic alterations and pathologic conditions.
- Genetic screening is the process by which individuals or populations can be assessed for various genetic disorders to detect the presence of a gene before it expresses as a genetic disease or to identify the carrier of a recessive trait.
- Many genetic disorders are not treatable with conventional techniques. In many instances, the prevention of a genetic disease is only possible through genetic counseling of persons at risk.

Review Questions and Activities

1. The parents of a newborn with Down syndrome (DS) inquire about what could have caused this abnormality. One of the following responses is *not* appropriate:
 - a. DS was caused by an accidental chromosomal nondisjunction.
 - b. DS is an inborn error of metabolism.
 - c. DS is a rare event for the age group of these parents.
 - d. DS in this child could have been identified by prenatal chromosome analysis.
 The correct answer is b.
2. The same parents are concerned about the possibility of having other children with DS. What correct information can be conveyed to them?
 - a. Free trisomy 21 is not inheritable and therefore is unlikely to recur.
 - b. Future pregnancies may be tested prenatally.
 - c. Free trisomy is hereditary, and the recurrence risk for future pregnancies is high.
 - d. Both *a* and *b* are correct.
 - e. Both *b* and *c* are correct.
 The correct answer is d.

3. The parents of a newborn with phenylketonuria (PKU) ask what PKU means. One of the following is *not* a correct response to their question:
- PKU is an enzyme deficiency resulting in the inability to metabolize phenylalanine.
 - PKU is an inborn error of metabolism.
 - PKU results from a chromosomal abnormality called nondisjunction.
 - PKU is transmitted as an autosomal recessive disorder.

The correct answer is c.

4. What information should the same parents be given about the consequences of PKU?
- High dietary levels of phenylalanine may help induce enzyme production.
 - PKU is commonly associated with other congenital anomalies.
 - Failure to avoid dietary phenylalanine results in progressive mental retardation.
 - Mental retardation is inevitable.

The correct answer is c.

5. A woman is heterozygous for an *autosomal dominant* disease. If she mates with a normal man, what are the chances of the coupling producing an affected child in any pregnancy?
- 1:4
 - 1:2
 - 1:400 ($1/10 \times 1/10 \times 1/4 = 1/400$)
 - No risk, since she is a carrier and he is not.

The correct answer is b.

6. Three siblings have a *rare autosomal recessive* disease. Both parents are clinically normal. Which of the following statements apply?
- Both parents are homozygous for the normal allele.
 - Both parents are homozygous for the defective allele.

- All three children are homozygous for the defective allele.
- All three children are heterozygous.

The correct answer is c.

7. The term “autosomal recessive” refers to the mode of inheritance of a disorder:
- That is always expressed in heterozygotes.
 - Whose causative gene is located on an autosome.
 - That is always present at birth.
 - That cannot be transmitted from mother to son.

The correct answer is b.

8. Choose the correct statement about the carrier state:
- The son of a mother with hemophilia has a 50% chance of being a carrier.
 - The son of a woman with achondroplasia has a 50% chance of being a carrier.
 - The son of a man with achondroplasia has a 50% chance of being a carrier.
 - None of the above statements is correct.

The correct answer is d.

9. The son of a man with Y-linked hairy ears marries the daughter of a man with the same condition.
- All their children will have hairy ears.
 - All their boys will have hairy ears.
 - None of their children will have hairy ears.
 - Half of their boys will have hairy ears.

The correct answer is b.

10. If a man who is affected with an X-linked recessive disorder marries a woman who is phenotypically and genotypically normal,
- All his sons will be carriers.
 - All his daughters will be carriers.
 - Half his sons will be carriers.
 - Half his daughters will be carriers.

The correct answer is b.

Family Planning

The nurse often is viewed by the public as a person who has vast medical knowledge and is capable of communicating that knowledge in lay terms that are easily understood. Questions that arise vary from simple to complex. How would you answer the following questions?

- What is the difference in action of combined oral contraceptives and progestin-only contraceptives?
- How would you counsel an adolescent about contraception who is sexually active but insists that her parents must not know of her decision to be sexually active or to use contraceptives?
- What would you say to the 50-year-old woman who asks if she needs to use a contraceptive method?

Key Terms

Abortion	Emergency	Injectable contraception	Tubal ligation
Cervical cap	contraception	Ovulation prediction	Vaginal ring
Coitus interruptus	Family planning	Sperm capacitation	Vasectomy
Contraception	Implantable	Spermicide	
Diaphragm	contraception	Sterilization	

Competencies

Upon completion of this chapter, the reader should be able to:

1. Discuss the currently available methods of contraception.
2. Identify the risks and benefits of each form of contraceptive device.
3. Discuss the mechanism of action of each form of contraception.
4. Describe the steps in successful reproductive decision-making.
5. Describe some of the implications of an unplanned and unwanted pregnancy.
6. Use the nursing process to determine a client's need for contraception.

Family planning involves cognitive decisions and behavioral practices that enable a woman to conceive a wanted pregnancy and avoid an unwanted or a badly timed pregnancy. Family planning decisions are complex and may be made by the woman, her partner, or the couple in cooperation. These decisions are made in a number of ways.

Each year in the United States, 49% of pregnancies are unintended (Dailard, 2000). The unintended pregnancy rate is approximately 3.5 million pregnancies per year in the United States (La Valleur, 2000). A pregnancy may occur at a time in a woman's life that she recognizes is inappropriate for having a child. Many of these unplanned and badly timed pregnancies involve women under aged 20 years. This chapter prepares the nurse to assist women of childbearing age in many different settings to adapt and identify their health care needs regarding how many children they will have and the timing of having children.

In this chapter, reproductive decision-making is discussed as are currently available methods of contraception and nursing care to meet the health care needs of women of childbearing age. For the nurse, an understanding of reproductive decision-making is important because many times women do not recognize choices they have. Understanding there is a choice is necessary before the woman can determine if she wants a method of contraception and which method is best for her.

REPRODUCTIVE DECISION-MAKING

In nearly every situation in life, one has choices about the actions one takes. Many of the choices have such obvious negative consequences that they are quickly eliminated and thus it may appear as if there are no choices. For example, every student has a choice to refuse to turn in required course work, take examinations, or attend classes. Most students do not consider these options viable choices because the consequences generally are undesirable.

In reproductive decision-making, **contraception**, or prevention of pregnancy, often is the topic for which couples will seek information. Interestingly, despite the fact that choosing a contraception method often is a decision made jointly by couples, little is known about how men and women differ in this regard. Grady, Klepinger, and Nelson-Wally (1999) found that women ranked pregnancy prevention as the most important factor and ranked the health risks associated with the method and protection from sexually transmitted diseases (STDs) second. By contrast, men considered protection from STDs as the most important factor. It is likely that women make most decisions regarding reproduction because the direct consequences of pregnancy have the greatest impact on women.

Ideally, reproductive decision-making is a rational process based on the premise that human beings are agents with free will. Nurses need to honor the choices of

Figure 14-1 Rational decision-making in family planning is based on having accurate information about various options and their associated risks and benefits.

their clients and become aware of their personal values. This awareness is helpful so that the nurse does not impose personal values on clients. Rational decision-making is a logical process based on accurate information. A rational approach allows for an active rather than a passive approach to decision-making. An active approach involves projective planning in which individuals assess the situation; consider available options; and examine the risks, benefits, and consequences of various options (Figure 14-1). Box 14-1 identifies the steps in this process.

Factors Affecting Reproductive Choices

Although the rational process appears straightforward, in reality, decision-making is complex. In a study of 800 women, 75% changed methods at least once and reported

Box 14-1 Steps in Rational Decision-Making

- Recognize that there is a decision to be made and identify the problem.
- Seek information about options for problem resolution.
- Evaluate the options based on risks, benefits, and feasibility.
- Select the most acceptable option.
- Develop a realistic plan to implement the option.
- Implement the option.
- Evaluate the plan and make revisions or adaptations to resolve obstacles.

1,889 method choices and gave 1,036 reasons for changing (Matteson & Hawkins, 1997). In another study that examined prenatal contraceptive decision-making with postpartum behavior, only 54% of women planning to use oral contraceptives actually used them and 31% of women planning to use condoms used them (Miller et al., 2000). Psychological factors, sociocultural factors, and spiritual and religious beliefs and values influence choices. Many women find themselves with unintended pregnancies because they were passive and made no decision. Reproductive decision-making can be life altering and is an area in which nurses often are engaged with clients in helping to make these decisions.

Psychological Influences

Reproductive decisions often are influenced by feelings about one's self. For example, a young man may feel his self-concept is enhanced by performance in sexual activity. A young woman may feel that achieving pregnancy enhances her self-esteem. Sometimes women may agree to sexual activity to satisfy a sense of belonging, to feel needed, or to feel important. The accompanying emotional issues involving sexuality and relationships may cloud a logical process.

In their study of female psychology, Gilligan, Ward, & Taylor (1988) found that girls make decisions based on relationships rather than by using an objective, purely rational process. The importance of the role of attachment and connection in young girl's decision-making is reiterated over multiple studies, which may help to understand the gender differences in reproductive decision-making. Ironically, the use of contraception is lower in couples who have just met than in couples with an established relationship. In a study of sexually active females under 18 years of age, 52% who had just met their sexual partner used no method compared with 24% who were going steady (Manning, Longmore, & Giordano, 2000). Adolescent girls who first had sex with a man 6 or more years older than they had an even greater decreased rate of practicing contraception.

Pender's (1996) Health Promotion model specifies personal and experiential factors as strong predictors for health-promoting behaviors. Pender also identifies a client's perceptions about the benefits and barriers to a health-related behavior as core areas of intervention. A sense of *self-efficacy*, or judgment about personal capability to execute actions, is another psychological aspect of health behaviors.

Sociocultural Influences

The immediate social situation or social group greatly influences reproductive decision-making. Decisions often reflect the patterns of one's immediate social group. Pender

(1996) identified family, peers, providers, norms, support and models, and the situational influences as important contributors to client behavior. Cultural values regarding sexuality and gender roles, the power dimensions of adolescent's lives, and economic disadvantage exert powerful influences on decision-making (Gage, 1998). Adolescents, in particular, are influenced by peer pressure and may subject themselves to unprotected intercourse through the belief that everyone does it. The peer group also may influence the adolescent girl if the group regards the use of contraception as a label of sexual activity, thus dissuading the use of planned contraception. With these pressures, she may not consider the consequences, weigh the options, or consider her own needs and aspirations. Oddens (1997) found that contraceptive use was principally determined by social influences, attitudes, and self-efficacy.

Social circumstances are significant in making decisions regarding reproductive actions. For example, a woman with little money may not be able to afford to purchase contraceptives. A homeless woman may not use contraceptives because it is inconvenient and she has nowhere to keep them to have available when needed. A woman also may agree to sexual intercourse through the influence of romantic surroundings and a persuasive partner.

Cultural beliefs, values, and customs structure gender roles and reproductive behavior. It is important for nurses to understand the client's cultural beliefs about the acceptable age of childbearing, marriage requirements, how the father is chosen, spacing of pregnancies, and health behaviors during pregnancy. The general culture influences behavior through movies, music, and other media. Exposure of young children to explicit sexual activity has resulted in increasingly younger children acting and dressing as adults. Some have speculated that this exposure contributes to early sexual activity in adolescents.

Spiritual and Religious Influences

Spiritual and religious beliefs impact reproductive decision-making. Many belief systems condone sexual activity only within marriage, and some view sexual activity only for the express purpose of procreation. In other systems, sexual intimacy between a couple may be viewed as being sacred. The Roman Catholic Church, for example, does not condone the use of most contraceptives or abortion. The only acceptable method is natural family planning. For Muslims, although contraception is acceptable, there may be religious objections to abortion.

Readiness for Decision-Making

Honoring the client's need to make the best decision for herself, while providing the best information and facilitat-

Nursing Tip

CLINICAL ASSESSMENT OF REPRODUCTIVE DECISION-MAKING

- Is the client free to make a choice?
- Is the client competent to make a choice?
- Does the client recognize situations in which she has a choice?
- Does the client have adequate knowledge to make an informed choice?
- Can the client reasonably implement the choice? What are the barriers or obstacles to using this contraceptive method?

ing the rational decision-making process, is best achieved through a process of shared decision-making. This process is increasingly advocated as the ideal model for the medical encounter and has the following characteristics: client and provider are 1) both involved, 2) share information, 3) build consensus regarding the plan, and 4) reach an agreement on implementation (Charles, Gafini, & Whelan, 1997).

Freedom to Make Choices

Rational decision-making is based on the premise that clients are agents with free will to make choices; however, in reality, not all clients are free to make choices. Women who are victims of rape or sexual violence have had their freedom compromised. In some states, minors are not free to obtain contraceptive methods or abortion without parental consent. In other states, minors seeking medical care, including contraceptive information, methods, and in some cases abortions, are considered emancipated minors. Thus, health care providers can legally provide services without parental notification, approval, or consent. Nurses need to be aware of institutional policies and state practice regulations.

Many health care providers assume that the woman is free to make reproductive decisions independently; however, in many cultures this is not the case. The decisions regarding children and contraception reside with the husband, are shared between husband and wife, or involve the entire extended family.

Competence to Make Choices

Cognitive skills of abstract thinking are necessary to contemplate the risks, benefits, and consequences of various options. Persons without these skills need special considera-

tion, and the health care provider may need to take more responsibility in the decision-making process to find a responsible party to make decisions. Young adolescents may not have developed abstract thinking and the ability to project into the future to process the potential consequences of sexual intimacy. In these cases, nursing interventions may need to facilitate the development of these skills and the processing of projecting the consequences of choices.

Recognition of Decision Points

Decisions are more likely to be reactive or passive, and therefore not reasoned, when the client is unaware that she is at a decision point or that options are possible. One nursing intervention may be simply to make the client aware that she has an opportunity for choices. For example, a young girl may not recognize that she can refuse to have intercourse unless her boyfriend uses a condom. Closely related to the recognition of choice is being aware of options. For example, a woman cannot make a decision to use an emergency method of contraception after intercourse if she is unaware of that option.

Three decision points are relevant to contraceptive use: 1) sexual activity, 2) preventive contraception, and 3) emergency contraception. Differentiating these decision points may be useful in recognizing opportunities for choices.

Sexual Activity

Some women make generalized decisions about sexual activity. For example, a woman may decide to be abstinent until after marriage, or after finishing school, or until she gets a job. Another may feel that if she has a sexual encounter with a particular individual, then she has made a decision related to that relationship and no longer has choices as to whether she will have sexual relations with that person in the future.

Choices about sexual activity often are not made proactively. Many women think that proactive decisions inhibit spontaneity. Women should recognize that they have choices regarding if, with whom, when, and where intercourse should occur. Each opportunity for intercourse is a decision point.

Preventative Contraception

Most contraceptive decisions are made to avoid or postpone pregnancy. In contrast, making a decision to have a baby is the most proactive approach. Some women do not use contraceptives because they feel they are not vulnerable to pregnancy because they are too old or too young. Many women fail to use contraception when they have sporadic sexual encounters or are not in a stable relationship. This is not a good rational decision because pregnancy can result from one sexual encounter and the chances for partner support are decreased.

Emergency Contraception

Postcoital contraception, also known as **emergency contraception**, is now available and includes pregnancy termination, morning-after contraception, and RU 486. Many women however are not aware of this availability. Because a postcoital method may be inconsistent with some belief systems, preventive contraception may be more appropriate.

Knowledge Level

Informed reproductive decision-making involves more than awareness of options; it requires accurate information regarding the risks, benefits, and consequences of each option. Informed reproductive decision-making includes weighing the risks, benefits, and consequences of not using contraception. This process allows the client to make a choice regarding the risk-benefit ratio with which she is comfortable. Knowledge of how to effectively use the contraceptive method also is important and needs to be considered (Figure 14-2). A survey by Fuchs, Prinz, & Koch (1996) found that most women are poorly informed about oral contraceptive use and are largely unaware of the important long-term noncontraceptive benefits.

Implementation of the Choice

The nurse also must be aware of contraindications and obstacles to use. In this process of information sharing, the

Figure 14-2 Clients must understand and return-demonstrate proper use of contraceptive devices to ensure their effectiveness.

nurse might share her knowledge of medical contraindications. For example, a woman with a history of thromboembolism should not take certain oral contraceptives. The client also might share her knowledge of potential obstacles to use. For example, an adolescent may be uncomfortable touching herself and thus would be a poor candidate for the female condom or many of the barrier methods.

Possible barriers and obstacles should be explored: Which actions on the part of the client are necessary to effectively use the chosen method? An adolescent without transportation may not be able to come to the clinic to get a monthly injection. When a teenager is living at home and believes her parents will not approve of contraception, a method that provides evidence for her parents to detect is not a good choice. A woman may choose condoms as her preferred method; however, if her partner refuses to use them, she needs to have an alternative plan. A woman may choose oral contraceptives but, in reality, cannot remember to take them regularly.

By assessing the decision-making process and the client's knowledge, the nurse can be more effective in facilitating satisfactory use of contraceptives. This interactive approach involving the client and family members as appropriate may promote greater effectiveness of contraceptive strategies.

CONTRACEPTIVE METHODS

Contraceptive methods currently available are either reversible or permanent (Figure 14-3). Reversible methods vary in the time required for reproductive capacity to return on discontinuance, and they vary in the frequency of administration necessary to prevent unwanted pregnancy. Permanent methods vary in regard to when the method becomes permanent. For example, oral contraceptives

Figure 14-3 In addition to face-to-face teaching, clients should be offered printed information on family planning choices.

must be taken daily, whereas injectible methods may require monthly administration or action of the medication may last as long as 3 months, depending on the method chosen. An excellent example with regard to permanent methods is that the vasectomy is not considered permanent until follow-up sperm counts show that the count has approached or reached zero.

Reversible Methods

The numbers and kinds of reversible contraceptive methods is ever expanding. Each year several new products are marketed that are designed to refine those products already available or meet the needs of women who experience side effects.

Oral Methods

Oral methods of contraception include combined oral contraceptives and progestin-only contraceptives.

Combined Oral Contraceptives

Combined oral contraceptives have been available to women since the 1960s. The Food and Drug Administration approved this type of contraception in 1960 (Speroff & Darney, 1992). Approximately 60 million women worldwide have used combined oral contraceptives as a method of choice (Speroff & Darney, 1992).

There are three basic types of combined oral contraceptives (COC): monophasic, biphasic, and multiphasic pills. Monophasic COCs contain estrogen and progestin in the same dosage for 21 days of the menstrual cycle. If 28 pills are in the package, the remaining 7 pills may be inert or iron pills. Biphasic pills may have a stable dose of estrogen throughout the cycle and an increase in progesterone in the second half of the cycle, or the dosage of both hormones may change in the second half of the cycle. This type of COC was designed to alleviate problems some women have with breakthrough bleeding. Multiphasic COCs have three different dosages of estrogen and progesterone during the monthly cycle. This type of COC also was designed to alleviate the side effects and breakthrough bleeding some women experience with monophasic or biphasic COCs.

Pharmacology

Combined oral contraceptives are composed of steroids of the hormones estrogen and progesterone. Two types of estrogens have been used in the formulation of COCs. Mestranol was used in the pills having a higher dose when COCs initially were developed. It was determined, however, that mestranol was broken down to ethinyl estradiol before its use. In contemporary COCs, ethinyl estradiol is the only estrogen available in these preparations.

The net effect is that estrogen prevents breakthrough bleeding by potentiating the action of progestin, and enabling lower doses of progestin to be used for the same effect.

By contrast, progestin diminishes the release of leuteinizing hormone (LH) by the anterior pituitary gland. LH ordinarily is released in pulses, with a sharp increase in pulsatile action immediately before ovulation. In fact, a surge of LH is responsible for release of the mature ovum at the time of ovulation. Progestins make cervical mucous less receptive, making it impervious to sperm passage. Progestins make the endometrium less receptive to implantation. Progestins also influence secretions and peristalsis of the fallopian tubes, impeding mobility of the sperm and ovum.

Types of Combined Oral Contraceptives

Numerous preparations of COCs are sold by various pharmaceutical companies (Figure 14-4). Each year there are additional kinds of preparations added to the list. The wide variety of preparations meets individual needs and reduces undesired side effects or management problems. Table 14-1 contains some of the currently available preparations.

Efficacy

The combined oral contraceptive is the most effective reversible method available to women today. The failure rate is less than 1% (Jensen & Speroff, 2000).

Benefits and Risks

Combined oral contraceptives offer contraceptive benefits and noncontraceptive benefits. Both kinds of benefit make

it to a woman's advantage to choose oral contraception. COCs are relatively inexpensive, safe, effective, and easy to use. Return to fertility is almost immediate on discontinuance of this method.

Contraceptive Benefits

Over the past 30 years, no drug has been as well studied as has the COC. Most women who use COCs do so for contraception. COCs are highly reliable. When used appropriately, COCs are more than 99% effective (Jensen & Speroff, 2000). Successful use of COCs is highly related to the woman's understanding about how the preparation works and compliance with certain practices. These practices are summarized in the Client Education Box.

Noncontraceptive Benefits

Combined oral contraceptives offer several important noncontraceptive benefits that reduce morbidity and mortality in women. The number of these recognized benefits has increased with data gathered from many women who have used COCs over many years (Burkman, 2001).

✿ *Protection Against Ovarian Cancer* Ovarian cancer is the fourth leading cause of cancer death in American women and has the highest mortality rate of any gynecologic cancer. Its onset is insidious. By the time of detection, ovarian cancer has metastasized in 60% of cases. There is a survival rate of 40% at 5 years for women treated for ovarian cancer.

When a woman has ever used them, COCs offer a 40% to 80% reduction in the risk for ovarian cancer (Burkman, 2001). The degree of protection increases with the length of use. A minimally protective effect is present with 3 to 6 months of use. The protective effects of COCs last at least 15 years after discontinuance. This reduction in risk is present in all four subtypes of ovarian cancer.

✿ *Protection Against Endometrial Cancer* The incidence of endometrial cancer is reduced by the use of COCs. Overall, studies suggest that there is a reduction in risk of 50% beginning approximately 1 year after initiation of use (Burkman, 2001). The reduction is apparent in all

Figure 14-4 Birth control pills.

UNDERSTANDING COCs

Clients who are considering the use of combined oral contraceptives should have the benefit of information about mechanism of actions, benefits, risks, adverse effects, and contraindications to assist them in making their decision.

Table 14-1 Currently Available Combined Oral Contraceptives

Monophasic Preparations		Biphasic Preparations	Multiphasic Preparations
Brevicon	Norethin 1/35 E	Ortho-Novum 10/11	Jenest
Demulen	Norethin 1/50 M	Gracial	Ortho-Novum 7/7/7

Modicon	Ovcon-50		
Nelova 1/35E	Ovral		
Nelova 0.5/35	Alesse		
Nordette	Mircette		

histologic subtypes of endometrial cancer. Protection lasts up to 15 years after discontinuance of the medication.

✿ *Reduction in Incidence of Salpingitis* Salpingitis has been reduced with the use of COCs. The mechanism of action is thought to be a chemical reaction in the woman's body that changes the cervical mucous and impedes ascent of infectious organisms. It has been estimated that a 50% reduction in hospital admissions for salpingitis can be attributed to COCs (Burkman, 2001).

✿ *Reduction in Incidence of Ectopic Pregnancy* Combined oral contraceptives have been given credit for reducing the rate of ectopic pregnancy by approximately 90% (Burkman, 2001). The mechanism of action is thought to be through inhibition of ovulation. This is a secondary benefit to preventing salpingitis.

✿ *Prevention and Treatment of Functional Ovarian Cysts* The relatively new low-dose COCs reduce the incidence of functional ovarian cysts by preventing ovulation. Preparations containing 50 µg of ethinyl estradiol have been associated with reducing cyst formation. If a woman has recurrent functional cysts, use of COCs may eliminate recurrence (Hatcher et al., 1998).

✿ *Reduction in Incidence of Anemia* Combined oral contraceptives reduce the incidence of anemia in two ways. Women who use these preparations are likely to have lighter menses, resulting in less blood loss. The 28-day formulations also supply iron replacement. This protection lasts beyond the treatment period with COCs.

✿ *Menstrual Cycle Benefits* Women who have heavy menses and those with painful menses benefit from the use of COCs. The resulting increase in progestin is likely to decrease flow and reduce or eliminate cramping some women experience during menstruation.

✿ *Reduction in Incidence of Benign Breast Disease* The reduction of benign breast disease is thought to be due to inhibition of ovulation. When a woman ovulates, certain proliferative breast changes occur. When ovulation ceases, these changes typically do not occur. The decrease in benign breast changes occurs even at the lowest dose of oral contraceptive.

✿ *Reduction in Acne* Acne can vary from person to person and can be worse at certain times in the same person. Certain COCs can be very effective in reducing or eliminating the incidence of acne. In the very young woman who has acne the benefits increase if she also has menstrual cramping or functional ovarian cysts.

✿ *Improvement in Bone Mineral Density* Bone mineral density peaks in women between the ages of 20 and 25 years, stays constant for approximately 10 years, and progressively decreases during the later reproductive years (Burkman, 2001). Estrogens act on bone by increasing absorption of calcium and directly decreasing reabsorption of calcium through inhibition of osteoclasts. One case control study indicates that there is a 25% reduction in hip fracture risk among women who use COCs.

Client Education Box

Oral Contraceptives

Women who are going to use combined oral contraceptives (COCs) should understand several important points about their successful use.

1. COCs, especially low-dose preparations, are more likely to be effective when taken the same time every day.
2. COCs may be begun on the Sunday after the first day of the woman's menses. If she begins the pill immediately it should be effective in 7 to 10 days. If she wants to be really safe, she may want to consider using a backup method with the pill for the first month.
3. The woman should know that COCs do not offer protection against exposure to the human immunodeficiency virus (HIV). She or her partner should use a condom in combination with the pill for this type of protection.
4. The woman needs to know that there are various types and dosages of COCs, and they are not necessarily interchangeable.
5. When a woman forgets to take one pill, it should be taken when she remembers; the next pill should be taken at the regularly scheduled time.
6. When a woman misses more than one pill, there is the possibility of escape ovulation. She should use a backup method along with the pill for 7 days or refrain from intercourse for the remainder of the cycle (Hatcher et al., 1998).
7. When starting a new preparation, the woman should know it might take 3 months for hormone levels to stabilize. Breakthrough bleeding may diminish after the third cycle is completed (Lynch, 2000).
8. The woman should be aware of signs and symptoms that should warn her to discontinue the pill immediately, including the following:
 - Visual loss, diplopia, or blurred vision
 - Unilateral numbness, weakness, or tingling
 - Severe pains in the chest, left arm, or neck
 - Hemoptysis
 - Severe pain, tenderness, swelling, warmth, or palpable cords in the legs
 - Slurring of speech
 - Hepatic mass or tenderness
 If any of these signs or symptoms occurs, the woman should stop taking her pills immediately and contact a health care provider immediately.
9. The woman should know about less serious conditions that may occur and do not require immediate discontinuance of the pill but do require evaluation by a health care provider. Many of these symptoms and conditions can be easily alleviated or treated so that the woman may continue to use combined oral contraceptives. The use of COCs in the presence of relative contraindications requires clinical judgment on the part of the health care provider (Speroff & Darney, 2001). Relative contraindications include migraine headaches, hypertension, uterine fibroids, gestational diabetes, elective surgery, epilepsy, sickle cell disease, diabetes, and gall bladder disease.

✿ *Reduction in Risk for Colorectal Cancer* There is growing epidemiologic evidence that oral contraceptives protect women against colorectal cancer. Although the exact mechanism of action for this protection is unknown, it has been hypothesized that reduction in bile acid concentration may explain the protective effect (Burkman, 2001). The reduction in risk may be from 40% to 50%.

✿ *Reduction in Risk for Uterine Fibroids* Uterine fibroids are benign uterine tumors that increase in size and cause heavy menses. Research has shown a 70% reduction

in risk for developing fibroids among women using oral contraceptives (Jensen & Speroff, 2000).

Indications

Combined oral contraceptives are used specifically for family planning but also may be used to treat certain gynecologic conditions. Young women often have problems with cycle control. These women may benefit from the use of COCs to regulate irregular cycles, reduce flow, and control dysmenorrhea. Women with polycystic ovarian syndrome may benefit from COCs because they reduce

circulating androgens. Premenstrual symptoms may be improved with the use of COCs. Older women often experience anovulatory cycles with heavy bleeding owing to unopposed estrogen and also can benefit from COCs. This type of bleeding often is associated with perimenopause. COCs also can help alleviate other perimenopausal symptoms as well in women who do not have contraindications up to age 50 (Long, 1998).

Contraindications

Absolute and relative contraindications have been described related to oral contraceptives. If the woman has an absolute contraindication to the pill, she should not be given oral contraceptives under any circumstances. If she has a relative contraindication to the pill, she may take the pill under certain circumstances with direct supervision of her physician. Box 14-2 describes the absolute contraindications to oral contraception, and Box 14-3 describes the relative contraindications.

Side Effects

Most women experience relatively few side effects of the pill. Many times, side effects may be eliminated by changing pill formulation or dosage. Some side effects that have been reported are weight gain, breast tenderness, breakthrough bleeding, depression, decreased libido, and nausea. Table 14-2 describes the side effects and their relationship to hormones in the pills.

Another common concern is the effect of COCs on the lipid profile (Long, 1998). The concern was that the pill had adverse effects on the lipid profile by causing elevated triglycerides, which have been associated with cardiovascular disease and stroke. It appears that low-dose pills and the new progestins have moderated this risk for users.

Progestin-Only Contraceptives

A progestin-only contraceptive also is referred to as a minipill. This type of preparation is especially attractive for women who want oral contraception and cannot take COCs. This would include women who cannot take or do not tolerate estrogen, lactating women, and women with chronic medical conditions.

Three brands of progestin-only pills currently are available in the United States. The trade names are Nor-Q.D., Micronor, and Ovrette. Nor-Q.D. and Micronor contain norethindrone, 0.35 mg; Ovrette contains norgestrel, 0.075 mg.

Pharmacology

Unlike the COC, the minipill does not act by preventing ovulation. Instead, its mechanism of action is that the progestin acts to make the endometrium hostile to implantation and the cervical mucus becomes thick and impermeable

Box 14-2 Absolute Contraindications to the Use of Combined Oral Contraceptives

- Presence or a history of deep venous thrombosis or pulmonary embolism.
- Cerebrovascular accident or a history.
- Coronary artery or ischemic heart disease, or a history of either.
- Structural heart disease complicated by pulmonary hypertension, atrial fibrillation, or subacute bacterial endocarditis, or a history of any of these conditions.
- Diabetes with nephropathy, retinopathy, or neuropathy, or other vascular disease.
- Diabetes of over 20 years duration.
- Breast cancer.
- Pregnancy.
- Lactation.
- Liver problems.
- Headaches.
- Major surgery.
- Cigarette smoker over the age of 35 years.
- Blood pressure levels over 160/100.

COC CONTRAINDICATIONS

Be sure to tell your clients that certain drugs interact with COCs to reduce their efficacy, including:

- Carbamazepine (Tegretol)
- Griseofulvin
- Phenobarbital
- Phenytoin (Dilantin)
- Rifabutin
- Rifampin
- Topiramate

Data Adapted from Hatcher, R. A., Trussell, J., Stewart, F., Cates, W., Stewart, G., Guest, F., & Kowal, D. (1998). *Contraceptive Technology* (17th ed.). New York, NY: Ardent Media, Inc.

(Speroff & Darney, 1992). Approximately 40% of women will ovulate while taking the minipill.

Efficacy

The minipill is considered to be more than 99% effective when used properly. It must be taken at the same time each day because there is a higher potential for ovulation and pregnancy than with the COC when a dose is late or missed. There is no significant metabolic effect, and fertility returns to normal almost immediately after discontinuance (Speroff & Darney, 1992).

Benefits and Risks

Minipills are of benefit to women who are unable to take COCs. In lactating women and women over the age of 40 years, the protection approaches 100% with proper use (Speroff & Darney, 1992). This high rate of efficacy in these groups may be due to the decreased fertility in this client population. The World Health Organization states that progestin-only pills have no adverse effects on lactation and can be started as early as 6 weeks postpartum (Adams, 2000). The minipill also is useful for women who experience decreased libido with COCs. The minipill offers many of the same noncontraceptive benefits as do COCs; however, these benefits may be at a reduced level. Because it is thought that the minipill produces no metabolic effect, it should be safe for use in women who have diabetes and those over the age of 35 years. Return to fertility is almost immediate on discontinuance.

In the first year of use, there typically is a 5% failure rate among the general population. This rate is slightly higher than that of COCs but better than use of no contra-

ceptive, which has a pregnancy rate of 80% within 1 year of unprotected intercourse.

Women who use the minipill will develop more functional ovarian cysts, which usually will resolve without treatment. The major problem with use of the minipill is that of breakthrough bleeding.

Indications

As is the combined oral contraceptive, the minipill is designed to be used as a contraceptive. It also may be used to decrease bleeding related to unopposed estrogen. Some minipills can be used for emergency contraception, which is discussed later in this chapter.

Contraindications

Minipills should not be used in the presence of pregnancy. Progestin is considered a teratogen to the unborn fetus. The minipill also is contraindicated in women who have breast cancer, women taking certain medications, and women who have liver disease.

Side Effects

The major side effect of the minipill is irregular bleeding. Women who use this method may not have regular menses for the duration of its use. They may have irregular periods of spotting. Because the bleeding is light, however, this side effect is not bothersome for some women.

Intrauterine Methods

The intrauterine device has been available in the United States for more than 70 years, although it has been accepted widely as a contraceptive device only for the past 40 years (Figure 14-5). Present perceptions of this method are strongly influenced by some problems that arose with one particular IUD in the 1970s. That IUD was called the Dalkon Shield. Some women using Dalkon Shields developed pelvic inflammatory disease (PID). At the time, there was much discussion about safety, resulting in all but one type of IUD being removed from the market. Today, there is some discussion that the major contributing factors to removal from the market were ignorance of the facts, fear of medical liability, inadequate medical training in insertion, and confusion about the mechanism of action. As a result, physicians stopped recommending this method (Department of Health and Human Services [DHHS] & The National Institute of Child Health and Human Development [NICHD], 1996). The IUD has been re-released for use but is not as widely used as it was before removal from the market.

Two types of intrauterine devices currently are available in the United States. Paragard T 380A is a T-shaped device made of polyethylene, and Progestasert is a T-shaped device made of ethylene vinyl acetate copolymer.

A.

B.

Figure 14-5 A. Intrauterine device (IUD). B. Proper insertion of an IUD.

Composition

The Paragard has a 380-mm² exposed surface of copper on its arms and stem. The Progestasert contains a reservoir of 38 mg of progesterone that is released at a rate of 65 µg/d (Nelson, 2000). Some other types of IUD from previous years with an unlimited life span may remain in use even though they are not available on the market today.

Mechanism of Action

It is thought that the IUD works by interfering with sperm transport from the cervix to the fallopian tubes. This interference makes viable sperm scarce in the fallopian tube. It is also thought that the IUD inhibits sperm capacitation and survival. **Sperm capacitation** is the process by which the sperm becomes hypermobile and there is a breakdown of the plasma membrane and merging with the aerosmal membrane which allows the sperm to bind with the zona pellucida of the ovum (Speroff, Glass, & Kass, 1999). It is thought to inhibit implantation. It also is thought that the IUD alters the biochemical or cellular composition of uterine fluid, or both, causing impairment of the viability of gametes (DHHS & NICHD, 1996).

The copper IUD is a functional spermicide. The copper ions released from the device interfere with sperm motility and create a reaction to the foreign body that results in a spermicidal endometrium (Nelson, 2000). Progestasert is believed to act through thickening the cervical mucus and rendering it impermeable to sperm.

Efficacy

The copper IUD has a first-year failure rate of 0.7% with typical use. The copper T has a 10-year failure rate of 2.1% to 2.7% (Nelson, 2000). Progestasert has a first year failure

rate of 2% with typical use. The median time from removal of the IUD to planned pregnancy is 3 months (Nelson, 2000).

Benefits and Risks

In properly selected women, the IUD can offer a method of contraception for those who cannot or do not want to take oral contraceptives. The woman should be in a mutually monogamous relationship with her partner. The IUD is ideally suited to women that have chronic medical problems that restrict their use of hormones (Kjos, 1997). Unlike pills that must be taken daily, the IUD provides prolonged protection. Paragard is approved for 10 years of use before replacement; Progestasert is approved for 1 year of use before replacement (Stewart, 1998).

The IUD requires little maintenance. The woman should check the length of the tail string in her vagina after each menses. If the string is not found, she should notify her health care provider immediately.

Insertion issues are related to IUDs. The two most serious problems are vasovagal response and uterine perforation. A vasovagal response involves rapid decrease in blood pressure on insertion of a probe or IUD into the uterus. It occurs in approximately 1% of women on manipulation of the cervix. This response usually is mild and transient; however, occasionally, the woman will require resuscitation. Therefore, resuscitation equipment should be immediately available.

Perforation of the uterus occurs in approximately 1 in 770 to 1,600 insertions (Nelson, 2000). Most perforations occur when the uterine sound is inserted to determine the depth of the intrauterine cavity. Using current techniques that do not require the use of uterine sound has reduced this risk.

Indications

Client selection is an important consideration when using the IUD. The woman should have had a previous pregnancy, must not have a history of PID, and must be in a monogamous relationship. The woman who has never been pregnant has a smaller uterine cavity and thus is at risk for expulsion.

Mishell (1996) indicated four misconceptions that prevent more women from choosing IUDs. The first reason is the fallacy that IUDs work as an abortifacient, resulting in failure of implantation of a fertilized egg. The second is that IUDs cause pelvic infections or PID. The third fallacy is that IUDs cause ectopic pregnancies. The fourth reason is the belief that the problems encountered in the past with the Dalkon Shield are common to all IUDs.

Contraindications

Nelson (2000) enumerates contraindications for IUD insertion. General contraindications include pregnancy, acute cervicitis, a distorted uterine cavity, uterine or cervical carcinoma, unexplained vaginal bleeding, severe immunocompromise, and multiple sexual partners.

Specific contraindications for IUD insertion include issues specific to copper or progesterone (Nelson, 2000). Contraindications to copper devices include uterine cavity size of less than 6 or greater than 9 cm, copper allergy, Wilson disease, severe anemia, heavy menses, and severe dysmenorrhea. Contraindications for the progesterone device are uterine cavity size of less than 6 or greater than 9 cm, a history of ectopic pregnancy, and diabetes.

Side Effects

Bleeding and cramping are the two most common side effects encountered after insertion of the IUD. These symptoms usually are minimal and temporary; however, occasionally, they occur to the extreme, necessitating removal of the device.

Other adverse effects include infection, accidental pregnancy, and expulsion of the device (Nelson, 1995). Infection is related to insertion and STD. These side effects make client selection a very important factor.

Intravaginal Methods

The **vaginal ring** (which delivers steroids through the vaginal mucosa) is a contraceptive device that had its beginnings in the 1970s (Ballagh, 2001). It became apparent that drug absorption could occur in the vaginal mucosa. Duncan at Upjohn first patented vaginal delivery of sex steroids through a polysiloxane tube or disk in 1970. Since that time, more than a dozen patents for contraceptive rings have been filed.

Various ring designs have been used. Modifications have been made to ensure sustained, even steroid release

over a period of time. The result has been a highly effective product.

Composition

Vaginal rings are available that contain progestins alone or a combination of estrogen and progestin.

Mechanism of Action

The steroids are absorbed through the upper vaginal mucosa. In the combination form of the intravaginal ring, ethinyl estradiol is released at 20 µg/d and norethindrone at 1 mg/d. These dosages are equivalent to those in oral contraceptives. The mechanism of action is through prevention of ovulation, increased viscosity of cervical mucus, and endometrial atrophy.

Types of Intravaginal Devices

Ballagh (2001) described various types of vaginal rings. The progestin-only rings may include progesterone, etonogestrel, levonorgestrel-norgestrel, megestrol, nestorone, or norgestrienone. Combined estrogen-progestin devices can contain the previously mentioned progestins in combination with ethinyl estradiol.

Benefits and Risks

One of the benefits of the vaginal ring is that it does not require the rigor necessary to use oral contraceptives. The vaginal ring allows a sustained release of steroids over a 3-week period. The method is reversible by the woman. The only requirement for discontinuance is nonreplacement of the device at the end of the use-free week. Acceptance of the ring is high among women, except those who find placing a foreign object in their vagina unacceptable (Grow & Ahmed, 2000).

Indications

The vaginal ring is designed for women who do not want to use a method that must be administered daily, for example, women who travel or who do not have a perma-

Nursing Tip

VAGINAL RING

The vaginal ring is designed to be left in the vagina for 3 weeks and removed for 1 week to allow menses. The ring may be removed or remain in place during intercourse.

nent place to store pills. The woman who uses the vaginal ring must be comfortable inserting and removing an object from her vagina. Vaginal rings also are useful in relieving menopausal symptoms.

Contraindications

Because the steroids from the ring are absorbed directly from the vaginal mucosa into the bloodstream, use of the vaginal ring is contraindicated in women who cannot use oral estrogen or progestins.

Adverse Effects

Occasionally, the vaginal ring can be expelled when straining to have a bowel movement or on tampon removal. Some women experience discomfort with intercourse when the vaginal ring is in place. Some women have an odor that they attribute to the ring. Some women also complain of vaginal discharge they attribute to the vaginal ring.

Barrier Methods

Barrier methods of contraception include condoms, diaphragms, and cervical caps. Spermicide is a chemical barrier method.

Condoms

Condoms are available for men and women. Condoms are the most frequently used barrier method of contraception. Six billion condoms were sold worldwide in 1990 (Speroff & Darney, 1992). They are sold without a prescription at most drug stores and in other public places. Condoms are available in various colors and textures and with a lubricant inside that contains a spermicide (Figure 14-6). Condoms have a typical effectiveness rate of 88% and a theoretical ef-

Figure 14-6 Male condoms.

