Nursing assessment of the genitalia of newborns forms the basis for parental interaction with the infant. The determination of sex is done briefly by inspection only in the delivery room and communicated to the parents. A detailed inspection and further examination is the responsibility of the nurse in charge of the newborn's care. Parents want to see that their infant is normal and looks normal. Any observed difference increases their anxiety. The nurse must have the sensitivity to address these issues with the parents and be prepared to correct misinformation that would affect the parents' ability to interact with their infant in a positive manner.

Circumcision of Male Infants

Circumcision of male infants is usually performed in the nursery and is the personal choice of parents based on their cultural, ethnic, and religious perspectives. Circumcisions for religious purposes may be performed at another site, and elective circumcisions during the first 2 weeks of life may be performed in a private office or clinic. In each case, the role of the nurse is to inform the parents of the risks and benefits of the procedure and address concerns to achieve a fully informed decision. Risks for the infant include infection, hemorrhage, skin dehiscence, adhesions, urethral fistula, and pain (Wong et al., 1999). Bene-

fits to the infant are decreased incidence of urinary tract infections in the first 3 months of life (Schoen, Colby, & Ray, 2000) and possible prevention of penile cancer (Wong et al., 1999). In the circumcision procedure, part of the foreskin is removed by clamping and cutting with a scalpel (Gomco or Mogen clamp) or using a plastic ring with a string tied around it to trim off the excess foreskin (Plastibell). Small sutures or pressure from the plastic ring are used to prevent bleeding and promote wound closure.

Nursing care of the circumcised infant is directed toward providing pain relief before the procedure; comfort before, during, and after the procedure; and skilled observation for bleeding or voiding difficulties. It is the responsibility of the nurse to examine the equipment before the procedure for cleanliness and matching parts. Substitute parts that are not made by the same manufacturer may slip and cause the infant additional discomfort. For at least 2 hours before the procedure, the infant is given nothing by mouth to prevent vomiting or aspiration. Pain relief measures to be considered are: a local dorsal penile nerve block; application of EMLA cream (topical mixture of anesthetics), approximately 1 to 2 g, for 60 minutes before the procedure under an occlusive dressing; and a ring block. EMLA cream is used as a topical anesthetic without nerve blocks and also used with nerve blocks to anesthetize the site of injection. Proper pain relief requires that the cream be applied for at least 1 hour prior to the procedure and the application site varies with the nerve block used. The cream is applied to the foreskin and base of the penis for the dorsal penile nerve block and the foreskin and shaft of the penis for the ring block. The cream should be replaced if the infant urinates during the topical anesthetic period. The penis and scrotum are gently cleaned with a mild soap and warm water and dried. The cream is re-applied to the area required for anesthesia.

The infant is gently restrained during the circumcision procedure on a special board or apparatus with Velcro straps that limit extremity movement near the operative field. The nurse may consider shielding the infants' eyes from the lights, playing soothing music in the background, or stroking the infant's head, shoulders, or upper extremities during the procedure. Pacifiers soaked in a sugar-water solution (dissolve 1 tablespoon sugar in 4 tablespoons of sterile water) have been shown to be effective in distracting infants from the procedure (Wong et al., 1999). Once the procedure is complete, the infant is released from the restraints and comforted by the nurse, if the parents are not present. The infant is brought to the parents as soon as possible after the procedure. The choice of dressings or treatments of the circumcision site depends on the method of circumcision. Petroleum jelly (Vaseline) or A & D ointment is applied with 4 × 4 gauze as a dressing to cover the site when a clamp has been used to cut the foreskin. No dressings are needed when the

Plastibell is used. The nurse applies the diaper loosely over this area to prevent any rubbing, pressure, or friction on the penis. When the infant is brought to the parents, the nurse explains the procedure, allows the parents to

Client Education

Circumcision Care

The nurse instructs the parents to carefully apply and remove the diaper over the circumcision site to prevent rubbing. During the first 24 hours, it is recommended that the site be checked by the parents or the nurse every 30 minutes for the first 2 hours and then every 2 hours afterward (Williamson, 1997). The site is checked for excess bleeding or swelling, and the diaper can be felt for dampness to indicate the infant has urinated. The infant must demonstrate an ability to void after the procedure, because edema at the operative site may occlude the urethra or the urethral meatus. Dressings, if present, are changed at least three times in the first 24 hours. The old dressing is removed; the area gently wiped clean with a warm, damp gauze and dried; and a fresh dressing with jelly or ointment applied. Infant acetaminophen (Tylenol) drops are continued every 4 to 6 hours for the first day after the procedure. They are discontinued when the parents feel that their infant is no longer displaying signs of discomfort, pain, or irritability. On the second day, a yellowish exudate appears, which is part of the healing process. The nurse instructs the parents not to remove this or disrupt it when cleansing during the dressing change. Dressing changes are continued for three days after the procedure. If the parents do not notice any swelling, discharge, bleeding, or reddening of the penis, they may discontinue dressing changes but need to watch the area very closely for the next week. The parents may want to change the infants' diapers more frequently to avoid the healing penis being exposed to stool in the diaper. The nurse emphasizes that discharge, swelling, or redness indicates signs of infection. Parents who report less than six diaper changes a day need to be concerned that their infant is having difficulty voiding after circumcision. Signs of infection, failure to void adequately, or excessive bleeding from the operative site must be reported immediately to their health care provider.

A Circumcision Story

The nurse checks the infant's identification band against the signed consent form.

A circumcision restraint board safely immobilizes the infant during the procedure.

The uncircumcised penis and genital area are exposed.

The physician dons sterile gloves.

Antiseptic solution is applied to reduce the risk of infection.

This baby is expressing his opinion of the procedure.

Infants are often offered a pacifier or other soothing measure to help calm them during the procedure.

A sterile drape is applied to provide a sterile field.

Kelley clamps are used to extend the prepuce.

A small incision is made in the prepuce.

The incision will help accommodate use of the circumcision cone.

The clamps are left in place as the prepuce is retracted over the glans.

A circumcision cone is placed over the exposed glans penis and the prepuce is drawn up around it.

The clamp is applied and tightened for 3–5 minutes to reduce bleeding and circulation in the prepuce.

The prepuce is cut away at its base.

The prepuce is completely removed.

After removal of the cone, the newly exposed glans penis is gently swabbed with sterile gauze.

Sterile dressing is carefully applied to protect the circumcision area.

The newly circumcised penis will be completely healed within about a week.

The infant rests following the procedure.

inspect the circumcision site, addresses their concerns, and instructs both parents on circumcision care.

Musculoskeletal System

The musculoskeletal system is on constant display when the infant is moving and exploring its environment. From extending legs and kicking to extending arms and sucking on fingers, the infant is discovering that it can move. Visual inspection of the infant reveals any movements that are compromised by injury or birth trauma. Stretching of the extremities often leads the infant to extend the toes and fingers; this confirms movement for the examiner. The nurse carefully observes the extremities for differences in size or length. Acondroplasia is a congenital condition that nurses observe first in newborns who have a small thoracic cage, lack the ability for elbow extension, and appear to have shortening of the humerus and femur (Jones, 1997). These infants are often referred to as dwarfs and have respiratory and neurologic problems in addition to their skeletal defects.

Watching the infant move in the supine position and then changing the infant to the prone position gives the nurse a good indication of muscle strength and tone. Failure to move the lower extremities may suggest a lesion or damage to the spinal cord. Asymmetrical movement may indicate nerve damage or a fracture from birth trauma. A newborn infant who does not move or feels “floppy” when turned over may have hypotonia, or decreased muscle tone, from a period of anoxia either in utero or during labor and delivery. Hypertonia, or increased muscle tone, in the presence of small, brief tremors, twitches, or myoclonic jerks, is a characteristic of neonatal abstinence syndrome (Wong et al., 1999). The newborn expresses withdrawal symptoms of drug exposure through these movements. The nurse, through careful inspection and observation, can identify elements of the musculoskeletal examination for further evaluation.

Common Variations

After inspection, palpation of the musculoskeletal system begins with the shoulders and moves inferiorly to the feet. Muscles and bones are palpated for symmetry and amount of tissue present. Joint rotations are checked by gently passive range of motion. Neck rotation is the first and most important motion to be examined. Infants must exhibit full neck rotation passively. Neck rotation may be hindered by torticollis, in which the head is held to one side with the chin pointing to the other side, or by congenitally missing portions of a cervical vertebra. As infants grow and develop, they turn their head to discover the location of sound and begin “tracking” the sound with their eyes. Proper neck rotation assists in the refinement of hearing and in the development of sight. Head lag is assessed by

gently pulling the infant up and watching its head gently fall back as it clears the surface of the crib. In this position, the nurse can also inspect the neck to make sure that there is no thyroid bulge. This maneuver also assists the nurse in evaluating upper body muscle tone and strength in the arms and shoulders.