CONDOM USE

Care must be taken to leave space at the end of the male condom when it is applied. If this space is not allowed, there is a tendency for the condom to break. The condom must be removed before the penis becomes flaccid. The condom also must be secured at the base of the penis as it is removed to avoid having the condom remain in the vagina when the penis is withdrawn.

fectiveness rate of 98%. The difference in the two rates has to do with improper use, lack of use, and breakage.

The female condom has been available since the 1990s (Figure 14-7). It is inserted into the vagina and covers the perineum. It is a polyurethane sheath 7.8 cm in diameter and 17 cm long. It contains two polyurethane rings. One ring is at the closed end of the sheath and is designed to be placed into the vagina. The ring at the open end remains outside the vagina after insertion. The outside portion of the female condom provides some protection for the external genitalia of the woman and the base of the penis of the man during intercourse. Unlike the lubricant in the male condom, the female condom does not contain spermicide.

Male condoms have been available for centuries and have been made of sheepskin and other materials. Currently, the most prevalent material is latex. Latex condoms have pores small enough to protect against the HIV virus and herpes simplex viruses.

Mechanism of Action

The condom acts as a barrier to prevent sperm from entering the vagina during intercourse. Both types of condom are designed for single use. Because the mechanism of action is as a barrier, a worn or torn condom negates its action.

Benefits and Risks

Condoms are inexpensive, readily available, require no contact with the health care system, and when used properly are quite effective as a method of contraception. When applied properly, condoms are almost as reliable as the oral contraceptive. The major risks of contraceptive failure with the condom involve use failure caused by breakage, accidental removal, or partner dissatisfaction with its use.

A.

B.

Figure 14-7 A. Female condom. B. Proper insertion of a female condom.

Indications

Both male and female condoms are indicated for use as a contraceptive device and as a method to prevent STDs. There are a number of reasons a couple may decide to use the condom as the primary form of contraception.

Contraindications

Condoms should not be used by the person with an allergy to latex.

Side Effects

If a person is sensitive to latex or spermicide, hypersensitivity reactions to the male condom may develop. Hypersensitivity is less likely to develop with use of the female condom because it is not made of latex.

Diaphragm

The **diaphragm** is a latex device available by prescription from a health care provider. The woman must be meas-

ured for adequate fit. Diaphragms are measured in millimeters and come in several sizes and styles to meet the needs of nulliparous and multiparous women. Measurement is so important to effectiveness that a woman must be refitted if she delivers a child or has a substantial weight change (Figure 14-8).

Mechanism of Action

The diaphragm is designed to provide a barrier between the cervical os and semen. The diaphragm is fitted snugly behind the symphysis pubis anteriorly. The sides of the diaphragm should extend laterally to encompass the entire cervix and rest in the lateral fornices. In the posterior dimension, when fitted properly, the cervix rests inside the diaphragm. A spermicidal gel is placed inside the dome of the diaphragm and around the rim to ensure that sperm do not enter. If intercourse is undertaken more than once, additional spermicide should be applied into the vagina. The diaphragm should remain in place for 6 hours after intercourse. On removal, care should be taken to wash the diaphragm with a mild soap and water solution before it is returned to its case for storage.

Benefits and Risks

The diaphragm is a long-established contraceptive device that requires little upkeep. Its theoretical failure rate is 6%, giving it the potential as an excellent method of contraception. The failure rate in typical use is somewhat lower (18%) because of the need to insert the diaphragm before intercourse. It must be left in place for 6 hours after inter-

Nursing Alert

EXTRA PRECAUTION

Cautious women should use a spermicide as a secondary means of contraception in case of failure of the primary mode.

A.

B.

Figure 14-8 A. Diaphragm with contraceptive jelly. B. Various sizes of diaphragms to be fitted by health care provider.

Client Education

Diaphragm Care

When cleaning the diaphragm for storage, cornstarch or powder should not be used on the diaphragm. These substances can affect the integrity of the latex. When vaginal lubricants are used for intercourse, they should be water-based. Petroleum-based products increase the risk of disintegration of the latex.

The diaphragm must be positioned properly on insertion to avoid exposure of the cervix by the erect penis. This requires that the woman feel comfortable enough with checking the placement of the diaphragm with her fingers after insertion for proper placement.

The diaphragm requires care and proper storage. When these precautions are not taken, there is risk of use failure. The result may be an accidental pregnancy. When intercourse is repeated without additional application of spermicide there is risk for acquiring STDs and unintended pregnancy.

course and may remain in place up to 24 hours (Speroff & Darney, 1992). When properly cared for, the diaphragm can be used for many years without replacement. However, it must be inspected frequently for holes or deterioration of the latex.

Contraindications

There are no contraindications for the use of a barrier device. However, women who have allergies to latex or spermicide would probably not want to use this method. Hatcher et al. (1998) suggest that women at high risk for failure use another method. Women at risk are those who have intercourse three or more times per week; who are under aged 30 years; whose personal style or sexual patterns make consistent use difficult; who have had previous contraceptive failures, who have ambivalent feelings about the desirability of a pregnancy; and who intend to delay and not prevent pregnancy. These women are least likely to have success with this method.

Cervical Cap

The **cervical cap** is a rubber barrier device designed to be applied to the cervix (Figure 14-9). It must be fitted to the woman by the health care provider to conform to the cervix. When properly fitted, the cervical cap is a few millimeters in diameter larger than is the cervix. The device is folded for insertion and fits against the cervix with suction. Once inserted, the device must be checked to ensure it is applied to the cervix and that suction is applied. Spermicide is placed in the dome of the cup and remains in place until the cervical cap is removed.

A.

B.

Figure 14-9 A. Cervical cap. B. Proper insertion of a cervical cap.

Benefits and Risks

The cervical cap is similar to but has an advantage over the diaphragm. Additional spermicide does not need to be applied with each act of intercourse. The cervical cap can be left in place for 36 to 48 hours after intercourse but should not remain inserted for prolonged periods of time. After a few days women may complain of a foul-smelling discharge.

Some women cannot wear the cervical cap because of irregularity of the cervical contour or other reasons. The cap must be left in place for 6 hours after intercourse because there may still be motile sperm in the vagina. Because the efficacy of the device depends on maintaining suction of the cap against the cervix and there may be dislodgement of the device during intercourse, the possibility of an accidental pregnancy exists.

Adverse Effects

When a cervical cap is left in place too long the potential for infection and cervical erosion exists. Antibiotics to treat the infection and another method of contraception may be required until the infection is healed. Cervical erosion may affect the outcome of the woman's Pap smear and also may necessitate removal of the device and use of another method.

Spermicide

Spermicide is a chemical method of contraception based on varying formulations of the chemical nonoxynol. The

delivery system for this chemical can be foam, sponge, gel, cream, suppository, or film (Figure 14-10). This type of contraceptive has a failure rate of about 20% when used alone. When used in combination with another barrier method, its rate of effectiveness increases. Hatcher et al. (1998) suggest that the combination of spermicide and a barrier method, backed up by abortion for failure, is one of the safest contraceptive options. Each spermicidal device must remain in the vagina for a period of time after intercourse that is sufficient to kill the sperm. This means the woman should not bathe or douche for 6 hours after intercourse.

Types of Spermicide

Contraceptive gel or cream is designed to be used in combination with diaphragms and cervical caps. Spermicides however can be used alone. Spermicides come with applicators, and therefore, a measured dose of the product will be used with each application. Contraceptive sponges also are designed to be used alone. Suppositories can be used alone or with a condom. The woman must allow 15 to 30 minutes before intercourse for dispersion of the medication. Contraceptive film can be used alone or in combination with a diaphragm or cervical cap. When used alone, the film should be placed high in the vagina in contact with or near the cervix. When used with the diaphragm, the film should be used inside the diaphragm near the cervix. Fifteen minutes is required for the insert to dissolve so that the spermicide is available for use.

SPERMICIDE USE

When using one of the spermicides for contraception, a second application of the product is necessary when intercourse is repeated.

Mechanism of Action

Nonoxynol 9, the spermicide available in the United States, is a surfactant that destroys the sperm cell membrane. Other spermicides are used in other parts of the world.

Benefits and Risks

Spermicide may lower the risk of becoming infected with a STD by as much as 25% (Hatcher et al., 1998). Spermicides are stored easily for those who have intercourse infrequently. Another benefit may be that the male partner does not have to be involved with this type of method. It is an excellent backup method in case a woman runs out of pills or expels her IUD.

One of the disadvantages of this type of product is allergy or sensitivity to the ingredients. This sensitivity will result in skin irritation. Frequent use results in a greater likelihood of irritation. Some of the products effervesce and some women dislike this feeling. Use of the sponge or diaphragm may result in frequent yeast infections.

Implantable Methods

When **implantable contraception** (contraceptive device surgically implanted) is discussed, Norplant comes to mind (Figure 14-11). This device has been available in the United States for approximately 10 years. Several types of implantable devices are available. Over 6 million women worldwide have used Norplant (Meckstroth & Darney, 2000).

Meckstroth & Darney (2000) discussed the new types of implantable devices that are becoming available. Norplant is still available in the standard six-capsule form; a new device that contains two rods of levonorgestrel is available, which is called Jadelle. A second type of implant called Implanon is available in a single rod for implantation. Uniplant is a silastic capsule containing norgestrel acetate that can be implanted as a single silastic capsule. Biodegradable implants include Capronor and Anuelle, which are under investigation. Capronor is a single biodegradable capsule, and Anuelle is marketed in the form of biodegradable pellets.

A.

B.

C.

Figure 14-10 Spermicides. A. Foam. B. Sponge. C. Film.

Figure 14-11 Implantable contraceptive.

Composition

Each of these implantable devices contains a progestin. Norplant contains 6 levonorgestrel capsules. Jadelle contains 2 levonorgestrel capsules. Implanon contains a single rod of the progestin etonogestrel, which is a metabolite of desogestrel. Uniplant contains norgestrel acetate, which is a 19-nor-progesterone derivative. Nestorone is a potent progestin. Capronor contains levonorgestrel and Anuelle contains norethindrone (Meckstroth & Darney, 2000).

Mechanism of Action

Pregnancy is prevented in several ways. Inhibition of ovulation is one mechanism of action but not the primary one. Some women continue to ovulate infrequently. Changes in the cervical mucus and endometrium is the primary mechanism of action.

Efficacy

Several factors that affect the efficacy of this method include progestin concentration, the woman's weight, and her age. Another factor in effectiveness is the period of time that has passed since insertion. Implantable devices are thought to be more effective initially when inserted in the first 5 to 7 days of the menstrual cycle. A backup method is used for 1 week after insertion.

Benefits and Risks

A benefit of this type of contraceptive method is that once implanted, the woman has long-term contraception. Norplant is effective for 5 to 7 years' use, although it has been approved for 5 years' use. Norplant II/Jadelle has been approved for 3 to 5 years' use before replacement is re-

Box 14-4 Relative Contraindications to the Use of Implantable Contraceptives

1. Heavy cigarette smoking in women over 35 years of age (15 or more cigarettes daily).
2. History of ectopic pregnancy.
3. Diabetes mellitus.
4. Hypercholesterolemia.
5. Severe acne.
6. Hypertension.
7. History of cardiovascular disease.
8. Gallbladder disease.
9. Severe vascular or migraine headaches.
10. Severe depression.
11. Chronic disease that affects the immune system.
12. Concomitant use of certain medications such as phenobarbital, phenytoin, carbamazepine, and rifampin.

Adapted from Speroff L. & Darney P. D. (2001). *A clinical guide to contraception*. Baltimore, MD: William & Wilkins.

quired. Implanon has been approved for 3 years' use before replacement is required. Uniplant has been approved for 1 year of use; Nestorone has been approved for 2 years' use; Capronor is approved for 1 year of use; and Anuelle is approved for 2 years' use.

Implants require a minor surgical procedure for insertion and removal. Removal sometimes can be complicated by broken or deeply placed implants or bleeding. Scar tissue around the implants may also contribute to difficulty in removal.

Indications

Implantable devices are designed to be used only for contraception.

Contraindications

Absolute contraindications for this type of product include active thrombophlebitis or thromboembolic disease, undiagnosed genital bleeding, acute liver disease, benign or malignant liver tumors, and known or suspected breast cancer. Refer to Box 14-4 for additional contraindications.

Side Effects

These implants are thought to have little metabolic effect. Menstrual changes occur in about 75% of users (Meckstroth & Darney, 2000). Alterations in the pattern of men-

strual bleeding may occur. In the first 3 months of use, menses are likely to be prolonged, with spotting between menses. Other side effects that occur less frequently include headaches, weight change, acne, ovarian cysts, and mood changes.

Some women have a local foreign body reaction producing inflammation and occasionally infection of the insertion site. There are no data suggesting the products used in implants can potentiate autoimmune disease (Meckstroth & Darney, 2000).

Injectable Methods

Two types of injectable contraceptives currently are available in the United States. Depo-Provera (depot medroxyprogesterone acetate, or DMPA) is a progestin-only formulation administered intramuscularly (IM) every 3 months (Figure 14-12). Lunelle is a combination of medroxyprogesterone and estradiol cypionate (MPA/E2C). This combination injection is designed to be given IM monthly.

Mechanism of Action

Depot medroxyprogesterone acts by inhibiting ovulation. The 150-mg dose inhibits ovulation for 3 months. The mechanism of action for Lunelle also is through inhibition of ovulation, and a dose of 0.5 mL provides contraception for 1 month.

Benefits and Risks

Depot medroxyprogesterone allows for 3 months' contraception without any effort on the part of the woman. DMPA is effective and well tolerated by most women and is safe for use by women who are lactating.

Figure 14-12 Injectable contraceptive.

If subsequent DMPA injections do not occur within 14 weeks, there is real potential for method failure and an unplanned pregnancy. Clients should be instructed to come in for re-injection immediately at 12 weeks to avoid an unplanned pregnancy.

Lunelle has a very high efficacy. Its failure rate is estimated at 0.1 per 100 women-years (Kaunitz, 2000). Return to fertility is rapid after discontinuance of the injection.

In contrast with DMPA, Lunelle must be administered monthly. This regimen requires more frequent reproductive decision-making. The safety and adverse event profile are similar to that of combined oral contraceptives.

Indications

Depot medroxyprogesterone and Lunelle are used for contraception.

Contraindications

Contraindications for DMPA include known or suspected pregnancy, undiagnosed vaginal bleeding, active thrombophlebitis, history of thromboembolic disorder, current or past history of cerebrovascular accident, liver dysfunction, known or suspected malignancy of the breast, and known hypersensitivity to DMPA.

Contraindications for Lunelle include known or suspected pregnancy, undiagnosed vaginal bleeding, thrombophlebitis or a history of thrombophlebitis or thromboembolic disease, cerebrovascular disease, coronary artery disease, cholestatic jaundice, and carcinoma of the endometrium. Known hypersensitivity to the medication also is an absolute contraindication.

Side Effects

The side effects of DMPA can include menstrual, weight, and mood changes. Menstrual changes are very common in women who use DMPA. In the first 3 months of use, heavy and irregular bleeding is most common. After 3 months, amenorrhea becomes more common. Menstrual

TIMING OF INJECTABLE CONTRACEPTION

It is best to administer either injectable product, DMPA or Lunelle, within the first 5 days of the menstrual cycle to ensure that the woman is not pregnant and allow time to prevent ovulation.

Research Highlight

DMPA and Weight Changes

Purpose

To determine the effects of DMPA on weight.

Method

This observational study was undertaken in Thailand, where DMPA is a prevalent means of contraception. Two groups of women, with 50 women receiving depot medroxyprogesterone (DMPA) and 50 women receiving intrauterine devices, were compared on age, parity, income, body weight, and blood pressure at the onset of contraception and at 120 months.

Findings

The mean body weight at 120 months for the group receiving DMPA was 60.5 kg \pm 7.5 kg; the mean body weight for the group receiving the IUD was 62.1 kg \pm 9.3 kg. No statistically significant difference was seen in the two groups based on body weight or blood pressure.

Nursing Implications

Nurses are in the position to answer client's questions about weight gain with various contraceptives. Despite anecdotal information, research has not been able to validate significant weight gain with DMPA (Depo-Provera).

Taneepanichskul, S., Reinprayoon, D., & Jaisamrarn, U. (1999). Effects of DMPA on weight and blood pressure in long-term acceptors. *Contraception*, 59, (3), 301–303.

disturbances are likely to be the reason women discontinue this form of contraception.

Weight gain is a problem encountered by many women and is a factor involved in discontinuance of contraception. Some women who use DMPA complain of weight gain. This weight gain however has not been validated by controlled studies.

The overall incidence of depression in women who use DMPA is low but does exist. Women who use Lunelle are less likely to experience menstrual changes. They may experience weight gain similar to that with DMPA. There are no reports of mood change with Lunelle. There have been reports of decreased libido with both products.

Natural Family Planning Methods

Two methods are available as natural family planning devices. Coitus interruptus is primarily controlled by the man, and ovulation prediction is primarily controlled by the woman.

Composition

Coitus interruptus involves removal of the male penis from the vagina before ejaculation. It is probably one of the least effective methods of contraception, with a failure rate of 19% (Hatcher et al., 1998). This method however is much preferable to using no contraceptive method with a failure rate of 85%.

Ovulation prediction, also known as the rhythm method, is the female natural family planning method. The woman predicts her fertile period through the use of basal body temperature charts, cervical mucus changes, or both. She abstains from intercourse for the period of time during which she is fertile. When timing intercourse, the woman must determine the day on which she ovulates and take into account that the male sperm is active for 48 hours and the ovum is susceptible to fertilization for 24 hours.

Mechanism of Action

Both of these methods, in fact, are barrier devices because they place time or distance between the sperm and ovum to prevent conception.

Benefits and Risks

These methods are inexpensive and, when used properly, can be effective. Caution must be used with coitus interruptus because seminal fluid may escape before ejaculation and before removal of the penis from the vagina. The result can be an unwanted pregnancy.

With ovulation prediction methods, it is not safe to assume that because ovulation occurred on day 14 of one cycle that it will do so each month. Ovulation at another time can result in an unplanned pregnancy.

Indications

Natural family planning methods are for those persons who do not believe in or cannot use other methods. These methods are vastly more reliable than intercourse without the use of any method.

Contraindications

There are no known contraindications to natural family planning.

Emergency Contraception

Emergency contraception is available to prevent unintended pregnancy. This type of contraception has been available in the United States for approximately 20 years but it is not widely used or known by women. In the United Kingdom, however, the method has been used over 4 million times with few reported side effects (Grow & Ahmed, 2000).

Several types of postcoital contraception are available. Hormonal methods include administration of the COC, progestins, gonadotropin-releasing hormone (Gn-RH) agonists, antiprogestins, and high-dose estrogen Gn-RH agonists. The copper IUD also may be used for these purposes. Surgical abortion is also an option.

Combined Oral Contraceptives

In 1974, Yuzpe published the first results of successfully using 100 µg of ethinyl estradiol and 1 mg/dL norgestrel in combination as a single dose for emergency contraception. The current standard is to give the equivalent of 100 µg of ethinyl estradiol and 1 mg of levonorgestrel in combination for this purpose (Hatcher et al, 1998). The medication must be initiated within 72 hours of unprotected intercourse, and a second dose of the medication is given 12 hours after the initial dose. Table 14-3 summarizes some of the protocols used in contemporary health care.

Mechanism of Action

If COCs are administered before ovulation, ovulation may be delayed or suppressed for that menstrual cycle. The suppression is through action on the anterior pituitary. If administered after ovulation, the action is thought to be

Table 14-3 Emergency Contraception with Combined Oral Contraceptives

Trade Name	Dosage
Ovral	2 pills immediately and 2 pills in 12 hours
Lo/Ovral	4 pills immediately and 4 pills in 12 hours
Nordette	4 orange pills immediately and 4 orange pills in 12 hours
Levlen	4 orange pills immediately and 4 orange pills in 12 hours
Alesse	5 pink pills immediately and 5 pink pills in 4 hours
Tri-Levlen	4 yellow pills immediately and 4 yellow pills in 4 hours
Triphasil	4 yellow pills immediately and 4 yellow pills in 4 hours
Prevens	2 pills immediately and 2 pills in 12 hours

Adapted from Hatcher et al., 1998.

through suppression of endometrial hormone receptors, possibly leading to inadequate maturation of the endometrium and thus preventing implantation (La Valleur, 2000).

Efficacy

After treatment, the pregnancy rate ranges from 0.5% to 2.5%. The variation has to do with when in the menstrual cycle the woman had unprotected sex, how soon she received treatment, and whether the woman develops side effects such as vomiting.

Benefits and Risks

Emergency contraception with COCs offers women a chance to prevent an unwanted pregnancy for a number of reasons. There are no noncontraceptive benefits to be had because of the short-term nature of this regimen.

Risks with this method include failure of the method to prevent pregnancy. Failure will result in the woman having to decide whether to seek pregnancy termination or continue the pregnancy.

Indications

Postcoital contraception is designed as a secondary method of contraception, not as a first choice. Women who repeatedly find themselves in need of this type of contraception are not being proactive in their reproductive decision-making and require counseling.

Contraindications

The only absolute contraindication to emergency contraception with COCs is pregnancy. Use of progestin-only

emergency contraception may be best for the woman with a history of thromboembolism.

Side Effects

The major side effects of emergency contraception using COCs are nausea and vomiting. Providing an anti-nauseant medication before taking the COCs can reduce this side effect. There may be an increased incidence of ectopic pregnancy if conception does occur. There may be menstrual disturbance even in the absence of pregnancy because of the high doses of hormones involved in emergency contraception regimens. Other side effects can include headache, fatigue, and mood swings (La Valleur, 2000).

Progestin-Only Pills

Levonorgestrel has been used in Europe and China for emergency contraception. It is given in a dose of 0.75 mg within 72 hours of unprotected intercourse, and the dose is repeated in 12 hours (La Valleur, 2000). Hatcher et al. (1998) determined that this dose could be obtained by taking 20 yellow tablets of Ovrette immediately and 20 additional tablets in 12 hours. Currently, one 0.75-mg formulation is available that is marketed solely for emergency contraception. The trade name is Plan B. Each of these packets contains two levonorgestrel tablets. One tablet is for immediate use, and the other is for use in 12 hours. This medication must be used within 72 hours of unprotected intercourse (Speroff, 2000).

Antiprogestins

Mifepristone (RU 486) is a synthetic steroid that prevents progesterone from binding to its receptors. Mifepristone has been used extensively in Europe as an abortifacient and as an emergency contraceptive method (Thomas, 2001).

Benefits and Risks

A benefit of this type of emergency contraception is that it is a medical rather than a surgical approach to pregnancy termination. This method is less invasive and has fewer complications than does surgery. Pills are easier to obtain than is a surgical procedure and are very effective. Despite the many benefits, this drug has been very controversial in this country because of questions about when life begins.

Indications

Mifepristone has been investigated for use as an abortifacient and as an emergency contraceptive method. Mifepristone is more effective the earlier in the pregnancy it is used (Cates & Ellertson, 1998).

Contraindications

Contraindications to administering this drug are known or suspected pregnancy unless there is commitment to preg-

nancy termination. Mifepristone also is not used with known or suspected ectopic pregnancy or if there is an undiagnosed adnexal mass. Mifepristone should not be used in clients who have adrenal failure and clients who use long-term steroid therapy. It should not be used in clients who have hemorrhagic disorders or who are using anticoagulants. Clients who have an allergy to the product should not use it.

Side Effects

The major side effects are cramping and vaginal bleeding. Cramping usually can be managed with Tylenol with codeine. Aspirin and ibuprofen are avoided because they are antiprostaglandins and would tend to negate the actions of mifepristone. Bleeding usually is mild but occasionally can be heavy, depending on the age of gestation. When heavy bleeding is a problem, dilatation and curettage may be required.

Intrauterine Devices

Intrauterine devices can be used for emergency contraception. The device should be inserted within 5 to 10 days after unprotected intercourse. In addition to the usual mechanism of action, an IUD inserted for emergency contraception acts as a toxin to the blastocyst (La Valleur, 2000). The IUD is extremely effective as an emergency contraceptive in selected clients.

Surgical Methods

Abortion can be a medical or a surgical procedure. Discussion about the medical method is in the emergency contraception section of this chapter. The purpose of abortion is to terminate a pregnancy. It is not designed to be used as a primary method of contraception but is more appropriate as a backup method in case of failure of the primary method.

Although this surgical procedure has been legally available in the United States since 1973, abortion is still very controversial. Many Americans do not approve of pregnancy termination in any form. The result of this division of thought has been observable in numerous attempts to reverse legalization of abortion. Zealots have tried to prevent women from entering clinics where abortions are performed, picketed clinics, and even have bombed abortion clinics.

Several methods are used for abortion. The choice of methods depends on factors such as the gestational age of the pregnancy. Vacuum extraction can be used only early in the pregnancy. Dilatation and evacuation have been used to abort pregnancies that have progressed beyond the time at which vacuum extraction or aspiration is possible.

Permanent Methods

Sterilization refers to the use of a surgical procedure to produce permanent loss of reproductive capability. Surgical sterilization has become very common for married couples who have decided to permanently limit the size of their family. More women have surgical sterilization than do men.

Female Methods

Worldwide more than 190 million couples use sterilization as their contraceptive method (Pati & Cullins, 2000). Sterilization is the most prevalent method used by married couples in the United States and is used by 39% of couples. Female tubal sterilization, also called **tubal ligation**, accounts for 72% of the sterilization procedures performed in the United States. Female sterilization can be done by tubal ligation or hysterectomy. Hysterectomy usually is used when a gynecologic problem exists at the same time the woman wants permanent sterilization. When a woman has no gynecologic problem, tubal ligation can be performed immediately after delivery by minilaparotomy. A small abdominal incision is made through which the fallopian tubes are grasped and a segment of each is removed. Tubal ligation at any other time usually is a laparoscopic procedure in which a small periumbilical incision and a small lower quadrant incision are made. The tubes may be cauterized, or a clip may be placed on the tube to allow for later removal (Figure 14-13). The woman considering tubal ligation should know that it is a permanent sterilization method. Reversal of this procedure has been done; however, such attempts are not always successful and can be expensive.

Some health care providers believe the appropriate time for a woman to have a tubal ligation is early in the

menstrual cycle so there is no possibility for pregnancy. Many times the woman is using birth control pills as a method of contraception, which lessens the importance of when the procedure is done because the woman is not ovulating. If the woman is taking birth control pills, the remainder of the cycle of pills should be taken after the procedure to prevent hormonal problems associated with stopping the pills before the cycle is completed.

Benefits and Risks

Tubal ligation is effective immediately and is considered permanent. These are two very great benefits for women and couples who have finished childbearing. There are no devices to use or details to remember. Laparoscopic tubal ligation can be performed easily on an outpatient basis. It is quite common for a woman to have the surgery on Friday and return to work on Monday.

Although the tubal procedure is considered permanent, there is a small failure rate. Occasionally, the tube will reopen. When this occurs, an unwanted pregnancy may result. In this case, some women have had the procedure a second time. Others decide they want their partner to undergo the next procedure.

Indications

Permanent female sterilization should be reserved for those women who have completed their family. A common discussion with these women includes directions by the health care provider for the woman to consider what her thoughts would be if something would happen to her existing family. If the woman thinks she might want to have more children under those circumstances, she may be encouraged to use a different method of birth control.

Contraindications

Contraindications for this method include women whose health condition is not good enough to withstand the procedure. This contraindication is uncommon.

Adverse Effects

Tubal ligation is a common procedure but is not without complications. The woman has a risk of death from anesthesia or infection. The mortality rate of tubal ligation has been reported to be 1 to 2 deaths per 100,000 procedures. This mortality rate compares favorably with that of hysterectomy, which is 5 to 25 deaths per 100,000 procedures, and childbirth, which is 8 deaths per 100,000 live births in the United States (Pati & Cullins, 2000). Other potential injuries include hemorrhage and damage to the bladder or bowel. Another long-term potential adverse effect is that the woman may regret having had the procedure. The final adverse effect would be failure of the procedure to provide contraception.

Figure 14-13 Tubal ligation.

Male Methods

The male sterilization procedure is called vasectomy. The vas deferens transport sperm from the epididymis to the seminal vesicle for mixture with other seminal fluids before ejaculation. **Vasectomy** ligates the vas deferens, thus interrupting sperm transport (Figure 14-14). The procedure can be done in an outpatient setting under local anesthesia.

As is sterilization in women, vasectomy is considered permanent. Reversal of the procedure has been done but is not always successful. Postoperative follow-up is important in vasectomy because the sperm count does not immediately decrease to zero. Vasectomy is not considered effective until the man has two negative sperm counts.

NURSING IMPLICATIONS

Nurses often are in a position to teach about contraception and counsel women who are undecided about the method

Figure 14-14 Vasectomy.

Web Activities

1. Go to the NARAL homepage at www.naral.com. What are the issues of interest to this group?
2. Go to nlrc.org. What is the agenda for this group?

of contraception they want to use. The nurse must stay informed about the new technologies that are being developed because many times these methods may be preferable for the woman for a number of reasons.

Advanced practice nurses in many settings are able to prescribe contraceptive devices. It becomes even more important for this group of nurses to be informed about currently available contraceptive devices and methods.

Key Concepts

- To use a contraceptive effectively requires the use of a rational decision-making process.
- To use the least effective contraceptive method will prevent unwanted pregnancy significantly better than will unprotected intercourse.
- Complex factors influence a couple's choice and use of contraception.
- To assist couples in family planning, the nurse must realize the couple may have a very different value system from that of the nurse. The nurse will need to understand the client's perspective to be helpful.

Review Questions and Activities

1. What is the difference in the mechanism of action between combined oral contraceptives and the minipill?
2. Which factors are involved in the reproductive decision-making process?
3. What is the major limitation of the combined oral contraceptive?
4. What are the absolute and relative contraindications of COCs?

5. What is the difference between monophasic, biphasic, and triphasic birth control pills?
6. What time limitations are involved with emergency contraception?
7. What are the reasons the IUD is not used more widely?

UNIT IV

Pregnancy

Normal Pregnancy

*F*or a woman, pregnancy is a time of great change and adaptation. Many times, women proceed through the process unaware of the total picture. Nurses can play a vital role in helping a woman achieve a healthy, successful pregnancy by supporting, nurturing, educating, and caring for the pregnant woman and her family. Small gestures, such as always remembering her name, inquiring about family happenings, and being supportive and nonjudgmental, aid the nurse in rendering accurate, effective, and sensitive care. To be a nurse and provide care to a woman during this special life transition and to provide that care with compassion and respect is a great privilege.

Key Terms

Amenorrhea
Ballottement

Couvade
Goodell's sign
Hegar's sign

Hyperemesis gravidarum
Linea nigra
Physiologic anemia of pregnancy

Quickening
Striae gravidarum
Supine hypotension

Competencies

Upon completion of this chapter, the reader should be able to:

1. List the presumptive, probable, and positive signs of pregnancy.
2. Describe the anatomic and physiologic adaptations to pregnancy.
3. Explain how the anatomic and physiologic adaptations to pregnancy relate to the common discomforts of pregnancy.
4. Outline self-help tips to assist the client in relieving the discomforts of pregnancy.
5. Describe methods of teaching health topics to the pregnant woman.
6. List the developmental tasks that successfully integrate the motherhood role into the woman's personality.
7. Explain how understanding a client's culture can affect her plan of care.

Pregnancy is a time of enormous change in a woman's body and mind. These changes affect her physical well-being, self-esteem, interactions with others, daily activities, and future plans. She looks for answers to questions that arise during her pregnancy from many different sources. The nurse's role is uniquely suited to forming a professional bond with the pregnant client and to offering impartial and accurate information that will guide her 9-month journey.

The nurse-client relationship can serve as a "safe haven" for the pregnant woman to ask questions and discuss concerns. Initially, the questions are related to how the pregnancy and birth of the newborn will affect her activities of daily living, her relationship with others, and her interaction with her health care providers. The information may not always be sought by direct questions; therefore, the nurse must be skilled in interviewing and physical assessment techniques with which to meet the woman's needs.

A woman's body changes dramatically to maintain a viable pregnancy. The knowledge and understanding of how these changes occur gives the nurse the ability to assess, make diagnoses, plan, intervene, and evaluate to ensure that the expected outcomes are achieved.

SIGNS OF PREGNANCY

There are many signs of pregnancy. Some signs are suggestive of pregnancy and are referred to as *presumptive*

(subjective) signs; these signs could be caused by other conditions, so they do not establish a diagnosis of pregnancy. *Probable* (objective) signs of pregnancy can be documented by physical examination and are signs that are most often only characteristic of pregnancy; these findings could also be caused by other conditions, however, and therefore do not establish a diagnosis of pregnancy. Only three physical findings can establish a diagnosis of pregnancy; these are referred to as *positive* signs. In today's fast-paced world, women are more likely to use an over-the-counter home pregnancy test at the first hint of pregnancy and later seek final confirmation from their healthcare provider.

Presumptive Signs

Amenorrhea, absence of menses for 3 or more months, is usually the first sign to alert a woman to a possible pregnancy. Other factors, such as excessive exercise, emotional stress, chronic disease states, the onset of menopause, and the use of oral contraceptives, can stop regular periods. The cause of amenorrhea should be assessed and validated.

Nausea and vomiting is another subjective sign that can appear after the first missed period and continue into the fourth month of pregnancy. Women most often report feeling sick in the morning, hence the phrase "morning sickness," but nausea and vomiting may occur at any time of the day. The cause is not clear; it may be the increased

levels of hormones. Many women report that emotional factors, noxious smells, irregular eating schedules, and fatigue contribute.

The fatigue of pregnancy is an overwhelming need for rest and sleep and is distressing. The client may voice concerns that she is more tired or drowsy after a normal day during pregnancy than she was after a normal day before she became pregnant.

In the first few weeks of pregnancy, the pressure exerted on the bladder by the enlarging uterus causes urinary frequency. In the second trimester, the uterus grows into the abdomen, somewhat relieving the pressure. Late in pregnancy, as the fetus grows and descends into the pelvis, urinary frequency returns. Do not assume urinary frequency is caused by the changes of pregnancy; assess for signs of infection.

Changes in the breasts are another presumptive sign of pregnancy. Increased amounts of estrogen and progesterone cause the breasts to swell and become tender. The initial changes in the breasts are similar to the changes that occur in the menstrual cycle. As the pregnancy progresses, the tenderness subsides, but growth of breast tissue continues.

A woman's first awareness of fetal movement is called **quickenings**. The movement is usually described as a fluttery feeling, similar to being excited and having "butterflies." Quickening is initially felt between 18 and 20 weeks of gestation, but may be felt by the multigravida as early as 16 weeks. The documented date of the first fetal movement can be used in conjunction with other data in determining the expected date of delivery.

Probable Signs

At 8 to 10 weeks' gestation the bimanual pelvic examination will document an enlarged and softened uterine body. Uterine enlargement is more definitive if the growth is progressive. The fundus should be just above the symphysis pubis at 10 to 12 weeks and at the umbilicus at 20 weeks. Abdominal enlargement mirrors the uterine growth and is especially evident earlier in the pregnancy of the multigravida. A woman may hear comments from well-meaning friends and family about the way she is carrying the baby. The nurse can alleviate her concerns by telling the client about the individuality of each pregnancy.

There are other changes that may be noted on physical examination. Softening of the cervix is called **Goodell's sign**; normally the cervix is firm. The color change from pink to bluish-purple in the mucous membranes of the cervix, vagina, and vulva is identified as **Chadwick's sign**. The increased vascularization in this area causes the color change and is attributed to the increase in the estrogen hormone. **Hegar's sign**, usually evident at 6 to 8

Figure 15-1 Ballottement.

weeks' gestation, is the softening of the isthmus of the uterus, often referred to as the lower uterine segment.

During the fourth or fifth month, if the fetus is pushed upward through the vagina or abdomen, the floating fetus rebounds against the examiner's fingers; this is known as **ballottement** (Figure 15-1). This occurs only while the fetus is small in comparison to the amount of amniotic fluid.

Today, pregnancy tests are available in inexpensive commercial kits that can be done quickly. Tests that are performed by trained personnel are highly accurate and, with correct technique, precise. Most pregnancy tests work on the same premise: they identify human chorionic gonadotropin (hCG) hormone, or a subunit, by detecting an antibody to the hCG molecule in urine or serum. Commercial laboratory tests that measure hCG in the urine are accurate close to 100% of the time and can detect a pregnancy as early as 10 days after conception. The hormone hCG can be detected in maternal blood at 7 days after conception with sensitive assays; the exact level of hCG can assist in dating the pregnancy. Most sensitive commercial test kits can detect a pregnancy with precision after the first missed period.

Home pregnancy test kits are readily available and relatively inexpensive. Similar to the urine test done in the physician's office or laboratory, the test is sensitive for the presence of hCG in urine. Although the tests have become simpler to use, the number-one concern is operator error. A false-negative result can mislead the woman, who may ignore the presumptive signs of pregnancy and cause a delay in seeking prenatal care. A positive test result may cause a delay in seeking follow-up care, because many women feel the first visit to a practitioner is only for diagnosis of pregnancy. Preconception counseling is crucial

for educating women on caring for their body before pregnancy. At that time, it is beneficial to share information on the appropriate management of pregnancy diagnosis and the initiation of prenatal care.

Positive Signs

Positive signs (noted by the examiner) that confirm the pregnancy are fetal heart sounds and fetal movement and visualization of the fetus during ultrasound.

The fetal heartbeat can be auscultated with a fetoscope at 18–20 weeks. The heartbeat can be detected at 10–12 weeks with an electronic doppler. Normal fetal heart rate is 120 to 160 beats/min.

The earlier the fetal heart beat is detected, the more likely it may be confused with other sounds that can be detected in pregnancy. The uterine souffle is the sound made by the increased amount of blood perfusing the uterus and mimics the maternal pulse. The sound heard as the blood flows through the umbilical cord is called the funic souffle.

Fetal movement detected by a qualified examiner is another sign that is diagnostic of pregnancy. At 18 to 20 weeks' gestation, the movement is felt as a faint fluttering and progresses to rolling and kicking in the late second and third trimester. The movement in later gestation can often be seen on visual inspection of the abdomen.

The use of ultrasound is very common in today's obstetric practice. The ultrasound examination is accomplished by placing a transducer on the abdomen above the symphysis pubis (Figure 15-2). A normal pregnancy can be detected at as early as 4 weeks' gestation, using the last menstrual period for dating. Thus, confirmation of the pregnancy is possible before some common tests for hCG in the urine show positive results. The fetal brain and heartbeat can be visualized by 8 weeks' gestation.

ACCURATE DETECTION OF THE FETAL HEART RATE

To ensure an accurate diagnosis of the fetal heart beat, it must be distinguished from the maternal pulse. To do this, the fetal heartbeat should be auscultated, while simultaneously assessing the maternal radial pulse.

The use of a transvaginal transducer placed into the vagina is helpful when using ultrasound to confirm a pregnancy or seek pathology in the obese woman or to detect a pregnancy in a complicated case. The fetal heart rate can be detected via transvaginal ultrasound as early as 4 weeks after conception. A transvaginal ultrasound examination produces better visualization than abdominal ultrasound, and cannot only detect an early pregnancy but also extrauterine structures, such as an ectopic pregnancy or ovarian mass (Gabbe, Niebyl, & Simpson, 1996).

EXPECTED DATE OF DELIVERY

The mean duration of pregnancy can differ between groups of women by ethnicity, geographical location, or age, but the most common period used as the mean is 280 days, or 40 weeks from the first day of the last period. Nägele's rule is the most commonly used calculation for date of expected delivery. To calculate the gestational or menstrual age, add 7 days to the date of the first day of

EXAMPLE OF NÄGELE'S RULE

First day of last period was January 12, 2001.
 Calculate: $1/12/2001 + 7 \text{ days} = 1/19/2001$
 Count back 3 months to October. The expected delivery date is 10/19/2002.

the last normal menstrual period and count back 3 months.

This date is an estimated date of delivery and it can be inaccurate by 2 weeks. Because gestation, measured in weeks, is so important for the management of the pregnancy, other clinical indicators should be monitored. During the first physical examination, the size of the uterus can be determined; the fetal heart rate can be heard at 10 to 12 weeks by electronic Doppler ultrasound; the first fetal movement can be felt at about 20 weeks; and the measurement of fundal (top of the uterus) height with each prenatal visit can track gestational age (Figure 15-3). If the results of the physical examination do not correspond with the estimated weeks of pregnancy, as determined by calculating the delivery date, an ultrasound examination may be performed between 12 and 18 weeks to obtain fetal measurements that result in a more accurate delivery date.

Figure 15-3 Approximate height of the fundus as the uterus enlarges.

PHYSIOLOGIC ADAPTATION TO PREGNANCY

Many physiologic changes take place in a woman's body when she is pregnant. The nurse and client must be able to distinguish between those changes that are normal adaptations and responses to the pregnant state and those changes that are outside the realm of normal and require intervention.

Reproductive System

Each organ of the reproductive system undergoes dramatic changes during pregnancy.

Uterus

Although every system in a woman's body changes to adapt to the growing fetus, the uterus undergoes the most dramatic transformation (Figure 15-4). Beginning as an almost solid organ the size of a human fist, the uterus enlarges to a thin-walled, hollow organ that can hold a volume of 15 to 20 liters. The initial changes in the structure of the uterus are caused by hypertrophy, the enlargement of existing myometrial cells, with only a small percentage of the growth attributed to hyperplasia, the increase in the number of myometrial cells. The increased production of estrogen and progesterone is thought to initiate the process of uterine growth, but the exact trigger mechanism is unclear. This hypothesis is based on the observation that uterine hypertrophy occurs even if the

Figure 15-4 The configuration of muscle layers allows the uterus to expand evenly in all directions during pregnancy.

embryo has implanted outside the uterus (Blackburn and Loper, 1992).