The second most important joint to assess in newborns is the hip joint. Developmental dysplasia of the hip (DDH) can easily be missed in a newborn and, if not treated, can go on to interfere with the infant's future ability to retain balance and walk. Hips are evaluated by inspection of skin folds on the thighs in the supine and the prone positions. Asymmetrical skin folds may indicate a hip problem. Leg length and knee height are also inspected for unevenness. Palpation of the hips begins with the nurse gently moving the lower extremities in a kicking motion in order to ease the infant's distress during the hip evaluation. The nurse places her hands on the infant's thigh with the tips of her fingers encircling the head of the femur and her thumb and index finger securing the knee joint. From this position, the Barlow maneuver exerts a downward pressure on the head of the femur in an attempt to dislodge the head of the femur from the acetabulum. The Ortoloni maneuver is either a circular rotation of the femoral head or an inward-outward motion that attempts to “relocate” the head of the femur displaced by the Barlow maneuver in the acetabulum (Figure 32-24). Normal hip joints are moved easily and the nurse may feel crepitus or a slight grinding (a hip click) as the head of the femur is manipulated in the socket. Hip dysplasia is very common in infants who had in breech position in utero or breech deliveries. It is confirmed by the inability to move the leg easily in the hip joint and by feeling the head of the femur come out of the hip socket (a hip “clunk”). Many infants who had breech presentations have hyperextended knee joints that give the appearance of hip dysplasia but, on examination, the head of the femur remains firmly in the socket of the acetabulum. These leg positions gradually return to normal flexed positions. The nurse may examine the infant's hips and feel looseness in the hip joint even when the femoral head remains secure in the joint. Maternal hormones during pregnancy and delivery not only cause joint laxity in mothers but also can affect the joints of their infants.

The remaining joints are assessed by passive range of motion and by observing the infant moving or being moved. The last joint to be assessed is the ankle joint. Position of the infant during pregnancy may lead to bowed legs, ankle deformities, or unusual positions of the feet. Pronation (inward turning) of the feet in newborns is common and gently stroking the infant's insole will illustrate for the nurse the ease at which the infant's foot assumes a normal position. A severely pronated foot that the nurse is unable to place in normal alignment is inspected for the

Figure 32-24 Ortoloni maneuver.

posterior alignment of the heel and the knee. Medial displacement of the heel from the posterior knee alignment may indicate the presence of a *club foot*, which can be confirmed on X-ray films. A club foot is usually placed in a cast during the early days of infancy, and mothers are instructed by the nurse in the care of the cast. Parents who express concern about their infant's feet "turning in" can be shown a simple exercise (stroking the outside of the infant's foot) that encourages the foot into a straight position.

Common Problems

Before any musculoskeletal assessment of the newborn infant, the nurse must inspect and palpate for broken bones. The infant should not be moved or positioned until this is done. The most common bone fracture is the clavicle, which occurs during delivery when the shoulders of the infant do not rotate easily. Palpation of both clavicles can confirm a separation between the ends of the bone at the fracture site or crepitus. Symptoms of fractures are swelling or edema at the fracture site, a bruise at the site, or infant irritability when moved. Experienced nurses who care for infants recognize the difference between an infant's fussiness at being disturbed and cries of pain. Other common fracture sites include the humerus, the ribs, and the skull. Definitive diagnosis is always made from X-ray films. Fractured clavicles heal by themselves over time, and the mother is taught to position the infant on the side opposite the injury. Special care is taken by the nurse to teach parents how to hold and support their infant's head and shoulders until the fracture heals. Humeral fractures are usually casted; rib fractures may be wrapped; and skull fractures are usually monitored in an intensive care unit.

Developmental dysplasia of the hip (DDH) results from a flattening of the acetabulum during pregnancy from its normal round, cup-like shape. This usually results from the infant in utero remaining in a breech position with legs extended upward during the period when bone growth occurs. The outer portion of the acetabulum becomes flat instead of curling around the head of the femur. The ability to secure the leg in the hip socket is lost. DDH can be diagnosed on physical examination by positive findings on the Barlow and Ortoloni maneuvers, unequal leg length, unequal knee height, and abnormal gluteal fold counts anteriorly or posteriorly. Diagnosis is confirmed by X-ray of the hip. Treatment for DDH involves placing the legs of the infant in abduction in a special harness, called a Pavlik harness. This harness remains on the infant for approximately 3 to 6 months, until new bone growth forms around the head of the femur and creates the normal cup-shaped hip socket.

Some infants may have extra digits and toes (**polydactyly**) or digits and toes that appear to be linked together by webbing of the skin (**syndactyly**). Extra digits on the hand are often located below the fourth finger attached to the palm by a thin cord of skin. They appear to have the same size as the fourth finger and may even have a fingernail. These digits need to be palpated by the nurse for the presence of bone. Bone indicates that surgical removal is necessary. The lack of bone is an indication that the extra digit may be tied off with suture silk. Tying off occludes the capillary, preventing circulation to the digit, and the digit undergoes necrosis and eventually falls off. Extra digits and toes tend to run in families, and parents will often describe relatives, other infants, or previous personal experiences with them. Webbing of toes does not

interfere with balance or walking, and many parents do not choose to have the toes surgically freed from each other. Webbing of fingers is usually corrected for cosmetic and functional reasons.

Hands are inspected for palmar creases. These creases were noted earlier in the gestational age examination of the feet, but not of the hands. Three to four curved palmar creases are usually noted in normal newborns. A single, straight crease appearing in the middle of the palm is called a simian crease. These creases, unilaterally or bilaterally, by themselves are not an indicator of a special condition. However, with the presence of other symptoms, they may be associated with congenital syndromes, particularly Down syndrome.

Nursing Implications

The nursing assessment of the musculoskeletal system identifies the movement abilities of the newborn infant as well as movement limitations resulting from malformations or birth trauma. Through this assessment, the nurse determines the appropriate positioning for the newborn, exercises to enhance future abilities (if needed), and further follow-up or diagnostic evaluations. The nurse can raise parental awareness of their infant's movements, teach parents and family members proper holding and resting positions, and reinforce specific care needs of the newborn after discharge.

Neurologic System

The neurologic assessment concludes the physical assessment of the newborn infant. This assessment consists primarily of reflexes and other movements from which the nurse estimates the level of neurologic function. Reflexes can be divided into minor and major reflexes. Minor reflexes include: finger grasp, toe grasp, rooting, sucking, head righting, stepping, and tonic neck. Major reflexes indicate normal neurologic function; they are the gag reflex and the Babinski, Moro, and Galant reflexes.

Common Variations

Finger or palmar grasp is tested by watching infants curl their fingers around an object (usually the smallest finger of the nurse) placed across the palm. Plantar grasp by the toes is assessed in exactly the same manner, placing the object on the sole of the foot. Rooting and sucking are noted by stroking the infant's cheek and observing the infant turn toward the finger, open his or her mouth, and suck on an object placed in its mouth. Head righting is evaluated by lifting the infant in the prone position and gently stroking the back along the spinal cord. The normal infant attempts to hold the head up and arch the back at the same time. The stepping reflex is demonstrated by holding the infant upright with legs flexed and brushing

the soles of the feet on a flat surface. The infant picks up his or her feet and puts them down again in a stepwise fashion, imitating walking. The tonic neck reflex is often called the "fencing" reflex. The infant, in the supine position, extends the arm and leg on the side to which the head and jaw is turned and flexes the arm and leg on the opposite side.

The major reflexes need to be evaluated carefully by the nurse. A successful gag reflex is necessary for an infant to be able to expel material from the back the throat to avoid choking. Eliciting the Babinski reflex involves the upward stroking of the plantar surface of the foot from the heel to the toe, applying a slight pressure. Proper response to this stimulation is the incurving of the toes as in the plantar grasp with uncurling and fanning out (stretching out) of all the toes. The Moro reflex can be tested at the same time the head lag is assessed. As the infant head is elevated off the surface a release is mimicked and the bilateral arm extension and leg flexion movements that are indicative of the correct Moro response can be assessed. It is inappropriate to check this reflex in infants by making a loud clap sound to "startle" them. The responses of the infant may not be consistent with the Moro movements because the infant reacts to the movement of air across their body generated by bringing hands together in order to clap or to the sound of the clap itself.