It is not until the twelfth week of gestation, when the fetus reaches a crown-to-rump length of 8 to 9 centimeters, that the growth of the uterus can be attributed to mechanical distention. The increase in intrauterine pressure results from the growing fetus, placenta, and increase in volume of amniotic fluid. Growth of the uterus is not symmetrical and occurs predominantly in the fundus. The walls of the uterus become thin but are strengthened by the accumulation of fibrous tissue in the muscle layers and an increase in elastic tissue. At twelve weeks, the fundus rises above the symphysis and begins to displace the intestines. It will continue to grow upward and slightly rotate to the right. When the pregnant woman is upright, the broad and round ligaments anchor the gravid uterus and the anterior abdominal wall provides support. The weight of the uterus may produce tension on these ligaments that causes inflammation and discomfort. In the supine position, the uterus of the pregnant woman falls backward and puts pressure on the vertebral column and the great blood vessels.

Uteroplacental Blood Flow

Although not visibly evident to the pregnant woman, the changes that begin at conception progress rapidly. The placenta is mature at 8 to 10 weeks and remains larger than the fetus until 15 to 16 weeks. To achieve adequate exchange of nutrients and waste, there is an increase in the supply of blood to the uteroplacental unit. The body is able to accommodate the necessary volume by increasing the number and diameter of the vessels feeding the uterus. The proportion of the blood volume needed to perfuse the uterus and intervillous space increases over the weeks of gestation. By term, a total of 20% to 25% of the maternal cardiac output is used to supply the uterus and placenta (Haun, 1991).

Uterine Contractility

The uterus is never quiescent; even in the non-pregnant state the uterus will contract (Blackburn and Loper, 1992). Contractions in the first trimester are undetected by the maternal client, but she can feel contractions late in the second trimester. Normally these early contractions are irregular and painless and are referred to as **Braxton Hicks contractions**. As the pregnancy progresses toward full term, Braxton Hicks contractions can become more regular, occur at more frequent intervals, and cause discomfort. The client may make several visits to her practitioner or to the hospital only to be told that she is in “false labor.” At this point, the woman may become embarrassed and doubt her ability to recognize the symptoms of true labor. One component of prenatal education is to communicate

Client Education

True v. False Labor

The following are symptoms of true labor which help to differentiate from symptoms of false labor

- Pain begins in the lower back and moves forward across the lower abdomen.
- Contractions intensify and do not ease, despite the level of the client's activity.
- Contractions most often become progressively more frequent, regular, and painful.
- To check for contractions, place your hand on the fundus or top of the uterus; during the peak of the contraction the degree of firmness should be similar to the firmness felt when touching your forehead.
- Bloody show from the vagina is present and is pinkish or blood-streaked.
- If the membranes rupture, the fluid may either leak or gush from the vagina (about 15% of time the membranes rupture before labor begins).

If there are any questions, contact a healthcare practitioner.

to the client the symptoms of preterm and term labor and the importance of notifying her health practitioner if she has any questions.

Cervix

Although the cervix does not undergo the same dramatic changes as the uterus, it plays an instrumental role in the maintenance of the pregnancy and the delivery of the infant. In the prepregnant state, the cervix is firm and feels similar to the top of the ear. As early as 4 weeks after conception, biochemical changes occur and cause the connective tissue of the cervix to become swollen with water (edematous) and congested with blood (hyperemic). These changes, in conjunction with the hypertrophy and hyperplasia of the cervical glands, demonstrate the characteristic cervical softening of Goodell's sign and cervical cyanosis of Chadwick's sign. At this time, a digital examination of the cervix demonstrates a softened consistency, similar to the feel of the ear lobe.

The changes that occur in the cervix demonstrate the amazing adaptability of the body. The cervix provides sup-

port to maintain an intact pregnancy and, as delivery approaches, it softens and opens to allow delivery of the infant.

A mucus plug forms within the cervix and serves to protect the fetus and the membranes from bacteria that may ascend through the vagina during pregnancy. As labor becomes imminent, the mucus plug is expelled (sometimes over a period of time) as the cervix begins to dilate. As the cervix dilates, small arteries may burst and the blood mixes with the normal mucus, producing what is known as bloody show.

Vagina, Perineum, and Vulva

In preparation for the delivery of the neonate, there is increased vascularization, softening of the connective tissue and hypertrophy of the smooth muscle in the vagina, perineum, and vulva. The vagina turns the characteristic purplish color of Chadwick's sign and vaginal secretions increase as a result of increased vascular engorgement. The walls of the vagina must expand without trauma during the delivery, therefore the mucosa thicken and the rugae (vaginal folds) become pronounced. Upon vaginal examination, the caregiver may note that the rugae that line the lower portion of the anterior wall of the vagina are so enlarged that they protrude through the vulva.

As the physiologic changes progress, the cells of the vagina contain increasing amounts of glycogen. The cells slough off the walls of the vagina and contribute to the increase in discharge. The *Lactobacillus acidophilus* found in normal vaginal secretions breaks down the glycogen into lactic acid (Cunningham, MacDonald, Gant, et al., 1997). The environment of the vagina is acidic and prevents the growth of many bacterial infections. If the client complains of increased vaginal discharge, the amount, color, consistency, and odor of discharge must be assessed so that an appropriate diagnosis can be made. One of the most frequent infections in pregnancy is a vaginal yeast infection (candidiasis), which grows readily in the normal acidic discharge.

Ovaries

Once conception has occurred, the production and release of follicles from the ovaries ceases. The corpus luteum is formed within the ovary and secretes progesterone, with production peaking at 8 days. Progesterone is necessary for the maintenance of the pregnancy, so that if implantation occurs, the trophoblast secretes hCG to stimulate the corpus luteum to continue with the production of progesterone (Tucker and Loper, 1992). The placenta begins manufacturing progesterone at 6–7 weeks gestation. At this time the placenta assumes this function and the involution of the corpus luteum begins.

Breasts

The changes in the physical characteristics of the breasts are caused by the increased production of estrogen and progesterone. Early in pregnancy, the breasts become full and tender. In preparation for feeding the infant, the number of mammary alveoli increase and the breasts become physically larger. As the breasts enlarge, a web of veins may become visible under the skin. The pregnant woman may question the slightly reddened or darkened, depressed streaks that appear on the skin of the breasts. These striations (stretch marks) occur most often on breasts that enlarge significantly. The striae eventually fade to a soft silver color, but do not disappear completely. The areolae broaden and become darker in color as a result of increased pigmentation. The tubercles of Montgomery are sebaceous glands located on the areolae that become more visible through hypertrophic changes. In preparation for lactation, the glands secrete a substance that helps maintain the suppleness of the areolae. Increased sensitivity of the now larger and more erect nipple contributes to the later establishment of lactation. The pregnant woman may notice leaking of colostrum, a protein-rich yellowish fluid, from her breasts after the first few months of pregnancy.

Women with small breasts may welcome the increase in size, but women with large breasts may find it difficult to tolerate. Wearing a properly fitted bra that supports the breasts should be emphasized in early prenatal visits.

Hematologic System

The changes in the hematologic system occur to maintain homeostasis during the pregnancy and the postpartum period. Blood volume increases to nourish the fetus and to protect the mother from excessive blood loss during and after delivery and placental separation. Being aware of these changes and how they affect normal hematologic values helps the nurse in identifying the difference in expected adaptations and pathologic alterations (Table 15-1).

Blood Volume

The blood volume of the pregnant woman is 40% to 50% more than the prepregnant state. Obese women and women who have multiple fetuses or a fetus that is large for gestation age may attain a blood volume that is double their usual blood volume. Progesterone causes the tone of the vasculature to relax and enables the body to accommodate the massive increase in blood volume that is necessary to meet the increased needs of the pregnancy. Hypervolemia of pregnancy is an expected and necessary change and affects the plan of client care.

Table 15-1 Normal Changes in Maternal Laboratory Values

Test	Normal Value	Change during Pregnancy
Hematocrit	37%–47%	Decreased
Hemoglobin level	12–16 g/dL	Decreased
Platelet count	150,000–350,000/mm ³	Increased after delivery
Partial thromboplastin time (PTT)	12–14 sec	Slightly decreased
Leukocyte	6.0(4.5–11) × 10 ³ /mm ³	9.2(6–16) × 10 ³ /mm ³
Fibrinogen level	250 mg/dL	Increased

Burrow & Duffy (1999).

Plasma volume begins to increase at 6 to 8 weeks' gestation, increases rapidly until about 32 to 34 weeks, and then reaches a plateau until term. The increase in the plasma volume is 40% to 45% and measures 1200 to 1600 mL above prepregnant volume. As in most changes that occur during pregnancy, the exact mechanism that triggers this change is not well understood. One influencing factor may be increased hormone production. Another close link may be the changes that take place in the fluid balance in the renal and cardiovascular systems.

Blackburn and Loper (1992) noted that placental mass and birth weight are positively correlated with plasma volume, demonstrating the close relationship of fetal weight to plasma volume. In pathologic states, such as pregnancy-induced hypertension, there is a decrease in plasma volume related to the changes that occur in the vasculature. A common risk factor for the fetus of the woman with pregnancy-induced hypertension is fetal intrauterine growth retardation. The knowledge of this risk factor enables the caregiver to individualize the client's plan of care to obtain the best outcome.

Red Blood Cells

An increase in the number of red blood cells is another significant adaptation to pregnancy. The red blood cell mass increases up to 33% (450 mL) with iron supplementation and increases up to 18% (200 mL) without supplementation (Blackburn and Loper, 1992). The volume increase is progressive without the plateau at term that is observed in the plasma volume.

During the pregnancy, the plasma begins to expand earlier and to a volume three times greater than the red blood cell mass. The disproportion of these volumes causes a dilution of the red blood cell mass, thus lowering the hemoglobin of the pregnant woman and resulting in a phenomenon called **physiologic anemia of pregnancy**. Because this anemia is caused by normal physiologic changes in blood volume during pregnancy, it is not considered a true anemia. The average hemoglobin level of

Critical Thinking

Physiologic Anemia of Pregnancy

Joan is a 16-year-old African American with a pregnancy at 28 weeks' gestation. She is attending high school and plans on living at home when the baby comes. She is feeling more tired than usual. Laboratory samples are drawn and analyzed; her hemoglobin level is 8.5 mg/dL and hematocrit is 30%.

What are the mainstays of Joan's diet? Has iron supplementation been prescribed? Is she taking the supplement? Is Joan well hydrated? What fluids is she drinking?

the pregnant woman at term is 12 mg/dL, with a mean hematocrit of 33.8%. Although the normal hemoglobin level can drop up to 2 mg/dL with the normal dilution of the red blood cell mass, Blackburn and Loper (1992) state that true iron deficiency anemia should always be considered, especially when the hemoglobin level drops to 10.5 mg/dL or less.

Blood Coagulation

Neither bleeding time or clotting time change in the normal pregnant woman, but there is still a popular belief in the hypercoagulability of pregnancy. Gabbe, Niebyl, and Simpson (1996) noted that although there are increases in some of the clotting factors, especially fibrinogen, the hypercoagulability of pregnancy is more likely attributable to the higher incidence of thrombus formation and coagulopathies during pregnancy. When evaluating the pregnant woman, remember that the highest incidence of thromboembolism is in the postpartum period.

Cardiovascular System

To maintain a viable pregnancy, the cardiovascular system undergoes major but reversible changes in cardiac function and hemodynamics. These changes are triggered by the increase in circulating hormones: estrogen, progesterone, and prostaglandin.

Heart

The position of the heart is changed by the inability of the diaphragm to fully expand, increasing intra-abdominal pressure. The heart is pushed upward and to the left and rotated slightly, as shown in Figure 15-5. On radiographic film, the heart may appear enlarged. The position is influenced by other anatomic changes, and the varying degrees of these changes in individual pregnancies make it difficult to diagnose cardiomegaly by X-ray studies alone.

There are no significant changes in the electrocardiogram (ECG) of the pregnant woman. In 90% of pregnant women, a systolic heart murmur can be heard at 20 weeks' gestation and disappears shortly after delivery. Also, in the majority of pregnant women, a third heart sound, or gallop, can be easily detected. Diastolic murmurs are rare in normal pregnant women and the cause of these sounds

should be investigated. A murmur known as the “mammary souffle” can be heard in the left and right side between the first, second, and third intercostal spaces. The increased blood flow to the breasts is believed to be the cause of this continuous murmur.

Cardiac Output

During pregnancy, there is an increase in cardiac output beginning as early as 10 weeks and peaking at 20 to 24 weeks. Cardiac output is calculated by the heart rate times the *stroke volume*, the amount of blood leaving the heart. Early in pregnancy the increase in cardiac output is caused by an increase in the stroke volume, and the heart rate remains at the prepregnant rate. As the pregnancy progresses, the heart rate increases by up to 20 beats/min and the stroke volume declines to prepregnant rates. By means of the increase in the heart rate, the blood volume needed to adequately provide blood flow to the fetus and the maternal vital organs can be maintained. In the nonpregnant woman, average cardiac output is 4.5 L/min with the uterus receiving 2%; at term in the pregnant woman, cardiac output is about 6 L/min with about 20% going to the uterus. The percentage of the cardiac output that is mapped to the other organs remains relatively the same in the nonpregnant and pregnant woman. Because of the overall increase in blood volume, the amount of blood available to most vital organs increases.

Blood Pressure

It would seem logical to assume that the increases in the blood volume and cardiac output of the pregnant woman would lead to elevated blood pressure, but other adaptations take place to prevent this from occurring. Both systolic and diastolic blood pressure actually decrease in the first trimester by 5 to 10 mm Hg and 10 to 15 mm Hg, respectively, and begin to rise at 22 to 24 weeks, returning to normal prepregnant readings at term. The decrease in the blood pressure is probably a result of the effect of increased circulating hormones, which, in turn, decrease the peripheral vascular resistance. This adaptation must be

Figure 15-5 The position of the heart is changed during pregnancy. The solid line demonstrates how the heart is pushed upward and to the left and rotated slightly.

Nursing Tip

ASSESSING BLOOD PRESSURE

Prepregnant blood pressure measurements, instead of first trimester readings, should be used as the baseline when ruling out pregnancy-induced hypertension.

understood when assessing the blood pressure late in the second and into the third trimester.

The ability of the pregnant body to compensate for the increased blood volume results from the increased capacity and compliance of the vascular system. Venous pressure in the upper extremities is unchanged. In the lower extremities, the pressure may gradually increase as the uterus enlarges and begins to exert pressure on the inferior vena cava and pelvic veins. The increase in pressure below the level of the uterus can result in the development of varicose veins in the legs and perineum. When the pregnant woman is in the upright position, the uterus can interfere with the blood return to the heart. Blood pools in the lower extremities and may contribute to the dependent edema that may occur in the last half of the pregnancy. The lower extremity blood congestion seen in pregnancy can be alleviated by lying in a lateral recumbent position (Figure 15-6). Prenatal education should include teaching pregnant women to avoid prolonged standing, use support hose, and take frequent rest breaks.

Systemic Vascular Resistance

In pregnancy the increase in cardiac output and the slight decrease in mean arterial pressure results in a decrease in the *systemic vascular resistance*, or total circulatory resistance. Increased hormonal activity relaxes smooth muscle, causing vessels to dilate and thus allowing the body to accommodate the increased blood volume without pressure changes. The uteroplacental circulation provides a new and large capacity organ that diverts a portion of the increased cardiac output. Finally, increased circulating levels of prostaglandin during pregnancy serve to buffer the effects of certain vasoconstrictors. These adaptations allow the pregnant woman to accommodate the larger volume of cardiac output without the injurious side effects expected in a nonpregnant woman.

Figure 15-6 Resting in the lateral position helps to alleviate pooling of blood in the lower extremities.

The Effect of Positioning during Pregnancy

As the pregnant woman approaches term, she may report that lying on her back (supine) causes her to feel light-headed, dizzy, or faint. The symptoms are a result of the hypotension that occurs when the weight of the gravid uterus partially occludes the vena cava and descending aorta. The occlusion of these vessels may cause a decrease in the blood return from the lower extremities to the heart, therefore causing a decrease in cardiac output and a decrease in blood pressure. If the decrease in cardiac output is prolonged, blood flow to the placenta can be affected and fetal hypoxia may occur.

Supine hypotension, also known as vena cava syndrome, occurs when the pregnant woman is supine. The enlarged, heavy uterus presses on the inferior vena cava causing a reduced blood flow back to the right atrium (Figure 15-7). The pregnant woman experiences dizziness; clammy, pale skin; and lowered blood pressure. The situation is relieved when the pregnant woman lies on her side.

The effect of positioning on the ability of the heart to pump adequate amounts of blood should be included in prenatal education sessions. When women want to lie on their backs, instruct them on the hazards of the supine position and the necessity of using a wedge under their hip to laterally tilt the uterus, alleviating vessel compression. Instruct the woman to turn to her side if she experiences the symptoms of hypotension and to use the side-lying position when resting.

Respiratory System

Changes that occur in the respiratory system are necessary to meet the increased demand for oxygen by both the pregnant woman and her fetus. These changes are both mechanical and biochemical and improve the efficiency of the maternal respiratory function.

Changes in Mechanical Function

The thoracic cavity changes early in pregnancy, contradicting the idea that anatomic changes that occur in the respiratory system result solely from the enlarged uterus and the increase in intra-abdominal pressure. The growing uterus does change the size and shape of the abdomen, causing the diaphragm to rise 4 centimeters above the normal nonpregnant resting position. Diaphragmatic excursion is increased, rather than decreased. The chest circumference increases 5 to 7 centimeters, and the transverse diameter increases approximately 2 centimeters (Gabbe, et al., 1996). Blackburn and Loper (1992) state that the flaring of the lower ribs increases the subcostal angle from 68 to 103 degrees at term. Changes in the structure of the respiratory organs takes place to prepare the body for the enlarging uterus and increased lung volume.

Figure 15-7 A. Supine hypotension can occur when the woman is in the supine position. The weight of the gravid uterus may partially occlude the descending aorta and vena cava. B. Maintaining a lateral position alleviates the compression.

Effects of Progesterone

The level of circulating progesterone increases as the pregnancy progresses. Progesterone works by direct stimulation of the central respiratory system to increase tidal volume and decrease blood P_{CO_2} . The increased awareness of breathing or dyspnea experienced in pregnancy may be related to this change. Progesterone also plays a role in de-

creasing airway resistance by relaxation of smooth muscle, thus improving the efficiency of breathing.

Lung Volumes and Gas Exchange

Respiratory rate does not change significantly, so lung volume changes are based on mechanical and hormonal or biochemical influences. The greatest change is the 30% to

40% increase in tidal volume, which is the amount of air inspired and expired with each breath. The functional residual capacity, the volume of gas that remains in the lungs at the end of a normal expiration, is decreased by 20% because of the elevated position of the diaphragm. The volume changes help maintain a better mix of air and a more efficient method of gas exchange.

Lung volume changes and the effect of progesterone cause a state of compensated respiratory alkalosis. The

purpose of the increased P_{aO_2} and the decreased P_{aCO_2} of maternal circulation is to facilitate the removal of carbon dioxide from the fetus. The decreased maternal P_{aCO_2} level is compensated by increased renal secretion of bicarbonate, allowing the maternal arterial pH to remain within normal limits.

Gastrointestinal System

There are anatomic and physiologic changes that occur in the gastrointestinal and hepatic system. These changes are necessary to support maternal and fetal nutrition but are also the changes most often associated with the common discomforts of pregnancy. As shown in Figure 15-8, many organs of the gastrointestinal system are displaced or compressed by the gravid uterus.

Mouth

Estrogen causes increased proliferation of blood vessels and connective tissue in the gums, causing them to become soft and edematous. The tissue is friable and may bleed easily. Chewing can cause discomfort and make meeting nutritional demands more difficult. Poor oral hygiene, periodontal disease, and increased maternal age may increase the incidence of gingivitis. Contrary to folk beliefs, there is no evidence that pregnancy increases the incidence of dental caries or tooth loss.

The saliva becomes more acidic, but an increase in the amount of saliva is not a normal change in pregnancy. There is an unusual condition called ptyalism, or an increase in saliva, that usually occurs in pregnant women who are experiencing nausea. Gabbe and colleagues (1996) state that many experts believe ptyalism is the inability to swallow the saliva normally during periods of nausea and vomiting. Ptyalism can begin as early as 2 to 3 weeks and occurs most frequently in the daytime and disappears after delivery.

Some women develop pregnancy tumors in their mouths (Figure 15-9). These growths are usually benign.

Figure 15-8 Crowding of abdominal contents by gravid uterus.

Figure 15-9 Pregnancy tumor. (Courtesy of Dr. Joseph L. Konzelman, School of Dentistry, Medical College of Georgia.)

The vascular proliferation occurs secondary to hormonal changes. These changes may not resolve at the end of pregnancy.

Esophagus

Changes in the esophagus are caused by the effects of progesterone on smooth muscle. Peristalsis of the esophagus decreases and relaxes the lower esophageal sphincter. These changes and the increase in the stomach pressure of the pregnant woman can potentiate acid reflux from the stomach into the lower portion of the esophagus. The burning sensation in the middle of the chest is called pyrosis, or heartburn.

Stomach and Intestines

When assessing the stomach and intestines, some physical findings may be changed because of the displacement of these organs by the enlarging uterus. Bowel sounds may not be evident in the four normal quadrants of the abdomen, and the appendix may be found as high as the right flank. Changes in the tone of the stomach and delayed stomach emptying may contribute to the early nausea and vomiting that sometimes accompany pregnancy.

Acid production in the stomach is decreased in the first and second trimester, gradually returning to normal prepregnant levels at term. Because normal acid production returns at term and stomach emptying is slowed during labor, the oral intake of the pregnant woman must be assessed for 6 to 8 hours before labor, because vomiting and aspiration are major risks during the administration of general anesthesia.

The progressive slowing of intestinal motility correlates with the increase in the production of progesterone as pregnancy moves to term. The slowing progression of the intestinal contents allows more efficient absorption of nutrients and fluids but also contributes to constipation. Another annoying problem, flatulence, results from the slowing of contents through the intestinal tract and the bowel compressed by the gravid uterus.

Gallbladder

The effect of progesterone on smooth muscle also decreases the tone and motility of the gallbladder. The cholesterol in the bile of the pregnant woman is more likely to crystallize, resulting in gallstones being more frequently retained.

Liver

The liver is physically displaced by the enlarging uterus, which can make the diagnosis of hepatomegaly difficult. Blood flow to the liver is not markedly changed, although

the proportion of the cardiac output sent to the liver is decreased.

The most remarkable changes are in the laboratory and clinical signs that stem from the changes in the liver of the pregnant woman. These findings are commonly seen in clients who have liver disease, but in pregnancy these changes are normal. Findings include spider angiomas and palmar erythema, found in 70% to 90% of normal pregnant women. These physical findings disappear after delivery. Although liver function remains unchanged, the normal changes seen in laboratory findings of the pregnant woman are also seen in clients with liver disease. These changes include a serum albumin concentration that is decreased by 30% at term; a serum alkaline phosphatase level that is increased to two to three times normal levels; and a serum cholesterol level that is twice the level of the nonpregnant woman (Gabbe, et al., 1996).

Endocrine System

Changes in the endocrine system are manifested in many ways.

Thyroid

The thyroid gland enlarges slightly from increased vascularity and hyperplasia of the tissue. The gland does not enlarge to the extent that was once thought, and therefore any extraordinary growth should be assessed. The normal relationship of the hypothalamus, pituitary, and thyroid glands is believed to remain intact and the pregnant woman remains euthyroid. Cunningham and colleagues (1997) state that the changes that occur in the regulation of thyroid hormone production are related to high estrogen levels, effects of the placenta on function, and decreased availability of iodide resulting from increased renal clearance. These complex alterations in thyroid regulation do not dramatically change laboratory analysis but do cause a progressive increase in the *basal metabolic rate* (BMR). There is a 25% increase in the BMR, which is defined as the amount of oxygen consumed by the body over a unit of time (mL/min). The increase may be characterized by an increased pulse rate, heat intolerance, and elevated level of cardiac output.

Parathyroid

The parathyroid glands secrete parathyroid hormone, which is responsible for calcium and phosphorus metabolism. In pregnancy, the secretion of parathyroid hormone increases to meet the demands of the growing fetus for calcium. Total circulating calcium levels are decreased in pregnancy, probably resulting from fetal demands, the increase in glomerular filtration rate (GFR), and increased plasma volume.

Pituitary

The pituitary gland enlarges, with the most significant growth in the anterior pituitary. During pregnancy, the production of hormones responsible for ovulation is suppressed in the anterior pituitary; the production of prolactin is increased. Prolactin works in conjunction with other hormones for breast development in preparation for lactation. Oxytocin is produced in the hypothalamus, and the posterior pituitary stores and secretes the hormone. Oxytocin produces the uterine contractions during labor and is necessary for the ejection of breast milk. There is increased sensitivity by the myometrium to the effects of oxytocin as the pregnancy advances, probably a result of the increasing levels of estrogen.

Adrenal Glands

The adrenal glands do not change appreciably in size during pregnancy. Cortisol and aldosterone are two hormones secreted from the adrenal cortex that are important in pregnancy.

Cortisol

Cortisol works at multiple sites in the body to promote the metabolism of carbohydrate, protein, and fat. When the body needs more energy, cortisol activates gluconeogenesis to increase blood levels of glucose. Although the secretion of cortisol is decreased in pregnancy, it is hypothesized that the metabolic clearance of the hormone is slowed, thus maintaining higher than normal levels of circulating cortisol.

Aldosterone

During pregnancy the secretion of aldosterone increases, as does that of renin and angiotensin II. Renin is released from the kidneys in response to decreased perfusion pressure in the kidney. At this time, angiotensin II levels rise and act upon the maternal adrenal glands to secrete higher levels of aldosterone. It has been hypothesized that the increased circulating levels of aldosterone may protect the pregnant woman from the excessive sodium loss that is attributed to elevated progesterone levels during pregnancy.

Pancreas

The pancreas, an endocrine gland, secretes insulin from the beta cells of the islets of Langerhans. During pregnancy these beta cells increase in number and enlarge in size and cause the changes that occur in carbohydrate metabolism during pregnancy.

Placenta

Endocrine activities of the placenta are important to preserving a viable pregnancy and to the metabolic adaptations that must take place for the fetus to develop.

Human Chorionic Gonadotropin

Human chorionic gonadotropin (hCG) is secreted by a mass of trophoblastic tissue surrounding the embryo. The detection of hCG is used to confirm pregnancy. In early pregnancy, the corpus luteum increases progesterone and estrogen levels that are necessary to maintain the pregnancy. The function of hCG is to maintain the corpus luteum until the placenta is sufficiently developed to produce the needed hormones. As the pregnancy advances, hCG is involved in the suppression of the immunologic response of the maternal body to the fetus.

Human Placental Lactogen

Production of human placental lactogen (hPL) begins soon after implantation; levels gradually rise and peak at about 36 weeks. This hormone is involved in the process of making adequate glucose available for fetal growth, through the alteration of the maternal carbohydrate, fat, and protein metabolism. The hPL lowers the sensitivity of maternal cells to the action of insulin and then improves the ability of the body to metabolize and use fatty acids for energy. Therefore, as glucose levels decrease, the levels of hPL increase to allow the available glucose to be used for fetal development and growth.

Estrogen

Estrogen levels increase rapidly early in pregnancy, slow between 24 and 32 weeks' gestation, and increase again toward term. The production of estrogen is dependent on the interaction between the maternal and fetal components of the placenta. Estrogen plays an integral role in:

- ✦ Increasing blood flow to the uterus by promoting vasodilation
- ✦ Changing the sensitivity of the respiratory system to carbon dioxide
- ✦ Softening of the cervix, initiating uterine activity, and maintaining labor
- ✦ Developing the breasts in preparation for lactation and secretion of prolactin by the pituitary gland

Progesterone

Progesterone is produced by the corpus luteum in the first 5 weeks of pregnancy and then by the placenta until term. Elevated levels of progesterone ready the uterus for implantation, relax the smooth muscle of the uterus to prevent spontaneous abortion, and work to prevent a maternal immunologic response to the fetus. This hormone also relaxes smooth muscle of the gastrointestinal tract to decrease motility and improve absorption of nutrients. Relaxation of the smooth muscle of the urinary tract enlarges the ureters and bladder to increase capacity. Progesterone also plays a role in development of the alveoli and ductal system to prepare the breasts for lactation.

Changes in Metabolism

The metabolic changes that occur in pregnancy are all directed at providing the needs of the developing fetus, meeting the increased physiologic demands of the pregnancy, and providing energy for the woman throughout her pregnancy, labor, and delivery.

The metabolism of carbohydrates in the pregnant woman adapts to provide a constant source of glucose for the growing and developing fetus. In a fasting state, the pregnant woman experiences hypoglycemia, and a state of ketosis develops more quickly than in the nonpregnant woman. The speed at which this maternal response occurs is probably a result of the constant need of the fetus for glucose and the ability of the pregnant woman to more quickly utilize fat for energy. In contrast, a pregnant woman who eats a normal meal produces more glucose, insulin, and triglycerides than a nonpregnant woman does. The increased amounts of glucose and the decreased sensitivity to insulin by the cells therefore produces high amounts of circulating available glucose for the fetus. This adaptation is sometimes called the diabetogenic effect of pregnancy.

Gestational diabetes results from the inability of the pancreas of the pregnant woman to produce enough insulin to move the necessary glucose into the cells for energy production. When this happens, hyperglycemia may need to be regulated by changes in diet. Ketoacidosis may occur in a pregnant woman in whom diabetes has just been detected. Gabbe and colleagues (1996) state that because the pregnant woman is naturally in a state of insulin resistance with lipolysis and ketogenesis, ketoacidosis can occur in pregnant women with a blood glucose level as low as 200 mg/dL. To treat this disorder, the quick return of metabolic and fluid levels to normal values is necessary.

In the first two trimesters, there is an increase in triglyceride synthesis and the storage of fat at central sites. Later in the third trimester, there are more nutritional demands, both for glucose and fatty acids, by the fetus, and fat stores begin to decrease. The ability to more readily use fat as an energy source is a way to conserve glucose for the fetus and high-priority maternal needs.

Iron is necessary for the formation of hemoglobin, the oxygen-carrying component of the red blood cell. With red blood cell volume increasing by 30%, there is an increased need for iron. The intestinal tract increases its ability to absorb iron, but dietary intake and maternal stores are usually not adequate to meet all of the needs. The transport of iron across the placenta to the fetus, especially in the third trimester, takes place at the expense of maternal iron stores. Iron supplements are usually prescribed to maintain the maternal iron stores and decrease the chance of iron deficiency anemia.

Retention of water is a natural and expected part of pregnancy, resulting from changes in water metabolism. According to Cunningham and colleagues (1997), it occurs as a result of several factors:

1. The plasma osmolality is lowered in pregnancy, mainly because of the reduced serum levels of sodium and protein.
2. The intravascular pressure and permeability increase.
3. The fetus, placenta, and amniotic fluid increase the demand for fluid.

The total average volume retained can be as much as 6.5 liters. Normal water retention causes the dependent edema seen in the lower legs and ankles, most often at the end of the day. Edema that is not relieved by the elevation of the legs or excessive edema in the face, hands, or sacral area deserves further assessment (Figure 15-10).

Weight Gain

Weight gain in pregnancy is variable and recommendations should be individualized. The prepregnant weight and the pattern of weight gain that occurs over time are important factors. Tulman, Moren, and Fawcett (1998) note women with extreme prepregnancy body weights, either low or high, plus pregnancy weight gain have an increased

Nursing Alert

SIGNS OF DIABETIC KETOACIDOSIS

- Elevated blood glucose level >200
- Polydipsia and polyuria
- Nausea and vomiting
- Headache and malaise

Figure 15-10 Elevating the feet while seated can help relieve edema of the ankles and feet.

Nursing Tip

GRADING DEPENDENT EDEMA

The severity of edema is documented by grading and noticing trends in the changes.

- 1+ Slight pitting
- 2+ A somewhat deeper pit than in 1+
- 3+ The pit is noticeably deep; the dependent extremity is swollen and full
- 4+ The pit is deeper yet and lasts when the finger is removed; the dependent extremity is shiny, with extremely taut skin

risk for maternal and neonatal complications. Except at the extreme ends of the scale, a good clinical outcome is possible within a wide range weight gain. The average weight gain for healthy primigravidae is 12.5 kg (27.5 lb). Of this, the fetus, placenta, amniotic fluid, uterus, increase in maternal blood volume, breasts and the retention of water account for 9 kg (Figure 15-11). The National Academy of Science (1990) recommends the following: 12.5 to 18.0 kg (27.5 to 39.6 lb) for underweight women, 11.5 to 16.0 kg (25.3 to 35.2 lb) for normal-weight women, and 7.0 to 11.4 kg (15.4 to 25 lb) for overweight women.

In a research study, Tulman and associates (1998) examined the relationship of prepregnant weight and pregnancy weight gain as it relates to functional status, number of physical discomforts, and energy level. The results showed that the women who gained the most weight in their third trimester had a greater decrease in their functional status. The results of this nursing research suggest that nurses should be cognizant of their clients' pattern of weight gain and its effect on the woman's ability to perform her activities of daily living. Nutritional counseling is an important intervention, not only for the pregnant woman, but also for the postpartum period.

Urinary System

Changes in the urinary system, both anatomic and physiologic, are necessary for the synchronous functioning of adaptations that occur in other body systems. The key to assessing the renal system is remembering that the parameters of normal renal function are changed and that an awareness of these changes is necessary to make appropriate clinical judgments.

Anatomic Changes

As early as 16 weeks, the kidneys change in size and shape, resulting from the dilation of the renal ureters and

Figure 15-11 Monitoring weight gain at each prenatal visit helps the client to maintain a healthy pregnancy.

pelvices. The right kidney and ureter are larger than the left, probably because of the structural changes in other organs. Early in pregnancy, the enlargement may be caused by the effect of hormones that cause increased tone and decreased motility of the smooth muscle. After 20 weeks' gestation, the ureters are compressed at the pelvic brim by the growing uterus. Above the pelvic brim, the ureters are elongated and twisted, with a capacity to increase urine volume as much as 25-fold. Pooling of the increased volume of urine can lead to: 1) an increased incidence of pyelonephritis, 2) difficulty in the interpretation of radiographic studies of the renal system, and 3) interference with the accuracy of diagnostic studies, such as a 24-hour urine sample analysis.

By the end of the second trimester, the bladder is displaced upward and forward by the gravid uterus. The structural changes that occur with this displacement can lead to urinary frequency and incontinence. In most women, this is the first experience with incontinence, or involuntary loss of urine, and many will mistake it for the rupture of placental membranes late in pregnancy. The

Research Highlight

Prepregnant Weight and Weight Gain during Pregnancy: Relationship to Functional Status, Symptoms, and Energy Level

Purpose

To examine the relationship of prepregnancy weight and pregnancy weight gain to functional status, physical symptoms, and physical energy.

Methods

A longitudinal panel, with data, collected at the end of each trimester for 222 women whose pregnancies were low-risk, drawn from another study. The Inventory of Functional Status: Antepartum Period was the instrument used to measure functional status. To assess the physical symptoms a 21-item symptoms checklist was used. A one-item question was given to elicit the client's energy level. To calculate the body mass index (BMI) the formula (weight [kg]/height [m²]) was used. Weight and height were self-reported.

Findings

Pregnant women who gain weight above the recommended levels in their third trimester have a decrease in their functional status. There were no significant differences in physical symptoms and energy level. The researchers speculated that excessive weight gain can contribute to an increase in energy expenditure and that this may contribute to the difficulty in completing daily activities.

Nursing Implications

The findings confirm the need for nutrition and exercise counseling during pregnancy to help the woman understand the benefits that can be achieved. Interventions to assist a woman in maintaining her functional status may help her continue to participate in social and family activities throughout her pregnancy.

Tulman, L., Morin, K. H. & Fawcett, J. (1998). Prepregnant Weight and Weight Gain During Pregnancy: Relationship to Functional Status, Symptoms, and Energy. *Journal of Obstetric, Gynecology, and Neonatal Nursing*. 27 (6), 629–634.

tone of the bladder is relaxed and capacity and the pressure within the bladder increases. These changes, along with the edema of the bladder mucosa, make this area susceptible to infection and trauma.

Physiologic Changes

Blood flow to the kidneys increases by 35% to 60%, as a result of the increase in cardiac output. In turn, this leads to an increase in the GFR, or the rate that water and solutes filter through the glomeruli, as much as 50% by 12 weeks' gestation. The increase in the GFR leads to the following changes:

1. Increased urine flow and volume
2. Decreased serum blood urea nitrogen (BUN), creatinine, and uric acid levels
3. Increased nutrients delivered to the kidneys

4. Increased filtration and excretion of water and solutes

5. Altered renal excretion of drugs, resulting, at times, in subtherapeutic blood levels

Urinalysis

The alterations that occur in tubular function increase the reabsorption of sodium, chloride, glucose, potassium, and water to prevent the depletion of these solutes. Because of the increased perfusion rate, at times reabsorption is not complete and there is a loss of glucose in the urine. Levels of glucose in the urine vary day to day and slightly elevated levels are not uncommon, but an assessment for gestational diabetes should be considered if glycosuria is recurrent. In normal pregnancy, small amounts of protein may occasionally spill into the urine. Proteinuria levels

Nursing Alert

URINARY TRACT INFECTION

The changes that occur in the urinary tract make the pregnant woman more susceptible to infection. Symptoms include urinary frequency, urgency, dysuria (painful or difficult urination), and pyuria (pus in the urine). If untreated, the infection can ascend and pyelonephritis, a serious medical complication of pregnancy may develop. Urinary tract infections can also lead to premature labor, if left untreated.

above 300 mg in 24 hours warrant further investigation, especially when accompanied by hypertension.

Glucose and protein in the urine lead to a higher susceptibility to urinary tract infections.

Integumentary System

The skin undergoes many changes that rarely cause significant physiologic problems. It is the emotional distress caused by the cosmetic alterations (that may persist until after delivery) that are problematic. Most of these skin changes disappear or lessen after the delivery of the newborn. Some of these changes are also seen in women who are taking birth control pills, which leads experts to think that the changes are related to the increase in circulating estrogen.

The vascular changes that occur may lead to changes in the integumentary system. Spider angiomas and palmar erythema, which can be found in pathologic disorders such as liver disease, are also found in pregnant women and they usually occur together. Spider angiomas or nevi usually appear between 8 and 20 weeks' gestation in about 75% of pregnant women. The nevi are central dilated arterioles that are visible or raised, with radiating

Figure 15-12 Dark line of pigmentation called linea nigra, may appear in midline of abdomen, from symphysis pubis to umbilicus.

Client Teaching

Preventing and Coping with Chloasma: “Pregnancy Mask”

1. Wear sunscreen in the daytime and protect yourself from direct sunlight.
2. If skin is very dark, seek the advice of a professional dermatologist.
3. Use a cover stick to neutralize the dark skin before applying makeup.
4. Darkened pigment usually fades once delivery occurs.

branches. Appearing most often on the face, neck, throat and arms, they may be distressing to the pregnant woman. Most often the nevi fade or disappear after delivery. There is a familial tendency for palmar erythema, which appears during the first half of the pregnancy. This skin change, which causes a mottling of the fleshy portion of the palm and redness of the fingers, may be caused by an increase in estrogen level, because it disappears after delivery.

Hyperpigmentation, caused by elevated hormones, is usually visible primarily on the nipples, areolae, umbilicus, perineum, and axillae. The dark line in the midline of the abdomen caused by hyperpigmentation is called **linea nigra** (Figure 15-12). Women may also experience dark blotching on the face (Figure 15-13), similar to that seen in women who take birth control pills. This condi-

Figure 15-13 Blotches on face during pregnancy are known as chloasma. (Courtesy of Timothy Berger, MD, Chief, Department of Dermatology at San Francisco General Hospital)

tion **chloasma**, is commonly called the “mask of pregnancy.” The condition may be a concern to the pregnant woman because of the cosmetic effect. Chloasma may disappear after pregnancy but often only fades. Preexisting nevi may also be affected and become darker during pregnancy. The management of these nevi should include close observation and the removal of nevi that change rapidly.

Changes that occur in the connective tissue during pregnancy can lead to the formation of **striae gravidarum**, which occurs in approximately 50% of all pregnant women. Women who have a genetic disposition may develop pink-to-purple lines on the skin from the stretching that occurs during growth of the fetus. These lines, as seen in Figure 15-14, usually appear on the breasts, lower abdomen, and upper thighs and fade to a silver color with time. “Stretch marks” do not ever completely disappear, and there is no prophylactic skin treatment to prevent them.

Musculoskeletal System

To maintain balance with the shift in weight from the growing uterus, the lumbar spine forms an exaggerated forward, convex curve (lordosis) (Figure 15-15). The body adjusts the center of gravity over the lower extremities and, unfortunately, this adjustment is often the cause of low back pain in later pregnancy. Ligaments in the pubic symphysis and sacroiliac joints soften from the effects of the hormone relaxin. This adaptation is necessary to ready the body for vaginal delivery but can also cause pelvic discomfort and an unsteady gait as the pregnancy nears term. Falls are a common occurrence; women should be instructed to wear flat, well-fitting shoes.

Figure 15-14 Striae gravidarum (stretch marks) are pink to purple streaks on skin. Marks are a result of linear tears in connective tissue of skin as body enlarges.

Eyes

Changes that occur in the eye normally do not affect vision, other than the transient loss of accommodation (the power of the eye to alter the convexity of the lens according to the nearness or distance of an object) that has been reported (Blackburn & Laper 1992). Ocular pressure, which is slightly decreased, is thought to change from the increased outflow of vitreous. The cornea becomes thicker, probably caused by edema. If the woman wears contact lenses, she may notice that her normally comfortable lenses are now bothersome.