The Galant reflex, or trunk incurvation reflex, is observed when the infant is held in a prone position and the lateral aspect of the leg is slowly stroked from below the knee superiorly to the buttocks. The infant reacts by moving its buttocks toward the side that is stroked in a curving movement. When this reflex is elicited correctly, the reaction is quite dramatic. The nurse can use this reflex to demonstrate to parents the capabilities of their infant.

Common Problems

The most common neurologic injury seen in newborns is at the brachial plexus from difficulties experienced rotat-

THE GALANT REFLEX

This reflex occurs when the infant is held securely in the prone position with its arms and legs dangling off the surface of the crib. The infant's legs are gently extended from a flexed position before the reflex motion is attempted. Leg extension is necessary to see the proper incurvation of the trunk and buttocks.

ing and delivering the infant's shoulders. This injury can be differentiated from shoulder dystocia, which is noted in newborns as temporary decreased movement and muscle tone in a shoulder and upper arm that improves rapidly after delivery. A form of brachial plexus injury, Erb's palsy, is easily detected from the position of the arm in the supine position. The infant's arms are normally flexed and moving. An infant with Erb's palsy has one or both arms extended in the supine position with hand extension. The arm does not spontaneously move into a flexed position. Palpation of the extremity reveals decreased muscle tone, decreased grasp reflex, and negative arm recoil on the affected side. This arm position has been called the "waiter's position" because it imitates a waiter with the arm at the side and the hand held out for a tip. The majority of brachial plexus injuries resolve within the first 2 weeks of life. The nurse assesses grasp and muscle tone frequently in these infants to monitor the resolution. Positioning of the infant requires placing the arm gently in flexed position at rest and supporting the arm while holding. Mothers can assist in the resolution of this injury by performing simple arm strengthening exercises that passively flex and extend their infant's arm at each diaper change.

Infants that have severe neurologic injuries from the birthing process or during embryonic development are assessed in neonatal intensive care units. Newborn infants who have difficulty breathing, moving extremities, or lack appropriate muscle tone are monitored closely on this unit. Brain damage or paralysis of extremities may result from periods of *anoxia* (oxygen deprivation) during development or during labor. Oxygen deprivation is one of the causes of cerebral palsy and may result in difficulties with swallowing, breathing, or movement in newborns. Manifestations of cerebral palsy in newborns occur in proportion to the amount of oxygen deprivation. The nurse may notice, at one extreme, an infant with a slight decrease in movement with diminished reflexes, and at the other extreme, no movement and no reflexes, with numerous differences between these extremes.

During the embryonic process, the brain and spinal cord are formed by the closure of the neural tube within the first 30 days of pregnancy. The failure of this tube to close at the posterior end results in a lesion that may contain a fluid or a section of the spinal cord. This condition is called spina bifida and is diagnosed during pregnancy. At birth, spina bifida presents as a skin-covered sac between the fifth lumbar and first sacral vertebrae posteriorly. The sac may contain an extension of the dura mater and fluid called a meningocele and usually does not result in any decrease in motor movement below the waist. A sac that contains dura mater, fluid, and part of the spinal cord is much more serious. This sac is called a myelomeningocele and does result in loss of bladder and lower bowel control and motor function below the waist.

Treatment of spina bifida varies according to the nature of the lesion. Usually, surgical closure of the lesion is required to prevent infection. A variation of spina bifida is called spina bifida occulta, which is a defect in the spinal vertebrae with no protrusion of the dura mater, fluid, or spinal cord that would interfere with motor function.

Incomplete closure of the anterior end of the embryonic neural tube causes a condition called anencephaly, which results in sections of the brain, forehead, skull, and occiput missing. Newborns with this condition are placed on respiratory and cardiac monitors to assess viability and shielded from visitors and curious onlookers.

Nursing Implications

Assessment of the neurologic system in newborns, particularly reflexes, is an important indicator of the newborn's development during pregnancy and the labor and delivery process. The developing fetus and the process of birth are vulnerable periods for the newborn, placing the newborn at risk for neurologic conditions that may be devastating to parents who are expecting a normal child. The nurse can be alerted to subtle changes in infant reactivity or the obvious signs of a neurologic deficit. Changes that warrant further investigation must be carefully communicated to the parents and preparations for care after discharge discussed with the parents and family members.

Body Size Classification

At the end of the physical assessment, the nurse measures the length of the infant from head to heel, with the infant's leg gently extended. This measurement, along with the head circumference and weight obtained in the delivery room, form the basis for the size classification for the infant. These measurements are plotted using the gestational age by examination, as determined earlier. Ideally, all three measurements, when plotted, fall on the same portion of the scale. Commonly, two out of the three measurements are similar. The infant's size is determined by which area two out of the three measurements fall, with the weight percentile range given preference. Infants whose scores fall on the graph under the tenth percentile are classified as small for gestational age (SGA). Infants whose scores fall between the tenth and ninetieth percentile are classified as appropriate for gestational age (AGA), and infants whose scores fall above the ninetieth percentile are classified as large for gestational age (LGA). Depending on where the graphed points fall, an infant may be additionally described as "borderline" LGA or AGA to illustrate extremes of the classification ranges.

After size classification is determined, the nurse must determine the accuracy of the graphing in comparison to

Critical Thinking

Newborn Size

Ask yourself the following questions:

1. What does the graph reveal as the largest part of the infant?
2. What does the physical examination reveal as the largest part of the infant? Is this the same result as the graph?
3. Are the length and head measurements falling at approximately the same percentile range on the graph?
4. Which two out of the three measurements graphed are the closest together in terms of the percentile range and why?

The head of the newborn infant should be the largest part by graph and visual examination. Length and head measurements should fall within the same range on the graph. Embryonic development proceeds from head to toe in utero. Head and length measurements that are close together on the graph suggest that the development of this newborn infant has proceeded normally during this pregnancy.

Any measurement that the nurse suspects is inaccurate should be measured again and plotted on the graph with a notation that the measurement was retaken for the official infant record. Once the physical assessment and size classification are complete, the nurse can report to the parents on the condition and characteristics of their infant. The nurse can bring the completed size graph to the parents to show them exactly where their infant's measurements fall on the graph.

the physical presentation of the infant recently examined. Because these measurements begin all future determinations of infant growth and development from growth curves, the nurse must develop an intuitive feeling that they are accurate.

ADDITIONAL ASSESSMENTS

After the initial physical examination, measurement, and size classification has been completed, the responsibility of the nurse changes to promoting opportunities for the parents and infant to interact and be with each other.

Periodic Shift Assessment

Periodic shift assessments are done at regular times, usually every 4 hours, to ensure infant physiologic stability and to alert the nurse to any changes in the newborn's condition. Parents can provide information, which along nursing expertise, and judgment of the newborn's condition all part of ongoing assessment. The medical staff should be informed immediately of any changes in the condition of the newborn.

Periodic assessments include vital signs; body weight; feeding and elimination details; hydration status; respiratory and cardiac function, and hip movements for DDH. Vital signs during the first 24 hours of life include: a heart rate that averages between 100 and 130 beats/min, a respiratory rate below 60 breaths/min, and a body temperature above 97°F. Blood pressure is usually not included in the periodic assessment, unless specifically ordered. Weight after the first 24 hours of life should show a loss, as the newborn is expending energy to breathe, maintain cardiac circulation, eat, and eliminate urine and stool. Diapers are checked for urine and the presence and color of stools. Stools should reflect a gradual change in color and consistency, from the dark-colored, thick meconium stools to brown-yellow, pasty transitional stools, and finally to yellow, loosely formed stools (Figure 32-25). Hydration status can be assessed through noting skin turgor and changing diapers. Newborns should have six to ten diaper changes a day for urine, but the stool content in these diapers may vary. The newborn respiratory and cardiac systems are assessed by the nurse at every periodic assessment. The nurse is particularly alert for signs and symptoms of respiratory distress, including intercostal retractions, noisy breathing, sternal retractions, nasal flaring, central cyanosis, tachypnea, and irritability. During the cardiac assessment, the nurse should listen carefully for any arrhythmias and heart murmurs. Murmurs that persist beyond the first 24 hours of life need further evaluation. Lastly, the nurse performs the Barlow and Ortoloni maneuvers to screen for DDH. Positive findings should be reported immediately if the nurse notes new findings at this time. The nurse records in her notes the results of her periodic assessment and tells the parents that the newborn infant is stable and normal.

Quick Examination

Quick examinations are performed when the nurse relieves another nurse and assumes the care of a newborn, either for a short period or for the remainder of the shift. The nurse assesses physiologic stability by examining the lungs and heart of the infant and taking its temperature. The nurse compares these findings with the documentation in the newborn's chart and the nursing report re-

A.

B.

Figure 32-25 A. Meconium stool; B. Breast-milk stool.

ceived on the status of this newborn. The nurse also should notice the reactivity of the newborn and record the state of the infant as asleep, awake, quiet, active, or irritable. Quick examinations are also performed on newborns when a nurse notices a odd behavior or something in passing that the nurse feels is unusual and should be assessed. This is a skill developed by nurses with experience in caring for newborns. These nurses have the ability to form an opinion about a newborn's condition from a quick look at a newborn at a mother's bedside or in the nursery.

Interactional Assessment

The interactional assessment of the newborn involves an assessment of the infant's reactivity to the environment and parental interaction with the infant. The newborn's reaction to the extrauterine environment fluctuates widely over the first 10 days of life, as the physiologic systems adjust to regular patterns of breathing, circulation, feeding, elimination, and sleeping (Pressler & Hepworth, 1997). There are six behavioral states: 1, deep sleep; 2, light sleep; 3, drowsy; 4, quiet alert; 5, considerable motor activity; and 6, crying (Brazelton, 1973). The nurse is aware of these newborn behavioral states and does the handling and examinations of the newborn during state 3 or state 4. Newborns who are at state 5 or state 6 are too irritable to be easily examined, because the examination intensifies and prolongs the motor activity and crying. The nurse can intervene by cuddling the infant, talking to the infant in a soothing voice, and waiting until the infant calms down. During the interactional assessment, the nurse notes the

state of the infant, any changes, and the length of time the infant takes to go from one state to another. This time-frame assists the nurse in forming an assessment of the infant's neurologic organization in the early days of life. Substance abuse during pregnancy interferes with and prolongs the newborn's ability to move from one state to another. These newborns are often described as "irritable" or "difficult" by parents who spend a great amount of time and effort attempting to calm them.

The nurse observes the interaction between the parents, family members, and the newborn. The nurse initiates attachment of the newborn to the parents and the family and the attachment of the parents and the family to the newborn with the first bedside visit. The newborn is placed in the arms of the parents, and the nurse describes the infant's unique qualities and features. Common parental reactions to newborn infants include touching their infant, exploring and examining all of the body parts, massaging the infant's abdomen, stroking the face, and cuddling (Wong et al., 1999). This process assists the parents in identifying "their baby" and begins the attachment of the mother to the newborn. At this time, the nurse can instruct and demonstrate holding positions for the infant (Figure 32-26).

The involvement of the father and siblings is actively promoted by the nurse as part of the interactional assessment. Paternal engrossment has been defined in the research literature as the father's ability to be preoccupied and interested in the newborn infant (Wong et al., 1999). Fathers want to be able to touch, explore, and hold their infant. The nursing role in promoting the early stages of paternal attachment is to allow private time between both

parents and their newborn. The nurse may accomplish this objective by bringing the newborn and leaving it at the mother's bedside, closing the door to the mother's room, and taking siblings on a tour of the hospital or down to the cafeteria or gift shop. Children react differently to newborns, depending on their age. School-aged and younger children focus on the newborn's face and touching the infant instead of holding the infant. The nurse can teach sib-

lings proper holding of the infant and infant transfer with the parent's permission.

The interactional assessment of the newborn and the family is accomplished by the nurse at least once a shift. The nurse notes the state of the newborn, the family members present, who is holding the newborn, and the reactions to the newborn by the holder or other family members. The nurse can use this time to address any concerns

Client Education

Holding and Transfer Positions

Newborns after delivery are able to see best at a distance of 8 to 10 centimeters from an object. The holding position for newborns that maintains this distance and that has parent and infant facing each other is called the *en face* position. The advantage of this position is that the newborn can gaze on the holder and attend to something that can be seen. Placement of arms and hands for holding a newborn depends on which side the newborn is to be held. For the left side, the left arm encircles the head and shoulders of the newborn with the left hand holding the left thigh of the infant. The right arm encircles the legs and the right hand supports the newborn's back. The nurse emphasizes that the head of the infant must be supported at all times, because of the inability of the infant's neck muscles to support the head at this time. The nurse can demonstrate head support to the parents by wrapping a hand around the infant's neck and placing the thumb and third or fourth finger underneath the newborn's jaw on both sides if its head. For feeding, the newborn can be held in the mother's lap at a 45° angle to promote swallowing and decrease air going into the newborn's stomach. For transferring the infant from one person to another, the nurse can actively illustrate the transfer. The nurse holds and supports the infant and walks to the parent for transfer. The infant is placed in the parent's outstretched arms and not released until the parent informs the nurse that he or she has control of the infant. Release before that time may cause the infant to be dropped, because the parent does not have a secure enough hold on the infant. The nurse emphasizes that one of the most important aspects of holding positions is the opportunity for parents to interact with and talk to their infant.

the parents or family have regarding their infant. The nurse should assess how well the family has understood the instructions on infant holding and positioning and, if necessary, reinforce and support efforts to follow the nursing instructions. Parental or familial interactions that the nurse observes with the infant that are not positive or are neglectful should be reported and confirmed by other nursing staff.

FACTORS THAT PLACE THE INFANT AT RISK

Besides the physical assessment of the infant, the nurse also evaluates other influences and conditions that impact on the health and well-being of the infant. These influences and conditions are evaluated for every infant, even those infants that are rooming-in with their mothers. It is during this evaluation that the nurse develops a plan of care for the infant and parents.

Physical

Physical factors that are assessed in the newborn period relate to birth injuries, congenital conditions, and temperature control. Bruising, edema, lacerations, and bone fractures are conditions that are detected on the initial physical assessment. The nurse plans care for the infant based on minimizing further injury to the site by proper positioning or protecting the injury site with antibiotic ointment or a gauze bandage. Teaching projects for the parents are designed to alleviate concern and anxieties, continue appropriate care regimens, and emphasize follow-up visits. Congenital physical conditions, such as malformations of the extremities or a cleft lip and palate combination, require special nursing sensitivity to the requirements of the infant. The infant requires special care and protection from curious onlookers who are not family members.

The last physical influence on an infant's health is the infant's ability to maintain its body temperature. Infant body temperature should range between 97°F and 100°F axillary temperature. Body temperatures of less than this value may indicate that an infant is too cold and needs to be re-wrapped. An infant with a body temperature outside this range should be evaluated for possible sepsis. Temperatures are taken about 30 to 45 minutes after nursing interventions. Repetitive low or high temperatures in a newborn infant may indicate an infectious process. Parents can be taught how to read a thermometer and to take their baby's temperature properly. The nurse can give the parents guidance for assessing temperature at home and appropriate actions to take in the event that temperature is outside the normal range.

Psychological

During the period of recovery from labor and delivery, the mother may be unable to care for the newborn infant and need assistance from the nurse, the father, or other family members. The mother may require intravenous fluids or medication that interfere with her ability to hold, cuddle, or breastfeed her newborn. Pain, uterine cramping, and discomfort from an incision site may contribute to positioning difficulties for the mother. Mothers admitted to intensive

care units for observation and monitoring of symptoms experienced during labor and delivery are not able to care for their newborns. Visits to these units for the family members and the newborn are limited by the policies of the unit.

Psychological conditions that place an infant at risk are those conditions that inhibit interactions between the infant and the parents or primary caretaker, such as separation, rejection, or sensory or neural disorders. Mothers and fathers who are eager to see, hold, stroke, and explore their newborn are learning to accept this new tiny person into their life. Other parents may be disinterested, disappointed in the physical appearance or gender of the infant, or unable to adjust to having an infant with a physical problem. A normal, healthy infant is the dream of all parents. Anything that disrupts this image of the baby, whether it is the physical condition of the infant, medical or nursing statements concerning the infant, or the infant's behavior, may cause the parents to change their responses to the infant (Stern & Hildebrandt, 1986). This places the infant at risk for inappropriate caregiver interaction and possible neglect.

Family

The family constellation and organization are important in planning for care of the newborn. The nurse is able to gather information from parents and other family members concerning their plans after discharge, household arrangements, services needed, and follow-up care. Families with little financial support can be referred to community agencies and services for assistance. This assistance may include formula or food for breastfeeding mothers (Women, Infants, & Children [WIC] programs), diapers, housing or shelter, transportation, and health care for the mother and infant. Young mothers, especially teenagers, may be eligible for teen clinics that provide resources and follow-up services for them.

The nurse can assess the reactions of the siblings to the newborn and initiate interventions to help the parents introduce the infant to siblings. The nurse plans for the care of the infant and designs teaching projects to facilitate the understanding and participation of all family members within the unique family situation that is presented.