DISCOMFORTS OF PREGNANCY

An important nursing responsibility during the prenatal period is educating the client regarding the discomforts that occur during pregnancy and how to remedy these, or feel better. These discomforts are usually related to the changes necessary to adapt to the growing fetus that are occurring in the body systems. Information on why the woman feels the way she does and self-help remedies usually assist in making this time more comfortable. Another

SIGNS OF POTENTIAL PROBLEMS IN PREGNANCY

Immediate assessment is required for:

Problem	Possible Cause
Persistent vomiting	Hyperemesis gravidarum
Bright red vaginal bleeding	Abruptio placenta, placenta previa
Edema of the hands and face	Preeclampsia, hypertension
Body temperature above 101°F (38.3°C)	Infection
Persistent abdominal pain, with or without a rigidity	Abruptio placenta
Epigastric pain, unrelieved by comfort measures	Preeclampsia
Dysuria	Urinary tract infection
Intermittent back pain, pelvic pressure, or abdominal pain or pressure	Preterm labor
Visual disturbances	Preeclampsia, hypertension
Changes in fetal movement	Potential fetal stress

important aspect of counseling on the discomforts of pregnancy is to help the pregnant woman distinguish between a normal discomfort and a sign that may signal a real problem in the pregnancy.

Nausea and Vomiting of Pregnancy

The discomfort of nausea and vomiting of pregnancy (NVP) can range from mild nausea (with or without vomiting) to severe vomiting (**hyperemesis gravidarum**) that occurs throughout the day. Although NVP is referred to as morning sickness, episodes can occur throughout the day. The cause of NVP is not known, but it is speculated to be related to increased levels of hCG and estrogen. Emotional factors and irregular eating habits have also been cited as possible contributors to this discomfort. The discomfort of NVP cannot be completely eliminated, but can be minimized by self-help measures. Recent research suggests that there may be a protective benefit of NVP in that it shields the fetus from potentially harmful pathogens, such as those found in undercooked meat.

Hyperemesis gravidarum is a serious complication of pregnancy and must be managed under the close observation of a health care provider. Dangerous sequelae of hyperemesis gravidarum can include weight loss, dehydration, electrolyte imbalance, and starvation.

Heartburn

Heartburn is a frequent complaint throughout pregnancy and results from the reflux of gastric acid contents into the esophagus and sometimes into the mouth. The changes that occur in the gastrointestinal system, such as decreased stomach and intestinal motility, softening of the cardiac

Critical Thinking

Nausea and Vomiting of Pregnancy

Two weeks ago Mehalia purchased a home pregnancy test, which gave positive results after she missed one of her regular periods. She has called the clinic and is experiencing nausea and vomiting.

Formulate questions for Mehalia that will help you determine the severity of her NVP and the potential for hyperemesis gravidarum, centering on:

- Frequency of vomiting
- Pain or fever
- Tolerance for food and fluids

Client Education

Nausea and Vomiting in Pregnancy

- Drink plenty of fluids, 6 to 8 glasses of water daily, to maintain hydration.
- Avoid fluids that contain caffeine or carbonation.
- Eat a diet that is high in protein and carbohydrates, in 5 to 6 small meals daily.
- Eat crackers throughout the day to avoid an empty stomach.
- Pay attention to your senses; avoid noxious odors, such as tobacco smoke, and tastes that may nauseate you.
- Limit stressful events and get plenty of rest; avoid being in a hurry, especially in the morning.
- Consider acupuncture or acupressure to assist in relieving nausea.

Client Education

Heartburn in Pregnancy

- Monitor your diet for foods that cause upset. Keep a list.
- Avoid drinking large amounts of liquid with meals; instead, spread fluid intake throughout the day.
- Remain sitting upright for at least 30 minutes after a meal and sleep with an extra pillow at night to keep the head elevated.
- Don't bend at the waist, always bend at the knees, maintaining a more upright abdominal posture.
- Try lying on your right side and using relaxation techniques to calm your stomach and promote digestion.
- Take commercial calcium-containing low-sodium antacids just before meals; check with your practitioner for brand preferences.

sphincter and esophagus, and displacement of the stomach by the uterus, seem to contribute to the burning sensation that is felt behind the sternum and in the epigastric area. Instruct the client to call her health care provider if self-help measures or antacids do not relieve persistent heartburn. Epigastric pain or right upper quadrant pain, especially when associated with edema of the hands and face, proteinuria, and elevated blood pressure, could indicate a problem in the liver.

Constipation

Constipation is another discomfort related to the changes that occur in the gastrointestinal tract. Increased levels of progesterone cause the relaxation of intestinal smooth muscle, which leads to decreased motility and increased capacity, allowing more time for the absorption of nutrients. Although this process benefits the nutrition of the mother and fetus, it can cause bloating, increased flatulence, and hard stools that aggravate hemorrhoids. Assess the frequency of bowel movements in women taking iron supplements, because iron supplements may cause constipation.

Fatigue

The fatigue that pregnant woman feel in the first trimester is real and sometimes distressing for the “superwoman” of today. The tiredness is legitimate and may seem over-

Client Education

Constipation in Pregnancy

If you are constipated and taking iron, do not stop taking your supplement. Try these self-help tips first.

- Increase the fiber in your diet by eating fruits and vegetables raw (or vegetables slightly steamed). Whole grains are also a good source of fiber.
- Drink plenty of fluids, avoiding caffeine; keep in mind that increasing your fiber without increasing your fluid can worsen constipation.
- Exercise to stay regular; walking, swimming, or cycling 3 to 4 times per week for 20 to 30 minutes is recommended.
- Try to establish a regular time for your bowel movement and never ignore your body's signals.

Client Education

Fatigue in Pregnancy

Find a comfortable and reasonably quiet place and try meditation. Close your mind to external sensation and outside stimulation. Pick one of the following five methods to achieve a single focus:

1. Meditative repetition: repeat a rhythmic chant, most commonly called a mantra, that is chanted over and over
2. Visual concentration: stare at an image, such as a candle, flower, or fruit
3. Repetitive sounds: listen to a sound, such as a drum, chimes, or a waterfall
4. Physical repetitive motion: perform motions such as rhythmic breathing or a rhythmic aerobic exercise
5. Repeated tactile motion: hold or manipulate a small object, such as a rosary or tumble stone

whelming but is of no special medical significance. The best advice for the busy pregnant woman is to give in and rest when she feels the need. She may need to take shortcuts in her daily life, and she should know that the fatigue usually disappears by the fourth month. Alleviating stress through meditation or relaxed breathing may assist in coping with the feeling of being tired.

Frequent Urination

Urinary frequency ranks at the top of the list of the most common complaints of pregnancy. In the first trimester, before the uterus ascends above the symphysis, the weight of the enlarging uterus irritates and puts pressure on the bladder. Frequent urination diminishes slightly in the second trimester, returning near term. When talking with clients, differentiate between urinary frequency and the symptoms of a urinary tract infection. If the woman has symptoms such as pain or burning urgency when urinating, a health care provider should be notified. Kegel exercises (contracting the muscles of the pelvic floor) help to prevent urinary stress incontinence.

Epistaxis and Nasal Congestion

The capillaries inside the nose become engorged with blood during pregnancy, leading to edema and hyperemia

Client Education

How to Perform Kegel Exercises

1. In the first 3 months of pregnancy, lie on your back with both knees bent to perform this exercise; after the third month, sitting or standing is a better position.
2. Contract the muscles that surround the vagina and anus and hold for 5 seconds, then slowly release. These are the same muscles you would use to stop urination. Isolating these muscles requires practice.
3. Do at least 25 to 50 repetitions. You may want to space them out during the day.

of the nasal passages. These changes can lead to *epistaxis*, or nosebleed, and nasal congestion, which can worsen in the winter months when conditions are dry and the use of home heaters is prevalent. The congestion and dryness of the nose may lead to more frequent blowing of the nose. With mucous membranes engorged with blood, blowing the nose gently may prevent epistaxis. The nurse can recommend that the client sleep with a cool mist humidifier and use commercially prepared saline spray. If the congestion becomes severe enough to interfere with activities of daily living, the client should consult her practitioner.

Client Education

Varicose Veins in Pregnancy

- Maintain good circulation in your legs; avoid sitting, standing, or crossing your legs for long periods, and wear maternity support hose during the day.
- Elevate your legs as often as you are able or flex your feet several times every few minutes while sitting.
- Take breaks and short frequent walks when performing intense, stationary work.
- Wear clothes that fit loosely and avoid wearing knee-high hose that may constrict the blood vessels in the legs.

Varicosities

Varicosities are dilated veins that occur most often in women who have a genetic predisposition for them. The valves in the veins can become incompetent, allowing a reverse of blood flow. In pregnancy, these veins may be more pronounced because of the increased blood volume, the changes in venous pressure that occur because of the enlarged uterus, and increased time in the standing position. On assessment, changes may be noted that range from mild discomfort after long periods of standing to severe tortuous and bulging blue veins that require long periods of rest with the legs elevated. Occurring most often in veins of the lower extremities, varicosities may also be present in the veins of the vulva and rectum (hemorrhoids).

Hemorrhoids

Hemorrhoids are varicosities of the rectum, which may occur outside the anal sphincter or inside the anal sphincter. Typically, hemorrhoids that are already present are exacerbated by the changes that occur in the body during pregnancy. Other factors that may exacerbate hemorrhoids are prolonged sitting or standing, straining at stool, and pushing in the second stage of labor. Hemorrhoids may continue to be problematic into the postpartum period.

Client Education

Hemorrhoids in Pregnancy

- Maintain healthy and regular bowel habits.
- Try a sitz bath: sit for about 20 minutes in a tub filled with warm water to which you have added a half-cup of baking soda.
- Apply cool compresses or cotton balls soaked with witch hazel to the swollen hemorrhoids. Commercial preparations that contain witch hazel or anesthetic compounds are also available.
- If hemorrhoids are protruding from the anus, gently push them back into the rectum. Using a glove and lubricant, gently press the hemorrhoid back through the anus and hold for a few seconds. This may be most comfortably achieved after a sitz bath.

Client Education

Back Pain in Pregnancy

- Be aware of your posture; be sure your neck, shoulders, and back are straight and your pelvis is tilted slightly forward.
- Bend at the knees, never at the waist.
- Wear comfortable, low-heeled shoes.
- Elevate one foot when standing for extended periods of time (Figure 15-16).
- Practice deep breathing and relaxation exercises that focus on the upper body.
- Get a massage to relax tired muscles.

Figure 15-16 Keeping one foot elevated during prolonged periods of standing can help relieve back pain.

Back Pain

The back pain of pregnancy usually occurs in the lumbar region and becomes more problematic as the uterus enlarges. Low back pain is a common complaint in pregnancy and results from the changes in posture as the uterus grows. Obesity and previous problems with back pain are also risk factors. The degree of pain is closely linked to the strain of bending, lifting, and walking. The use of good body mechanics when performing these activities limits the potential for severe injury.

Leg Cramps

Leg cramps are thought to be the result of an imbalance between the electrolytes calcium and phosphorus. During pregnancy, the ratio of calcium to phosphorus is difficult to maintain because of changes in renal absorption and diet. The decreased circulation to the lower extremities produced by the pressure of the uterus may also contribute to painful cramps. The woman may awaken at night with painful knots in the calf muscles. When the cramp occurs, getting out of bed and walking usually relieves the pain. If the pain is too severe to walk, the woman should be instructed to sit with her legs and knees straight, grab her toes, and flex her foot. A partner can also assist in relieving leg cramps by flexing the foot forward (Figure 15-17). Instruct the client to do flexibility or stretching exercises before going to bed.

Health Promotion

When considering health behavior changes, remember what it is like to be the individual attempting to change

Figure 15-17 Leg cramps can be relieved by flexing foot toward knee.

Critical Thinking

Health Promotion

Formulate responses to these comments made by nurses that help nurses understand the importance of avoiding making assumptions about clients when instructing them on changing health behavior.

1. "The health change is obviously the right thing to do and everyone is motivated to change if good health is the outcome."
2. "I understand the problems concerning not changing, but why does the client not understand?"
3. "The time for change is now and if the client is not ready, then this session is over. I can only give her the advice, she has to decide to change."

what may be long-standing habits. The nurse, as the health care provider, understands the need to change certain behaviors to achieve and maintain wellness, but the client is the person who must be ready to change.

Many women must make changes in their daily lives to achieve and maintain a healthy pregnancy. When planning education for women concerning the lifestyle changes that may need to be made, be sure to complete a physical examination, but also understand the woman's educational background, value system, and cultural beliefs. To implement change, there must be a readiness to change. If this is a new idea to the woman, she may need to complete several stages of readiness before she is able to think about changing a behavior. Relaying the importance of the change and convincing her that she can successfully make the change are also necessary. The manner in which the information is presented can either motivate the woman to change or build a wall of resistance. As a health care provider, the nurse must be sensitive to the fact that communication techniques can either make the process more difficult or can assist in the adjustments that need to be made.

Employment

At least one-half of the women of childbearing age in the United States are in the workforce. Cunningham and associates (1997) noted that women now have the legal right to work during pregnancy, and employers cannot deny any job to a woman because she is pregnant. If a job requires

excessive standing (more than 8 hours), frequent rest periods or intermittent walking should be included in the work day. Women should be instructed to avoid any work or play that may cause severe physical strain or fatigue.

Travel

Travel during pregnancy has not been shown to be harmful to the pregnant woman or her fetus. Most airlines have requirements for the woman who is traveling close to her expected date of delivery. Instruct the woman to discuss travel plans with her health care provider.

When traveling in a car, it is appropriate to use a properly positioned three-point safety restraint. The woman should be instructed to adjust the lap belt so that is positioned under her abdomen and low across her hips and the shoulder harness so that it is snug between her breasts (Figure 15-18). With any mode of travel, frequent rest periods are advantageous.

Smoking

The effect of smoking on the fetus is well-documented. Newborns born to mothers who smoke have lower birth weights, a higher incidence of sudden infant death syndrome (SIDS), a higher incidence of premature birth, and are more likely to have episodes of apnea (Cunningham, et al. 1997). The discussion concerning smoking cessation should occur in the preconception period. The nurse should assess for smoking in every client of childbearing age, review the negative effects of smoking on the fetus, and suggest ways to assist the client in quitting the smoking habit. The nurse should first understand the long-term

Figure 15-18 Car seatbelts should be secured low and snug under abdomen and across hips.

REFLECTIONS FROM A NURSE

"I cannot understand. I had just explained how detrimental smoking was to her baby, and in the her next breath, she wanted to go smoke a cigarette. What should my response as a concerned health care provider be?"

addiction of cigarette smoking and then work with the woman to assist in identifying her motivation to smoke. From this assessment, a plan of care can be outlined to begin the process of changing health behavior.

Alcohol Use

Women who are pregnant or are considering becoming pregnant should abstain from consuming alcohol. Experts have been unable to identify exactly how much alcohol is too much. Again, the time to identify an alcohol problem is before the woman becomes pregnant. Explaining the deleterious effects of alcohol on the developing fetus may be enough motivation for the social drinker to stop, but women who are addicted to alcohol need professional assistance and may benefit from a referral to a treatment program.

Illicit Drug Use

Large doses of illicit drugs or street drugs, such as opium derivatives, amphetamines, or barbiturates, can cause low birth weight and fetal distress (Cunningham, et al., 1997). A health care provider team that has an established program should manage the pregnant woman with a drug addiction. The newborn needs special care if the mother has remained on drugs throughout her pregnancy. If the nurse identifies a woman who has a drug addiction, quick referrals are the best avenue to obtaining a reasonably positive outcome.

Medication Use

During preconception counseling the health care provider should assess the medications that the woman may routinely consume. Almost all drugs that affect the mother systemically cross the placenta and affect the fetus. Therefore the best advice to the pregnant woman is to avoid taking any medications or herbal preparations without consulting her provider. If a drug is prescribed during pregnancy, the risk-benefit ratio should be weighed and discussed with the woman.

PSYCHOSOCIAL ADAPTATIONS TO PREGNANCY

There are developmental challenges that must be met to move to the next stage of life. Pregnancy is a maturational crisis that causes a paradigm shift for the woman and her family members. To successfully move into the new role of parenting, both the woman and her partner must complete certain tasks. The movement through this journey is affected by many variables, both internal and external. In the role of the nurse, understanding the psychological adaptations that are necessary in moving into the parenting role helps with supporting and caring for the family unit.

Psychological Responses to Pregnancy

Because pregnancy is an event that happens over time, the woman's responses are episodic in nature. Her response to certain changes may be somewhat exaggerated, while other changes are accepted with little concern. Being able to provide unbiased counsel to these women and their families is important and assists in the smooth transition from a childless couple to a family.

Acceptance of the Pregnancy

The nurse should not automatically assume that every woman has planned her pregnancy. Approximately 31% of births in the 5 years preceding 1995 were reported as unintended (Henshaw, 1998), with unintended pregnancy defined as one in which the woman did not want to have the infant or had decided not to have more children. The definition does not suggest that she will be unsuccessful in her progress through the adaptation and acceptance of her pregnancy. In fact, ambivalence to the pregnancy is a very normal initial response, and discussion concerning this topic is a productive intervention. Many women express concern over the timing of the pregnancy, wishing that planned goals or criteria had been met before becoming pregnant. Other women worry about how an infant will affect their career or their relationships with family and friends. These feelings can be confusing for the woman who feels conflict instead of elation. As her pregnancy progresses, the physical changes of an enlarging abdomen and fetal movement bring reality to her situation. As she accepts this reality, she becomes tolerant of the discomforts she may be experiencing. At this time, reassurance that what she is feeling is normal and that her conflicting feelings about the pregnancy will resolve are appropriate.

REFLECTIONS FROM A MOTHER

"In my second year of graduate school, while working part-time, I was shocked and disappointed to learn that I was pregnant. My initial reaction was, 'Oh no, not now!' I was so ashamed by the way I was feeling toward being pregnant. We had always planned to have a baby, but there were so many things we still wanted to accomplish before starting a family."

Time for Reflection

During the first trimester the woman often turns inward and reflects on what "being pregnant" means. There are few physical signs of an impending newborn, so the unstable moods that sometimes accompany early pregnancy may be unnerving to the woman and her partner. As the pregnancy advances, the focus becomes the growing fetus. Many women disengage from familiar outside activities and focus on issues that result in a safe and healthy pregnancy. At times, the plans for the newborn may completely monopolize her attention, and her partner may feel neglected or left out of the planning. The introversion that occurs is a normal psychological adaptation to the journey to motherhood. The nurse can discuss these issues with the couple and assist in providing suggestions to maintain the focus on the family.

Body Image Changes

The initial changes that occur in the woman's body validate her pregnancy, and she may demonstrate pride in her changing body. As the pregnancy progresses, her increasing size, waddling gait, and posture changes may become distressing. The discomforts of pregnancy that accompany the physical changes may add more distress to an already stressful time. Women who are experiencing difficulty adapting to the pregnancy because of real or imagined issues, such as single parenthood, marital problems, financial issues, dread of the future, or an uninterested or absent partner, typically have a more difficult time accepting the physical changes of pregnancy. The nurse and client can discuss the issues and look for solutions. It may be helpful to focus the client on the idea of pregnancy as a time-limited event.

Becoming a Mother

As the woman moves toward the maternal role, she has hopefully accomplished previous life transitions, has adequate role models, has an interpersonal support system, and the acceptance of others. During the transition, the woman is in a state of internal disequilibrium and may demonstrate disorganized behavior. The behavior may result in mood swings and changes in normal roles and relationships. Pregnancy and role changes are a life crisis. During a crisis, the woman and her family may be more open to the health care provider's expert advice and guidance. It is an important time because the change that occurs in the newly pregnant woman is integrated into her personality as her maternal identity. The incorporation of the maternal identity into the woman's life is a process that leads to the acceptance of the new infant as her child.

Development of the Maternal Role

Rubin (1984) describes the steps that must be accomplished to successfully move into the maternal role and the tools the new mother uses to accomplish this transition.

Mimicry

The pregnant woman uses mimicry in role transition when she seeks out other women who are pregnant or have been pregnant and asks to share their stories and customs. She solicits the different opinions of these experts and tries to obtain consensus before deciding which aspects of motherhood she will incorporate into her new role. Wearing maternity clothes before they are necessary, or imitating the waddling gait of other pregnant women demonstrates a trying on of the role. The role models also serve to plot a course for the expected sequence of events or changes during pregnancy. The woman finds comfort in knowing what to expect, although information that does not seem pertinent to her stage of pregnancy may be temporarily disregarded. An example of premature information would be showing a woman in her first trimester how to bathe or feed the baby. The information is stored in her memory and will be reviewed when it is more pertinent to her stage of pregnancy.

The woman's mother is the model most closely mimicked. She has an expectation that she will experience the same prenatal course and delivery as her mother experienced. When this sequence of events does not progress as anticipated, the woman may become distressed and worried. At this point, it is important to discuss with the client the differences that occur in every woman's pregnancy.

Role Play

Role play happens intermittently and is the woman's opportunity to try on the mother role. When the opportunity

arises, she may offer to hold, feed, or play with a child in front of an observer. If she receives a positive response from both the infant and the observer, this encounter bolsters her confidence in successfully becoming a mother. If the infant or the observer rejects the woman, she will feel as if she has failed and will expect rejection with the next encounter. Helping the woman understand that acquiring the skills necessary for motherhood is a process that continues throughout life is a sound approach.

Fantasy

Fantasizing is common in the pregnant woman and involves imagining the infant and how she will fare as a mother. Dreams may initially focus on what the infant will look like or how the infant will look dressed in baby clothes. To test her ability to solve similar issues for her child, the mother may relive, through her dreams childhood conflicts that may have been left unresolved. As the woman moves closer to delivery, she may have dreams that question her maternal skills or her ability to cope with motherhood and a career. Fantasies are the woman's way of working through conflicts and readying herself for the motherhood role. Offering a listening ear and reassurance that dreams and fantasies are a normal adaptation to her changing role is a positive intervention.

Role Fit

After the woman has acquired a set of maternal role expectations, she matches her expectation to the actions of other mothers. As she “tries on” the different behaviors, she will either accept or reject them as agreeable to her view of the motherhood role. The investigation into the appropriate skills necessary for motherhood suggests that throughout her pregnancy the woman has successfully taken the necessary steps toward the maternal role. In sessions with new mothers, discussing ideas of motherhood and offering informational sources reinforces positive perceptions of the new role.

Maternal Tasks

In the work of Rubin (1984) a list of maternal tasks are discussed. These tasks are identified as developmental milestones that the woman must accomplish to successfully incorporate the maternal identity into her personality.

Safe Passage

The goal of safe passage is to achieve a healthy pregnancy and an intact newborn with no detrimental effects to the mother. In the first trimester, the woman will focus on herself and her pregnancy. Later in the second trimester, she becomes very aware of her responsibility to protect the fetus and does this by adhering to different aspects of her prenatal care. As she moves closer to delivery, her

thoughts shift to mother and baby as a couple: what happens to one will happen to the other. The pregnant woman will seek out role models and expert advice on the best way to proceed through the pregnancy and delivery and on to parenting.

Acceptance by Others

The woman's world before pregnancy is dependent on the social interactions of the family and secondary groups, such as community activities, school, or work. Initially, the secondary groups are significant to who the woman is and how she defines her life's meaning. Throughout the pregnancy her family and especially her partner become the motivational force behind her desire to be successful as a mother. To succeed, the mother becomes aware of sacrifices that will need to be made. If she has other children, she will have to assist them in adapting to the growing family.

During this time, the most important role for the nurse is to listen to the woman's concerns and offer assistance, when applicable, in a nonjudgmental manner.

Binding in to the Child

In the first trimester, the woman focuses on herself and maintaining the pregnancy. Once fetal movement is felt, in the second trimester, the fetus becomes real and she begins to feel there is significance in working to meet the challenges of becoming a mother. At this time, the fetus becomes an independent person and all of the mother's being is directed toward the newborn's safe arrival.

Critical Thinking

Successful Role Adaptation

Rosie is a teen who is pregnant with her first baby, and she is approaching her eighth month. She is in the office for her prenatal visit and has brought her girlfriend; they are going to a party at a friend's house later that night.

1. How can you determine if Rosie has accepted her pregnancy?
2. What behaviors would you expect Rosie to report to indicate that she is successfully adapting to her impending role as mother?
3. What questions will you ask to determine if Rosie understands the changes that she will have to make in her lifestyle to care for her infant?

Giving of Oneself

The experience of pregnancy and childbirth could not be endured without the prospect of a healthy newborn as the outcome. Pregnancy is a time of giving gifts between couples, family, and friends. The grandmother may give the baby a family heirloom and a friend may give a baby book. The partner gives the woman a child and the woman gives the fetus a healthy diet and often eliminates unhealthy habits. The act of giving a gift is not the primary focus for the woman, but the communication of appreciative approval helps the woman to endure the changes and discomforts of the pregnant body. Health care providers who give generously of their time to answer questions and provide guidance reinforces the importance of the sacrifices that must be made to achieve a successful pregnancy and healthy family.

Conflicting Developmental Tasks

Because pregnancy is not always a planned or intended developmental stage of the woman's or her family's life, there may be other developmental tasks that are in the process of being accomplished. These tasks may conflict with or make the accomplishment of the role transition more difficult.

An example would be the teen mother who is working on the developmental aspects of adolescence while attempting the transition to the motherhood role (Table 15-2). Many times, the tasks overlap or conflict. When this

happens, the role of the nurse is to assist in isolating the issues and to assist the teen in working through each one. The nurse may want to enlist the assistance of professionals that specialize in the care of teens or assist the teen in finding a support group for pregnant teens.

Becoming a Father

Traditionally, an assumption was made that the father of the infant was also the husband of the mother. Today, more babies are being born to single mothers, and the situation of caring for a woman without a husband is common.

The transition to fatherhood is made easier when there is a bond or relationship between the man and the woman. It is important to successful fetal attachment for both the mother and the father that the parents are united and their feelings are mutual. Wilson, White, Cobb, Curry, Greene and Popovich (2000) described mutuality as a close and emotional relationship in which each participant is secure in their own identity. In relationships that foster clear communication and the recognition that different roles are necessary to foster a healthy family, a new being can readily be accepted as a member. In families without a husband-father, the nurse can investigate how other family members may fit into the structure. A female partner, grandfather, or close friend may be the father figure in a particular family. Assisting the woman in identifying her

emotional needs as she moves into the motherhood role helps her to adjust to any deficits that may be noted.

Transition to Fatherhood

Men have their own unique transition that must take place to incorporate the identity of father into their personality. In accepting the pregnancy, the man needs to perceive that certain goals have been accomplished before the birth of the newborn. Has he thought about becoming a father at some point in his future and has he accepted the end to his childless period? Men are concerned about the financial and emotional stability of the couple and how they will fare with this new individual entering their lives. If these questions are not positively answered, there may be some ambivalence to the pregnancy on the part of the man. The nurse's knowledge of social and community resources is helpful in assisting the couple with role adjustment.

The Stress of the Paternal Role

The adaptation of the male to the fatherhood role is a life crisis, just as it is for the woman accepting the maternal role. The woman needs her partner to be empathic, trustworthy, reliable, and available to assist in the successful completion of pregnancy and childbirth. These responsibilities, plus the change that will occur in the lifestyle of the couple, cause stress in the structure of the family. Often men note that potential financial issues, learning new routines, work conflicts, fewer hours of sleep, and caring for the infant are issues that may block the evolution of the fatherhood role. In a relationship, the woman is usually the man's emotional counselor, and in the parent role, the woman is most often focused on the needs of the newborn and not available to help the man through his challenges. The successful role adaptation of the man to fatherhood is typically closely related to the emotional health of the couple's relationship.

The custom of taking on symptoms of pregnancy and childbirth by the man is called **couvade**. There are many different theories that identify possible reasons for this condition; these include sympathy and identification with the pregnant woman, being left out, feeling guilty about putting the woman in this condition, or the stress of living in such an unpredictable situation. The symptoms may appear around the third month or at delivery and may include nausea and vomiting, abdominal pain, weight gain, food cravings, fatigue, and mood swings. Of course, these symptoms could signal illness, so a full assessment is necessary. Becoming more involved in the pregnancy, or seeking out knowledge concerning areas that the father feels insecure about, may alleviate the symptoms of couvade.

Bonding Between the Father and Infant

Fathers bond in much the same way as mothers do. Looking at and touching their infants, perceiving the infant's characteristics as unique and perfect, being attracted to the infant, and feeling happy are strong indicators of successful attachment. Early physical contact and involvement in the newborn's care are important for future positive father-child adjustment.

The Family

The family is a dynamic and complex unit that adapts to each individual's role changes and crisis resolution. The success of the family depends on the ability to continue to move forward on the developmental course while each individual moves through their own maturational and situational crises. As we enter the 21st century, the process of family life takes on a different look from the families of the early to middle 20th century. Parents may be unmarried, not living together, of the same sex, older, adoptive, or grandparents who are raising the infant.

The participation of caregivers outside the family, i.e., day care providers, is a challenge for families. The close extended family that was traditionally relied on for support and help with child care is often not geographically or financially able to assist. Nurses are finding that knowledge of community resources is necessary in assisting many of these families with the challenges of day to day living.

Duval (1985) has described developmental tasks that are necessary in the successful transition to the family role. They include adapting relationships to the realities of pregnancy; planning for the pregnancy, childbirth, and parenting; and reevaluating financial responsibilities for the impending family. The couple needs to orient themselves to their new roles and have insight into how their relationships with other family members will change. Sexual relations during pregnancy and after childbirth are different from the experience of the past. Dividing the new responsibilities that come with this change in family life, such as who takes the infant for newborn checkups or

Nursing Tip

FAMILY VARIETY

In providing care to families, remember that the content of the family is the key to assisting members through a crisis and not the form that the family takes.

wakes up in the night for feedings, is a necessary task. Depending on the working status of the couple, making decisions on the physical care of the newborn will rank high on the list of tasks. In general, maintaining the morale of the family and adapting to the rapidly changing environment is most important.

Siblings

When children are already present in the family, the parents may have questions on how to handle the announcement of the expected newborn. The age of the child may dictate the timing of the announcement. If the sibling is under age 2, it may be best to wait until the fifth or sixth month to explain about a new brother or sister. A 9-month pregnancy progresses slowly for a child this age. If the mother is obviously not feeling well from the discomforts of pregnancy, it may be advantageous to tell the young child about the pregnancy. The young child may be afraid that mother is sick and that something bad will happen to her.

All children should be acquainted with the baby before it is born (Figure 15-19). There will be many questions, and these should be answered in a straightforward age-appropriate manner using the correct terminology. The nurse and the couple can discuss available age-specific books that can be used to explain the growth of the fetus as the pregnancy progresses. Children between the

ages of 3 and 12 may want to track the growth of the fetus as the months progress. The older child can accompany the mother on her prenatal visits and listen for the baby's heartbeat. Also, involving siblings in preparing the home for the new baby can help them to feel that this is their baby too. Especially for the younger siblings, advance notice of the hospital stay and helping them to understand that they will be taken care of while the mother is away is extremely important. Including the child in the care of mother and baby can help with the transition once the infant is born. The nurse can assist the family in understanding that the sibling may not be immediately elated to have to share the parent's attention with this little stranger. The parents need to provide a smooth transition by keeping the sibling informed of coming events. The nurse can advise the family to monitor the attention that is showered on the new arrival and to provide a similar level of celebration for the brother or sister.

Grandparents

The grandparents' level of involvement in the pregnancy and birth of their grandchild is dependent on many variables. Today, geographic distance to the new family may not allow the level of involvement that was experienced by their grandparents. Grandparents today are typically expected to be available for the young family if an emergency arises. The new parents may call and ask advice or seek counsel from the experienced older parents. The financial situation, health, mental capacity, and working status influence the grandparents' ability to assist the new parents.

In today's family, both grandparents may be involved in careers and be focused on a retirement goal. The younger grandparent may have difficulty adjusting to the connotation of aging when they are called grandmother or grandfather. Grandparents with an active business and social life may resist being involved at the level others feel is appropriate. The conflict between reality and expectations can cause discord between family members. Nurses can discuss these issues during prenatal visits to assist the new parents in planning the involvement of the grandparents in ways that fit into everyone's lifestyle.

A growing phenomenon in the United States is the increasing number of grandparents who are raising their grandchildren. In 1997, Thomson, Minkler, and Driver (2000) reported, 3.7 million grandparents had taken their grandchildren into their homes to raise; of these, 2.3 million were single grandmothers. Many times, the parents are not living in the home with the family, which places great stress on the unprepared guardians. Grandparents are attempting to accomplish their own developmental tasks and the new role of late parenting may cause confusion and social and financial concerns.

Figure 15-19 Young children can be encouraged to be involved in the pregnancy to develop a connection with the baby before birth.

CULTURAL CARING

What is a culture? The word is used to describe the intellectual, social, and artistic styles of a group of people, but for this discussion, we are referring to the customs, beliefs, and behaviors that have been learned through association with a particular group of people (Galanti, 1997). The learned behaviors of individual cultures are shared within the group and passed down to future generations. But there are factors that can dilute the culture and cause members to stray from their specific culture. When an individual has lived among people of another culture, especially since childhood, or has achieved a different social or economic class, their behaviors may deviate from their cultural heritage. The dilution or absence of the original culture is the reason why individuals should not be stereotyped. For example, the nurse assumes that because a woman appears to be from Mexico that she has or wants a large family. If the woman was born and raised in the United States in a predominantly Caucasian environment, a large family may not be a priority. It is acceptable to generalize concerning cultural behaviors, if this is used only as the beginning of an assessment to ascertain the true feelings of the individual client.

Because each person has values that are important to them, there are values that different cultures view as important. In the United States, freedom, independence, and autonomy are values that many people feel are important. In many cultures, remaining in the family home where members can assist each other with day-to-day activities is far more acceptable than obtaining independence from the family. The view of family involvement sometimes causes conflict with the American health care system's values of efficiency and self-control. Some cultures want the involvement of their family members in decision making and

care and as intermediaries. Nurses must avoid ethnocentrism, i.e., the view that a certain culture's way of doing things is the only appropriate way, and attempt to be open-minded concerning the individual's values, beliefs, and behaviors, the view that is called cultural relativism (Galanti, 1997).

A person may see illness differently from the dominant health care community norms. Most medical models in the United States rely on the belief that germs, viruses, and environmental toxins cause disease and that health can be maintained through diet and exercise. Galanti (1997) states that, in some cultures, the world view is focused on the belief that these aspects of life are out of human control and in the hands of a greater being. Some cultures also relate to the natural aspect of all things and strive to obtain harmony with the earth. These individuals may prefer to treat ailments with herbal medicine or through prayer, touch, or meditation. There are cultures that do not view pregnancy as a medical condition, so the pregnant woman may not see the necessity of prenatal care. In these situations, it is necessary to explain the importance of health teaching and maintenance and not assume that everyone views healthy behaviors in the same way.

Another aspect of cultural differences that often becomes evident in pregnancy is the relationship of the father and mother. Most Americans believe that the man or partner should be involved in every aspect of the pregnancy and delivery. In some Middle Eastern families the man is present during the pregnancy and delivery to protect the woman's virtue, not to assist the woman with the birth. The woman of Mexican heritage may prefer her mother to attend her delivery, and the man may feel that his presence is inappropriate.

Nurses have an opportunity to act as advocates to the women of different cultures that make up the American population. Nurses can design and implement programs that integrate the customs and values of the culture into the care of pregnant women. Mayberry, Affonso, Shibuya and Clemmens (1999) described a health care program, "*Malama Na Wabine*", or Caring for Pregnant Women for the native Hawaiian, Filipino, and Japanese women living in Hawaii. Mayberry and associates designed the program to acknowledge the value and self-esteem of the women they served by incorporating their customs and beliefs into every aspect of their care. Examples of cultural interventions that were used in the program included:

1. Enlisting the assistance of local cultural healers to participate in the program as recruiters and caregivers.
2. Using "talk story," a form of communication that is used by the women in this culture to deliver knowledge.

PREPARATION FOR THE INFANT

A lack of preparation for the birth of the baby may indicate a problem in meeting the task of role transition. However, some cultures or families do not actually purchase any items for the baby until after birth, because purchasing gifts for the baby before birth is believed to bring bad luck. Nurses must be sensitive to cultural practices different from his or her own and not assume that the couple who has not established a nursery before the birth is not eagerly awaiting the new baby's arrival.

3. Helping women choose a name for their newborn that honors their culture.
4. Providing *lomilomi* massage, which demonstrates health promotion, as part of the care of the woman and newborn.

The nurse's role in caring for clients of different cultures is to develop an individualized plan of care for each woman that supports her beliefs and customs and, at the same time, provides healthy and safe interventions for a positive outcome.

COMPLEMENTARY THERAPIES

Consumers of health care are turning to complementary therapies in large numbers. The odds that a pregnant client is practicing some type of complementary therapy are high. Strasen (1999) defines "complementary medicine" as any practitioner or practice that is not in the realm of traditional medicine. This definition opens up a wide range of healing methods to consumers as a complement to what maybe viewed as usual health practices. Assisting clients to feel good on emotional, spiritual, and physical levels is a common goal of complementary therapists. Frequently, complementary practitioners may view their role much the same as the holistic role of the nurse, i.e., to assist the client in bringing optimal health to the body, mind, and spirit.

In pregnancy, most of the complementary therapies practiced today can be beneficial in assisting the woman with easing the discomforts of pregnancy and providing mental calm in the midst of a fast-paced world. The area in which caution may be necessary is that of herbal medicine. In 1994, the FDA passed the Dietary Supplement Health and Education Act (DSHEA), which places herbal products within the dietary supplement category and, with this act, herbal preparations became available over the counter. To date, there is no regulation of the quality of these supplements, and research into the effects of these supplements on pregnancy is just beginning. Women who request information on the use of herbs during pregnancy should be advised to avoid using them in any form during the first trimester and to seek the advice of their health care practitioner concerning the use of herbs in later pregnancy.

Because a large number of women are using complementary therapies, the nursing assessment should include questions concerning these practices. The information enables the nurse to advise the woman on the continuation of these therapies or to seek further consultation concerning the safety of the practice during pregnancy.

NURSING PROCESS

The nursing process in the care of the pregnant woman represents a map for the most direct route to wellness. The steps included in the nursing process operate in a continuum to provide a framework for individualizing the client's care.

Assessment

In performing the client assessment, there are many tools available to the nurse. Prerequisites for a thorough assessment include being nonjudgmental, open-minded, empathic, and a skilled interviewer; having a knowledge of physical assessment skills and parameters; and exhibiting the ability to communicate and to collaborate. As the assessment is continuous, every time the nurse has contact with the client, her family, her friends, or other health care professionals, a synthesizing process should take place.

Interviewing is a skill that is essential to the nurse's data collection. The data that is collected should come directly from clients and their families. An important aspect of interviewing is to listen in an unbiased manner, understanding that the client and her family are the experts in this portion of the data collection. The questions should explore biophysical, psychosocial, cultural, and spiritual aspects of the client's well-being. The interview is an opportunity to begin to develop a relationship with the client and accumulate a primary list of needs.

The setting, client complaint, and client status guide the direction of the physical assessment and at what point in the health continuum that the nurse-client interaction occurs. In a physician's office the role of the nurse may be to assist with the assessment and in the emergency room an initial focused assessment may be appropriate, but on hospital admission after stabilization, the nurse should complete a full physical assessment. The nurse caring for the pregnant woman must remember that there are two clients, the woman and her fetus; each requires an assessment that entails specific parameters. During the prenatal course, the nurse plans and organizes the care process over a period of time, documenting the outcomes clearly. The assessment data that is contained in the prenatal record provides a basis for the prenatal needs assessment and also for the intrapartum and postpartum needs assessment.

Data obtained from diagnostic studies is included in building the database. Studies that are completed in the prenatal period are used to identify client care needs throughout pregnancy, labor, and delivery. Computerized documentation that can be shared between the prenatal provider's office and hospital or birthing center is invaluable because of easy access at all hours of the day or night.

Nursing Diagnosis

Nursing diagnoses provide a uniform method of communicating the pregnant client's concerns and needs. The nursing diagnoses reflect the nurse's clinical judgment concerning actual or potential problems for the client, the family, or the community. When prioritizing needs of the pregnant women, the nurse should involve the client, family, and other disciplines to be sure the plan is correctly focused and realistic.

Outcome Identification

The pathway for nursing care is outlined in the outcomes defined for the nursing interventions. For the pregnant woman, outcomes are typically centered on nursing diagnoses relating to a healthy pregnancy, successful adaptation to new family roles, and preparation for motherhood. In identifying desired outcomes, the nurse should make every effort to involve the pregnant client's partner or family, according to client wishes, and to incorporate the client's personal goals for her pregnancy.

Planning

Once the nursing diagnoses and outcome statements have been developed, the nurse and client should plan care that will result in an achievable and desired response of the client, family, or community to the nursing interventions. Planning should take into account such factors as quality of life, acuity of medical condition, resources, time, finances, and situation. Working with the client to establish an individualized plan of care is important, because both the client and the nurse are accountable for accomplishing the planned outcomes.

Nursing Intervention

Interventions are derived from the nurses' knowledge base and through consultation with other disciplines. The interventions should be based on scientific principles and implemented with an understanding of where the pregnant client is on the continuum of wellness. Other healthcare providers may complete some of the interventions that are

Nursing Tip

SUCCESSFUL EVALUATION

Questions that the process of evaluation will answer are:

1. Were the diagnoses correct?
2. Have the outcomes been met?
3. Should the interventions be changed?
4. Have new problems occurred?
5. Should new healthcare providers be involved?
6. What interventions were most effective and should other interventions be included?
7. Are new outcome criteria required?

The evaluation process should be thought of as a flowchart of the client's care with ongoing assessment of the client's needs.

included in the plan of care for the pregnant client, and the role of the nurse may be coordination or delegation. It remains the nurse's responsibility to ensure that the plan of care is updated as the interventions are completed; this is accomplished through complete documentation at each prenatal visit.