Environment

In addition to observing the parental and family dynamics, the nurse plans for newborn care by eliciting information about the home environment. Environmental conditions that place the newborn at risk are smoking in the home, inadequate heating or cooling, lack of kitchen facilities, water from a well, and pets. Infant exposure to second-hand smoke is believed to cause respiratory infections in infancy. Smokers are encouraged not to smoke around the infant and, preferably, to smoke outside rather than in the

home. Temperature regulation is important for the newborn. Newborns can become chilled or overheated if placed near ceiling fans, window air conditioners, or space heaters or when left in cars. The best position for the newborn is at the opposite end of a room from the fan, air conditioner, or heater. Space heaters are not recommended, owing to the danger of fire. However, many older, unheated homes use them for heat, and parents must be made aware of the danger and the necessity of flame-retardant clothing for infants. Infants should not be left unattended in cars because cars may overheat in the summer. Parents should be asked whether or not they have kitchen facilities, i.e., a refrigerator, stove, and running water. Formula and breast milk should be refrigerated and reheated on a stove or under running hot water. Water from a well should be tested every year to make sure that it is safe for consumption. Pets, especially long-haired dogs and cats, carry dander and hairs that might cause future allergies and sensitivities in newborns.

Illness and Infection

Infants of mothers whose delivery took longer than 18 hours after the rupture of membranes are at risk for a septic infection. Infants of mothers who had infections before delivery or who had a body temperature during labor above 100.4°F are at risk for infection (Mitchell, Steffenson, Hogan, & Brooks, 1997a).

The most common maternal illness at delivery is **chorioamnionitis**, which is an infection of the amniotic fluid surrounding the infant in utero before delivery. It is detected by the appearance of foul-smelling amniotic fluid at delivery, uterine tenderness, maternal fever and tachycardia, and infant tachycardia (Mitchell et al., 1997a). Newborn infants of mothers with these symptoms should be evaluated thoroughly for developing signs and symptoms of infection, which, in newborn infants, include lethargy, decreased appetite, jaundice or pallor, fever or chilling, increased respiratory or heart rate, or a general appearance of not “looking well” (Mitchell, Steffenson, Hogan, & Brooks, 1997b). Newborn infants with suspected infection are examined, tested, and often started on antibiotics. Infants with confirmed infections are placed on a prescribed intravenous antibiotic regimen for 7 to 10 days.

One of the causes of chorioamnionitis is group B streptococcal (GBS) infection which is the leading cause of bacterial meningitis and sepsis in newborns. GBS and *Escherichia coli* infections account for 70% of all cases; *Listeria monocytogenes* is the causative agent in 5% of cases (Taeusch & Ballard, 1998). Early onset of meningitis in the newborn infant is usually caused by exposure to infection in utero or during passage through the birth canal. Women usually are tested for GBS colonization during their prenatal care, usually after 35 weeks of pregnancy. Many women exhibit no symptoms of infection but can transmit the infec-

CULTURALLY APPROPRIATE CARE

Optimal care practices for infants should be attuned to the family's cultural and ethnic environment without sacrificing the infant's health and well-being. Achieving this delicate combination results in the provision of culturally sensitive care (Andrews, 1992) and creates a maternal and familial impression that the nurse understands and appreciates the relationship of this newborn infant to the family and their environment.

tion to their fetus during labor and delivery if membranes have ruptured (Mitchell et al., 1997a). Mothers known to be colonized with GBS before delivery are treated with intravenous penicillin G every 4 hours during labor (Mitchell et al., 1997a). Newborn infants of these mothers are monitored closely for the first 48 hours after delivery for early presentation of the infection. Treatments for suspected early-onset infection include immediate intravenous antibiotic therapy, obtaining cerebrospinal fluid and blood samples for culture, complete blood cell counts with differential, and a chest X-ray film. Rapid nursing assessment and medical intervention are needed to prevent some of the devastating sequelae from this neonatal infection.

NURSING IMPLICATIONS

Nursing care of the newborn infant after delivery is based on an accurate assessment of the infant's physical condition and any other factors affecting its health and well-being. The infant's physical condition is determined from the physical examination and additional frequent assessments of behavior, feeding, and elimination patterns. Familial and maternal conditions necessitating special procedures or treatment regimens are incorporated into the nursing plan of care.

Promotion of Physiologic Stability

The primary nursing goal in the care of the newborn infant is the maintenance and promotion of physiologic stability. Body temperature control, positioning, creation of a non-stressful environment, and establishing regular routines for newborn infants are the major concerns of nurses during the first several days of life. Creating a non-stressful environment is important for the development of infant behavior and reactivity patterns. Elimination of noise from beepers, monitors, telephones, televisions, and radios help to soothe a distressed infant. Carpeting reduces noise from

traffic and dimming the lights reduces glare and assists infants in opening their eyes more easily. Infants who are fussy and irritable require a response from a caregiver that may consist of touching, talking to the infant, or holding or rocking them. The earliest beginnings of Erikson's trust versus mistrust developmental stage begins shortly after birth, when the infant senses that someone responds to his or her needs. To assist nurses in providing this response, nurseries often encourage foster grandmothers and other volunteers to feed and hold newborn infants when their mothers are unable to do so.

Newborn Care

The care of the healthy newborn focuses on the feeding and elimination pattern of the infant and the parent's adjustment process to the care demands of a new infant. Nurses are able to prepare new parents for their future life at home with a new baby by using anticipatory guidance and by teaching skills in baby care. Nurses are often the first health care provider to answer parents' concerns about their infant. During the period after delivery, the nurse must not only assess the health and well-being of the infant but also to determine how well the parents are coping with the new and frequent demands for their attention and time.

Sleep and Activity

Newborn infants spend the majority of their time sleeping and brief periods awake and actively exploring their environment. It is not unusual for newborns to sleep 16 hours a day. Proper sleeping conditions for infants are placement in the supine position on a flat surface without a pillow and covered with a blanket in a crib or bassinet separate from the parents' bed. Sleeping infants should be protected from air currents generated from ceiling fans and air conditioners that may lower their body temperature. Infant sleep-wake periods do not always coincide with a parent's need for rest. Often, parents are awakened several times during the night by an infant needing feeding or attention. The first several months of an infant's life are spent trying to establish a sleep-wake schedule that allows both parents and infant to rest. The most common complaint of parents during the neonatal period is lack of adequate sleep. Encourage parents to rest while their infant is sleeping, instead of catching up on housework, chores, or the demands of other children or the partner (Ruchala & Halstead, 1994). Nurses can play a role in acknowledging parental frustrations during this time by being receptive to inquiries and providing guidance toward positive interactions between infant and family during this time. Infants who are awake and alert can respond to voices and noises and need sound and touch stimulation to begin to explore their environment. The more an

infant is able to interact with family members and explore the surrounding environment, the easier it becomes for the infant to achieve developmental milestones and develop a unique personality.

Cord and Skin Care

Umbilical cord and skin care are additional concerns of new parents. The umbilical cord may or may not be stained with a bacteriostatic dye, but it is left clamped when the parents take the infant home. The clamp prevents blood from oozing from the cut cord and remains in place until the cord has dried and shriveled. Nurses can teach parents to look for cord discharge, redness, or oozing, which may be signs of infection. At each diaper change, the cord is swabbed with alcohol on a cotton ball at its base, where it attaches to the umbilicus, and the diaper is folded around the base, leaving the cord exposed to air. Somewhere between 7 and 14 days after delivery, the cord will fall off, leaving behind a moist stump inside the umbilicus, usually yellow in color. This stump requires application of alcohol or warm water and drying to continue the drying process of the stump for another 3 to 5 days after the cord has fallen off.

Many new parents may have cultural practices regarding the umbilical cord. Some families may attach belly bands, coins, cotton balls, or other objects to the umbilical cord to prevent umbilical hernias. Families should be encouraged to keep the area clean, dry, and open to the air as much as possible in keeping with their cultural beliefs.

The nurse can demonstrate proper cleansing of the diaper area with a warm, moist cloth, followed by drying with another cloth, and then replacing the diaper. Infant skin may feel dry to parents; the nurse can recommend a lotion that is hypoallergenic to be applied in a thin coat two or three times a day. Vaseline petroleum jelly and baby oil are not recommended as skin lubricants because they retain moisture and prevent air from contacting the skin. Parents are taught by the nurse to sponge-bathe their infant until the time when the cord falls off. Warm water and a mild soap is used to sponge-bathe the infant from the neck down. The infant's face is cleansed with warm water because the skin on the face has less natural oil and is subject to drying if soap is used. The parents are taught to bathe their infant in sections, drying each section before they proceed to another. This preserves the infant's body heat. Baby shampoo is used for washing the infant's hair. After shampooing and drying, the infant's head is covered. Hooded bath towels are available at stores that specialize in infant clothing and are ideal for keeping the infant's head warm after the bath. Lotion may be applied after the bath. After the cord falls off, the infant can be held securely in a shallow basin for bathing. Bath time can be a special time for parents to interact and play with their infant.