Evaluation

The nurse must assess the pregnant client's response to the interventions, and then make adjustments to the plan of care. By interviewing the client at each prenatal visit, the nurse can ascertain the client's comfort level with the plan of care and make adjustments as new diagnoses present or other factors change.

Nursing Tip

SUCCESSFUL PLANNING

Because the plan of care is a communication tool to organize and prioritize the client's care, all entries should be timed, dated, and initialed.

Critical Thinking

Additional Nursing Diagnoses

Refer to the case study of 16-year-old Rhonda. Develop a care plan that includes these additional nursing diagnoses:

- Compromised family coping
- Risk for impaired parenting
- Deficient knowledge (infant care)
- Home maintenance management, risk for impaired

Case Study/Care Plan

ADOLESCENT PREGNANCY

Rhonda is a 16-year-old female at 26 weeks' gestation. Her vital signs are within normal limits and her weight gain is at 17 pounds. She states she is still smoking because she is concerned about gaining too much weight. She presents to the clinic for only the second time, complaining of difficulty having a bowel movement. Rhonda has stopped taking her prenatal vitamins because one of her friends told her they could make her constipated. She is living with the father of her baby. She continues to wear the clothes she wore before she was pregnant, although they appear tight and uncomfortable.

Assessment

- Age 16 at 26 weeks' gestation
- Vital signs normal
- Risk for fetal injury results from maternal smoking and lack of prenatal care
- Constipation
- Body image disturbance

Nursing Diagnosis

Risk for fetal injury related to cigarette smoking and limited prenatal care

Expected Outcomes

The client will:
 Verbalize understanding of the risk to the fetus from cigarette smoking
 Verbalize importance of prenatal visits to maintain a healthy pregnancy
 Demonstrate lifestyle changes that reduce the risk to the fetus

Planning

Collaborating with client, determine desired means of delivering necessary information, based on client's learning style and preferences.

Nursing Interventions

Rationales

- | | |
|---|---|
| 1. Stress the importance of ongoing prenatal care to monitor the growth of the newborn and to prevent maternal complications. | 1. Many teens feel well and do not understand the necessity of prenatal visits. |
| 2. Explain the hazards to the fetus from maternal cigarette smoking. | 2. Smoking can cause growth retardation and an increased incidence of SIDS. |
| 3. Help client to identify her motivation to smoke and her motivation to stop smoking. | 3. Teen mothers are more receptive to changing health habits if the reasons are outlined in a nonjudgmental manner. Offering the option of cutting down and then quitting may soften the request. |
| 4. Refer her to a support group or find another teen who has successfully stopped smoking to discuss options with her. | 4. Engaging Rhonda in group or peer support sessions may help her to feel less socially isolated. |

Evaluation At Rhonda's next visit, she was able to verbalize the necessity to stop or at least curtail her smoking. She had cut her smoking down to three cigarettes a day and was working to completely stop smoking. She still appeared doubtful that the prenatal visits were necessary. Refer Rhonda to the clinic's teen childbirth classes.

(continued)

Nursing Diagnosis

Constipation related to smooth muscle relaxation, slowed intestinal motility, ingestion of iron supplements, and diet.

Expected Outcome Rhonda will maintain her normal pattern of bowel function.

Planning Determine with client her usual bowel patterns and what routine would make her comfortable.

Nursing Interventions	Rationales
1. Assess for prepregnant elimination patterns.	1. With appropriate diet, usual elimination patterns should be maintained.
2. Assess for dietary history and make recommendations based on nutritional needs	2. A dietary history tells the practitioner what modifications need to be made.
3. Instruct on the benefits of increasing fiber intake. Consult the dietitian to identify high-fiber foods that are acceptable to a teen. (fruit and salads may be the most acceptable to the teen).	3. Adequate bulk and fiber assists in regulating bowel movements; a teenager's eating habits are influenced by peer pressure.
4. Advise client to increase fluid intake, avoiding drinks with caffeine. Encourage water, flavored water, fruit juices, or sports drinks.	4. An increase in fiber without an increase in fluids may compound the elimination problem.
5. Encourage mild exercise, such as brisk walking or riding a bicycle.	5. Exercise promotes peristalsis and may help to prevent constipation.
6. Encourage client to continue taking prenatal vitamins and, if constipation remains a problem after dietary adjustments, contact the healthcare provider.	6. Remind the client that prenatal vitamins are important to a healthy pregnancy and to the proper development of the baby.
7. Caution against the use of stool softeners or laxatives.	7. Never take medications that have not been approved by a healthcare provider.

Evaluation The nurse called Rhonda at home 5 days after her visit. She had increased her fluid intake to 6 to 8 glasses per day of water or a sports drink. She was eating fresh and dried fruit and salads. She continued to take her prenatal vitamins and her bowel movements had returned to her normal pattern.

Nursing Diagnosis

Disturbed body image related to pregnancy, as evidenced by wearing of prepregnancy clothing.

Expected Outcome Client will: verbalize understanding and acceptance of body image changes that are occurring

Demonstrate a positive self-image by maintaining an appropriate appearance

Planning Collaborate with client to understand her self-image and what she is or is not willing to change.

Nursing Interventions	Rationales
1. Determine Rhonda's attitude toward her pregnancy, changing body image, and her peers' and significant other's reactions. Suggest that her significant other accompany her to her next prenatal visit.	1. Her views on her pregnancy affect how she feels about her body and about becoming a mother. The father of the baby is a strong influence on health behaviors.
2. Identify Rhonda's sense of self-esteem in relationship to her pregnancy and her new role. Assess her relationship with her mother and the availability of other female role models.	2. Honest, nonjudgmental, respectful treatment facilitates interactions with the client. Female role models are helpful in the transition to the motherhood role.

(continued)

Nursing Interventions

3. Review the physiologic changes of pregnancy and why these changes are necessary for the development of her fetus; assure her that mixed feelings are normal.
4. Assess her ability to purchase or borrow comfortable maternity clothes. Make a referral to social services or targeted case management for assistance.

Rationales

3. Show her that the changes in her body are normal and beneficial to the growth of the fetus. Talking through her feelings helps to decrease the stress she may be feeling.
4. Embarrassment concerning financial issues may prevent her from purchasing or borrowing appropriate clothing.

Evaluation The case manager made a visit to Rhonda's home with several maternity outfits that were appropriate for a teenager. She discussed the role of parenthood with both Rhonda and her significant other. While in the home, she assessed the couple's plans for caring for the infant and adapting to the changes they need to make in their lifestyle. Rhonda had new questions about the changes occurring in her body and felt comfortable discussing these with the case manager.

Key Concepts

- The presumptive signs of pregnancy are the subjective signs noted by the woman and include amenorrhea, nausea and vomiting, urinary frequency, changes in the breast, and quickening. Probable signs of pregnancy are the objective signs noted by the examiner, such as uterine enlargement, Goodell's sign, Chadwick's sign, Hegar's sign, and positive results on pregnancy tests. Detecting the fetal heart rate and fetal movement and visualization of the fetus by ultrasound are the positive signs of pregnancy.
- There are anatomic and physiologic changes that occur in virtually every body system of the pregnant woman. These changes are necessary to accommodate the growing fetus.
- Plasma volume increases by 50%; red blood cell volume increases by 18% to 30%. The disproportionate increases in volume cause a dilution of the red blood cell volume that results in the physiologic anemia of pregnancy.
- Maternal cardiac output increases from 4.5 L/min to 6.0 L/min. The uteroplacental unit requires approximately 17% of this volume to achieve adequate perfusion.
- In preparation for lactation, the number of mammary alveoli increase, the breasts become physically larger, areolae broaden, nipples become firmer and more erect, and the tubercles of Montgomery, sebaceous glands, begin to secrete a substance that keeps the areolae supple.
- The position of the heart is changed; it is pushed upward to the left and rotated. These changes mimic cardiomegaly on normal radiographic films. In 90% of pregnant woman, a systolic heart murmur can be heard at 20 weeks' gestation.
- When the woman lies in the supine position, the gravid uterus may compress the vena cava and descending aorta. The compression can cause maternal hypotension and decrease the blood return to the heart.
- Many of the discomforts of pregnancy can be linked to changes that occur in the body systems to accommodate a pregnancy.
- Blood flow to the kidneys is increased, which in turn increases the glomerular filtration rate. Because of this increase, absorption is not always complete and glucose periodically spills into the urine. Protein may also be detected in the urine, but proteinuria of more than 300 mg in 24 hours warrants further investigation, especially when accompanied by hypertension and edema.
- Individuals, as well as families, are challenged to successfully accomplish developmental tasks that move them toward role adaptation.

- Siblings need assistance in dealing with the changes that occur when a new individual is brought into the family.
- An assessment to identify cultural values, customs, and beliefs should be completed for every client. The information gathered should be incorporated into the client's plan of care.
- The involvement of the client, her family, and the community is the key to planning a realistic and achievable plan of care.

Web Activities

- What resources can you locate that give mothers self-help tips on alleviating the discomforts of pregnancy? Do they offer resources to download?
- What types of organizations offer this information?
- Would you encourage your clients to use the Web? If so, what type of advice would you give concerning the use of Web resources?

Review Questions and Activities

1. All of the following are considered presumptive (subjective) signs of pregnancy except:
 - a. Nausea and vomiting
 - b. Urinary frequency
 - c. Fetal heart beat
 - d. Fatigue

The correct answer is c.

2. During pregnancy, the plasma volume increases by 50% and the red blood cell volume increases by 18% to 30%; the disproportionate increases results in the following:
 - a. Iron deficiency anemia
 - b. Sickle cell anemia
 - c. Thalassemia
 - d. Physiologic anemia of pregnancy

The correct answer is d.

3. An assessment to determine what aspects of the client's culture may affect her plan of care should include:
 - a. Traditional customs and behaviors related to preparation for birth
 - b. Beliefs related to who should be present at the birth
 - c. Values related to congenital defects
 - d. All of the above

The correct answer is d.

4. A new baby affects the family unit, especially the newborn's siblings. What measures should be avoided in helping siblings adjust to the transition?
 - a. Involve the sibling in planning the nursery.
 - b. Answer questions in a honest and straightforward manner.

- c. Use age-specific books to inform the sibling of the fetus' growth.
 - d. Avoid telling the sibling when it is time to go to the hospital for delivery.

The correct answer is d.

5. Maternal cigarette smoking can be hazardous to the growing fetus. Which of the following is not a common risk of maternal cigarette smoking?
 - a. Heart defects
 - b. Increased incidence of SIDS
 - c. Low birth weight
 - d. Increased incidence of apnea

The correct answer is a.

6. When a pregnant woman lies in the supine position, what potentially harmful physiologic processes occur?
 - a. Increased edema in the hands and face
 - b. Maternal hypotension
 - c. Decreased blood return to heart
 - d. After a prolonged period, decreased oxygen to the fetus

The correct answer is d.

7. During adaptation to the role of motherhood, the woman must accomplish all but which of the following developmental tasks?
 - a. Giving of oneself
 - b. Binding in to the child
 - c. Fantasizing or dreaming
 - d. Shift her affections and alliance from her husband to the developing infant.

The correct answer is d.

8. Complementary therapy is becoming more accepted in the United States. Which of the following therapies would you as the nurse be cautious about suggesting to the pregnant woman?
- Reflexology
 - Meditation

- Herbal therapy
- Imagery

The correct answer is c.

Management and Nursing Care of the Pregnant Woman

Nursing care centered around health promotion and health maintenance during pregnancy presents an excellent opportunity for nurses to teach mothers about normal changes expected and alert them to a variety of risk factors. You may be in contact with clients who have thoughts, values, feelings, and circumstances that are different from your own. Examine your feelings and values elicited by the following questions:

- How do I feel about my own past or potential future experiences with pregnancy? Would my feelings be different about a planned compared with an unintentional pregnancy?
- How do I view all the physical changes that occur during pregnancy? How do I feel about these things happening to my body?
- Have I ever known a woman who did not value prenatal care as a priority in her childbearing life? How do I feel toward her and her family?
- What are my feelings about the varying degrees of importance attached to childbearing in my culture? In other cultures?
- How do I feel about families having several babies while they are receiving public assistance or welfare? What are my feelings as I see them for prenatal care?

F.P.A.L.	Midpelvis	Pelvic inlet	Primipara
Gravida			

Competencies

Upon completion of this chapter, the reader should be able to:

1. Discuss the advantages of preconception care and counseling for a woman and her partner who are planning a pregnancy.
2. Discuss factors related to accessing prenatal care.
3. Describe areas of physical and psychosocial assessment that are covered in an initial prenatal visit and in subsequent visits.
4. Summarize normal physiologic changes encountered during each of the three trimesters of pregnancy.
5. Explain nursing interventions and teaching points used to assist clients in dealing with the commonly occurring discomforts of pregnancy.
6. Describe risk-assessment measures recommended for routine prenatal visits in uncomplicated pregnancies.
7. List eight danger signs for which clients should be taught to seek immediate medical attention.
8. Discuss the teaching materials and aids available to nurses and clients.

Most health professionals who provide perinatal care can readily and easily explain the goal of prenatal care. They report, very succinctly, that the goal is the delivery of a healthy infant by a healthy mother at the end of a healthy pregnancy. Indeed, this is the ideal outcome that, if achieved with each pregnancy in the United States, would be very impressive in light of the goals listed in *Healthy People 2000* and *Healthy People 2010*.

Pregnancy and childbirth are normal physiologic processes that traverse dynamic, but still normal, changes from conception to delivery. The nurse has a unique opportunity to reinforce the normalcy of these processes and, at the same time, assess clients for possible deviations that require intervention. Additionally, the nurse can interpret for clients the changes that are taking place and provide valuable guidance for clients and their families, thereby facilitating their progression through the process with understanding and confidence.

Early contact between the health care team and the pregnant client provides the opportunity to address the

complementary yet separate concepts of health promotion and health maintenance. **Health promotion** consists of education and counseling activities that help enhance and maintain health and healthy behaviors. The focus is on increasing knowledge to foster deliberate, active participation in achieving or attaining an optimal state of well-being. **Health maintenance** is the concept of prevention or early detection of particular health deviations through routine periodic examinations and screenings. Prevention is the primary goal; earliest possible detection and eradication or alleviation is the secondary goal. Part of this process is the identification of risk factors, particularly in vulnerable populations.

BENEFITS OF EARLY CARE

For many years health care professionals have supported the idea that the general health, and particularly the nutritional status of a woman before pregnancy, is the best predictor of her pregnancy outcome. Generally stated, the

healthier the client before pregnancy and the better her nutritional state, the better the pregnancy outcomes, especially in terms of the baby's health. Although this may be accepted as an accurate statement, the nurse must not overlook the elements involved here. It is unlikely that a state of good health "just happened" for those particular women. Closer examination usually reveals that a conscientious self-help effort took place to produce this healthy state. These efforts encompassed good nutrition patterns, regular exercise, and avoidance of known deterrents to good health. Additionally, these women were probably diligent in seeking routine periodic health examinations and in maintaining the recommended immunization status.

PRECONCEPTION CARE

With the empirical evidence available suggesting that healthy infants are born to mothers who were in optimal health before pregnancy, researchers have undertaken an examination of factors of importance before pregnancy and, thus, even before early prenatal care. This approach is **preconception care**, or consultation with health care professionals by a client before pregnancy to facilitate optimal pregnancy outcomes (Figure 16-1). Proponents of preconception care emphasize that the most critical and vulnerable time for a developing fetus is the interval of days 17 to 56 after fertilization of the ovum. These earliest days usually have passed before even the most conscientious client seeks prenatal care. Therefore, in order to avoid known potentially damaging agents to the embryo, preconception care can be even more valuable than early prenatal care (Perry, 1996). Hazards encountered during this time frequently translate into high infant morbidity or mortality rates.

Figure 16-1 Many couples visit their health care provider for preconception counseling.

Researchers have carefully examined maternal and perinatal morbidity and mortality rates for many years. The elements of these statistics, such as incidences of stillbirths, preterm births, congenital defects, and spontaneous abortions, have been categorized and classified in many different ways. Data are available relative to total numbers of incidences from year to year, incidence by socioeconomic group, by race or ethnic group, by maternal education level, and by early compared with late entry into the health care system for prenatal care. Despite all that is known about the statistical correlations and relationships between and among these factors and pregnancy outcomes, little progress has been made in decreasing the negative outcomes. In other words, knowledge of factors associated with poor pregnancy outcomes does not automatically translate into lowering of subsequent morbidity and mortality rates.

Two problems for the neonate, low birth weight and congenital anomalies, have remained a challenge for health care professionals (Cefalo & Moos, 1995). Obstetrical care procedures and practices are not proving to be the answer to these two persistent problems in the United States. As Cefalo and Moos pointed out, the incidence of low-birth-weight neonates is not significantly different from that in the mid 1960s; more striking is the fact that the incidence of congenital anomalies has only minimally decreased in the last century. According to the Centers for Disease Control and Prevention, the most favorable data reflected only a 2% per year decrease in the incidence of neural tube defects, congenital rubella syndrome, and Rh hemolytic disease.

Early prenatal care is acknowledged as an important factor in achieving positive pregnancy outcomes, even though documentation of the cost savings (by decreasing the number of low-birth-weight and premature babies) is elusive (Huntington & Connell, 1994). Stated another way, the cost of care for premature and low-birth-weight infants is known; however, what is unknown is the numbers of these at-risk births that are remedied by early prenatal care. In many instances of early prenatal care, low birth weight and congenital anomalies (with varying degrees of severity) continue to occur in infants.

Preconception Assessment

Preconception care is ideally managed by specialists in gynecology and perinatology and involves a team approach. The team leader may be a physician, nurse practitioner, Certified Nurse Midwife, or other comparably trained professional. Findings during the initial session may indicate the need for inclusion of other personnel on the team. For example, an endocrinologist can provide valuable input for a client who has diabetes or a geneticist may clarify risk factors for a client with a family history of genetically transmitted disorders.

Critical Thinking

Congenital Anomalies as a Major Cause of Infant Deaths in the United States

You often work with clients who give birth to infants who have congenital anomalies with known causes. Examine your feelings about the client's responsibilities for a birth anomaly.

- Did they knowingly risk exposure to any teratogens?
- Were they innocent victims of exposure?
- Are your feelings toward these clients different?
- Is the quality of your care influenced when you feel a client has been careless in taking care of herself and her developing fetus?

Many of the elements of preconception care can be introduced in a variety of health care settings. In the absence of an available specialized team, nurses in primary care settings (particularly in the community) can initiate care and distribute literature during routine health screenings or during group classes for health promotion (Perry, 1996). Clients interested in having children “some day” should have access to all information pertaining to factors associated with healthy pregnancy outcomes.

Early Interventions

Cefalo and Moos (1995) have summarized the components of preconception care into three general categories. The first category is systematic identification of risks from the comprehensive histories of the client and her partner, such as social factors, medical concerns, nutritional status, family structure, reproductive issues, medication use, and history of infectious disease. Next is the provision of educational materials that are indicated for each individual client and her partner. These should be factually accurate and culturally sensitive materials. Third, access to complementary and supplementary services such as special nutritional counseling or smoking cessation programs should be facilitated.

PRENATAL CARE

Early prenatal care presents benefits to the client, her partner, her family, and the health care team assuming responsibility for her care. Numerous teaching opportunities arise, especially regarding interpretation of normal physio-

logic changes that occur as the pregnancy progresses. In addition, psychological concerns can be addressed early on, thus avoiding stress and undue concern for clients. In summary, early prenatal care allows psychological, physiologic, cultural, and social concerns to be addressed while maternal and fetal well-being and the overall pregnancy status are monitored simultaneously.

Availability and Accessibility of Care

Many clients have reported that a major factor in seeking early prenatal care is access to care. Location of facilities and ease of getting into the “system” frequently are cited as factors that determine when a client goes in for her first visit. Whereas many clients seek care from physicians with offices in medical complexes or corporate-type buildings, many others prefer a neighborhood clinic where they have more convenient access. Nurse practitioners and nurse midwives practice in a variety of settings but generally are found in community clinic settings. When the work setting is in the community, nurses can glean a clearer understanding of their clientele, possible environmental concerns, and available resources. Additionally, the nurse can develop a deeper cultural sensitivity to clients and their families.

The report of The Pew Health Professions Commission (1991), *Healthy America: Practitioners for 2005*, presented an agenda for action as a guide for schools and professionals themselves. The focus was twofold: present competencies expected of health care practitioners, and present strategies for achieving changes that must occur in the education of health care professionals. The report is replete with emphasis on delivery of primary care that is community-based, teaching oriented, and involves clients and families in decision-making. The emphasis of this report reinforces what nurses have known for years: community-based health care by well-educated professionals that involves client and family involvement in mutual decision-making is ideal for the childbearing family.

Facilitation of Client Access to Care

Approaching the health care system can provoke fear in many clients, especially those with language or cultural differences. Additionally, concerns about costs and lack of knowledge regarding affordable resources can be deterrents for clients needing prenatal care. A very helpful model has been presented by McFarlane (1996) that uses a grass-roots approach for facilitating entry into the health care system for primary care. This particular program, called *De Madres a Madres*, or “Mothers to Mothers,” is

truly community-based. It is centered around training selected women in the community and increasing their knowledge of community resources and the health care system. These women, in turn, assist other women in their community by sharing resource information and facilitating entry into the primary care setting. Empowerment of community residents is the basis for the success of such programs (McFarlane & Fehir, 1994).

Public education programs can be very effective in facilitating early and consistent use of prenatal care. The nurse can make a valuable contribution to these programs by participating in public service announcements or becoming active in organizations, such as the March of Dimes, whose efforts are directed toward formal educational programs and development of professional and lay literature.

Barriers and perceived barriers to adequate prenatal care have been studied for many years. Through the years, as poor pregnancy outcomes have become associated with late or limited prenatal care, more research has emerged related to the reasons for limited care. The Institute of Medicine (Brown, 1998) published a compilation of such studies and an in-depth review of numerous programs throughout the United States developed to enhance use of prenatal care. Numerous studies report typical, predictable barriers: finances; transportation; inconveniences of language, clinic hours, and location; and work schedule problems. More recently, clients have reported concerns about the possibility of being asked to have an abortion, having their baby taken away, or facing deportation because of their lack of citizenship.

Many communities have programs or plans to assist clients with the specific concerns listed previously. Barriers

can be viewed as challenges awaiting creative or innovative solutions. The nurse should be tuned in to self-imposed barriers of clients that reflect a poor understanding of or attaching little value to prenatal care. Situations of this nature require a sensitive approach to fact-finding regarding the client's and family's beliefs and values. This information can then be incorporated into a teaching plan that encourages early and consistent prenatal care. As an example, most clients and their partners value the health of their children, even in the absence of concern about their own immediate health state. The value of prenatal care can then be presented in terms of a healthy start for their baby at birth.

Components of Prenatal Care

Once the client and her partner have entered the health care system for prenatal care, several areas of assessment and monitoring will be covered at each visit. Depending on the findings for each individual case, the monitoring may vary slightly at each visit. For example, a client with prepregnancy diabetes may receive more frequent or closer monitoring for complications associated with diabetes. Other clients would receive routine (prescriptive) monitoring for glucose in the urine.

Based on assessments, specific client education or anticipatory management usually is indicated. Regardless of individual conditions or circumstances, all prenatal care covers assessment of maternal and fetal well-being from all aspects: physiologic, psychologic, economic, and sociocultural.

The Initial Prenatal Visit

The initial prenatal visit, especially in the absence of preconception care and counseling, can be rather lengthy. At this time a detailed medical history and physical examination are completed for baseline data. Accuracy of this baseline data is particularly important because health care providers will be referring back to it throughout the pregnancy. Nurses can assist clients through this time-consuming process by pointing out the importance of each step and by emphasizing that subsequent visits should be briefer.

As appropriate, nurses should congratulate clients for seeking early prenatal care and encourage early prenatal care for subsequent pregnancies. Aside from the logical benefits of early care, the physical examination for pregnancy confirmation, determination of uterus size, and measurements of the pelvis can be done more easily and with more comfort for the client in early pregnancy than later in the pregnancy. The practitioner also can make a

ENCOURAGE THE CLIENT TO KEEP ALL APPOINTMENTS FOR PRENATAL CARE

- Provide the client with a schedule of frequency of visits by trimester.
- Emphasize the timing of various screening and monitoring activities at each visit. Explain why the time of the monitoring is so important.
- Point out the importance of all screening and monitoring activities scheduled. Indicate which tests are for the mother's benefit and which are for the baby's benefit.

more accurate physical assessment when the client is not in an advanced state of pregnancy.

Pregnancy Confirmation

Many times clients and partners appear at a prenatal clinic for one distinctive purpose: to find out for sure if they are pregnant or not. Some clients may have already conducted an at-home pregnancy test and are seeking validation of the results. The availability and affordability of over-the-counter test kits have made them increasingly popular. However, the accuracy of the results is highly dependent on proper use of the kits, a point emphasized in the manufacturers' instruction sheets. Confirmation of pregnancy in the office or clinic setting usually is by means of a urine test for the presence of human chorionic gonadotropin (hCG). If necessary, a blood test for the same placental hormone can be performed (Cunningham, MacDonald, Gant, Leveno, Gilstrap, Haulcius & Clark, 1997).

Estimation of Due Date

After confirmation of a pregnancy, the next logical query from prospective parents is to estimate the date the baby is due to be born. This is commonly and historically referred to as the **EDC**, or expected date of confinement, reflecting the notion of the mother being confined to a specific area for the delivery. Other terms in common use are **EDD** for expected date of delivery, or **EDB** for expected date of birth. Clients usually refer to the EDB as their due date.

The EDC usually is calculated from the menstrual history, using a method called **Nägele's rule**. The calculation begins with the *first* day of the last menstrual period (or **LMP**); from this date, 3 months are subtracted and then 7 days are added. For example, if the first day of the LMP was September 15: $LMP - 3 \text{ months} + 7 \text{ days} = EDC \text{ 9/15}$ ($- 3 \text{ months} = 6/15 (+ 7 \text{ days}) = 6/22$).

The resulting calculated EDC is based on the presumption of ovulation occurring 14 days *before* the next anticipated period rather than 14 days *after* the last period began. This calculation usually is confirmed by a second method, measurement of uterine size, particularly as the pregnancy progresses. Neither method alone is deemed to be exact; however, the correlation of the findings of the two methods is fairly reliable. In clients with irregular menses, uterine size can be helpful in either confirming or redating the duration of the pregnancy.

Pregnancy wheels (Figure 16-2) are used to determine the EDC by aligning the arrow of the first day of the LMP and then reading off the date that corresponds with the 40-week mark. Aside from the dates, pregnancy wheels usually contain other information, such as corresponding weight and length of the fetus and height of the fundus at various weeks' gestation.

Figure 16-2 Gestation wheel. Place arrow labeled *first day of LMP* on date of LMP. Read date at arrow labeled *expected delivery date*.

Determination of Gravidity and Parity

Gravidity and parity are elements of an obstetric history that reflect number(s) of pregnancies and number of births, respectively. Gravidity and parity are used much like a shorthand way of recording these aspects without using lengthy phrases. **Gravida** is the term reflecting the number of pregnancies, regardless of duration or outcomes. A client who is pregnant for the first time thus is a gravida 1, a client experiencing her second pregnancy is a gravida 2, and so on. Sometime the gravida 1 client is referred to as a *primigravida*, meaning, literally, that this is her first pregnancy. Accompanying the gravida number is **para**, which is the number of births after 20 weeks' gestation, whether live births or stillbirths. Additionally, the term para, when expressed as a single number, does not reflect the number of infants born at a delivery but rather the number of pregnancies that have gone past 20 weeks' gestation. Thus, a client who has had only one pregnancy and gave birth to term twins would be considered a para 1 (one birth past 20 weeks' gestation), gravida 1 (reflecting her only pregnancy to date). If this same client experiences a second pregnancy, she would, at that time, be considered a para 1 (birth of her twins), gravida 2 (second pregnancy), using the para-gravida system of classification for obstetrical status.

Para also can be used in a four-digit system that gives more detailed information about past deliveries. This system refers only to past pregnancies and their outcomes; it does not reflect a current pregnancy. The four digits (**F.P.A.L.**) indicate the following in this order: the number of full-term deliveries (usually considered to be 37 to 40 weeks' gestation), the number of premature or preterm deliveries (between 20 and 36 weeks' gestation), the number of abortions (induced or spontaneous terminations of

pregnancy before 20 weeks' gestation), and the number of living children born to the client who are alive at the time of data collection. This number does not include adopted children or infants born alive who later (at any age) died. As an example, a woman who has had three term pregnancies, delivered three live infants, but suffered the loss of her 6-year-old son in an accident would be considered a para 3-0-0-2.

This system of classifying deliveries may seem even more confusing than the para-gravida system; however, it provides more comprehensive information. Until this system becomes thoroughly familiar, the nurse may prefer to use a mnemonic device such as “Florida Power And Light” to remember the terms. (Students in the 60s and 70s used “Flower Power And Love”.) The nurse is encouraged to remember that the first three digits are in order of time in utero, from longest to shortest. Doing so may assist in remembering the digits and their representations.

Other commonly used terms to describe the parity status of clients are **primipara**, a woman who has experienced only one birth after 20 weeks' gestation, and **multi-para**, a woman who has had two or more births after 20 weeks' gestation.

Medical History and Family Medical History

Comprehensive medical histories for the client and her partner should be obtained. Information is gathered and recorded in such a manner that critical elements and risk factors pertinent to the pregnancy can be identified. Sometimes even the simplest data may give rise to early identification of risk factors or the need to monitor the pregnancy more closely. For example, age, race, ethnic background, and even address may not be viewed as crucial information, yet each can provide the health care professional with a wealth of information for monitoring. The age group identifies at-risk clients, such as teens and women of advanced age. Race and ethnic background can direct the need for monitoring for certain genetic conditions, such as the sickle cell trait or anemia or inborn errors of metabolism (see Chapter 13). Similarly, ethnic background can direct attention to potential associated problems such as Tay-Sachs disease. The client's or partner's work and residence addresses may be important factors in relation to known contaminants or pollution, ranging from allergens to toxic industrial materials responsible for disease and birth defects.

All entries in a client's records are purposeful and should be explored accordingly with the client and her partner. The medical history provides an excellent starting point for the nursing process, particularly the sharing of expert knowledge and analysis and interpretation of information. The mutuality of data exploration cannot be

Nursing Alert

IMMUNIZATIONS CONTRAINDICATED IN PREGNANCY

- Immunizations with live (attenuated) viruses should not be given during pregnancy because of potential damage to the fetus.
- Preconception care encompasses assessment of immunization status with the opportunity to update immunizations, assuming avoidance of pregnancy in the near future.

Immunizations may be given in the postpartum period with emphasis on the use of contraception (for at least 3 months) to avoid an immediate pregnancy with possible fetal harm.

overemphasized. Clients and their partners often have information readily available but are unaware of its significance to their health status without interpretation by caregivers.

Information gathered for the medical histories is the same as for any client, with a few exceptions. The elements of the medical history provide an excellent database to identify risk factors that may or may not affect the pregnancy outcomes. Additionally, the medical history flags some items to be monitored as the pregnancy progresses. The gynecologic and obstetrical histories become more important with a pregnancy because factors may require special attention not required if, for example, the client is seeking medical care for a broken ankle.

A psychosocial history can be helpful in making an assessment of readiness for parenting. This history identifies a pregnancy as an intended compared with an unintended or a wanted compared with an unwanted pregnancy and the client's attitude toward the pregnancy. Intervention and referral as indicated at this time may prevent a situation of child abuse in the future. Other areas to be assessed from this history are the client's expectations from the pregnancy and the baby, that is, whether they are realistic.

Also included in the social history of the client and her partner is the use of alcohol, tobacco, or drugs. Positive findings provide health maintenance and health promotion teaching opportunities for the prospective parents and their infant.

The Physical Examination

The initial prenatal visit includes a physical examination that, with some exceptions, follows the systematic approach seen in routine physical assessments. A complete physical examination usually is performed only at the time

Client Education

Prenatal Visits

For a client to understand her time commitment and plan ahead for prenatal visits, she should know how often her return visits will be scheduled:

- Up to 28 weeks' gestation (covers first and second trimesters), every 4 weeks.
- 29 to 36 weeks' gestation, every 2 weeks.
- 37 to 40 weeks' gestation, every week.

of the first visit. Thereafter, the elements of the repeat visits are very much abbreviated, yet specific to the progress of the pregnancy and the well-being of the mother and fetus. As the nurse explains the routine of subsequent visits, she can once again explain that future visits will be briefer.

Several physical findings in pregnancy are abnormal in nonpregnant clients. In addition, changes occur from trimester to trimester that vary from the baseline but still are normal anticipated findings. An example of the latter are the hemoglobin and hematocrit values. Assuming a normal baseline of 12 to 15 g/dL and 35% to 45%, respectively, the nurse would not be alarmed to see these values (especially hemoglobin) decrease slightly in the third trimester. As the circulating blood and fluid volume increases with the progression of the pregnancy (see Chapter 15), the appearance of a true decrease in hematocrit is given. In reality, the number of erythrocytes is essentially the same; however, the erythrocytes are suspended in a larger amount of fluid, thereby yielding a smaller percentage value. This effect is sometimes referred to as physiologic anemia of pregnancy.

Laboratory Tests

Comprehensive prenatal care indicates specific laboratory tests that need to be performed at the initial visit and periodically throughout the pregnancy. The timing of some laboratory testing is crucial for an accurate assessment. If blood is collected too early or too late in the pregnancy, the values will not be very reliable. For example, initial hemoglobin and hematocrit testing at 30 weeks' gestation certainly provides information to the nurse; however, without an early baseline for comparison, assessment of normal compared with abnormal changes is difficult. In addition, some laboratory testing is time-sensitive within a tighter timeframe. An example is the glucose testing in which the glucose level is measured from a blood sam-

LABORATORY TESTS AT THE INITIAL VISIT

1. Blood work: complete blood count, hemoglobin, hematocrit, Rh status, and blood type. Screening for sickle cell trait, as indicated. Serology for syphilis; rubella titer, human immunodeficiency virus (HIV), and hepatitis screening, as indicated or as per department policy or client request. Glucose screening if the first visit is at 24 to 28 weeks' gestation. Alpha-fetoprotein screening if the first visit is at 16 to 18 weeks' gestation.
2. Urinalysis (with culture, if indicated): examine for glucose, protein, erythrocytes, leukocytes, and bacteria.
3. Pelvic laboratory tests: Pap smear, cultures for gonorrhea, Chlamydia, and group B *Streptococcus* if the first visit is after 24 weeks' gestation.

ple drawn 1 hour after the client drinks a glucola preparation.

Ultrasonography

In addition to a urine or blood test for pregnancy confirmation, ultrasonography is often used, depending on the length of gestation. This technology has been refined throughout the years to a very high level of sophistication. It can be used to identify a yolk sac, a fetal heart before it is audible with Doppler ultrasonography, the sex of the fetus, and internal structures of the developing fetus. Routine use usually is limited to pregnancy confirmation; assessment of fetal development and well-being, as indicated; sex determination, if indicated or desired; and overall fetal size as term approaches.

Further use of ultrasonography is indicated in cases of unusual findings that suggest deviations from a normal prenatal course. Examples of these situations include a fundal height inconsistent with calculated dates of pregnancy (larger, often with multiple gestation or some known fetal anomalies, or smaller, which may indicate poor fetal growth), or inability to find the fetal heart beat using routine methods.

Pelvic Examination

The pelvic examination, including collection of pelvic cultures and smears and the performance of the bimanual examination usually is the last part of the initial physical examination. The pelvic laboratory specimens are collected

first. Some of these (e.g., for chlamydia and gonorrhea) may be by DNA probe or culture. The bimanual examination is done to determine the uterine size and to assess for deviations in expected shape or size. Normal cervical and uterine changes expected in pregnancy (see Chapter 15) also are noted.

Assessment of the Bony Pelvis

Assessment of the bony pelvis is necessary to determine the probability of a fetus of normal size being delivered vaginally. A client who has already delivered an infant of 7 pounds or larger is said to have a “tried” pelvis, one with large enough measurements for delivery of another infant of normal size. True measurement of the pelvic structure usually is done using X-ray films; however, a reliable indirect measurement is possible with a pelvic examination by a skilled nurse or physician. Borderline or questionable measurements are cause for either further evaluation or careful monitoring for labor progression.

The pelvis consists of four bones: two os innominate (or os cocci), the sacrum, and the coccyx. The ischium, ilium, and symphysis pubis are anatomic regions of the bones and should not be confused with actual bones. The joints formed by the four bones are the symphysis pubis, two sacroiliac joints (junction of the sacrum and each os innominate), and the sacrococcygeal joint (connection of the sacrum and coccyx). The status of these joints takes on greater significance as the pregnancy progresses and these joints “soften.”

The pelvis is visually divided into three planes. The first plane is the **pelvic inlet**, with the transverse segment being corresponding points on the brim of the true pelvis and the anterior-posterior points being the back side of the symphysis pubis and the sacral promontory. This anterior-posterior diameter of the pelvic inlet is the smallest diameter. This is called the **obstetrical conjugate**; it is measured indirectly by the diagonal conjugate (Figure 16-3). The examiner inserts the middle and index fingers of the examining hand and touches the tip of the middle finger to the sacral promontory. At this point, notation is made of where the examining hand touches the symphysis pubis. The measurement of this distance on the examiner's hand can be done with an obstetrical caliper (Figure 16-4).

From this diagonal conjugate, the obstetrical conjugate (smallest diameter) can be estimated fairly accurately by subtracting 1.5 or 2 cm. The resulting measure should be at least 10.5 cm, assuming normal thickness and tilt of the symphysis pubis. A smaller measurement requires further evaluation.

The second pelvis plane is known as the **midpelvis**. The smallest diameter of the midpelvis or midplane is the transverse or **interspinous diameter** (between the two ischial spines). The ischial spines are evaluated by palpation for their prominence or flatness (Figure 16-5).

Figure 16-3 Diameters of the pelvic inlet and outlet.

Prominent converging spines can compromise this diameter or, in the least, cause a “tight fit” for the fetal head, with possible tissue damage to the mother during delivery. The sacral curvature (or flatness) is evaluated. A curved sacrum allows more room in the midpelvis than does a flat sacrum, thus becoming somewhat of a compensatory mechanism for a marginal interspinous measurement.

The third plane, the **pelvic outlet**, is the plane of greatest compensation. The smallest measurement is the distance between the two ischial tuberosities; this measurement usually is called the **intertuberous** or **biischial diameter**. The size is estimated by the knuckles of the examiner's fist being placed across the perineum at the level

Figure 16-4 Obstetrical caliper.

Figure 16-5 Anterior view of the female pelvis.

of the tuberosities (Figure 16-6). Assuming a fist size of at least 8 cm, the knuckles usually do not touch both tuberosities simultaneously, indicating a diameter of 8 cm or greater. The anterior-posterior measurement is from the bottom of the symphysis pubis to the tip of the sacrum, at the sacrococcygeal joint, which usually is about 10 to 11.5 cm. The coccyx is evaluated for mobility by examination finger touch. A mobile nonprominent coccyx allows for some flexibility in the pelvic outlet plane. The angle of the subpubic arch is evaluated as part of the pelvic outlet. In the normal female pelvis, this angle is about 90 degrees

TEACHING PARTNERS HOW TO HELP PREVENT CLIENT ACCIDENTS AND FALLS

If the client's partner is made aware of pregnancy changes such as a shift in her center of balance and the softening of pelvic joints that result in "wobbly" ambulation, he can identify opportunities to be of assistance to her, particularly in avoiding falls or near-falls that easily can happen. He can do stooping and lifting for her, assist her with ambulation, particularly over irregular surfaces, help her in and out of the car, and assist her with stair steps. His attention to accident prevention is likely to be enhanced if he has an understanding of the physiologic changes that produce the risks.

and allows room for the upward extension of the fetal head at delivery (see Chapter 23).

Subsequent Visits

A schedule of future visits is given to each client. This time is an excellent opportunity to explain what is done at each visit, to give printed instructions and educational materials,

A.

B.

Figure 16-6 Measurement of the biischial diameter with (A) ruler or (B) clenched fist.

and to anticipate client concerns during the intervening time before her next appointment. The client should be given thorough instructions regarding nutrition and fluid intake (at least eight glasses of water a day plus other fluids), the normal changes of pregnancy, recommendations regarding exercise and general hygiene, and recommended treatment of various discomforts she may encounter as the pregnancy progresses. This is also an appropriate time to give the client printed materials about designated danger signs for which she should seek immediate assistance (Figure 16-7). Although these signs usually are not seen until the last trimester, it is still not too early to give clients these materials.

Each Subsequent Visit

To assist in proper monitoring of the pregnancy, the following are evaluated in each visit.

- ❖ **Blood pressure.** Blood pressure is evaluated for any increase from baseline (Figure 16-8). An increase may be an alert to the onset of **pregnancy-induced hypertension (PIH)**, also referred to as preeclampsia or toxemia of pregnancy. Typically, PIH is characterized by elevated blood pressure, persistent edema, and proteinuria. Guidelines for signs and symptoms that should be reported to the nurse or physician are included in the danger signs listed below.
- ❖ **Weight.** Weight is assessed for appropriate weight gain (Figure 16-9). Too little or too much gain requires further assessment and counseling. Either may be indicative of a high-risk pregnancy.
- ❖ **Fundal height.** Fundal height should be consistent with dates. The uterus is palpable above the symphysis at about 12 weeks' gestation; is midway

Figure 16-7 Supplying clients with information on a healthy pregnancy and potential risks and danger signs is an important nursing responsibility.

Nursing Alert

ATTENTION TO BASELINE BLOOD PRESSURE

At each prenatal visit the blood pressure finding should be compared with the baseline value. A client may have a blood pressure reading that seems to be within normal limits but is actually a significant increase for her. This is especially true for very young clients whose normal blood pressure values are around 90–92/58–60 mm Hg. In these cases, a seemingly normal blood pressure value of 120/82 mm Hg may be a caution flag for the need to monitor for further signs of PIH.