Diaper dermatitis results from mechanical irritation of the skin, the pH of urine, and decreased air circulation inside the diaper. Improper cleaning of the genital area and infrequent changes are all predisposing factors for the development of a diaper rash (Singleton, 1997). Once a redness of the skin in the irritated area occurs, the best treatment includes washing the area with warm water, drying thoroughly between diaper changes, eliminating cornstarch or other baby powders, leaving the diaper open the area exposed to air several times a day, and the use of A & D Ointment or petroleum jelly, which is washed off at each diaper changes (Singleton, 1997). Diaper rash that does not improve with these remedies within 2 to 3 days should be evaluated by a health care provider.

Criteria for Discharge

Newborn infants are often discharged with 24 to 48 hours of delivery, depending on the policies of the institution. Federal law requires insurance coverage for newborns for 48 hours after a normal vaginal delivery and 72 hours after a caesarean section delivery. The responsibility of the nurse caring for a newborn is to determine if the infant and the family meet the criteria for discharge. First, the infant must be physiologically stable. The infant should be a term infant; appropriate or large for gestational age; maintain an axillary temperature above 97°F, a heart rate between 100 and 150 beats/min, and a respiratory rate of less than 60/min; successfully pass urine and stool; feed consistently; and have normal findings on physical examination and periodic assessments (Burns et al., 2000). Second, the parents and family members should be knowledgeable in the care and feeding of the infant, signs and symptoms of illness, community resources for assistance, and locations with appointments for follow-up care. The nurse ensures that the prenatal screening has been done and recommends smoke detectors in the home, a safe sleeping position, and an infant car seat for the trip home (Burns et al., 2000). Infants, parents, and families that meet these criteria can be safely discharged at 48 hours after delivery or less (Banks & Thorne, 1997). Infants who do not meet the criteria should have parents referred to the medical staff for advice and guidance.

Research Highlight

Effect of Early Newborn Discharge

Purpose

To examine the effects of “Great Starts” early discharge follow-up on the future use of the urgent care clinic by newborn’s parents before the 2-week newborn examination.

Methods

The use of urgent care services was examined through record review. Included were records of 315 infants whose parents had participated in the “Great Starts” program. These records were compared with 324 newborn records who were born prior to the initiation of the program. These records were examined for use of urgent care services prior to their 2-3 week newborn checkup. The “Great Starts” program consisted of one appointment to the clinic within 2-3 days of discharge, at which time groups of 8-10 mothers, with their newborns, discussed infant concerns.

Findings

In the control group, 188 (58%) of 324 infants had urgent care clinic visits during the first 2 weeks of life. 90/315 (28%) In the period after the “Great Starts” program, 90 (28%) of 315 infants had urgent care clinic visits in the first 2 weeks of life.

Nursing Implications

The parents indicated that the normal 2-week visit after discharge was “too long to go” to address their concerns about their infant. This study presented an alternative for parents and assisted them in increasing their knowledge and ability to care for their infant. Because newborns are often discharged early from hospitals, in spite of the mandated 48-hour stay, parents have limited opportunities to have their concerns addressed within this timeframe. Once the newborn is discharged, there is no source for parental information except the check-up at 2 weeks of age or an urgent care facility. Nurses have the opportunity to be involved in collaborative efforts to provide cost-effective alternative sources and resources for these parents.

Nursing examinations of the newborn infant, including the physical and interactional assessments, form the foundation for the beginning of an infant’s life. The nurse applies knowledge and expertise to alleviate parental concerns about the health of their newborn infant, shares with them the unique characteristics of the infant, instructs parents on the care of their newborn, and supports the sociocultural traditions of the family in regard to caring for newborn infants.

Key Concepts

- The newborn's large surface area of skin, thin layer of subcutaneous fat, predisposes the infant to heat loss. Subsequently, nursing efforts are focused on assessing infant body temperature and maintaining normal temperatures by using blankets or radiant warmers.
- Newborn cardiovascular and respiratory stability in the extrauterine environment is achieved after transition, usually around 12 hours of life.
- The hemodynamic changes in the newborn cardiac system after delivery may lead to "flow murmurs" heard on auscultation, which normally disappear after 24 hours.
- Nurses perform four assessments on newborns when they are physiologically stable. These assessments are the full physical examination, periodic or shift assessment, the quick examination, and the interactional assessment.
- The full physical assessment of the newborn includes a general assessment, measurement of vital signs, body weight and measurements, and a full physical examination.
- The periodic shift assessment is done at regularly scheduled intervals. The nurse evaluates vital signs and weight, feeding and elimination, hydration status, cardiac and respiratory function, and checks for hip DDH.
- The quick examination is performed by the nurse who takes over the care of a newborn from another nurse. This examination is done when a nurse notices a particular behavior or cry from a newborn that needs further investigation. Body temperature, cardiac and respiratory status, and activity and irritability of the infant are assessed.
- The interactional assessment involves an estimate of the newborn's reactivity to being handled and to the environment as well as evaluation of familial interactions.
- The assessment of the newborn's body temperature, skin, and cardiac and respiratory status are the best indicators of newborn physiologic stability.
- The assessment of the musculoskeletal and neurologic systems provides the nurse with indications of disruptions in embryonic development or problems related to trauma experienced during labor and delivery.
- The accurate examination of the newborn genitalia provides parents with an indication of their newborn's gender and the opportunity for the nurse to reinforce what is "normal" with parents.
- Factors that may dispose the newborn to injury or infection are evidence of birth trauma, maternal infection during pregnancy or delivery, and unsafe handling of the infant by family members.
- Family or psychological factors that place the infant at risk are maternal inability to provide care, paternal noninvolvement, language barriers, and sibling rivalry.
- Environmental barriers that affect the well-being of newborns include a lack of kitchen and water resources, smokers in the home, pets, and inadequate or dangerous heating or cooling systems.
- Nursing care of newborns after delivery focuses on the promotion of physiologic stability, providing opportunities for optimal nutrition, protection from injury and infection, and enhancing appropriate interactions between the parents and the infant.

Review Questions and Activities

1. All of the following are assessed by the nurse after transition except:
 - a. Temperature
 - b. Body weight
 - c. Heart rate
 - d. Respiratory rate
 The correct answer is b.
2. The best response to a parent's question regarding the skin or hair color of their infant is:
 - a. "The color of the skin or hair reflects what the infant inherited from the parents."
 - b. "Skin or hair color always darkens during infancy."
 - c. "The color of skin or hair in a newborn is not an accurate picture of inherited characteristics."
 - d. "Newborn skin and hair color may change so that is difficult for you to picture the changes before they occur."
 The correct answer is d.
3. Which is the true statement regarding heart murmurs in the newborn period?
 - a. Heart murmurs that sound the loudest on auscultation indicate large heart defects.
 - b. Heart murmurs that are soft and barely audible on auscultation indicate small heart defects.

- c. Heart murmurs that appear on day 2 or 3 of life need further evaluation.
- d. Heart murmurs that are noted on the initial physical examination always disappear by day 2 or 3 of life.

The correct answer is c.

4. All of the following are signs of respiratory distress in the newborn *except*:
- a. Hyperglycemia
 - b. Nasal flaring
 - c. Grunting
 - d. Intercostal retractions

The correct answer is a.

5. Which of the following findings on the physical examination of a newborn is the clearest abnormal finding?
- a. Heart murmur
 - b. Tachypnea
 - c. Pronated feet
 - d. Hypotonia

The correct answer is d.

6. Which of the following findings on the physical examination of the newborn may be normal findings?
- a. Heart murmur
 - b. Erb's palsy
 - c. Leukocoria
 - d. Bivalved uvula

The correct answer is a.

7. All of the following are assessed during the musculoskeletal examination *except*:
- a. Muscle tone
 - b. Torticollis

- c. Stepping
- d. Range of motion

The correct answer is c.

8. All of the following may be causes of infant irritability *except*:
- a. Substance abuse
 - b. Hunger
 - c. Injury
 - d. Heart defects

The correct answer is d.

9. Which of the following positively influence the care of a newborn by family members?
- a. Feeding the newborn in the supine position in the crib.
 - b. Leaving the newborn in the nursery to be cared for by nursing staff.
 - c. Allowing the parents numerous opportunities to be with and care for their infant.
 - d. Removing all objects and jewelry placed on the infant by family members.

The correct answer is c.

10. The nurse assesses the interaction between the parents and their newborn by observing all of the following *except*:
- a. Feeding position
 - b. Display of affection between the couple
 - c. Holding position
 - d. Touching and stroking

The correct answer is b.

Newborn Nutrition

Guidelines from the American Academy of Pediatrics recommend breast-feeding and human milk as the standard for optimal infant nutrition in the first year of life. These guidelines are emphasized and current alternatives are presented for infants when breast-feeding and human milk feeding are not possible. Use the following questions to examine your knowledge and attitudes about infant nutrition:

- ❖ *What is my understanding of the differences in breast-feeding compared with formula-feeding related to infant growth and development?*
- ❖ *What are my own personal feelings and attitudes regarding infant feeding decisions?*
- ❖ *How do my past experiences related to infant feeding influence my ability to offer unbiased counseling and instruction to mothers?*
- ❖ *Do I believe that most lactation and breast-feeding problems are preventable and, with proper knowledge and technical skills, can be overcome?*

Competencies

Upon completion of this chapter, the reader should be able to:

1. Understand the composition and function of basic nutrients in human milk compared with artificial infant formula.
2. Describe the expected growth rates for normal full-term infants based on type of milk (human or artificial formula) received in the early months of life.
3. Describe the physiologic signs of adequate milk transfer in the infant who is exclusively breast-fed.
4. Identify strategies to improve infant growth rates in the infant who is exclusively breast-fed when growth faltering is diagnosed.

The newborn infant requires dietary energy for adequate growth and development. Determining the optimal nutrition for the healthy newborn infant has required extensive scientific investigation for decades. Infant nutrition research repeatedly concludes that human milk and breast-feeding are the gold standard to which all other forms of infant feeding alternatives should be compared. Reflecting on recent advances and knowledge on the benefits of breast-feeding, the American Academy of Pediatrics (AAP) revised its policy statement regarding infant nutrition. The AAP identifies breast-feeding as the ideal method of feeding and nurturing infants and recognizes breast-feeding as primary in achieving optimal infant and child health, growth, and development (American Academy of Pediatrics [AAP], 1997).

GROWTH AND DEVELOPMENT

Growth is the standard by which infant nutrition is judged. Birth weight triples and length increases by 50% during the first year. Infant growth is especially rapid during the first few months of life when weekly weight and length gains approximate 200 g and 1 cm, respectively. Brain growth is profound, tripling in size during infancy to reach 90% of adult size at 2 years of age (Dobbing & Sands, 1973; Widowson, 1991). Scientific evidence is emerging that different diets in early infancy can have long-term consequences (Barker, 1992; Sultan & Barker, 1994). This

so-called nutritional imprinting or programming affects metabolism, development, and disease processes later in life (Lucas et al., 1990; Mott et al., 1995).

Human milk has the distinct capability of providing not only energy to fuel growth but unique properties ben-

REFLECTIONS FROM A NURSE

"For years, I routinely promoted bottle-feeding because it was easy to see how much formula the babies consumed. It also was easy to teach mothers how to prepare the formula. Then I began to learn more about how formula was developed and how the formula companies were researching the composition of breast milk. I became convinced that, whenever possible, the best food for infants is their mother's milk. After more reading, I now feel that the babies whose mothers are not breast-feeding, for whatever reason, also are getting good nutrition as the infant formulas are getting more and more sophisticated."

feeding the infant's immune system and health status. Immune properties, most specifically secretory immunoglobulin A (sIgA), present in human milk, protect the infant from infection (Wold & Hanson, 1994). Studies comparing morbidity rates among feeding types found a lower incidence of otitis media, respiratory, and gastrointestinal (GI) infections in breast-fed compared with formula-fed infants (Scariati, Grummer-Strawn, & Fein, 1997; Dewey, Heinig, & Nommsen-Rivers, 1995; Kakai et al., 1995; Beaudry, Dufour, & Marcoux, 1995). Furthermore, breast milk has a direct effect on the infant's immune system (Hahn-Zoric et al., 1990; Pabst & Spady, 1990). These observations may explain why some evidence exists that breast-feeding protects against insulin-dependent diabetes mellitus, Crohn's disease, rheumatoid arthritis, malignant lymphoma, and allergic conditions (Virtanen et al., 1991; Mayer et al., 1988; Gerstein, 1994; Koletzko et al., 1989; Mason et al., 1995; Davis, Savitz, & Graubard, 1988; Shu et al., 1995; Wright, Holbert, Taussig, & Martinez, 1995; van den Bogaard, van den Hoogen, Huygen, & van Weel, 1993; Porro et al., 1993; Saarinen & Kajosaari, 1995). Recently, the content of long-chain polyunsaturated fatty acids, such as docosahexaenoic acid (DHA), present in human milk but not in formula, have received a significant amount of investigation. It has been determined that the presence of these fatty acids affects the composition of cell membranes in the brain and retina and also might affect development of visual acuity in the infant (Makrides, et al., 1994; Farquharson et al., 1992; Makrides et al., 1995; Jorgensen et al., 1996; Carlson, Werkman, & Tolley, 1996).

In terms of infant growth, optimal patterns for infants have been proposed. Growth charts are used to monitor individual infant growth patterns. Charts currently used throughout the world are based on the U.S. National Cen-

ter for Health Statistics (NCHS) reference data (U.S. Department of Health, Education and Welfare, 1977). For the first 2 years of life, these data are based on the Fels Longitudinal Study, conducted in Yellow Springs, Ohio, from 1929 to 1975 (Roche, 1992). These data have come under scrutiny for several reasons: 1) the low incidence of breast-fed infants in the cohort, 2) too infrequent measurements to capture adequate patterns of growth, and 3) the reference group used not being a representative sample.

It has been demonstrated in several studies that the growth patterns of breast-fed infants differ from the NCHS reference data (Binns et al., 1996; Dewey et al., 1995; Dewey, et al., 1992; Hitchcock, Gracey, & Gilmour, 1985). An explanation commonly given for this difference is that most infants in the NCHS cohort were formula-fed. In longitudinal studies continuing throughout the first year, breast-fed infants showed as rapid or more rapid weight gains compared with formula-fed infants during the first 2 to 3 months. In contrast, evidence from these data show formula-fed infants weigh more than do breast-fed infants during the later months of the first year. As a result of these findings, the World Health Organization (WHO) completed a comprehensive review in 1995 of the uses and interpretation of the growth standards currently in use. WHO concluded that the current NCHS growth reference is inadequate and recommended that a new international

Feeding Readiness Cues

Confirm that parents know to respond to early feeding readiness cues:

- Sucking movements
- Sucking sounds
- Hand-to-mouth movements
- Rapid eye movements
- Soft cooing or sighing sounds
- Fussiness

Nursing Tip

INFANT ASSESSMENT FOR INSUFFICIENT LACTATION

Possible signs of insufficient lactation in the exclusively breast-feeding infant-mother dyad in the first month after delivery follow:

- Low urination pattern (at least six wet diapers a day is the norm).
- Low stooling frequency (at least three yellow-greenish, seedy, soft stools a day is the norm).
- Minimal breast changes after delivery (such as fullness and leaking of milk).
- Very irritable or sleepy infant, nursing less than seven times a day.
- Weight loss of more than 10% of the birth weight, or continued weight loss after day 10 of life.

For the bottle-fed infant intake of 4 oz or more of formula taken every 2-3 hours, 6-10 feedings per day is the norm.

growth reference for infants was needed to more accurately reflect the population and current health recommendations. Given the differences in growth patterns based on feeding mode, however, concern exists that a growth reference constructed to be representative of a whole population may not be useful for judging the growth of either breast-fed or formula-fed infants (Garza, Frongillo, & Dewey, 1994). WHO has concluded that a multicountry growth study specifically designed to develop a growth reference of lasting value is necessary. The new reference sample should be based on breast-fed infants living in healthy environments that do not limit their genetic growth potential (de Onis, Garza, & Habicht, 1997).

Until such time that new growth references are available, health care providers need to take into account differences in growth rates based on feeding mode (Figure 33-1). Clinicians need to make appropriate recommendations to parents when observing negative deviations from the NCHS reference. Misinterpreting the growth patterns of healthy breast-fed infants by advising mothers to supplement unnecessarily or to stop breast-feeding altogether has profound public health significance. A general guideline is

Figure 33-1 Adequate nutritional intake is noted by an infant's overall healthy appearance and steady growth rate.