Figure 16-8 Blood pressure is measured at each prenatal visit.

Figure 16-9 Weight gain is tracked throughout the pregnancy.

Client Education

Weight Gain

Clients should be instructed in the importance of and necessity for a recommended weight gain of about 25 to 35 lb in a pattern similar to the following:

- First trimester: approximately 3 to 5 lb.
- Second trimester: approximately 12 to 15 lb.
- Third trimester: approximately 12 to 15 lb.

Remind clients that pregnancy is not a time for weight loss.

between the symphysis pubis and umbilicus at 16 weeks' gestation; and at the umbilicus at 20 weeks' gestation (now measuring 20 cm). Overall fundal height changes generally are reflective of fetal growth. Small uterine size for dates may indicate a fetus that is not growing appropriately; large uterine size for dates may be associated with a multiple pregnancy (more than one fetus), congenital anomaly, or another complication to be assessed. Measurement is by flexible tape measure (McDonald's method; Figure 16-10A,B) held by the examiner at either a curved pattern from the symphysis pubis to the fundus (top of the uterus), or a straight pattern from the symphysis pubis to the point where the examiner's hand is directly above the fundus at a 90-degree angle. Either method is acceptable but should not be interchanged because slightly different readings are obtained. Fundal height in centimeters correlates very closely with the number of weeks of pregnancy

A.

B.

Figure 16-10 Fundal height is measured by placing the end of the tape measure at the symphysis pubis and extending it in either a curved (A) or straight (B) pattern to the fundus.

Figure 16-11 Fetal heart tones are measured with a hand-held Doppler.

after 18 weeks' gestation. Discrepancies call for further evaluation.

- Fetal heart tones. Fetal heart tones are assessed for rate and rhythm (Figure 16-11). Normal rate is 120 to 160 beats per minute.

- Urine. Urine is tested for the presence of glucose or protein (albumin) (Figure 16-12). Clients should be instructed in obtaining a clean-catch urine specimen to avoid a positive protein caused by mucoid vaginal secretions in the specimen. Proteinuria may be in-

A.

B.

Figure 16-12 Urine is tested at each visit for glucose and protein. A. Client provides a clean catch urine sample. B. Nurse uses urine dipstick to measure glucose and protein.

dicative of PIH, especially if seen in the presence of elevated blood pressure and edema. Glucose in the urine may reflect the relatively normal change in glomerular filtration that allows the larger glucose molecule to be excreted. Further evaluation is still needed. Glucose screening usually is done between 24 and 28 weeks' gestation. If blood glucose is elevated, a glucose tolerance test usually is scheduled.

- **Edema.** Edema is evaluated at each visit. Dependent edema of the feet and legs is not unusual toward the end of pregnancy. A ring sizer can be used to screen for edema in the fingers. Edema of the face is more ominous; when this is noted, the client should be evaluated for other signs and symptoms of PIH. All edema should be assessed for pitting.
- **Other.** Each visit should include an opportunity for the client to ask questions and share concerns. Time

should be allotted to explore her adaptation to the pregnancy as well that of her partner. It should not be assumed that the client who has a history of alcohol, tobacco, or other drug use before pregnancy is not using that drug during pregnancy. Assessment and referral should be provided as indicated.

Selected Subsequent Visits

As previously noted, the first prenatal visit usually is the most detailed. Monitoring activities continue throughout the pregnancy, with some less frequent than others. In the absence of abnormal findings or the identification of risk factors that necessitate closer scrutiny, other evaluations are done only at selected visits or at particular times during the pregnancy. Some examples of periodic evaluations are as follows:

A.

B.

C.

D.

Figure 16-13 Leopold's maneuvers. A. First, the examiner palpates to determine which fetal part is in the fundus. Generally, it is the buttocks. B. Second, the examiner moves hands to the sides of the uterus and determines on which side of the mother the fetal back is located. C. Third, the examiner's hand is placed above the symphysis pubis to note whether the head or breech is near the pubic symphysis (this should correlate with the first maneuver). D. Fourth, the examiner changes position to face the client's feet, and palpates the sides of the abdomen to determine on which side the cephalic prominence presents.

- Additional pelvic examinations usually are not necessary until the time of weekly visits, which usually occurs in the last 3 to 4 weeks of an uncomplicated pregnancy. The cervix can be evaluated for softening, thinning, and dilation. An assessment can be made of the fetal presenting part and status of descent after lightening (see Chapter 15). Prior to this time, Leopold's maneuvers can be used to evaluate the size and position of the fetus (Figure 16-13).
- Laboratory tests. In the absence of anemia at the initial screening or development of signs and symptoms subsequently, hemoglobin and hematocrit screenings usually are not repeated until 28 to 34 weeks' gestation (third trimester) and again immediately before delivery. Alpha-fetoprotein screening is done at 16 to 18 weeks' gestation, glucose screening at 24 to 28 weeks' gestation, and culture for group B *Streptococcus* (GBS) at 35 to 37 weeks' gestation. Antibody titer for clients who are Rh negative is done at 22 weeks' gestation and as indicated. Triple screening (maternal serum alpha-fetoprotein, hCG, and estriol) sometimes is done at 16 to 18 weeks' gestation or 16 to 20 weeks' gestation as a combined evaluation of fetal well-being and for predictors of genetic or congenital anomalies (see Chapters 13 and 22). In some areas of the United States, triple screenings are used routinely; in other areas, they are used more on an as indicated basis (Table 16-1).

Client Education

Teaching Materials

A large variety of educational materials is available from a number of sources: books, pamphlets, brochures, videos, calendars with pregnancy tips and advice, and Internet sites increasing in number daily. Before recommending any particular materials or sources, be sure you have checked out the accuracy and thoroughness of the contents. Be familiar with the contents of all educational materials available from your work setting. Surf the Internet periodically to become familiar with available sites and their suitability for clients. Aside from recommending and interpreting educational materials, your professional responsibilities also include tactfully pointing out inaccuracies or inadvisable elements of such materials.

Table 16-1 Screening Tests in Pregnancy

Test	Results
Complete Blood Count	
RBC	3.75 million/mm ³ due to hemodilution.
WBC	Rises to 18,000/mm ³ by late pregnancy. Mostly an increase in neutrophils.
Hemoglobin (Hgb)	May decrease to 11.5g/dL later in pregnancy due to hemodilution. Repeat at 28 and 36 weeks.
Hematocrit (Hct)	33% lowest acceptable, due to hemodilution.
Blood Type	A, B, AB, or O
Rh factor	Positive or negative. If negative, do indirect Coomb's test. Check father's Rh.
Coomb's Test	Should remain negative. Retest Rh negative woman at 28 weeks.
Rubella Titer (HA1)	> 1 : 10 indicates immunity. < 1 : 10, immunize after birth of infant.
Blood Glucose	Should be 60–110 mg/dL. Retest at 24 and 32 weeks.
VDRL or RPR (Syphilis)	Should be negative.
Cervical/Vaginal Culture	Should be negative.
Gonorrhea	
Chlamydia	
Group B <i>Streptococcus</i>	
Hepatitis B Surface Antigen (HB _s Ag)	Positive indicates either active hepatitis or carrier state.
Antibody Titer HB _s Ag	Positive indicates immunity to hepatitis.
HIV (many states mandate that it be offered)	Should be negative.
Tuberculosis	Should be negative.
Skin tests: Mantoux or Tine	If positive, do chest x-ray.
Urinalysis	
Color, specific Gravity, pH, ketones, albumin, glucose	Same as nonpregnant. Repeat at 28 weeks. Trace of glycosuria may occur in pregnancy.
Alpha-fetoprotein (AFP)	Check with laboratory for normal range for each week of gestation. If elevated, may have neural tube defects. If decreased, may have Down syndrome.

Research Highlight

Collection of Specimens for Group B Streptococcus Screening

Purpose

To determine how well patients did in collecting group B *Streptococcus* (GBS) samples compared with physician collection and to determine patient preference for self-collection compared with physician-collected swabs.

Methods

Women receiving prenatal care from five family physicians and eight obstetricians in Toronto, Canada, constituted the sample. All 163 women were seen during a regular visit at 26 to 28 weeks' gestation. Each woman was given a questionnaire (survey) and instructions and directions for collecting her own vaginal-anorectal swab for GBS screening. After the woman completed the survey and obtained her own swab for culture, the physician then collected the GBS specimen in the usual manner.

Findings

Of the 163 matched pairs of GBS swabs, the researchers used any positive results as the gold standard and found the prevalence to be 24% (39 of 163). Patients detected 38 cases, whereas physicians detected a smaller number of 32. The sensitivities of these detections were 97% and 82%, respectively. The 161 surveys returned showed that 25% of the women preferred that their physician take the swab, and 75% were indifferent or preferred self-collection of the specimen.

Nursing Implications

Clients can be taught GBS collection that is at least as reliable as physician-collected swabs. Self-swabbing is an excellent opportunity for women to actively participate in their own care with confidence.

Molnar, P., Biringer, A., McGeer, A., & McIsaac, W. (1997). Can pregnant women obtain their own specimens for group B *Streptococcus*? A comparison of maternal versus physician screening. *Family Practice*, 14, (5), 403–406.

DISCOMFORTS OF PREGNANCY

The normal progression of a pregnancy to produce a healthy infant requires, by necessity, a variety of physiologic changes within the mother. Several of these changes have a cascading effect and subsequently produce conditions of discomfort. Whereas some clients view these as annoyances to be dealt with, others perceive them to be interferences that are sometimes intolerable. In most cases, a detailed explanation of what is happening and suggestions for alleviation are sufficient, especially when clients have a social support system in place. For the other category of clients, further exploration of their feeling about and attitude toward the pregnancy is warranted.

Recommendations to clients should be made with sensitivity to the client's cultural background. The nurse

should listen when clients want to discuss home remedies or alternative interventions for various problems. A sensible approach calls for ruling out known harmful practices (with careful explanations) and exploring all options that are within the realm of the client's social, cultural, or spiritual preferences and background. When clients are taught to blend cultural mores and self-care practices with specific basics of routine prenatal considerations (e.g., avoidance of alcohol, caffeine, and certain medications), they will be empowered to make wise choices for themselves. Furthermore, clients can share their new knowledge with others in their community. In doing so they foster the idea that clients can be proactive in their care, using health care professionals for joint decision-making and establishing mutual goals.

The following are some commonly encountered discomforts, their causes, and some recommended interven-

tions. Nurses are encouraged to review resources (such as the Internet) that are available and to assess information for accuracy and advisability, especially before referring clients to a particular website. All information should be consistent with normal, routine, and mainstream prenatal care protocols.

Urinary Frequency

The physical sensation of needing to void frequently, and sometimes accompanied by a feeling of urgency, is encountered primarily in the first and last trimester. The gravid, growing uterus presses on the bladder, and the fetus puts direct pressure on the bladder. In addition to these mechanical factors, the pregnant client also experiences an increase in circulating fluid volume, especially in the third trimester, and frequently an increased glomerular filtration rate, which further adds to frequency. The good news for clients is that they will experience some relief from this problem during the second trimester when the uterus is higher in the abdomen and the combined weight of the fetus and uterus is not as great as it is in late pregnancy. Clients should be cautioned not to decrease their fluid intake in an attempt to control urinary frequency. Doing so is appropriate only for short periods of time, such as a car trip for an hour or so, or in anticipation of a meeting of a similar time frame. Fluid intake for any 24-hour period should not be less than the recommended amount, or 8 glasses of water plus other fluids.

Nausea and Vomiting

Nausea and vomiting are problems usually associated with the first trimester. Although sometimes referred to as morning sickness, the nausea and vomiting may occur at any time of the day. A variety of stimuli, such as certain smells and, the sight of some foods, can produce the sensations. Nausea seems to be more of a problem than does vomiting. Many clients experience nausea, with minimal vomiting. The hormones of pregnancy are the generally acknowledged basis for morning sickness. General guidelines for prevention call for eating dry toast or crackers without liquids before getting out of bed. Avoidance of known offenders, such as spicy foods and acidic citrus fruit on an empty stomach, is recommended. Other measures may include favorite decaffeinated teas. Peppermint tea is preferred by many clients because it tends to calm a queasy stomach.

Indigestion

Indigestion is a common annoyance that shares some common causes with nausea. Also, the hormones progesterone and relaxin are implicated because they relax the

cardiac sphincter and allow reflux to occur. Many clients have identified specific offending foods and beverages that caused them problems, even before pregnancy. Obviously, these foods should be avoided as much as possible. If reflux is a problem at bedtime, the use of an extra pillow may be helpful in overcoming the gravity factor that can enhance reflux. Caution clients about the use of antacids, especially those with a high sodium content. Mild herbal teas of the client's preference should be encouraged.

Constipation and Hemorrhoids

Constipation and hemorrhoids are closely related and often contribute to each other. Constipation and subsequent straining with defecation contribute to the formation of hemorrhoids. As with edema, the sluggish circulation and venous return combined with the direct pressure of the uterus and fetus all make avoidance of hemorrhoids a challenge. Gentle evacuation is encouraged by ample fluid intake, a diet high in fiber, use of certain stool softeners, and walking (preferably at a brisk rate, if tolerated). High-fiber foods that also are good sources of iron include prunes and apricots.

Edema of Lower Extremities

Swelling of the feet and lower legs is most commonly seen later in pregnancy, with several factors coming together to cause it. The increased circulating fluid volume, relaxed blood vessels, sluggish venous return, and mechanical obstructive nature of the heavy uterus and fetus on vessels of the lower extremities all contribute to the problem. Avoidance of long periods of standing without walking around helps to prevent edema. Clients should be advised to have their feet and legs elevated as much as possible while sitting. Clients also should be cautioned to avoid sitting with the hips at a sharp angle when the feet are elevated because doing so will further impede venous return and aggravate the original problem. Moderate walking is of great help in controlling edema (contracting muscles facilitate venous return) and preventing constipation (walking increases peristalsis). Walking is also an excellent exercise for pregnant women, especially when done at a sensible pace, avoiding fatigue and extreme weather conditions. For clients fortunate enough to live near a seashore, wading in the surf is very therapeutic. Not only does this improve venous return from lower extremities but it does so at pressures that are ideal; that is, the pressure of the water is greatest at the bottom (feet) and decreases toward the surface (farther up the legs). Also, the psychological benefits of reflective thinking and clearing the mind contribute to the client's overall well-being.

Danger Signs to be Reported

With the availability of so much educational materials from a variety of sources, many clients are very knowledgeable about pregnancy and the various changes that occur. Even though information sources caution clients about the need for medical care and supervision, it remains the responsibility of the nurse to provide certain information without the assumption that clients have access to it elsewhere.

There are a number of possible events in pregnancy that reflect one or more complications, at best, these require assessment to rule out a problem. Whereas it may sound overreactive to refer to these as danger signs, and the policy of a clinic or facility may be to avoid use of the term danger for fear of alarming clients, it is imperative that clients be made aware of events that require immediate reporting to their health care provider. The nurse must reinforce the importance of reporting any of these things immediately, rather than making a note to report them at the next scheduled visit. A detailed explanation of the physiology and implications is not necessary for the client unless she requests it; however, she should know that immediate assessment is for the good of her health and her baby's health. Signs and symptoms that require immediate attention are the following:

- ✿ Any vaginal bleeding. The only exception to this is if a vaginal examination has been done within the past 24 hours and the examiner has told the client to expect some slight spotting of old blood. This phrase should be carefully explained, complete with a pencil drawing of how much spotting is acceptable. Some practitioners and physicians do not even mention the exception; they want to be notified of any spotting so they can assess it at that time.
- ✿ Swelling of the face and fingers. As a general rule, the higher the edema above the feet and ankles, especially in the face, coupled with suddenness of onset, the more ominous. This finding is usually associated with PIH.
- ✿ Severe headache that is continuous. Headache may be caused by a dangerously elevated blood pressure and associated with the onset of PIH. Other causes are possible.
- ✿ Vision changes, such as blurring or dimming of vision, or spots or flashes of light before the eyes. These changes also may be associated with PIH.
- ✿ Abdominal pain. There is no need to differentiate the epigastric pain of PIH from the onset of labor for the client; both require evaluation.
- ✿ Chills and fever. Instruct the client to report these and not to wait for other “flu” symptoms to appear.

- ✿ Persistent vomiting. Even though client may have read “somewhere” that nausea and vomiting are common in pregnancy, she should not dismiss persistent vomiting as normal.
- ✿ Sudden gush of fluid from the vagina. This usually signals spontaneous rupture of membranes and requires assessment for possible cord prolapse, prevention of infection, and evaluation for the onset of labor.

In instances in which the client, after receiving these instructions, reports events or symptoms that are subsequently evaluated as nonemergencies or not indicative of a

REFLECTIONS FROM FAMILIES

“During my last pregnancy the nurse gave me a list of things called ‘Topics to Report Right Away.’ One of the things listed was ‘Rupture of membranes or escape of fluid from the vagina.’ My neighbor, Rhonda, and I were out shopping. I was in my last month, with delivery about 3 weeks away. Just as we went back to the car and I reached to open the door, it happened. Fluid ran down my leg to about my knees. It wasn’t a lot, but it was there. I just wanted to go home and clean myself up. Rhonda asked me if this wasn’t one of the things I was supposed to report right away to my doctor. I called the office from her car phone. The nurse told me to come straight to the doctor’s office, which was about 2 miles from the mall. So we went. They checked me out right away and tested the fluid. It turned out to be urine! Can you imagine? I was so embarrassed. I told the nurse I’d never be back for that again. She told me that this happens a lot, and that I shouldn’t be embarrassed. She said I did the right thing. I felt better. And Rhonda didn’t laugh at me. Thank goodness she didn’t call my husband to meet us at the hospital!”

Case Study/Care Plan

CLIENT WITH A NORMAL PREGNANCY

Susan M. is a 30-year-old gravida 3, para 1, who is 20 weeks pregnant with a 5-year-old daughter at home. She experienced an early spontaneous abortion before her daughter was born. Her F.P.A.L. status is 1-0-1-1. She works full-time in a large downtown investment firm.

Susan and her husband bought a house in an adjacent rural area. They discussed the length of the daily commute for each of them, but decided it was worth it to live in their dream house.

This pregnancy was planned and has thus far progressed uneventfully. During her last prenatal visit she expressed a strong desire to avoid constipation with this pregnancy and to prevent hemorrhoids. She has been told by some co-workers that the more constipation she had, the more certain she was to develop hemorrhoids. Constipation had been a problem for her with the last pregnancy. Her nutritional status is good. She is taking a daily prenatal vitamin with iron, primarily because of her irregular eating habits at lunch. Weight is normal for height. Weight gain has been minimal. Immunizations are complete and current. She has no difficulty getting time off from work for prenatal appointments.

Assessment

Healthy 30-year-old with a 20-week intrauterine pregnancy. She has had no difficulties with this pregnancy. She is concerned about the health of herself and her family. She has strong family support from her husband and extended family. She works at a desk job 40 hours a week.

Nursing Diagnosis

Health-seeking behaviors: self-care of pregnancy related to the desire to prevent constipation and development of hemorrhoids, as evidenced by her expressed wish to avoid a previous experience with constipation.

Expected Outcomes After nursing interventions Susan will:

- Recall examples of foods and fluids recommended for their properties of constipation prevention.
- Report a pattern of regular bowel movements that do not require straining.
- Remain free of the signs and symptoms of hemorrhoids for the remainder of the pregnancy.

Planning

Because Susan has had a previous experience with constipation in pregnancy, it is important to explore with her those approaches that worked in resolving the problem. These approaches should be incorporated with any new recommendations. With her previous pregnancy, Susan did not understand the role of walking in preventing constipation; this intervention should be explored with this pregnancy.

Nursing Interventions

1. Review with Susan the major areas involved in prevention and resolution of constipation: diet, exercise, and fluid consumption.
2. Discuss things Susan did to alleviate constipation with her last pregnancy.
3. Encourage fluid intake of eight glasses of water daily, above other fluid intake.

Rationales

1. An accurate knowledge base is essential for clients to make informed decisions in caring for themselves.
2. Healthy self-care practices should be encouraged; others should be modified as indicated. Clients can be empowered in self-care with sensitive guidance and instructions.
3. Water is essential to prevent dry, hard stools. Fluids containing sugars and caffeine usually are excreted by the kidney without contributing to fluid content of the lower intestine.

(continued)

Nursing Interventions

4. Review and encourage intake of high-fiber foods (see Chapter 8). Focus on Susan's favorite foods as well as those she found helpful in her last pregnancy.
5. Encourage walking as a daily exercise.
6. Explore Susan's perception of iron supplement relative to constipation in the past pregnancy.
7. Review the list of stool softeners recommended for use as needed by Susan's physician and nurse practitioner.

Rationales

4. High-fiber foods, when combined with adequate fluid intake, form sufficient bulk in the stool to stimulate peristalsis. High-fiber dry foods, such as cereals, in the absence of adequate fluid intake can cause or contribute to constipation.
5. Walking helps to stimulate peristalsis and to stimulate the general circulation. Hemorrhoids are prevented by avoidance of constipation and prevention of sluggish pelvic circulation.
6. Whereas iron tends to contribute to constipation in some clients, it may be responsible for loose stools or diarrhea in others.
7. Some laxatives and oil-based stimulants can interfere with nutrient absorption and may cause harsh evacuations. The potential for dependence also exists.

Evaluation Susan was able to verbalize the role of fluids, diet, and exercise in preventing constipation and hemorrhoids. She had tried the recommended dried prunes with her last pregnancy but found that they worked better for her if she cooked them instead. Walking, particularly during her lunch hour, was convenient. She and her friend opted for daily walks around the perimeter of an enclosed ice skating rink located in a building adjacent to her office; this is a safe area where they can walk during any weather conditions. Susan reports having regular soft bowel movements with no straining. No signs of hemorrhoids.

complication, the nurse must be very tactful with and sensitive to the client. The nurse must not allow the client, or the client's family, to feel as though she has acted inappropriately. She should not be intimidated by thoughts of future false alarms.

NURSING PROCESS

Care of the pregnant woman is unique in that nursing care must be planned for two individuals, the mother and the fetus, with consideration for the family. The dynamic relationship between the mother and fetus must be the basis for all planning and interventions.

Assessment

Assessment is designed for early detection to facilitate prevention of complications. Assessment is done on the initial visit and includes a thorough maternal history and physical examination. This examination incorporates an assessment of the condition of the fetus and the maternal progress of

the pregnancy. During this assessment, the nurse should pay attention to the family's preparation for pregnancy, labor, and parenting. Actual and potential risk factors are identified. The objective of planning nursing care for the maternal-infant dyad is to minimize morbidity and facilitate the most positive birth experience for the mother and family.

Nursing Diagnoses

Nursing diagnoses common to women receiving prenatal care are likely to include the following:

- Deficient knowledge related to inexperience with the physiologic changes of pregnancy.
- Acute pain related to the physiologic changes in pregnancy.
- Imbalanced nutrition: more than body requirements related to excessive caloric intake.
- Deficient knowledge related to the importance of prenatal care.

Outcomes Identification

Outcomes planned for women experiencing an uncomplicated pregnancy may include the following:

- The client is able to remain free from the common discomforts of pregnancy.
- The client incorporates strategies to increase her comfort as the pregnancy progresses.
- Weight gain does not exceed 1 lb/wk in the first 36 weeks of pregnancy and 0.5 lb/wk the last month.
- The client comes regularly to her prenatal visits.

Planning

Planning should focus on the physical and emotional needs of the woman in relation to the changes she will experience in each trimester. The client's partner, family, or support system should be included in the planning, as desired by the client.

Nursing Intervention

The client should be taught strategies to deal with the common discomforts of pregnancy, because many of these can be prevented or minimized by lifestyle modifications. Many times it is difficult for a client to discriminate between a benign cause of discomfort and a serious complication; if discomfort does occur, the client should not hesitate to call the health care provider.

The client should also be taught expected weight gain parameters and common dietary pitfalls. The more weight a woman gains above 35 to 40 lb, the greater the risk of maternal-fetal morbidity, as well as health risks related to obesity for the mother after delivery.

The nurse should also be sure to teach the client the importance of early detection and treatment of abnormalities as well as the health-promoting benefits to herself and her baby. During the course of prenatal care, the mother will obtain information about lifestyle choices that ensure better health for her and her infant. Regular prenatal care allows for early detection and intervention for many pregnancy complications.

Evaluation

Each expected outcome must be evaluated with each client-nurse interaction to determine if the current goals have been accomplished or need to be modified.

Critical Thinking

Refer to the Case Study

Assessment: Do you think that her job (sitting at a desk, with very little walking) may contribute to Susan's possibly experiencing constipation?

Nursing Diagnosis: What are some other possible nursing diagnoses pertaining to health-seeking behaviors in women who are eager to be in control of their care?

Expected Outcomes: Is there a single outcome listed that is more important than the others? Or, are they all equally important in meeting the goal?

Planning: Which approaches might you take to be sure the planning phase is actually joint decision-making?

Interventions and Rationales: Examine these to see if you can identify any that may be unacceptable to a client who wants to be in control of her self-care activities.

Evaluation: If Susan developed constipation at a later point in her pregnancy, how would you revise the planning? What information would you need or which questions would you ask to say that a revised plan was necessary?

Web Activities

- Visit the web sites of some nursing organizations, such as the Association of Women's Health Obstetric and Neonatal Nurses (AWHONN) and the American Nurses Association (ANA). What information do they offer regarding nursing care of the women during an uncomplicated pregnancy? Do they also include any information targeted for the client?
- Find the sites listed in the Resources for this chapter. Read the information that will be most useful to you as you begin working with pregnant clients and their families.

Key Concepts

- Preconception care is the ideal approach to child-bearing. Many risk factors can be identified and dealt with before pregnancy begins.
- Health care communities must develop plans for availability and accessibility of prenatal care for their citizens. Barriers should be minimized.
- Early and consistent prenatal care is essential for proper monitoring of any pregnancy. Prevention of potential complications is possible with monitoring.
- The pregnancy experience can be enhanced when clients are aware of changes taking place in their bodies.
- Clients can be empowered with involvement in decision-making about their care.
- Nurses have a responsibility to review all materials recommended for client information.
- Danger signs in pregnancy may affect the health of the mother, baby, or both. Special attention is needed.

Review Questions and Activities

1. Low birth weight and congenital anomalies remain two problems on which prenatal care has had little impact in the past 40 years. Explain how preconception care can decrease the incidences of these problems.
2. Becky S. is seeing the nurse midwife with her fifth pregnancy. Her first two babies were born prematurely but are healthy youngsters now. Her third pregnancy resulted in a miscarriage at 18 weeks' gestation, and her fourth went to term with delivery of an 8 lb, 6 oz boy. How is her F.P.A.L. status correctly noted?
3. Diane's last normal menstrual period began on May 10th, and her pregnancy test (7 weeks later) was positive. Calculate her EDC. Give the month, date, and year.
4. Explain the physiologic anemia usually seen in pregnancy.
5. List one commonly encountered discomfort of pregnancy for each of the three trimesters. Explain why each is likely to occur in that particular trimester.
6. Discuss comfort measures for each of the three identified common discomforts.
7. What are some examples of pregnancy risk factors that can be identified from a client's psychosocial history? From her partner's medical history?
8. Your neighbor thinks she is pregnant and has made an appointment with her family doctor. How would you respond to her inquiry about what to expect during the visit?

Childbirth Preparation and Perinatal Education

Imagine you are pregnant with your first child. How might you answer the following questions to examine your personal beliefs regarding childbirth preparation:

- *What do I fear most about childbirth?*
- *What are my expectations?*
- *What would I need to know about how to manage the pregnancy?*
- *What would help me prepare for the birth experience?*
- *Which types of things would I like to know about caring for an infant?*
- *Who is qualified to teach prenatal classes, and how will I find a legitimate class?*
- *Which types of preparatory classes and activities are available to other family members?*

Key Terms

Childbirth education
Cleansing breath

Perinatal education

Competencies

Upon completion of this chapter, the reader should be able to:

1. Discuss the history of childbirth preparation classes and current trends in perinatal education.
2. Discuss the educational principles of adult learning and the group process as they relate to perinatal education.
3. Describe the major approaches to childbirth education.
4. Apply the strategies of paced breathing to enhance relaxation.
5. Discuss different strategies to enhance relaxation, such as biofeedback, imagery, touch, meditation, and music.
6. Identify options regarding labor and birth attendants, childbirth classes, and birth settings.

Childbirth education, more recently referred to as **perinatal education**, began as a consumer movement to humanize the birth experience and promote an active role by women in the birth process. Preparation for the birth and subsequent parenting responsibilities has expanded beyond learning breathing techniques for labor. The increasing involvement of the expectant woman's partner or supportive friends also has given rise to educational programs. The movement toward perinatal education has changed the hospital environment and now is an integral part of health care for childbearing women.

The movement toward perinatal education historically has involved nurses, both as consumers and educators. The Nurses Association of the American College of Obstetrics and Gynecologists (NAACOG), forerunner of the Association of Women's Health, Obstetrics, and Neonatal Nurses (AWHONN), developed guidelines for childbirth education in 1981, which were revised in 1987 and again in 1993 (AWHONN, 1993). These guidelines provide recommendations for improving the quality of perinatal education to promote healthy birth outcomes and emotionally satisfying birth experiences (AWHONN, 1993). Partnerships between health care providers and community resources provide a mechanism for offering educational preparation for childbirth and a link to support systems after the birth.

Many expectant women consider childbirth a significant challenge. Health care providers and systems have been responsive to changes suggested and, at times, demanded by childbearing families. Currently, expectant families have choices regarding care providers, birth attendants, delivery settings, and educational preparation formats. Nurses play a pivotal role in providing information and assistance to clients and their families and thus can foster active participation in and preparation for the upcoming birth. Many couples are motivated to learn and attend classes because they want strategies to cope with impending labor and ensure a healthy baby. Expectant parents often have a heightened interest in health-promoting behaviors during pregnancy. Thus, nurses have a golden opportunity to promote healthy lifestyles and meet the educational needs of the parents. Health education offered to families during pregnancy may form the foundation for lifelong health practices. Couples or persons who participate in group classes also often form continuing friendships. In both clinic and hospital settings, nurses also are in a position to use some of the techniques that have been developed to help women relax during labor and to teach clients who have not taken prenatal classes. Application of the nursing process assists the nurse to identify and meet the needs of expectant families. Evaluation of family outcomes leads to continued improvement in the approaches nurses use to prepare families for childbirth.

FROM CHILDBIRTH EDUCATION TO PERINATAL EDUCATION

The birth event often has been the focus of medicine and nursing. Early childbirth education classes were focused entirely on developing and practicing techniques for use in managing pain and facilitating the progress of labor. More recent developments in perinatal education have broadened the focus to incorporate family adaptation to the pregnancy and parental roles for the newborn. The relationship of the couple during pregnancy and incorporation of the infant into the family constellation now are included in perinatal education. The process of moving the parents into the roles of mothers and fathers is included, especially in the case of a first child. For families with children, with each subsequent pregnancy the family needs to re-establish these parenting roles. Family adaptation also includes the adaptation of siblings and the entire family unit. Additional content has been added to childbirth education curricula that includes breastfeeding, infant care, transition to parenthood, relationship skills, family health promotion, marital intimacy, and sexuality; some curricula have added the role of perinatal bereavement counselor (Humenick, 1999; 2000).

The childbirth education movement has had a significant impact on the delivery of perinatal health care. As consumers became more knowledgeable and active in decision-making, changes were made in hospital policies in regard to allowing nonmedical persons to be present at the birth, working in partnership with the laboring woman and her partner and providing more family-oriented maternity care. In 1996, the Coalition for Improved Maternity Services (CIMS) ratified a document called the Mother-Friendly Childbirth Initiative. This document was based on up-to-date research and the beliefs that childbirth is a natural process and that a wellness model of maternity services reduces interventions and provides cost-effective and improved care for all women (CIMS, 1996). Hospitals may receive mother-friendly designation by carrying out the philosophic principles and following the 10 steps outlined in the document.

History of Childbirth Education

Childbirth education is not an innovation of the last half of the 20th Century. Throughout history women have been providing informal education to other women about childbirth. Even with formalized childbirth preparation classes, many women are taught about childbearing and childrearing by their mothers and other family and friends. Childbirth education became very popular in the United States

and Europe over the past 50 years as a response to the **medicalization of childbirth** and the emergence of the woman's movement. This social movement did much to change the approach of the health care industry to childbirth. The woman's movement has helped give women more power in decision-making and the labor process, foster development of more family-centered care, foster the use of strategies to control stress and pain, and change the delivery of health care to a more holistic and humanistic model. In these areas the philosophy of childbirth education parallels that of nursing.

Early Childbirth Preparation

Across cultures, women have been assisting other women in preparing for childbirth and the role of mother and have been informally handing down these traditions. In many cultures, women attend the birth and support the mother whereas men are prohibited from attending the birth. Female midwives in Europe attended births until the 17th Century (Wertz & Wertz, 1989). During the 20th Century, childbirth moved into hospitals. As medical care became more oriented to specific diseases and as more technology began to be used, childbirth also became medicalized. This medicalization resulted in women being separated from family and, in many cases, a supportive environment. Childbirth began to be treated as are other medical or, more often, surgical events. The primary goal was a mechanically safe passage through the birth process for mother and infant. Many women and infants benefited from some of the medical interventions and methods of assessing the labor progress; however, the social, cultural, psychological, and spiritual aspects of childbirth often were ignored and replaced with an environment of surgical asepsis and technology (Davis-Floyd, 1992).

By the mid-1900s, most births occurred in hospitals and midwives were used only in remote areas. In the 1960s the prepared childbirth movement began. Through education of the public, hospital care changed to permitting support persons (often the husband) in the delivery room, allowing more time for mother and infant to stay together (e.g., by rooming-in, mother-baby care, or couplet care), and increasing support for breast-feeding. The emphasis on preparation and a more natural approach to birth has decreased many of the risks from unnecessary medical interventions and allowed a birth experience that better addresses the psychological, cultural, social, and spiritual aspects of the experience.

METHODS OF CHILDBIRTH PREPARATION

Early childbirth classes were held by the Red Cross and the Maternity Center Association in the early 1900s to teach

hygiene to women who were poor or immigrants and to provide information to cope with the stresses of birth (Zwelling, 1996). In Europe, a movement was beginning that spread from Russia to France (Lamaze method), with a parallel movement in Great Britain (Dick-Read method). In Russia, the concept of behavioral reconditioning was successfully applied to labor pains. This technique provided an excellent alternative to chemical means of reducing pain. The notion that pain could be controlled by psychological preparation became the foundation for childbirth education and preparation.

Lamaze Method of Psychoprophylaxis

Fernand Lamaze, a French physician, developed a version of psychoprophylaxis that became very popular throughout Western Europe. Lamaze pioneered this educational approach to childbirth preparation using body conditioning exercises, education, and relaxation techniques (Lamaze, 1972). Lamaze found that mental and physical conditioning were extremely effective in his own practice. These conditioned responses were acquired through training and repetition whereby the client learns to respond to pain with breathing and relaxation. American society was introduced to the Lamaze approach to childbirth through the publication of the book *Thank you, Dr. Lamaze* by Marjorie Karmel (1959), a client of Lamaze. Elizabeth Bing, author of *The Lamaze Method: Six Practical Lessons for an Easier Childbirth* (1967), along with Karmel formed the American Society of Psychoprophylaxis in Obstetrics (ASPO/Lamaze, later changed to Lamaze International, Inc.). This organization has certified programs and childbirth educators in the Lamaze method since 1965.

Most childbirth preparation classes offered in North America today provide content and instruction based on the Lamaze method. The fundamental techniques for instruction are conditioning, discipline, and concentration (Figure 17-1). Conditioning teaches the mother to adapt her responses to the physical and emotional demands of labor by becoming skillful in tuning into her body. Discipline enables the person to stick to the program or regimen because she has specific goals and is committed to accomplishing them. Concentration provides the essential mental edge so the woman can stay focused on the task at hand. Concentration breaks the flight or fight response by substituting muscle release and deep oxygenation for tension and breath holding.

Early Lamaze classes focused on getting the laboring woman into a comfortable position. Use of a **focal point** allowed the woman to concentrate on something other than the pain of labor. This focal point could be a picture, sound, or mental image. Practice during pregnancy allowed the woman to build up a discipline of concentra-

Figure 17-1 Couples practice conditioning and concentration techniques during childbirth preparation classes.

tion. The couple practiced using verbal and other cues to recondition the tension response to pain. For example, the partner might touch her on her neck and, through practice, she would develop a conditioned response of relaxation to that stimulus. Thereby the usual response to pain, which is tension, would be replaced by relaxation. Basic breathing patterns were taught to class attendees and practiced frequently in preparation for labor. The more time devoted to practice of the patterns the more automatic they will become and the more likely they will be used during childbirth. Originally, very specific breathing techniques were taught for different periods of labor. These techniques had many different names. As research advanced regarding the physiology of breathing and the understanding of relaxation during labor, paced breathing became more individualized and the centrality of relaxation became more important than were the specific breathing techniques. The most widely offered classes use this approach.

Dick-Read Method

Around the same time Lamaze was developing his psychoprophylactic method, British obstetrician Dr. Grantly Dick Read (1979) incorporated into his practice an educational program for the expectant mother. His goal was to decrease the amount of pain experienced during childbirth. He promoted the belief that the degree of fear could be diminished with increased understanding of the normal physiologic response to labor. Dick-Read's book entitled, *Childbirth without Fear*, (1979) advocated childbirth education from the first prenatal visit. Since the 1950s, the British National Childbirth Trust has trained childbirth educators and breast-feeding and postpartum counselors (On-deck, 2000). Select physical conditioning exercises were included in the program to strengthen the muscles used in

Research Highlight

Waterbirths: A Comparative Study on More than 2,000 Waterbirths

Purpose

To compare the safety and outcomes of three types of births: waterbirths, use of the Maia-birthing stool, and bedbirths.

Method

A prospective study of 7,508 spontaneous births in a large university clinic in Switzerland was conducted. Three types of birth methods were compared and described. The three groups were comparable in parity, age, and newborn birth weight. Vacuum extractions were excluded.

Findings

In this study, 2,014 were waterbirths, 1,108 were Maia-birthing stool births, and 2,362 were bedbirths. Episiotomies were performed in 12.8% of waterbirths, 27.7% of birthing stool births, and 35.4% of bedbirths (bedbirths also showed the highest third- and fourth-degree lacerations at 4.1%). These findings were statistically significant. Maternal blood loss was lowest, fewer painkillers were used, and the birth was rated more satisfying among the women experiencing waterbirths. Average arterial blood pH of the umbilical cord as well as Apgar scores at 5 and 10 minutes were significantly higher after waterbirths. Infections in neonates did not occur more often after waterbirth than after the other methods, and no cases of aspiration or water-related complications were reported.

Nursing Implications

Waterbirth and alternative forms of birthing, such as the Maia-birthing stool, do not demonstrate increased birth risks for mothers or infants with similar medical monitoring of birth.

Geissbuhler, V., & Eberhard, J. (2000). Waterbirths: A comparative study. A prospective study on more than 2,000 waterbirths. *Fetal Diagnosis and Therapy*, 15, (5), 291–300.

childbirth and assist in lowering the tension level during labor. Relaxation techniques were taught that interrupt the circular pattern of fear, tension, and pain (Figure 17-2). Breathing and relaxation techniques during labor are the key features of the Dick-Read approach to childbirth. Dick-Read also argued against “unnatural aids,” such as analgesics and anesthesia. Classes are available that follow the Dick-Read method.

Bradley Method

In 1965, Robert Bradley, a Denver-based obstetrician and follower of Dick-Read, wrote a popular book entitled *Husband-Coached Childbirth*. The key feature to this method is the involvement of the husband or significant other as a primary coach during the childbearing experience (Bradley, 1965). Use of conditioning, breathing, and

relaxation exercises are commonalities shared with the Dick-Read approach. The source of strength and support during childbirth is the partner or coach (Figure 17-3). Extensive preparation of the mother and coach is emphasized in the classes. A quiet environment for labor and delivery also is advocated. Classes are available that follow the Bradley method.

Expectant parents should be encouraged to carefully review the variety of classes available. Comparison of basic principles, theoretical foundations, and educator preparation and philosophy will assist the expectant parents in selecting a class best suited to meet their needs. Perinatal nurses often are asked to offer opinions regarding the types of childbirth preparations.

Women have increased their role as decision-makers regarding childbirth. Childbirth preparation classes provide information that allow families to be partners with

Figure 17-2 Breathing and relaxation techniques are practiced in anticipation of labor.

the health care team in their choice of anesthesia and analgesia and in making decisions about the birth setting and process. Perinatal education also includes support for breast-feeding, from education for decision-making early in pregnancy to support during the early postpartum period. Perinatal education also covers women's concerns in preparing for childbirth, starting before conception and lasting until the postpartum period. The focus is to prepare the woman and her family for the birth and care of an infant and for the impact the child will have on the family.

Figure 17-3 Partner support is a critical component of childbirth education courses.

Kitzinger's Psychosexual Method

Sheila Kitzinger developed a method of preparation for couples that focuses not only on the birth but on the relationship of the couple. Birth is seen as a mutual endeavor of the couple and an extension of their relationship of love. Her book entitled, *The Experience of Childbirth* (1981), promoted a reconceptualization of childbirth from a mechanical process of the fetus through the birth canal to a holistic experience that the husband and wife share as part of their intimate relationship. She advocated for political change in the way health care is delivered to birthing families.

Water Immersion

The healing powers of water have been heralded since ancient times and are associated with both ritual healing and general healing properties. The use of water during labor (Figure 17-4) and birth recently has become popular, albeit

Figure 17-4 Water therapy can be extremely relaxing to the woman in labor.

controversial (Koehn, 2000). A more contemporary movement centered in Moscow and France (Odent, 1984; 1990). Tcharkovsky, a Moscow swimming instructor, became interested in the ability of infants to adapt to water and promoted underwater birthing. In France, Leboyer promoted water immersion of the neonate immediately after birth. His book entitled, *Birth without Violence* (1975) and book and film *Loving Hands* became popular in the 1970s. In Pithiviers, France, Odent pioneered waterbirth and a method of working with families and providing an environment to allow the woman and her husband to instinctively find the right position and way of birth (Odent, 1984).

THEORETICAL BASIS FOR CHILDBIRTH PREPARATION

Strategies of prepared childbirth are based on the theories about pain management and personal mastery discussed subsequently.

Relaxation Theories

Relaxation is the central concept in preparation for childbirth (Humenick, Shrock, & Libresco, 2000). Relaxation is the antithesis of the stress response. Relaxation can assist in the cognitive skills of focusing and receptivity and in the acquisition of new skills. Stress or fear signal the fight or flight mechanism, which activates the sympathetic branch of the autonomic nervous system and thus increases the heart rate, blood pressure, and breathing. Fear and tension during labor result in tense muscles that use oxygen, making it less available to the uterus and fetus. Tense striated muscles contribute to an increased lactic acid buildup that impinges on pain receptors, increasing pain perception and fatigue. Resistance from a tense abdominal wall decreases the efficiency of uterine contractions. A tense pelvic floor creates unnecessary pain in the second stage of labor.

Relaxation strategies influence the cognitive thoughts that in turn influence fear and stress, thus reducing the perception of stressful stimuli. Conscious relaxation of other muscles allows the uterus and cervix to do their work unimpeded and more efficiently. When a woman can consciously control stress, her sense of mastery and self-confidence are increased. Right brain stimulation, such as imagery, color, music, rhythm, odors, and so on, can foster activation of the parasympathetic system and facilitate childbirth (Humenick, Shrock, & Libresco, 2000). During pregnancy a state of low sympathetic arousal increases oxygen and decreases the levels of stress hormones reaching the fetus. During labor this state of low sympathetic arousal reduces pain and increases oxygen and energy for

the work of labor. Relaxation aids in breast-feeding and the stresses of parenthood. The skills of evoking a relaxation response are useful throughout life. Often, childbirth preparation is the first time women and their partners learn about and practice relaxation techniques. Relaxation now is being taught in many other areas of health care as a treatment adjunct for many disorders.

Pain Management Theories

Several theories of pain management are used in childbirth preparation. Cognitive control works by modulating pain by focusing on mental activities rather than the pain. A laboring woman might focus on the motion of uterine contractions or the work of dilation of the cervix to dissociate the painful aspects from the source of stimulation (Jimenez, 2000). She also may use distraction techniques, such as watching TV, using paced breathing, and using visualization to interfere with the transfer of the pain message. These techniques are learned through cognitive rehearsal in preparation for labor. Desensitization also is used to help the person overcome fears.

Some physiologic theories have been proposed to explain how these techniques may reduce the pain of labor. Levels of endorphins or endogenous opiates have been found to be high during pregnancy and higher still during labor; these levels remain elevated in the postpartum period. Endorphins are natural pain inhibitors and are suppressed with use of exogenous opiates, such as meperidine (Demerol) (Jimenez, 2000). Research is being conducted on the effects of other endogenous substances, such as serotonin, oxytocin, and melatonin.

Melzak and Wall proposed the gate-control theory of pain in 1965 (Melzak & Wall, 1965). This theory states that

Nursing Alert

EFFLEURAGE

Light touch, such as effleurage, travels along the same small-fiber pathways as do pain stimuli and therefore can increase pain perception. Many women prefer a harder massage as labor progresses.

Relaxation and stress reduction are beneficial for many physical conditions and pain control. Positive effects also may be related to the special attention and support the laboring woman receives from the nurse, her labor partner, or a doula. This positive effect can reduce fear and pain. Other mechanisms may be related to the benefits of spiritual connection with the supportive presence of others who have intent to help.

pain stimuli can be modified as they travel on small-diameter nerve fibers along the ascending pathway through the spinal cord. A gating mechanism can be activated by sensations traveling through large-diameter fibers, which transmit messages more quickly than do the small fibers. This gating mechanism is activated by massage and by heat and cold. Habituation may occur in 15 to 20 minutes and may be mistaken for an increase in actual pain rather than in perception. Changing the site or type of stimulus can reactivate the “gate” (Jimenez, 2000).

RESEARCH RELATED TO CHILDBIRTH PREPARATION

Much of the focus in childbirth has been on pain reduction. However, research has repeatedly shown that maternal satisfaction with childbirth is more strongly related to the woman’s ability to participate actively in decisions related to the childbirth experience (Humenick, 1997). The focus of the media and many providers continues to be pain reduction. The first randomized controlled trial of epidural anesthesia in 1993 was stopped because ethical conflicts arose owing to an increase in the cesarean birth rate among women in the group receiving epidural anesthesia (Ondeck, 2000). Research is inconclusive regarding the physiologic effects of catecholamines and the use of anesthesia and analgesia during labor. These subjects currently are being debated among researchers and practitioners.

Some researchers believe that maternal stress levels contribute to the release of catecholamines, thus causing vasoconstriction of uterine blood vessels and resulting in lower levels of oxygen reaching the placenta and thus the fetus (Steiner, 2000). Concerns exist that this decreased oxygenation could contribute to fetal distress. The use of analgesia and anesthesia is supported because it reduces maternal stress, making birth less stressful for the mother and infant. In contrast, a body of research exists that suggests the presence of catecholamines is important to fetal survival and that the surge during labor is protective (Steiner, 2000).

The response of the fetus to catecholamines could be misinterpreted as fetal distress, because when fetal scalp blood pH levels were drawn, true asphyxia was present only in those with levels of catecholamines in excess of normal labor. These researchers concluded that the high levels of catecholamines found in normal deliveries protected the infant during the stress of the birth experience and also facilitated normal breathing in the first hours of life by increasing the metabolic rate and enhancing blood flow to vital organs. The risk of interfering with this healthy response should be considered in decisions of managing labor (Steiner, 2000). Childbirth educators are

Figure 17-5 The nurse knows that her encouraging words and soothing voice will help this first-time mother to relax as her labor progresses.

encouraged to employ evidence-based practice (Figure 17-5). This approach integrates research from various areas: education for the most effective methods and strategies, medicine related to the physiology of labor and fetal development, medical management of pregnancy and labor, and social sciences related to physiologic, social, cultural, and spiritual aspects of childbearing.

The strategies for labor have been strongly influenced by research. In 1993, Lamaze International, Inc., revised its guidelines related to breathing strategies based on the scientific literature (Nichols, 2000). Research into the various relaxation strategies, such as touch, music, and so on, also is increasing. As more nurses become aware of evidence-based practice and use of research results, perinatal education will be impacted.

STRATEGIES FOR LABOR MANAGEMENT

Prenatal or childbirth education may be with individuals, families, or groups. Nurses can design educational content using trimesters as guidelines, allowing for standardized content. Many agencies have designed specific classes for various topics and stages of pregnancy. Adaptations always must be made to accommodate individual family needs.

Relaxation Techniques

Relaxation is central to many of the techniques for coping with labor. Relaxation is a systemic response that reduces fear and tension during labor. Reduction in fear and ten-

Nursing Tip

RELAXATION

“Relaxation is the foundation of all childbirth preparation techniques” (Nichols, 2000).

sion facilitates the body’s efficient use of energy for labor, thereby reducing fatigue and thus making labor more effective. Tense abdominal muscles form resistance to uterine contractions and use oxygen, resulting in less oxygen available to the fetus. Tension increases lactic acid build-up, which increases pain. Relaxation during pregnancy results in increased oxygen to tissues and organs and fewer stress hormones reaching the fetus. Relaxation skills also are helpful after delivery in coping with the demands of a new baby and helping establish breast-feeding. Developing relaxation skills promotes the health of the entire family (Humenick, Shrock, & Libresco, 2000). The authors reviewed research studies on relaxation techniques for birth. Benefits extended into the postpartal period and included lower anxiety, less depression, increased self-esteem, and improved immune function. Several techniques are employed to promote relaxation. Some of the more popular techniques are described subsequently. Many of these techniques also are discussed in Chapter 4 on complementary and alternative therapies. The use of these techniques specifically for pregnancy and childbirth also is discussed subsequently.

Paced Breathing

Current scientifically based breathing techniques are flexible, individualized, and focused on using a slow-paced breathing rate throughout labor. Breathing strategies for labor now are understood to be a relaxation-enhancing strategy (Nichols, 2000). Breathing strategies are based on scientific understanding of respiration and changes during pregnancy and labor. Normal respiratory rates range from 12 to 16 breaths per minute. In pregnancy, the respiratory rate increases slightly, respiratory effort increases owing to uterine enlargement and resultant pressure on the diaphragm, and oxygenation requirements increase. The increased need for oxygen generally is accommodated by an increased depth of respiration and a slight increase in rate.

Paced breathing decreases stress and pain and increases relaxation. The term paced breathing now is used to describe the research-based breathing techniques used to decrease stress responses and thus decrease pain. Paced breathing has been shown to promote relaxation through reducing the sympathetic response of the autonomic nervous system and to stimulate the parasympathetic branch.

Figure 17-6 Using paced breathing, the laboring woman controls and regulates her breathing patterns.

This type of breathing also implies self-regulation. In 1983, Lamaze International adopted the standards for prepared childbirth based on the paced breathing patterns discussed subsequently (Nichols, 2000). Paced breathing techniques use a slow rate and individualized and flexible approaches to promote relaxation of the laboring woman (Figure 17-6).

Cleansing Breath

A **cleansing breath** is a deep relaxed breath, such as a sigh, designed to signal relaxation and provide deep ventilation. This breath often is used to signal the beginning of a contraction and separates the stimulus of the contraction that usually has a response of alarm and tension. Cleansing breaths often have been used along with a focal point to help the woman in labor concentrate and focus on relaxation. Contractions of the uterus or other muscles contracted during stress use additional oxygen and result in aerobic work. Cleansing breaths also help provide additional oxygen for the aerobic work of a contraction or can

Figure 17-7 Slow-paced breathing provides comfort to the mother and adequate ventilation to both mother and fetus during labor.

serve to repay the oxygen debt from previous work. Cleansing breaths should be effortless and as deep as is comfortable.

Slow-Paced Breathing

Slow deep breathing is associated with relaxation. Research had shown that slow-paced breathing is associated with increased relaxation and decreased anxiety, pain, psychological response to threats, and stress (Nichols, 2000). Early childbirth instruction differentiated between abdominal and chest breathing; current classes emphasize a more flexible approach.

The rate of breathing should be comfortable for the woman and provide adequate ventilation for the mother, fetus, and work of labor. A rate of half the woman's normal rate is appropriate during the early part of labor.

Nursing Alert

SLOW-PACED BREATHING

The rate of slow-paced breathing should be no less than half of the woman's normal respiratory rate. Less than this rate may not provide adequate ventilation.

Nursing Tip

EFFECTIVE BREATHING

Always work with the woman to help her breathe at her comfort level. Avoid complicated breathing techniques that interfere with relaxation. Remember that relaxation is the key.

Often, couples will learn the woman's normal rate and practice slowing breathing in preparation for labor (Figure 17-7). Abdominal or chest breathing may be used; however, confining the breathing to either area may interfere with relaxation, which is the main goal. Nose or mouth breathing may be used, whichever is more comfortable. If mouth breathing is used, moisture in the woman's mucous membranes will need to be replenished during labor. The woman should be encouraged to use the slow-paced breathing pattern for as long as possible. As labor progresses and habituation occurs, however, she may need to modify her breathing.

Modified-Paced Breathing

During increased work or stress, the respiratory rate increases. **Modified-paced breathing** paces this increase at a controlled rate. Patterned-paced breathing is a more rhythmic pattern and requires increased attention by the laboring woman. These techniques are learned and are best practiced during pregnancy for optimal use during labor. The rhythm aids the woman in concentrating and therefore increases her ability to relax. Respiratory physiology requires that the lungs adequately empty to result in good ventilation. Respiratory rates that are too fast decrease the tidal volume. It is recommended that the respiratory rate not exceed twice the woman's normal rate and that there be a balance of breathing deeply enough to cause alveolar ventilation but not so shallow as to stop air movement. When the woman feels as if she needs to catch her breath, she should deepen her breathing.

Nursing Tip

MAINTAINING MOUTH MOISTURE

Offer a laboring woman sips of water, clear liquids, or crushed ice to help keep her mouth moist, per physician or institution policy.

Patterned-Paced Breathing

Patterned-paced breathing is similar to modified-paced breathing but with the addition of a rhythmic pattern. One of the rhythms that frequently is taught in childbirth classes is 4—1, which means four light breaths plus one similar inspiration followed by an exhalation, such as that used when blowing out a candle. Different patterns may be used, such as 4—1, 6—1, 4—1. Many couples use pyramids or other patterns. The patterns sometimes help the woman to focus. Any pattern is encouraged as long as the basic principles of rate and relaxation are met.

Progressive Muscle Relaxation or Neuromuscular Relaxation

The technique of progressive muscle relaxation or neuromuscular relaxation uses the client's ability to recognize muscle tension and relaxation in her own body. The client thus learns to release muscle tension and relax through systematic contraction and relaxation of specific muscle groups. This technique generally is done with a partner who observes the tension in the muscle groups and cues the woman into achieving overall relaxation. This focused relaxation increases oxygenation to muscles, especially the uterus, and decreases the perception of pain. As couples practice this technique, some eventually are able to relax a muscle by applying a specific stimulus, such as touch.

Neuromuscular Dissociation

Neuromuscular dissociation focuses on differentiating tension from relaxation. The woman practices by tensing some muscles while simultaneously relaxing other muscle groups. This technique often is taught to couples. The partner checks muscle groups and coaches the client on relaxing and tensing various muscles. Eventually, couples may practice substituting a relaxation response rather than tension to painful stimuli.

Autogenic Training

Autogenic training is a form of passive concentration whereby the woman acquires control over autonomic processes through concentration on visual, auditory, or somatic imagery. The training often employs commands such as “My hands are warm” or “My arm is heavy.”

Meditation

Meditation has been used for centuries in Eastern religious and health practices. The meditative state is attained through quiet concentration on a mantra or a repetitious sound. The purpose is to empty the mind of thoughts and concerns, thereby quieting the mind and therefore the body. This discipline requires practice and may produce excellent reduction in anxiety.

Biofeedback

Biofeedback is the use of instruments to detect select physical status, making clients more aware of their physical state and thus enabling them to bring the physical state under voluntary control. Most biofeedback equipment monitors muscle tension, skin temperature, blood pressure, and brain activity. Clients increase their sensitivity to internal events and can learn to regulate heart rate and blood pressure, control symptoms, and stimulate a relaxed state. Humenick and Marchbanks (1981) indicate that some childbirth educators have the potential to be as accurate as is biofeedback equipment in determining the degree of relaxation.

Touch

Touch has been associated with comfort and caring across cultures and over time. Human touch is vital to the well-being of infants and has been used by midwives to support women in birthing for centuries. Various techniques of touch are used with women in labor that range from gentle comforting touch to massage and acupuncture (Figure 17-8). Infant massage historically has been used in India and recently has gained popularity in the United States. Therapeutic touch and healing touch are discussed in more detail in Chapter 4.

Imagery

Athletes may imagine a physical activity and public speakers and performers may prepare for a performance by visualizing the desired actions. Imagery also has been used in health care to prepare people for surgery, resulting in

Nursing Alert

IMAGERY

Although using imagery may seem harmless, psychological clinicians warn that it should not be used in clients who have psychoses or are mentally unstable. When using this technique with a group, the lights may be kept on and participants instructed to open their eyes if they are more comfortable. No more than 20 minutes should be spent in deep relaxation states because excessive use of imagery may be associated with withdrawal from everyday life, insomnia, and hallucinations. Unless they are experienced counselors, educators should never probe memories of past trauma that may be elicited or interpret images that clients may have. Clients taking medications for metabolic disorders should be monitored.

the need for less pain medication and decreasing complications. Imagery has been used to decrease headaches and lower blood pressure; it has been used in patients with cancer and those undergoing skin grafts (Achterberg, 1985; Achterberg et al., 1994). Although the scientific understanding of how imagery works is unclear, it appears that the brain does not differentiate between an image of reality and a visualized image (Steffes, 2000). Imagery has been used in childbirth, starting with the focal point for concentration and using pleasant images for relaxation training. Use of these images involves multiple senses, including vision, sound, and smell to transform pain into a less stressful sensation. Imagery in childbirth is used alone or in combination with other relaxation techniques. For example, Lamaze (1972) suggested that the laboring woman visualize contractions like waves in the rising tide and waning of contractions as the ebbing tide. Some childbirth educators encourage woman to visualize their cervix dilat-

ing during labor. Most people self-select and use the type of relaxation technique most comfortable for them. The Academy for Guided Imagery reported no adverse effects from the professional or lay community when imagery was used (Steffes, 2000).

Music Therapy

Music has been used as a therapeutic agent throughout history and across cultures. Early studies of the therapeutic properties of music were conducted in dentistry as a method to reduce pain (DiFranco, 2000). A meta-analysis of music in medical and dental literature indicates that music enhanced medical objectives in psychological, self-evaluative, physiologic, and behavioral observations (Standley, 1986). Music appears to have effects on the autonomic nervous system, immune system, and psychological system. In childbirth preparation, music is used alone or in

combination with imagery to induce relaxation and reduce pain. Halpern & Savary (1986) believe that the human biologic rhythm corresponds with a 4:4 musical beat and when exposed to a new rhythm, tries to balance by adapting to the new rhythm. Thus, some rhythms are soothing, others are rousing, and others are antagonistic to biologic rhythms. Repetition is a feature of music that, in combination with rhythm, may be calming (DiFranco, 2000). Low-pitched tones have a more relaxing effect than do high-pitched tones; intensity also is an important feature, with loud music increasing respiratory activity. Loud music increases the fetal heart rate. The effect of fetal intrauterine exposure to loud music or noise is unknown. Music has been used to facilitate calming in newborns. Personal preference also is important in selecting music.

Acupressure

Acupuncture and acupressure have been used for pain relief and anxiety reduction for thousands of years. A consensus panel of the National Institutes of Health (NIH) on the use of acupuncture and acupressure has concluded that these treatments may be effective for many pain-related conditions and the nausea related to chemotherapy and pregnancy (NIH, 1997). Data on the use of acupuncture and acupressure in childbirth is sparse; however, empirical evidence supports its use for the discomforts of pregnancy, labor, birth, and the postpartum period. Acupressure is similar to acupuncture but is not invasive and applies manual pressure to the acupuncture sites. Acupuncture requires administration by a trained professional; however, some acupressure techniques can be incorporated into childbirth preparation. The acupressure point may be tender to the touch and feels less resistant to the touch than do other points on the body. Generally, the thumb or finger is used to apply pressure. A point on the wrist is used for nausea in pregnancy (Figure 17-9). Points around the sacrum are

Figure 17-9 Acupressure to the wrist often alleviates the feeling of nausea in pregnancy.

used for labor pain and back pain. Before using or teaching clients the acupressure technique, the nurse should become familiar with the various points because some may induce labor contractions (Koehn, 2000).

SUPPORT DURING LABOR

One of the most significant elements of the childbirth education movement has been to legitimize the importance of the presence of a supportive person who stays with the woman throughout labor. Around the world, women support other women in childbirth. Since the 1970s in the United States, husbands or partners have moved into this role as a result of the childbirth movement. Since that time, many childbirth classes have described the father's role as coach and he was instructed to coach his partner through the various breathing techniques. This role has been challenged because many men feel the role is inappropriate. Currently, the father's role is more flexible but men are encouraged to accompany their partners through labor if the couple wishes.

Currently, health care professionals and doulas are employed more frequently by health care institutions or contracted by the family to provide support during labor. Whereas the role of support person seems ideal for the nurse, the greater the medical needs of the women the less available is the nurse to provide emotional support (Simkin & Fredrick, 2000). In addition to midwives and nurse midwives, a new group of health providers has emerged as labor companions. They have many names. Some are called birth assistants or labor assistants who often are laypersons with some midwifery skills. Doulas are labor companions trained and experienced in childbirth. They provide continuous emotional support, physical comfort, and informational support. The labor support person may be an untrained, inexperienced friend who accompanies the woman during labor. A monitrice is a nurse who can provide nursing care and assessment in addition to labor support.

Studies have demonstrated that women who were accompanied by doulas or montrices had better outcomes, including a lower rate of epidural use; fewer episiotomies; and in one study, a lower cesarean rate and less need for forceps (Klaus, Kennell, & Klaus, 1993; Hodnett and Osborn, 1989). Doulas and montrices generally work with mothers and fathers to help the couple work closely together and to support a positive experience for the family.

The support person works with the laboring woman to make sure she understands the physical changes of labor, encourages distracting activities and relaxation activities, and assists in finding comfortable positions throughout labor. (Some of these positions are illustrated in Figure 17-10.) Often, the nurse, nurse midwife, doula, or montrice works with the family before delivery and thus

applies the types of relaxation techniques the couple has been practicing.

Labor often has been regarded by health care providers as a high-risk medical event, using an active model of aggressively managing the labor process; alternatively, many childbirth educators and nurses view labor as a normal physiologic process (Wooley & Nelsson-Ryan, 2000). Some, echoing Odent's philosophy of intuitive birth—or the physiologic model—believe that labor can evoke a basic intuitive response that allows the woman the best experience.

Active Model

The active model of labor assumes that the second stage of labor is a singular event from the full dilation of the cervix to the expulsion of the fetus (Wooley & Nelsson-Ryan, 2000). Full dilation is assessed by vaginal examinations, and the woman is encouraged to bear down and push when complete cervical dilation and effacement has occurred. She often is instructed to take a deep breath, hold it, and push. She may be given anesthesia and analgesia. The fetus is carefully monitored and medical interventions are initiated if the process is prolonged.

Physiologic Model

The physiologic model supports the woman's natural process of labor and attempts to use interventions that enhance or replace the physiologic process (Wooley & Nelsson-Ryan, 2000). This model divides the second stage of labor into two phases: (1) the interval between full dilation and active and spontaneous bearing down; and (2) the press period, or the bearing-down phase, which extends from the time of active spontaneous pushing to the birth of the baby. Thus, the second stage may extend to 3 hours. The active model encourages the woman to actively and consciously push to shorten this stage. The longer stage of the physiologic model encourages the woman to follow the natural impulses of her body (Roberts, 1996). Following the natural impulses avoids involuntary pushing that may unnecessarily exhaust the woman and evoke a Valsalva maneuver, in which the intrathoracic pressure from straining impedes venous return to the heart and causes decreased cardiac output and disrupted blood to the uterus. The physiologic approach also encourages the woman to make whatever sounds are spontaneous. Many women will use an open glottis while pushing, which sounds more like grunting than straining when bearing down.

In a review of literature on the second stage of labor, Minato (2000) concludes that laboring down should be incorporated whenever possible in caring for laboring women. *Laboring down* refers to allowing the mother to rest while contractions produce the descent of the fetal head through the birth canal, until rectal pressure or other physical sensations of the urge to push occur. The mother

is not encouraged to push until after this rest period. This technique reduces maternal exhaustion, produces less perineal edema, and appears to have no adverse effects on fetal or newborn well-being.

Positioning during the second stage of labor can increase uterine efficiency and protects the perineum. In studies of nonmedicalized births, an upright position often is used. The upright position is described as an active position achieved by standing, sitting, squatting, or kneeling (Wooley & Nelsson-Ryan, 2000). These positions allow gravity to assist the work of the uterus, and they reduce back pain and the length of the second stage of labor. Many birthing beds or chairs have been designed to put the woman in a more upright position, which facilitates labor. Good evidence exists to support that the dorsal position for birth, which fails to use the forces of gravity, is unfavorable because it lengthens the labor and may cause fetal hypoxia and maternal hypotension. A birthing bed that allows the mother freedom of movement and a variety of active positions seems to be the optimal choice.

In the physiologic model, interventions follow the form of enhancing the physiologic process. For example, breast stimulation is used before administering oxytocin (Pitocin) to stimulate uterine contractions. Perineal massage during pregnancy and labor also is used to reduce lacerations. Extensive research supports the fact that routine episiotomies are not justified and carry additional unnecessary risks.

Families, either through their childbirth preparation classes or exposure to friends and the media, also develop a philosophy about labor. A supportive physical and emotional environment for the second stage of labor is important in any case. Health care providers are encouraged to work with the family regarding their philosophy of birth.

Parenting, Role Transition, and Family Adaptation

The perinatal educator approaches childbearing in a broader sense than the focus on the birth, incorporating education about family adjustment to the pregnancy and the new infant. Infant feeding and infant care are major components of client education.

ADDITIONAL CLASSES OFFERED TO CHILDBEARING FAMILIES

Special classes may need to be adapted for families. The following may need to be taken into consideration: cesarean birth, vaginal birth, vaginal birth after cesarean section, parents, grandparents, siblings, single parents, specific cultural groups, high-risk pregnancies, pregnant adolescents, parents with handicaps, parents with medical problems,

communication barriers, and preconceptional classes (AWHONN, 1993). Some of these classes are discussed.

First Trimester-Early Pregnancy Class

Early pregnancy classes are offered by hospitals that provide women's health care services. This introductory course focuses on the physiologic and psychological changes that occur during the first 3 months of pregnancy. Educators are able to respond to questions and, perhaps, decrease anxiety for clients through frank discussion and exploration of feelings during this initial stage of attachment to the growing baby. Hospitals also may view this class as a mechanism for marketing the services they provide; therefore, a tour of labor and delivery, nursery, neonatal, and postpartum units often is included in the class. The importance of continued prenatal care, education, and preparation is promoted. Additional classes or prepared childbirth and infant care programs may be introduced.

An important benefit of this type of class is education. An increased level of knowledge regarding changes that occur throughout the pregnancy is gained by the significant others of the expectant mother. Optimally, childbirth education is started before conception and includes ensuring the mother has appropriate treatment for minor health problems and begins good health habits. These health habits include good nutrition; avoiding alcohol, cigarette smoking, and other drugs; and avoiding exposure to toxic substances that could cause harm to the developing fetus. Ideally, childbirth education builds throughout the pregnancy, which allows for specific content to be covered in each trimester. Other material is introduced early and expanded or reinforced throughout the pregnancy. When the nurse has not been able to begin the education early in the pregnancy, the material should be covered whenever the client is available for teaching. Many facilities provide classes on specific topics that can augment formal childbirth preparation classes and individual teaching.

Content appropriate for teaching childbearing families is outlined for each trimester in Box 17-1.

Pregnancy Exercise Classes

The pregnant woman's desire to maintain or improve her physical conditioning in preparation for birth has resulted in the development of exercise classes designed specifically for pregnant women. The American College of Obstetricians and Gynecologists (ACOG, 1994) published guidelines for exercise during pregnancy that have become the standards for the content, exercise selection, and maternal parameters of these classes. Classes may be coordinated through sports medicine or hospital wellness de-

partments that use or rely on the expertise of exercise physiologists. Commonly, a physician's approval is required before acceptance into the program. Postpartum conditioning also has been included in some exercise programs that also serves to unite new mothers, resulting in the formation of informal support networks.

Mild exercise for strengthening muscles taxed by pregnancy or giving birth has been a standard part of perinatal education. Concerns have been raised about vigorous exercise during pregnancy, such as the risks for hyperthermia, fetal distress miscarriage, and maternal injury. The risks of vigorous exercise are low; in contrast, vigorous exercise has many benefits, including weight control, physical fitness, and positive mental health (Hammer, Perkins, & Parr, 2000). The first ACOG standards regarding exercise in pregnancy were published in 1985 (ACOG, 1985) and contained specific guidelines related to heart rate and duration. These standards were revised to be more flexible, indicating that continuing or beginning an exercise program during pregnancy is now viewed as safe (ACOG, 1994). The benefits of exercise during pregnancy include healthy weight maintenance, cardiovascular fitness, improved posture, positive psychological benefits, and fewer miscarriages; other benefits are relief of minor discomforts, easing of labor, prevention or treatment of pregnancy-induced complications of gestational diabetes, and possible prevention of pregnancy-induced hypertension (PIH) (Hammer, Perkins, & Parr, 2000). The benefits are weighed against the risks that include trauma, strains, and sprains. The risk of fetal hypoxia occurred only in women who were not physically fit and who engaged in sporadic vigorous exercise and, in some cases, high-altitude activities (above 9,000 ft) or scuba diving (exceeding depths of 12 to 16 ft). Fetal risks related to hyperthermia are greatest in the first trimester; core temperature of 102°F to 104°F may be related to neural tube developmental defects and teratogenesis. Pregnant women are advised to avoid vigorous exercise in hot ambient conditions (Hammer, Perkins, & Parr, 2000). Hypoglycemia can be avoided by consumption of a sports drink or fruit during (every 30 minutes) or after exercise. Women should maintain adequate hydration during exercise. Differences in health status, physical fitness, and previous exercise require that recommendations be individualized; monitoring may be advised (Figure 17-11).

Breast-Feeding Classes

Breast-feeding classes provide information and assist the mother in making a decision regarding breast-feeding. Participants are encouraged to attend these informational and supportive classes before delivery because they provide the knowledge related to the benefits, mechanisms, and skills of breast-feeding. Classes are commonly conducted by breast-feeding educators or, when possible, certified

Box 17-1 Specific Educational Content for Each Trimester

First Trimester

Knowledge of the Pregnancy

- Anatomy and physiology of pregnancy
- Physical and emotional changes related to pregnancy
- Fetal development
- Importance of prenatal care
- Diagnostic tests, such as chorionic villus sampling, amniocentesis, and ultrasonography
- Warning signs of complications
- Dangers of substance abuse and exposure to toxins and teratogenic hazards

Management of Pregnancy

- Morning sickness
- Sleep disturbances
- Libido changes
- Urinary frequency
- Fatigue
- Emotional lability

Relaxation Techniques

Introduction to stress management:

- Awareness of the stress response: breathing patterns, muscle-tension, and other physical symptoms of stress in contrast with relaxation
- Awareness of stimuli for tension and relaxation
- Introduction to relaxation techniques
- Slow-paced breathing
- Body awareness

Exercise and Nutrition

- Nutritional needs
- Vitamin supplements
- Exercise
- Body mechanics
- Stretching
- Kegel's exercises
- Pelvic tilt exercises
- Toning and aerobic exercises

Family Adaptation

- Choices of provider and birth setting
- Response to emotional and physical changes of pregnancy
- Sexuality
- Infant feeding method
- Exploring maternal and paternal roles
- Communication skills to discuss adaptive changes in the family
- Introduction of discussion of financial and spatial family adaptation to the expanding family

Second Trimester

Builds on previous teaching or incorporates previous trimester teaching if necessary

Knowledge of Pregnancy

- Physiologic changes of pregnancy
- Fetal development and characteristics
- Fetal movement
- Review of warning signs and complications

Management of Pregnancy

- Management of heartburn, back pain, and so on
- Changes in body and body image
- Comfort and hygiene measures

Relaxation Techniques

- Explore and identify techniques, such as imagery, massage, music, touch, visualization, and so on
- Work together as a couple (client and support person) to elicit relaxation to stimuli
- Practice slow-paced breathing, modified-paced breathing, and patterned-paced breathing

Exercise and Nutrition

- Continue good nutrition, and monitor weight gain
- Increase repetitions of exercise
- Modify activity related to physical changes

Family Adaptation

- Identity of the fetus as a separate individual and building maternal-fetal attachment

(continued)

Box 17-1 Continued

- Financial considerations; may include a discussion of working or career in relation to the pregnancy
- Paternal concerns: role in labor, role as father, financial concerns, and provision of safety for the mother and fetus
- Sibling preparation
- Preparation of the home for the infant
- Discussion of feeding choices for the infant
- Selection of a pediatric provider

Third Trimester

Often the time for formal classes and need to include all of the above if not already covered

Knowledge of Pregnancy

- Anatomy and physiology of late pregnancy
- Mechanisms and signs of labor
- Additional testing or medical information related to specific conditions
- Medications and anesthesia
- Policies and practices of the facility chosen for delivery
- Postdelivery physical and emotional changes
- Signs and symptoms of labor
- Warning signs of complications
- Progress of labor

Management of Pregnancy

- Preparation for labor
- Comfort measures
- Sleep patterns

Relaxation Techniques

- Practice relaxation techniques
- Practice all methods of breathing for labor
- Practice additional relaxation techniques

Exercise and Nutrition

- Continue good eating patterns
- Monitor appropriate weight gain
- Watch body mechanics, safety, and comfort
- Prepare for delivery: tailor sitting, pelvic tilt, and Kegel's exercises
- Perform walking and other conditioning exercises
- Introduce postpartum exercise

Family Adaptation

- Rehearse preparation for delivery and role of support person
- Evaluate family and extended family's preparation for birth
- Discuss normal appearance, care, and feeding of the infant
- Discuss breast-feeding techniques and preparation
- Discuss parental roles
- Discuss sexual adjustment

lactation consultants. Many health care organization and insurance plans also provide breast-feeding support classes and information for parents postpartally, which may gradually have an impact on the length of time an infant is breast-fed. Partners often gain a great deal of understanding and knowledge from attending these classes, and they can provide emotional support for the new mother.

Sibling Classes

The focus on family-centered maternity care has led to the inclusion of all family members in the preparation for

the upcoming birth. Classes for siblings are conducted in a relaxed atmosphere that allows family members to ask questions, practice infant care skills, and tour the facility where the mother and neonate will stay. Classes often target specific age groups, allowing for development of age-appropriate content. The use of slide presentations, coloring books, stuffed animals, and treats, such as cookies and punch, can prove very effective in familiarizing the child with the hospital environment. Sibling preparation is intended to decrease the anxiety experienced by both child and parent when a new family member is added.

Grandparent Classes

Many times grandparents are very active in the preparation for childbirth. Many changes in maternal and newborn care have occurred over the past several decades, especially in including extended family members in the preparation and care of the new infant. Grandparents can become familiar with changes in approaches to infant care, such as sleep position recommendations; infant feeding; and new products, equipment, or services available to the new family.

Vaginal Birth after Cesarean Preparation

Classes have been formed to accommodate the specific educational needs of women who have elected to attempt a vaginal delivery after a previous cesarean section birth. Class participants often spend the first part of the program discussing factors that contributed to the operative delivery. These factors may detract from the confidence the couple may have regarding labor. The program covers techniques and strategies for expectant mothers and support partners to use during labor that increase the likelihood of a successful vaginal delivery.

Infant Care Classes

The desire to prepare for parenthood is a concern of mothers and fathers. At times, care of the newborn can seem overwhelming to new parents. In many areas of the country classes are held that provide instruction on the safe and responsible approach to infant care. These programs typically include an American Heart Association infant cardiopulmonary resuscitation course and demonstrations covering basic newborn care concerns such as bathing and diapering. This course is an excellent way for parents and child care providers to acquire knowledge related to newborns and to discuss topics such as stimulation, feeding choices, safety concerns in the home environment, and adjustment to the parenting role.

PREPARATION FOR THE EDUCATOR ROLE

Nurses and laypersons may be certified as perinatal educators. The position statement of the International Childbirth Education Association (ICEA) states that no single training or academic background is necessary to become a childbirth educator (ICEA, 1999). AWHONN (1993) guidelines for nurses specify that perinatal educators are expected to have completed appropriate previous education and training and have experience in both general nursing practice

and teaching techniques. For nurses, some experience working in obstetrics or woman's health serves as a good background for the educator role. The guidelines describe teaching and content competencies.

Formal preparation for the perinatal educator role is available from several professional organizations, including the International Childbirth Education Association (ICEA), the Bradley method, ASPO/Lamaze, Prepared Childbirth Educators, Inc., and other organizations. Perinatal educators must be able to clearly communicate the following: scientific bases of pregnancy and the birth process, psychosocial and cultural aspects of childbearing, and most current information for promoting health throughout the pregnancy and preparation for birth. According to AWHONN (1993) guidelines, the educator should work as a team member and demonstrate a philosophy of perinatal education that honors pregnancy as a state of wellness and respects the beliefs and attitudes of families. Specific content includes health education regarding pregnancy and childbirth, specific coping and relaxation strategies for childbirth, preparation of support persons, and provision of anticipatory guidance for the family in the postpartum period.

Families are encouraged to be active participants in the education process, and one of the goals of the classes is to encourage the woman and her partner to take an active role in their health care and the birth of their child. Perinatal education is founded on the premise of freedom of choice based on information about the process and knowledge of options.

The nursing process can be useful in determining and meeting individual educational needs in addition to the anticipatory guidance that may be provided to groups or clients as part of standard care. Assessment of needs should occur during the first prenatal visit. Some of these anticipated needs may be based on trimesters and progression of the pregnancy.

Prenatal education must respond to changes in technology, consumer demands, and trends in health care services provided to expectant parents. The perinatal educator must be knowledgeable about the risks and medical management of pregnancy and birth and be able to prepare and interpret these to the client. The educator needs to be aware of the many educational products, such as literature, films, and other materials, that can be used effectively for family preparation for childbirth. Prepared materials should be assessed for accuracy of information, literacy level, and cultural appropriateness. Clients also are exposed to information about pregnancy and birth through the popular media. The educator should assist clients in interpretation of this information for accuracy and relevance to their situation.

Perinatal education can be in formal groups or with individual clients. Participation in formal prenatal education

Client Education

Good Posture during Pregnancy

- Standing: head should be held erect with chin tucked, shoulders relaxed, and knees slightly bent (Figure 17-11A).
- Sitting: knees should be level with or higher than hips; a pillow may be placed behind the lower back for comfort (Figure 17-11B).
- Lying on your side: a pillow should be placed under the upper leg, keeping the leg slightly flexed. A pillow also may be placed under the abdomen for support (Figure 17-11C).
- Lying on your back: A pillow should be placed under the knees to elevate the legs (Figure 17-11D); a pillow under the right hip displaces the uterus and prevents vena cava syndrome. This position should not be used after the fourth month of pregnancy.

Exercises for Pregnancy

Specific exercises can be taught to clients to help strengthen muscle tone in preparation for birth.

- The pelvic tilt reduces back strain and strengthens the abdominal muscles. Figure 17-11E illustrates how to perform the pelvic tilt in both a standing and kneeling position. Exhale, roll the hips and buttocks forward, hold for a count of five, then inhale and relax.
- Abdominal muscle tightening with every breath increases abdominal muscle tone. This exercise can be done anywhere in any position. While slowly taking in a deep breath, expand the abdomen. Then exhale slowly while pulling the abdomen in until the muscles are completely contracted. Relax a few seconds and repeat the exercise.
- Kegel's exercises strengthen and tighten the perineal muscles. Tighten these muscles and pull them up toward the vagina as if trying to stop urination midstream. This exercise also can be done anytime, anyplace.
- The tailor sit (cross-legged sit) stretches the inner thigh muscles; adding arm reaches stretches the sides and upper body and helps relieve upper backache. Sit cross-legged and stretch one arm high over your head, then release and exhale. Repeat on the other side. Figure 17-11F illustrates the tailor sit and arm reaches.

classes frequently is included in the plan of care for clients. It is important that an evaluation be conducted regarding how well the educational needs of the client are being met. Individualized teaching often is necessary to augment formal classes.

Organizations that Support and Certify Childbirth Educators

In addition to the organizations that support the various childbirth methods, such as the Bradley method and

Lamaze method, the following organizations have formed to provide information, publish journals, direct policy, and certify educators.

The International Childbirth Education Association (ICEA) was formed in 1960 by consumer groups (Ondeck, 2000). It certifies educators, holds regular conferences, and publishes the *International Journal of Childbirth Education*. The ICEA requires continuing education for recertification and supports workshops, conferences, and publications. The organization has issued several position statements that can be obtained through its website or from its headquarters. The ICEA has issued position statements on the following topics: substance abuse during

pregnancy, role and scope of the doula, assessment of fetal well-being during labor and birth, cesarean birth, vaginal birth after cesarean section, informed consent in pregnancy and childbirth, infant feeding, epidural anesthesia, role of the childbirth educator, and scope of childbirth.

The Council of Childbirth Education Specialists, Inc. (CCES), is an independent not-for-profit organization formed in 1972 to address the need for formal preparation of childbirth educators. Registered nurses and physical therapists who practice in obstetrics complete a 3-day training program to become certified as educators.

The AWHONN provides guidelines for nurses engaged in perinatal education. This organization also provides guidelines and information across the spectrum of perinatal nursing. *The Journal of Obstetric, Gynecologic, and Neonatal Nursing* (JOGNN) is the official journal of AWHONN. The AWHONN website also contains many publications related to guidelines for nurses in perinatal education.

Principles of Adult Learning

To teach effectively, nurses need to know the subject matter, the principles of adult learning, and the group process. Knowles (1980) identified the following five characteristics of adult learners:

1. Adult learners are independent and self-directed.
2. Adults have previous experiences that serve as resources for learning.
3. Adults have a readiness to learn that is based on current social roles and tasks.
4. Adults prefer to learn things that have immediate application.
5. Adults prefer a problem-oriented learning approach compared with a subject-oriented approach.

Nurses can incorporate these principles while developing an education plan for clients. Pregnancy is an ideal time to provide education because the family is approaching new or expanded social roles and tasks. The timing of the classes reflects a subject-oriented approach to an impending application, that is, the birth of the infant. Many prenatal education classes engage the participants in discussing their past experience and knowledge related to childbirth. These classes allow for much self-direction as the partners work out their own birth plan and rehearse strategies for labor.

Nurses can use these principles to direct group and individual client education, especially education of clients who do not participate in formal classes. The education of adolescents may require modification of content and presentation style.

Group Process

Because much of perinatal education is conducted in a group format, the educator must have a working knowledge of the group process (Figure 17-12). The advantages of working in a group include the additional support from the members, broader insight and sharing of experiences that members contribute, and subtle learning that comes from social interactions. A good educator not only focuses on presentation of material but incorporates the interactions and strengths of the group in teaching. Childbirth preparation classes generally are content-centered groups of 2 to 30 members (groups of 5 to 12 couples are optimal) who are focused on specific content and outcomes (Edwards & Nichols, 2000). Content-centered groups gather to acquire information about a topic from an expert. The group process includes presentation of scientific or academic information through a variety of methods and group interactions.

Childbirth education classes often are composed of couples who are in the same trimester of pregnancy, which helps to focus on common content. A process of warm-up, work, and integration is followed through the course and within each class (Edwards & Nichols, 2000). The warm-up allows the group to become acquainted and focused. The work phase is the introduction and processing of new material. Integration is the final process in which the material is integrated and preparations are made for termination of the class or group meetings. After the group has been established, the work phase is when the most active learning of new information and practice of skills take place. Often, childbirth classes consist of a series of classes at which new information is introduced and previous information is prac-

Figure 17-12 Many childbirth preparation classes are done in a group format.

ticed. Some classes invite previous class members who have delivered their infants to come to the group and discuss how they used the techniques during labor; this helps the class integrate the information. An important part of group process is planning the termination of the group. Often in the last class, little new information is introduced. Instead, rehearsals and integration of previous materials are the focus. Many groups will exchange information, and some will plan reunion meetings.

One technique in these classes is to divide into smaller groups for specific tasks. Often, small group activities are introduced during the first class to allow the group to become acquainted and to establish the group as a working unit. The first class also is the time to set out some of the expectations and instructions, such as type of clothing to wear if the group will be practicing exercises. The group process allows the members to feel there is consensus about problems and concerns addressed in the classes. For example, one educator asks the class what they would want to know if they went into labor (Edwards & Nichols, 2000). This information allows the educator to incorporate the concerns of the class into the class content.

According to AWHONN guidelines (AWHONN, 1993), the perinatal educator should be able to conduct a needs assessment, write goals and objectives, and use a variety of strategies in teaching. The perinatal educator should be able to create a flexible learning environment that fosters self-efficacy in the learner and uses principles of group process. The educator also needs to evaluate and refine the teaching accordingly.

CULTURAL CONSIDERATIONS IN CHILDBIRTH PREPARATION

Childbirth is enmeshed in cultural beliefs and values. These beliefs direct behaviors from conception through childrearing. Spiritual meanings pervade issues regarding when a soul enters the body and the vulnerabilities of the mother, fetus, and family during pregnancy and the birth processes. Cultural beliefs and traditions also dictate a great deal of maternal behavior during pregnancy, especially about activities that might have a negative effect on the baby. Many women will use amulets, charms, chanting, prayers, or special ceremonies to ensure the safety of their infant and themselves throughout the pregnancy and birth. Cultural practices also determine the place or setting for birth; who should be present at the birth; and in many cases, much of the process of birth and ceremonies surrounding the birth. For example, among Palestinians, men, pregnant women, and menstruating women should not be present at a birth (Shilling, 2000). Among Orthodox Jews, the husband may not touch his wife during

Critical Thinking

Considerations in Children

Examine your own cultural beliefs about birth. Imagine that you or your partner are pregnant and in an unfamiliar culture.

- Which things would you feel are necessary for a safe pregnancy?
- Who would you want to be present at the birth?
- Where and with whom would you want to give birth?

labor and cannot view the genital area during labor or delivery; childbirth classes are held with couples sitting around a table because men are not allowed to view another's wife performing exercises (Lutwak, Ney, & White, 1988). Many African American's will choose to have their mother or another close female as a support person during labor.

Many symbolic practices are associated with preparing for labor, such as undoing knots, opening windows, and avoiding ideas of getting stuck. Some childbirth educators incorporate visual exercises of "opening up" or cervical dilation. In many cultures, specific procedures, reflecting symbolic meanings, exist for cutting of the cord or disposal of the placenta and umbilical cord. Many traditions also exist related to particular foods that should or should not be eaten during pregnancy or when approaching labor. One example of a culturally adaptive way of delivering health care occurred in Chiapas, Mexico. When the Indian women in the town would not give birth in the newly built hospital, a local medicine woman was hired to set up an altar in a birthing room and deliver babies in the hospital (Shilling, 2000).

Expression of pain during labor reflects culturally appropriate ways of managing pain and the meaning of pain related to childbirth. Culture affects women's behavior during the postpartum period, for instance, the amount of activity she should engage in, her personal hygiene, and her relationship to other family members. For example, in some parts of India the mother of the husband may have the most authority regarding the care of the newborn. Some families may not want the mother or infant to wear white because it is the color of mourning. In some cultures, a woman who does not appear to pay much attention to her infant is protecting it from bad luck; whereas in others, it may be important for the mother to take the infant to bed with her (Shilling, 2000).

Research Highlight

Collaborative Research Project: Effectiveness of Birth Preparation Classes at a Community Hospital

Purpose

To explore the content and effectiveness of birth preparation classes at a community hospital. The questions included the following: Which aspects of the classes did the mothers perceive as most effective in coping with the birth experience? Was there a relationship between the selected coping strategies and the mother's overall childbirth satisfaction?

Methods

An exploratory descriptive design was employed. Using a convenience sample from women attending the childbirth preparation classes, 127 participants were tracked through the childbirth experience. Within 1 week after the birth, these participants were surveyed using the coping with childbirth questionnaire and the childbirth satisfaction scale. The return rate of surveys was 66%, or 75 participants. Descriptive statistics were used in the analysis. Content analysis was used for the questions on most helpful strategies used.

Findings

The participants were primarily Caucasian (98%), married (91%), college educated (84%), and having their first child (93%). All had a labor support person with them, and most (64%) planned to use anesthesia. Actual use of anesthesia was 74%, and 85% delivered vaginally. Most (85%) were satisfied with the overall experience. The presence of the support person, information about the hospital, process of labor and birth, medications, birth choices, complications of labor were identified as helpful elements of the classes. Slow-paced breathing was the most frequently used breathing technique (64%). The only significant correlation was related to information and satisfaction.

Nursing Implications

Similar with other research on childbirth education this study supports the importance of information, breathing techniques, and a support person as being helpful to mothers during childbirth. Variations among clients and labor and delivery experiences necessitates, including information about and practicing various pain control options to allow the couple to individualize methods.

Slaninka, S. D., Galbraith, A. M., Strzelecki, S., & Cockroft, M. (1996). Collaboration research project: Effectiveness of Birth Preparation Classes at a community hospital. *Journal of Perinatal Education*, 5, (4), 29–36.

Nurses should continually develop their cultural awareness and understand that much variation exists within cultural groups and between ethnic groups. Open-minded approaches to diverse ways of thinking and acting to accommodate their clients are the first steps in developing cultural competence. Astute nurses will incorporate cultural awareness into their assessments of individual families and endeavor to adapt their nursing care according to the family's cultural beliefs and practices.

VARIABLES INFLUENCING THE NEED FOR CHILDBIRTH PREPARATION

The mother's orientation to pregnancy and birth are important considerations. Some women see pregnancy and birth as a time of enjoyment, greater marital closeness, and eagerness to engage in prenatal classes for childbirth preparation; other women are extremely fearful and have a more

negative orientation. A woman's expectations and orientations about pain during labor will influence her decision regarding use of anesthesia and analgesia during labor. Several studies have been cited that mothers who received epidurals were less satisfied with the birth experience despite having less pain (Nichols & Gennaro, 2000). Nurses can be instrumental in helping pregnant women make informed choices regarding use of medications during labor.

Pain is influenced by many factors: fatigue, anxiety, presence of a support person, confidence in the ability to cope with labor, age, education, socioeconomic status, personal history, parity, and spiritual and cultural beliefs. In general, women from the middle and upper middle classes, women with a high level of education, multigravidas, and women with strong social support and a sense of mastery had the highest levels of satisfaction with the birth experience (Nichols & Gennaro, 2000).

Nurses can be instrumental in educating the client and family to prepare for childbirth, thus reducing some of the fears and anxieties about the birth process. Nurses also can help create an environment for birth that reduces stress and promotes comfort. Childbirth preparation has been found to have positive effects on the birth experience by stimulating a positive attitude and by reducing pain, the need for medications, and the use of forceps (Nichols & Gennaro, 2000). Reducing the need for medical interventions has significant benefits and reduction of risks for both mother and infant.

CHOICE OF PROVIDER

Ideally, selection of a health care provider before conception would result in the establishment of a strong client-provider relationship throughout pregnancy and childbirth. Realistically, often it is only after conception that many women begin the search for a provider. Women have many choices available in selecting a provider, including obstetricians, family practice physicians, certified nurse midwives, women's health care practitioners, and lay midwives. Before meeting with providers, expectant families should be encouraged to identify specific desires relating to prenatal, intrapartal, newborn, and postpartal care. Questions should be formulated to obtain information about approaches to obstetric care and practice standards to identify a provider most compatible with issues important to the client. The provider's educational background and preparation, specialty certification, and affiliation with birth settings are additional factors that may influence the client's selection. Economic considerations are increasingly important, because the development of health maintenance organizations and physician provider networks that are aligned with selected insurance carriers may limit the selection of providers and settings from which clients may choose.

Client Education

Health Care Providers

A number of health care providers are available to clients who are pregnant. Nurses may be asked to provide information about the credentials of various providers.

- **Obstetricians:** Licensed medical doctors who have specialty preparation in obstetrics.
- **Family practice physicians:** Medical doctors who are generalists and provide prenatal care and delivery services for uncomplicated pregnancies and referrals to specialists for high-risk pregnancies.
- **Nurse practitioners:** Nurses who specialize in women's health and provide prenatal and postpartal care. They generally work in collaboration with obstetricians who supervise the delivery.
- **Certified nurse midwives:** Licensed nurses certified to provide prenatal and postpartal care and perform uncomplicated deliveries. They also generally collaborate with physicians for high-risk care.
- **Lay midwives:** Unlicensed women who see clients and deliver infants in the home or community setting. In some states they are required to register with the health department.

CHOICE OF DELIVERY SETTING

Nurses frequently are a source of information used by families to reach a decision regarding the choice of a setting in which to give birth. Clients may choose from among five settings:

Home Birth

Home births represent a return to a common practice of the past. Certified nurse midwives are the most common providers of these services, with medical backup provided by a physician. Extensive preparation of the home environment and the expectant family is the underlying requirement for the home to be a safe alternative to hospitalization for childbearing. Active participation in decision-making in the comfort of a familiar environment is an important advantage to a home delivery.

Free-Standing Birth Center

Free-standing birth centers are located in relatively large urban cities and frequently are owned and staffed by nurse midwives and occasionally physicians. These centers offer the atmosphere and comfort of a homelike environment and often are located close to a hospital that provides obstetric services. Expectant parents come to the center at the beginning of the labor process and are able to deliver, recover, and complete a postpartum period in a home-type room. The care provider and family work closely together during the childbirth experience to balance individual desires and safety. Empowerment related to decision-making and active participation in the birth process frequently are cited as positive family outcomes from this delivery setting. A disadvantage that bears consideration is the fact that should significant obstetric complications arise, the client may require emergency transport to a hospital.

Birth Center in a Hospital

Available as an alternative to traditional labor and delivery units, birth centers in hospitals offer services to low-risk obstetric clients in a relaxing homelike environment. Providers in this setting primarily are nurse midwives who work collaboratively with obstetricians in developing a plan of care for clients. The opportunity to blend a midwifery approach to childbearing with the availability of surgical services, a pediatrician, and a neonatal unit is very appealing to many clients.

Labor, Delivery, and Recovery Unit

Labor, delivery and recovery (LDR) units are available in hospitals providing obstetric services to both low- and high-risk clients. Attractively decorated rooms are the settings in which the client completes the labor and delivery and then begins the recovery process. The length of the postpartum stay in this type of setting may be up to 4 hours followed by transfer of the client to a traditional postpartum unit (Figure 17-13).

Labor, Delivery, Recovery, and Postpartum Unit

Labor, delivery, recovery, and postpartum (LDRP) units in hospitals are designed to enhance provision of family-centered care. Clients are admitted to a suite for the birth of the child followed by a seamless transition to mother and infant care for the entire postpartum stay. The opportunity for increased continuity of care for all family members is a strong advantage of this setting.

Figure 17-13 Comfortable labor, delivery, recovery units and labor, delivery, recovery, and postpartum units are the norm in many hospitals today.

NURSING IMPLICATIONS

Nurses can help clients make informed choices regarding the most appropriate model of care and preparation for the birth. Nurses can assist clients to find and connect with a particular childbirth course that matches their needs and cultural beliefs. Techniques that have been developed in various childbirth preparation courses can be used with any client. It is helpful for the nurse to know a variety of techniques for client comfort because one technique will not work with all women. The techniques and philosophies regarding childbirth can be applied to make the hospital birth environment more family-centered and provide a more satisfying experience for the mother, infant, and entire family.

Web Activities

- Acorn Accords is a coalition that fosters optimal early parenting. It is forming an initiative for prenatal parent preparation. To view the working draft of their philosophy statement, contact the website at www.thewellspring.com/coalitionprinciplePts.html.
- Go to a local bookstore and examine the books and journals for expectant parents.
- Read women's magazines and critique articles related to childbearing women.
- Search the Internet for information for expectant parents and critique the information available.

Key Concepts

- The popularity of prepared childbirth classes coincided with the woman's movement and involved both nurses and lay educators.
- Nurses who are engaged in childbirth preparation have used an expanded approach: that of perinatal educator and can obtain additional certification.
- Childbirth education employed cognitive preparation and relaxation techniques to break the fear-tension-pain cycle.
- The leading methods of childbirth education were Lamaze, Dick-Read, Bradley, and Kitzinger.
- The theoretical basis for childbirth preparation were based on relaxation theories, and pain management theories.
- Although paced breathing is the most commonly used technique to decrease stress and increase relaxation, other strategies are also used. These include neuromuscular dissociation, autogenic training, medication, biofeedback, touch, imagery, music, acupressure, labor support.
- Many perinatal educators advocate a physiological model for second stage labor. This model encourages the woman to follow her natural impulses for pushing.
- Perinatal education has included classes on early pregnancy, exercise, breastfeeding, sibling preparation, grandparent preparation, vaginal birth after a cesarean (VBAC), and infant care classes.
- One of the main purposes of perinatal education is to facilitate the woman's decision making and preparation for childbearing.

Review Questions and Activities

1. How was the psychoprophylactic method of childbirth preparation introduced in the United States?
 - a. Through recommendations by the American College of Obstetricians and Gynecologists to hospitals
 - b. Through recommendations by the American College of Obstetricians
 - c. Through a consumer movement that began in the popular press
 - d. Through an official alliance with the French Obstetric Council

The correct answer is c.
2. Which principle of adult education by Knowles often is applied to childbirth education?
 - a. Women respond best to science-based techniques
 - b. Repetition of facts helps change behavior
 - c. Women respond to their social networks and learn best in groups
 - d. Adults learn best when there is immediate application

The correct answer is d.
3. What are some of the unique needs that might best be accommodated by a specialized perinatal education class?
4. Which childbirth preparation method specifically involves the husband with an active role in labor?
 - a. Bradley method
 - b. Kitzinger's psychosexual method
 - c. Lamaze method
 - d. Dick-Read method

The correct answer is a.
5. Which techniques are important in paced breathing during labor?
 - a. The mother should use patterned breathing as soon as she is in labor
 - b. The breathing technique needs to be individualized to the mother and her normal breathing pattern
 - c. Exaggerated blowing and vocalization in patterned-paced breathing are necessary for optimal benefit
 - d. Cleansing breaths should be avoided because hyperventilation may occur

The correct answer is b.
6. Which complementary therapies are useful in preparing for childbirth?
 - a. Herbal remedies
 - b. Trauma release
 - c. Visual imagery
 - d. Rebirthing

The correct answer is c.

Management and Nursing Care of the High-Risk Client

The birth of a child generally is thought of as a joyous occasion for families. Whereas many women experience an uncomplicated pregnancy and childbirth, complications can develop at any point in the pregnancy, labor and delivery, or postpartum period. These complications can lead to serious illness, injury, and even death for the pregnant woman and her baby and place tremendous stress on the family.

Key Terms

ABO incompatibility	Ectopic pregnancy	Nonimmune hydrops fetalis (NIHF)	Preterm labor
Abortion	Elective abortion	Oligohydramnios	Preterm premature rupture of membranes (PPROM)
Abruptio placentae	Gestational diabetes	Percutaneous umbilical blood sampling (PUBS)	Spontaneous abortion
Amniocentesis	HELLP syndrome	Placenta previa	Therapeutic abortion
Amnioinfusion	Hydramnios	Polyhydramnios	Thrombocytopenia
Cerclage	Hydrops fetalis	Postterm pregnancy	Thyrototoxicosis
Chronic hypertension	Incompetent cervix	Preeclampsia	Type I diabetes mellitus
Disseminated intravascular coagulation (DIC)	Induced abortion	Premature rupture of membranes (PROM)	Type II diabetes mellitus
Dizygotic	Ketoacidosis		
Eclampsia	Low-lying placenta		
	Marginal placenta previa		
	Monozygotic		

Competencies

Upon completion of this chapter, the reader should be able to:

1. Discuss potential complications of pregnancy-induced hypertension.
2. Apply the nursing process to plan and implement care for the woman with diabetes in pregnancy.
3. Discuss nursing interventions for the pregnant client who is experiencing vaginal bleeding.
4. Outline common risk factors for preterm labor.

The maternal mortality rate in the United States was reported to be 7.5 deaths per 100,000 live births from 1982 to 1996 (Centers for Disease Control and Prevention, 1998). Identification of common medical and obstetric conditions that place the client and fetus at increased risk for morbidity and mortality is essential in developing a nursing plan of care and achieving optimal outcomes for both. Assessment of family values, available resources, and learning needs also is a critical part of nursing care for these families who are at risk for serious health problems or even loss of a family member.

This chapter provides a broad overview of some common conditions that place mother and fetus at risk and provides guidelines for nursing assessments and interventions.

HEMORRHAGIC DISORDERS

Obstetric hemorrhage is a common cause of maternal mortality occurring in 1.4 per 100,000 live births (Chichakli et al., 1999). In this section some common causes of obstetric hemorrhage are discussed. The most common obstetric hemorrhagic event, postpartum hemorrhage, is discussed in detail in Chapter 28.

Abortion

Abortion is termination of pregnancy before fetal viability. This term usually is applied to pregnancy termination before 20 weeks' gestation. **Spontaneous abortion** refers to pregnancy termination that occurs naturally and commonly is referred to as miscarriage. Box 18-1 lists categories of spontaneous abortion.

Induced abortion is termination of pregnancy before fetal viability by medical or surgical intervention. Induced abortions may be **therapeutic**, in which case the pregnancy is terminated because of health risks to the mother in continuation of the pregnancy or for fetal disease. The terms **elective abortion** and voluntary abortion are used to describe termination of pregnancy before fetal viability at the request of the client.

Incidence

Most spontaneous abortions occur in the first trimester of pregnancy, possibly before the woman realizes she is pregnant. The exact cause of spontaneous abortion is not always identified. Approximately half of these losses are attributed to chromosomal abnormalities (Cunningham et al., 1997).

Box 18-1 Categories of Abortion**Complete**

All products of conception are expelled, and uterine bleeding and cramping cease.

Incomplete

A portion of the products of conception is expelled, and a portion is retained. Bleeding and cramping continue until the uterus is evacuated.

Threatened

Uterine bleeding and cramping occur; however the products of conception have not been expelled. Cervical dilation may occur.

Missed

A pregnancy becomes nonviable; no uterine bleeding, cramping, or passage of tissue has occurred.

Habitual

Term used to describe a woman who has three or more successive spontaneous abortions.

Clinical Presentation

Vaginal bleeding or bloody discharge in the first trimester of pregnancy with or without cramping is a sign of threatened abortion, although other causes of vaginal bleeding are possible. The amount of vaginal bleeding may be minimal but may persist for days or weeks. The presence of pain along with vaginal bleeding usually is a poor prognostic indicator for continuation of the pregnancy (Cunningham et al., 1997).

Management

Clients presenting with vaginal bleeding are examined to determine if cervical dilation has occurred, making abortion inevitable. Other potential causes of vaginal bleeding to be considered are cervical lesions and physiologic bleeding at the time normal menses would occur.

The woman with a threatened abortion may be managed expectantly, which may include bed rest and serial laboratory tests to assess for decreasing hemoglobin and hematocrit levels and the presence of infection. Pain medication may be necessary in some cases.

The client who experiences a spontaneous abortion is observed closely for hemorrhage after delivery. The physician will assess the client, fetus, and placenta to determine if all products of conception have been expelled. In the

FACTORS THAT MAY PREDISPOSE WOMEN TO POSTPARTUM UTERINE ATONY

- Overdistended uterus (e.g., from multiple gestation or polyhydramnios)
- Intrapartum oxytocin administration
- High parity
- Intrapartum administration of magnesium sulfate
- History of previous postpartum hemorrhage
- Distended urinary bladder

event of retained tissue or postpartum hemorrhage, curettage may be performed.

Nursing Care

Nursing care of the client experiencing an abortion or threatened abortion includes assessing for amount and character of blood loss, assessing for signs and symptoms of shock or infection, and responding promptly to complications. Resuscitative measures may be necessary, such as volume and blood replacement, oxygen therapy, and medical and surgical interventions. All procedures and the plan of care should be communicated clearly to the client. The nurse should provide emotional support to the client and family during this difficult experience. Spiritual support,

Client Education

Clients as Resources

Pregnant women are a very valuable resource in assisting with prenatal care. They are only able to help if they know what to expect. For example, some women can have spotting early in a pregnancy, and it is not serious. In other cases, spotting may suggest a missed abortion or ectopic pregnancy. You should teach clients that even if they think their spotting is not serious, they should notify their health care provider immediately so that the cause can be identified.

Figure 18-1 Sites of implantation in ectopic pregnancy.

client literature for education, and information about support groups where available may be offered.

Ectopic Pregnancy

Ectopic pregnancy is the implantation of the fertilized ovum in a location other than the endometrial lining (Figure 18-1). The most common implantation site is the fallopian tube; however, implantation may occur in numerous locations, including the ovaries, cervix, and abdomen (Hankins et al., 1995).

Incidence

In the United States, the rate of ectopic pregnancy in women 15 to 45 years of age is about 19.7 per 1,000 pregnancies (Tenore, 2000). Many factors contribute to ectopic pregnancy. Damage to the fallopian tubes from pelvic inflammatory disease (PID) is cited as the most common cause of ectopic pregnancy. *Neisseria gonorrhoeae* is a common causative organism implicated in the development of PID (Kamwendo et al., 2000). A previous surgery, chromosomal abnormalities of the embryo, the use of intrauterine contraceptive devices, ovarian hyperstimulation as the result of assisted reproductive technology, and peritoneal dialysis also have been implicated as causes of ectopic pregnancy (Hankins et al., 1995; Davison & Lindheimer, 1999). Ectopic pregnancy can be a life-threatening event because hemorrhage may occur with rupture if this complication is not diagnosed and treated promptly. Ectopic pregnancy is the leading cause of pregnancy-related deaths during the first trimester in the United States (American College of Obstetricians and Gynecologists [ACOG], 1999).

Clinical Presentation

The client with an ectopic pregnancy often presents with vaginal bleeding, severe abdominal and pelvic pain, tenderness of the abdomen on palpation, and severe pain on movement of the cervix on pelvic examination.

Management

Once an ectopic pregnancy is confirmed, medical management of the client may include surgery; administration of methotrexate, a drug used to resolve the pregnancy; or expectant management. Laboratory assessments include a complete blood count (CBC) to evaluate for blood loss and infection and a serum pregnancy test. The client also may undergo vaginal or abdominal ultrasonography to determine the location of the pregnancy. The site of implantation helps determine the medical management. A culdocentesis also may be performed to assess for the presence of nonclotting blood in the peritoneum (Hankins et al., 1995).

Nursing Care

Nursing care for the client experiencing an ectopic pregnancy includes assessment for the amount and character of vaginal bleeding and for signs and symptoms of shock. The nurse obtains laboratory tests and procedures, such as ultrasonography, and reports the findings to the physician promptly. The woman with an ectopic pregnancy often will experience a great deal of pain, and pain medication should be administered as ordered. The nurse prepares the client for the surgical procedure, including a clear explanation of the planned procedure. The woman who has an ectopic pregnancy may experience grief as a result of pregnancy loss. The nurse should offer emotional support, spiritual care, client literature for education, and information about support groups when appropriate.

PLACENTAL ABNORMALITIES

Abnormalities in placental form and function include placenta previa and abruptio placentae.

Placenta Previa

In placenta previa the placenta lies over or near the cervical os (Figure 18-2). There are three classes of placenta previa (Clark, 1999):

1. **Placenta previa** in which the cervical os is covered by the placenta in the third trimester of pregnancy.
2. **Marginal placenta previa** in which the placenta lies within 2 to 3 cm of the cervical os but does not cover it.

Figure 18-2 Placenta previa. A. Low implantation (marginal). B. Partial placenta previa. C. Total placenta previa.

- 3. Low-lying placenta** in which the exact relationship of the placenta to the cervical os is not determined, or in the case that an apparent placenta previa occurs before the third trimester of pregnancy.

Incidence

Placenta previa is a fairly uncommon complication of pregnancy; however, the consequences can be very serious for the mother and fetus. The incidence of placenta previa is reported to be from 0.3% to 2.0%, or 1 in 200 deliveries (Hendricks et al., 1999).

Previous cesarean section and induced abortion increase the risk for occurrence of placenta previa. The risk increases as the number of previous cesarean sections increases (Castles et al., 1999; Ananth, Smulian, & Vintzileos, 1997). Multiparity and advancing age of the woman also are associated with placenta previa, as is maternal smoking (Cunningham et al., 1997; Castles et al., 1999; Ananth, Smulian, & Vintzileos, 1999). Cocaine use by the mother is an independent risk factor for the development of placenta previa (Macones et al., 1997).

Clinical Presentation

The diagnosis of placenta previa frequently is made after onset of sudden, painless vaginal bleeding in the second or third trimester of pregnancy. The amount of bleeding varies and may stop spontaneously; however, in some cases, bleeding can be so profuse as to be life-threatening. The diagnosis of placenta previa is made after ultrasonographic examination.

Management

Management of the woman with placenta previa is determined by the degree of placenta previa present, gestational age of the fetus, and presence and amount of vaginal bleeding.

In cases of severe hemorrhage, delivery is undertaken despite the gestational age of the fetus. Volume resuscitation and transfusion of blood products frequently are required. An emergency cesarean section delivery is performed to prevent further blood loss that could occur with disruption of the placenta during vaginal delivery.

Laboring patients who present with a diagnosed placenta previa generally are delivered by cesarean section even in the absence of active bleeding. This decision is determined by the degree of placenta previa present. In the case of a marginal placenta previa, some clients are allowed to labor as long as facilities for an emergency are immediately available (Clark, 1999).

In the woman who is preterm and nonlaboring, delivery may be delayed if the bleeding has stopped or is minimal and the mother and fetus are in stable condition. The physician may order hospitalization until the time of delivery or may allow select clients to remain at home. The decision is individualized according to placental location, physician preference, and the condition of the mother and fetus (Maloni, Cohen, & Kane, 1998).

Nursing Care

Nursing care specific to the client diagnosed with placenta previa includes assessment for signs and symptoms of

vaginal bleeding, performance of laboratory tests as ordered, supportive care, and client education. A peripad count is kept and recorded for clients who have active vaginal bleeding, and the perineum is checked frequently for the presence of bleeding. A significant increase in bleeding should be reported to the physician promptly. A large-bore IV catheter often is placed for quick access in the case of acute hemorrhage. Blood typing and screening generally are ordered and should be kept current in the event a blood transfusion is required. In the client who has active bleeding, blood typing and crossmatching for several units of blood may be indicated.

Occupational or recreational therapy may be helpful to the woman who requires prolonged hospitalization. Social services should be consulted for client and family concerns, financial assistance, and travel and lodging arrangements. Thorough skin assessment and attention to hygiene are important aspects of nursing care when the woman is placed on bed rest with very limited physical activity. A mattress protective to skin and tissues may be useful to prevent skin break down and to help alleviate client discomfort.

Information should be given to the client and family regarding the proposed plan of care and the potential complications that may arise from this condition. On occasion, vaginal bleeding may begin with no warning and may be hemorrhagic in nature. This emergency situation is very alarming to the woman and family members. The nurse should make an effort to prepare them for this possibility, explain the series of events that would follow in preparation for an emergency cesarean section, and provide reassurance if this should occur. Women who are discharged with placenta previa should receive instructions to return immediately in the event of uterine contractions or vaginal bleeding.

Abruptio Placentae

Abruptio placentae (abruption) is separation of the placenta from its implantation site before delivery of the fetus (Figure 18-3). Bleeding associated with a placental abruption may be concealed in a space between the now detached placenta and uterus. More often, external vaginal bleeding is present. Placental abruptions can be total, with ensuing fetal death likely, or partial, in which case a portion of the placenta remains intact and perfusion to the fetus is possible (Cunningham et al., 1997).

Incidence

Abruptio occurs in about 1 in 150 deliveries (Cunningham et al., 1997). According to Chichakli et al. (1999), abruptio placentae was the leading cause of pregnancy-related deaths in the United States from 1979 to 1992.

Figure 18-3 Abruptio placentae A. Central abruption, concealed hemorrhage. B. Marginal abruption, external hemorrhage. C. Complete abruption, external hemorrhage (could also be concealed).

African American women in this study had a three-fold increased risk for death compared with Caucasian women.

The condition most commonly associated with placental abruption is hypertension in pregnancy (Hauth et al., 2000). Preterm premature rupture of membranes and maternal trauma, especially associated with high-speed automobile accidents also have been associated with abruption (Reis, Sander, & Pearlman, 2000). Cocaine use during pregnancy and cigarette smoking also have been associated with a large number of placental abruptions (Cunningham, et al., 1997; Castles et al., 1999; Ananth et al., 1999).

Clinical Presentation

The diagnosis of abruptio placentae may be difficult to make and often is made only after excluding other potential causes of the presenting symptoms. Common presenting symptoms are vaginal bleeding and abdominal pain, tenderness, or rigidity. On admission assessment, fetal heart sounds may be absent or there may be a nonreassuring fetal heart pattern and high-frequency uterine contractions on electronic fetal monitoring.

The amount of vaginal bleeding present does not necessarily reflect the extent of abruption. Up to 10% of women who have an abruption present with concealed bleeding. Ultrasonographic examination to assess the presence of an abruption often is not helpful in establishing this diagnosis (Cunningham et al., 1997; Clark, 1999).

Maternal morbidity in abruption is common and can be serious. In a review of pregnancy-related mortality in the United States, placental abruption was the leading overall cause of death as a result of hemorrhage (Chichakli et al., 1999). Acute blood loss from both placenta previa and abruptio placentae can lead to shock in the mother. Decreased perfusion to the kidneys during massive blood loss may cause oliguria, which usually responds to volume resuscitation with intravenous (IV) fluids and blood. Acute

Research Highlight

Measuring Perinatal Grief

Purpose

To develop a scale to measure perinatal grief intensity (PGIS) to predict the intensity of grief response to early pregnancy loss.

Method

A sample of 186 women who experienced a miscarriage before 16 weeks' gestation completed a Likert type-scale questionnaire. Factor analysis was performed.

Findings

Fourteen items were retained. Three factors were found to influence the intensity of grieving: (1) reality of the pregnancy and baby, (2) congruence between the actual miscarriage and the woman's standard of the desirable, and (3) confrontation of others, which is the ability of parents to make decisions or act in ways to increase the congruence. The most intense grief experiences were associated with parents for whom the pregnancy and baby were perceived as real, whose miscarriage experience was incongruent with the desired standard, and who perceived themselves unable to do anything about this incongruence.

Nursing Implications

The PGIS establishes beginning reliability and validity in predicting grief intensity. Although further testing will determine the usefulness with other types of pregnancy loss and establish levels of the predictive value of scores, a method of measuring perinatal grief may be helpful to nurses to determine the type of follow-up appropriate for families.

Hutti, M. H., dePacheco, M., & Smith, M. (1998). A study of miscarriage: Development and validation of the perinatal grief intensity scale. *Journal of Obstetric, Gynecologic, and Neonatal Nursing*, 27, (5), 547–555.

tubular necrosis and renal failure are serious complications that can occur when there is a delay in or inadequate treatment for blood loss and hypovolemic shock (Clark et al., 1997; Cunningham et al., 1997).

Abruptio is the most common obstetric cause of **disseminated intravascular coagulation (DIC)**. This process occurs as a result of excess consumption of some components of coagulation. With the massive consumption of circulating clotting factors and activation of the fibrinolytic system the client experiences hemorrhage, end-organ ischemia, vascular permeability, and hypotension (Sisson & Ruth, 1999; Clark et al., 1997; Cunningham et al., 1997).

Neonatal complications of placenta abruptio include preterm birth, anemia, and respiratory distress syndrome (RSD) (Crane et al., 1999). The perinatal mortality rate for abruptio placentae is reported to be from 20% to 35%, accounting for a large percentage of third-trimester fetal deaths. Even when infants survive, they may be seriously affected by the decreased perfusion to the placenta and may develop neurologic sequelae (Cunningham et al., 1997).

Management

The treatment for abruptio placentae depends on the condition of the mother and fetus. When bleeding is not severe and the mother is stable, fetal status and gestational age often determine the plan of care. The physician may choose to manage the woman who is stable with a preterm fetus expectantly under close observation and may employ the use of tocolytic agents to stop uterine contractions (Clark, 1999). The viable fetus that is near full term often is electively delivered to avoid a larger abruptio that could seriously compromise the fetus or result in fetal death (Cunningham et al., 1997).

In the case of acute hemorrhage, resuscitation with blood transfusion and IV fluids and immediate delivery are indicated. This life-threatening complication usually requires aggressive volume resuscitation with IV fluids, blood pressure support, oxygen therapy, and evacuation of the uterus (Clark et al., 1997).

In the event of an abruptio in which there is an intrauterine fetal death, delivery will be induced once

maternal stability is achieved, and the woman will be closely observed for complications.

Nursing Care

Nursing care of the client with an abruption includes an assessment of the amount and nature of vaginal bleeding. A peripad count may be indicated in the presence of ongoing bleeding. The nurse should palpate the uterus to assess for tenderness and rigidity and for the location and nature of pain. It is sometimes difficult for the client to describe the pain associated with an abruption when she also is experiencing painful uterine contractions.

In an acute bleeding episode, vital signs are monitored closely for signs of hypovolemic shock. The fetus may be compromised as a result of uteroplacental insufficiency, and therefore, continuous electronic fetal monitoring usually is employed for assessment of the viable fetus. In the event of hemodynamic changes in the client or a nonreassuring fetal heart rate, resuscitative measures should be initiated by the nurse and the physician should be notified immediately.

In the case of acute blood loss, a large-bore IV catheter is indicated for fluid and possibly blood replacement. The nurse obtains ordered laboratory tests that usually include blood typing and screening or blood typing and cross-matching, a CBC, and clotting studies. A Foley catheter is indicated, with hourly intake and output measured and recorded. The nurse may prepare the client for an emergency cesarean section, as indicated.

When induction of labor is ordered as a result of intrauterine fetal loss, the nurse should ensure adequate pain relief according to the client's wishes. The nurse should be familiar with the medications used to induce labor and their potential side effects.

Once stabilized, the client should receive a thorough explanation of her condition and that of the fetus. The potential complications and proposed plan of care should be discussed with the client and family. Grief support and spiritual care should be offered to the woman and family in the event of fetal or neonatal death.

LABOR DISORDERS

Disorders that fall into this category include incompetent cervix, preterm labor, and postterm pregnancy.

Incompetent Cervix

Incompetent cervix describes the often painless dilation of the cervix in which the pregnancy is lost and may result from a congenital cause such as diethylstilbestrol (DES) exposure, or an acquired cause, such as trauma to the cervix from previous gynecologic or obstetric procedures (Iams, 1999).

Incidence

The reported incidence of cervical incompetence varies greatly but may account for 8% to 15% of spontaneous pregnancy losses (Hankins et al., 1995).

Clinical Presentation

The diagnosis of an incompetent cervix may be made after repetitive spontaneous second-trimester pregnancy losses, incidentally on an ultrasonographic examination, or acutely with the advanced cervical dilation and effacement (Iams, 1999). The client may present with complaints, such as lower abdominal pressure, bloody show, or urinary frequency. As the bag of water protrudes through the cervix, small frequent contractions may occur.

Management

Management of cervical incompetence is achieved primarily through a surgical procedure, a **cerclage**, to suture the cervix. The suture usually removed in the late third trimester of pregnancy. Contraindications to this procedure include active vaginal bleeding, rupture of membranes, active labor, chorioamnionitis, and major congenital abnormalities of the fetus (Iams, 1999). Complications such as rupture of the membranes and ensuing intrauterine infection may occur with surgical intervention (Hankins et al., 1995).

Nursing Care

Nursing care for the client with an incompetent cervix includes obtaining a complete history of the events of current and past pregnancies. The client should be observed for signs of impending delivery, such as rupture of membranes, active bleeding, and regular painful uterine contractions. Emotional support is a key element of nursing care because these clients and families often are very anxious about the well-being of the fetus. The nurse should explain the plan of care and all procedures to the client and family.

Preterm Labor and Premature Rupture of Membranes

Preterm labor is defined as labor that occurs before 37 completed weeks' gestation. **Premature rupture of membranes (PROM)** is defined as spontaneous rupture of membranes before the onset of labor. **Preterm premature rupture of membranes (PPROM)** is PROM before 37 weeks' gestation.

Incidence

Preterm births account for approximately 8% to 15% of births in the United States; worldwide, 13 million prema-

Client Education

Preterm Labor

All pregnant women should recognize the signs and symptoms of preterm labor that can be stimulated by

- Urinary tract infection
- Diarrhea
- Dehydration
- Laxatives

ture infants are born, accounting for the overwhelming majority of perinatal morbidity and mortality (Althabe et al., 1999; Cunningham et al., 1997; Shellhaas & Iams, 1998).

Clinical Presentation

Despite vast improvements in obstetric care the ability to predict which clients will develop preterm labor, and therefore to have an impact on its prevention, has been unsuccessful (Althabe et al., 1999). Numerous risk factors for preterm labor have been cited, including the following: multiple gestation; previous preterm labor; exposure to DES; more than one second-trimester abortion; infectious causes, such as bacterial vaginosis; pyelonephritis; cigarette smoking; poor maternal weight gain; history of cervical conization; maternal age; and maternal parity (Schieve et al., 2000; McGregor & French, 2000; Kyrklund-Blomberg & Cnattingius, 1998). The most frequently cited risk factor is a history of a previous spontaneous preterm delivery. These clients have an increased risk for preterm delivery in their current pregnancy of about 2.5 times that of a normal pregnancy. A previous preterm delivery caused by PPRM and preterm labor are significantly associated with a similar event in the current pregnancy (Mercer et al., 1999).

The client who has preterm labor may present with a variety of complaints. Common sign and symptoms of preterm labor include uterine contractions, menstrual-like

Nursing Alert

COMMON TOCOLYTIC MEDICATIONS AND POTENTIAL COMPLICATIONS

Magnesium sulfate:

- Respiratory depression or arrest
- Pulmonary edema
- Hypotension
- Cardiac arrest
- Profound hypotension

Beta-adrenergics (ritodrine, terbutaline):

- Hyperglycemia
- Hypokalemia
- Hypotension
- Arrhythmias
- Pulmonary edema
- Myocardial ischemia

Indomethacin:

- Gastrointestinal bleeding
- Renal failure
- Hepatitis
- Premature closure of the ductus arteriosus, necrotizing enterocolitis, and intracranial hemorrhage in the fetus or neonate

Nifedipine:

- Profound hypotension
- Possible decrease in uteroplacental perfusion

Nursing Alert

TOCOLYTIC AGENTS

Tocolytic medications can have serious adverse effects. You must be knowledgeable about the tocolytic agent and carefully monitor clients receiving these medications.

cramps, dull backache, diarrhea or intestinal cramps, increased vaginal discharge, and vaginal bleeding.

Complications of preterm labor to the mother are related largely to the tocolytic agents used in treatment. See the Nursing Alert for common medications, side effects, and complications.

Infants with birth weights of less than 1,500 g or gestational age under 34 weeks have greatly increased risks for RDS, intraventricular hemorrhage, and necrotizing enterocolitis (NEC). Long-term complications of preterm birth include bronchopulmonary dysplasia, cerebral palsy, developmental delays, blindness, and deafness (Cunningham et al., 1997). Whereas the incidence of these major complications decreases in babies born after 32 weeks' gestation, other complications, such as feeding difficulties

and hypothermia, occur frequently until 35 weeks' gestation and can prolong hospitalization (Seubert et al., 1999). The preterm low-birth-weight infant generally is not discharged from the hospital until 35 to 37 postconceptional weeks, or approximately the time of the infant's original due date (Rawlings & Scott, 1996).

The economic impact of preterm births in the United States is enormous. Extended stays in the neonatal intensive care unit can cost hundreds of thousands of dollars. Estimated cost per first year of survival for premature infants ranges from \$74,000 to \$280,000 and is highly dependent on birth weight. The cost of hospitalization for infants having very low birth weight (less than 750 g) is approximately four times that for neonates weighing from 1,000 to 1,499 g (Rogowski, 1998). Compare this with the total birth costs of less than \$10,000 for term infants at 39 to 42 weeks' gestation (Luke et al., 1996).

Management

The treatment for preterm labor is intended to improve outcomes for neonates by prolonging the pregnancy or by affecting their adaptation to the extrauterine environment. Treatment options are highly individualized and depend on physician and client preference, gestational age of the fetus, and additional medical or obstetric complications.