Nursing Tip

INFANT ASSESSMENT

A general approach to infant nutritional assessment follows:

1. Use an accurate electronic scale to measure weight.
2. Use a length board.

to note weight gain of 20 to 30 g/d ($\frac{1}{3}$ to $\frac{1}{2}$ lb/wk) for the first 5 months, with a length gain of 0.80 to 1.07 mm/d (0.28 in/wk) and a head circumference increment of 0.3 cm/wk (Guo et al., 1991; Hamill et al., 1979).

Energy

Carbohydrates and fat meet the primary energy requirements for growth, metabolism, and activity. Protein also may provide energy. The most important function of protein in growth, however, is to provide the amino acids necessary for synthesis of body proteins and the hormones and enzymes that regulate metabolism (Carlson & Barnes, 1996). Most of the data available with regard to total energy expenditure and balance have been defined from measurements of intake rather than determinations of energy need. Indirect **calorimetry** has been the most common technique used. This procedure measures energy production through the assessment of oxygen consumption and carbon dioxide production. Direct calorimetry, which directly measures heat loss from the infant, also has been used to assess expenditure but with far less frequency. A newer approach for assessing total energy expenditure is the doubly labeled water stable isotope technique. Validation studies have shown good correlation between the doubly labeled water technique compared with more conventional approaches to total energy expenditure (Jones et al., 1988; Roberts et al., 1986).

Because the composition and quantity of human milk consumed by infants vary, absolute requirements cannot be determined; however, normal ranges can be estimated. The current recommendations for energy requirements for a term infant are 108 kcal and 100 kcal per kilogram of body weight from birth through 6 months and 6 months through 12 months, respectively (National Research Council [NRC], 1989). These revised estimates reflect more accurately the infant populations receiving human milk (Prentice et al., 1988; Waterlow, 1988). The general compositions of human, bovine, and several infant formulas are compared in Table 33-1.

Table 33-1 Composition of Human Milk and Formulas*

Selected Nutrients (100 mL)	Human Milk	Formulas**			
		Standard Cow's Milk-Based	Soy	Elemental	Preterm
Kcal	68	68	68	68	81
Carbohydrates (g)	7.2	7.0–7.3	7.0	7–9.1	9.0
Protein (g)	1.0	1.5	1.7–2.0	1.6–1.9	2.2–2.4

**Formulas with iron.

Protein

The amount of total energy intake utilized for growth is higher during the first 2 months of life than at any other time. During this most rapid period of postnatal growth, infants may use 60% of the protein they consume in producing new tissue. It has been calculated that about 45% of the dietary protein intake of human milk-fed infants comes from essential amino acids (NRC, 1989). In contrast, adults need only about 13% to 20% of their recommended protein intake in the form of essential amino acids.

There are significant differences in the digestibility and quality of human milk proteins compared with those of bovine milk-based formulas. The proportion of whey (supernatant) and casein (curd) in human milk is of interest. Human milk is more whey-dominant, with a whey-to-casein ratio of approximately 70:30 compared with 18:82 in bovine milk. In general, the whey fraction of soluble proteins is more easily digested and promotes more rapid gastric emptying (Billeaud, Guillet, & Sandler, 1990).

The type of proteins contained in the whey fraction differs in humans compared with bovine-derived formulas (Hambraeus, 1977). The major human whey protein is α -lactalbumin, a nutritional protein for the infant and a component of mammary gland lactose synthesis. Lactoferrin, lysozyme, and sIgA are specific human whey proteins involved in host defense and are present only in trace amounts in bovine-derived formulas. The major whey protein in bovine milk is beta-lactoglobulin, the protein implicated in bovine milk protein allergy and colic (Savilahti and Kuitunen, 1992; Jakobsson, Lindberg, Benediktsson, & Hansson, 1985).

In terms of protein requirements, doubts have been raised about whether the amount consumed by breast-fed infants is truly optimal (Foman, 1993). The theory has

been put forth that the composition of human milk represents an evolutionary compromise between the need of the infant and the needs of the mother, and that the lower milk protein concentrations may protect the lactating mother from becoming nutritionally depleted. This theory was tested in an intervention study in Honduras in which infants were randomly assigned to be exclusively breast-fed for the first 6 months, or to receive preprepared solid foods (including egg yolk) in addition to breast milk beginning at 4 months (Dewey et al., 1996). Neither weight nor length gain from 4 to 6 months differed between groups, despite a 20% higher protein intake in the supplemented group. In another study, 20 healthy full-term infants, 10 of whom were breast-fed and 10 formula-fed, were followed longitudinally from birth to 24 weeks postnatal age (Motil, Sheng, Montandon, & Wong, 1996). Lean body mass and body fat were determined at 6-week intervals. The gross efficiency of nutrient utilization was calculated for each infant from the cumulative dietary intake and the change in body composition over time. Data revealed similar length and weight gains and lean body mass and body fat **accretion** (growth in size, especially by addition or accumulation) between breast- and formula-fed infants, despite significantly higher nitrogen and energy intakes of the formula-fed group. The gross efficiency of protein utilization for lean body mass deposition was almost twofold lower in formula-fed compared with breast-fed infants. Results from these studies indicate that human milk protein is not likely to be a limiting factor with regard to the growth of breast-fed infants from birth to 6 months.

Fat

The fats in human milk provide approximately 50% of the calories in the milk. The lipid profile consists of 98%

triglycerides, 1% phospholipids, and 0.5% cholesterol and cholesterol esters (Jensen & Jensen, 1992). In addition, fats are an integral part of all cell membranes, provide fatty acids necessary for brain development, and are the sole vehicle for fat-soluble vitamins and hormones in milk (Hamosh, 1988). The total fat content of human milk is approximately 3.5% to 4.5%; however, it is the most variable component of milk, varying in content throughout lactation, and within and between feedings. The fat content of human milk increases markedly during a single feeding from a breast, with the concentration of *hindmilk* (that milk produced toward the end of a nursing interval) typically being twice that of *foremilk* (lower-fat milk secreted from the breast prior to milk ejection). In addition, fat content increases during the day, with early morning milk having the lowest fat content. Total fat content increases gradually from colostrum (2.0%) through transitional milk (2.5% to 3.0%) to mature milk (3.5% to 4.5%) (Bitman et al., 1986).

Another major difference between the fat in human milk and that in infant formulas is the absence of long-chain (more than 18 carbons) fatty acids in infant formula. Additionally, only traces of cholesterol are present in infant formulas compared with an average amount of 10 to 15 mg/dL in human milk. Recently, two of these very long-chain fatty acids, arachidonic acid (AA) (20-carbon chain) and DHA (22-carbon chain), have received a significant amount of investigation, specifically their role in the developing retina and brain (Carlson, Werkman, & Tolley, 1996). These fatty acids are components of phospholipids found in brain and erythrocyte membranes. AA and DHA have been identified as affecting growth and development of cognition and vision (Uauy & Hoffman, 1991; Carlson, Werkman, Rhodes, & Tolley, 1993).

Human milk fat digestion and absorption are facilitated by the complex organization of the human milk fat globule, the pattern of fatty acids, their distribution on the triglyceride molecule, and the presence of bile salt-stimulated lipase (Hamosh, 1991; Innis, 1992; Jensen & Jensen, 1992). These features are especially important for the preterm infant. Because lipid deposition and accretion of specific lipids occur in the last trimester of intrauterine development, very low-birth-weight infants are deficient in both specific metabolites and the enzymes needed for fat digestion and metabolism.

Normal daily fat requirements for newborn infants are 3.3 to 6.0 g/100 kcal, which represents 30% to 54% of calories. Special attention should be given to providing sufficient essential fatty acids (linoleic and linolenic). Linoleic acid content should be a minimum of 1% to 3% of total kilocalories in current standard infant formulas. Linolenic is the precursor to DHA and should be 0.5% of the total kilocalories (European Society of Pediatric Gastroenterology and Nutrition [ESPGN], 1991). Owing to the special

role of the long-chain fatty acids in neonatal brain development, and in normal nerve function at all ages, linolenic acid, AA, and DHA should be provided (Hamosh, 1991). It is interesting to note that several studies have shown that the fatty acid composition of the human milk lipid system is affected by maternal diet (Makrides, Neumann, & Gibson, 1996). For example, **vegan** mothers consuming no animal products and subsequently no DHA have low levels of DHA in their breast milk (Sanders & Reddy, 1992).

Carbohydrates

Carbohydrates provide fuel for fetal and neonatal metabolism, supplying both immediately usable and stored energy for macromolecular synthesis and tissue accretion (DiGiacomo, 1991). Approximately half of the glucose utilized is oxidized during normal metabolic processes whereas the remainder is used in nonoxidative pathways, such as in the synthesis of glycogen and fat (Denne & Kalhan, 1986). The neonatal brain is the major consumer of glucose, relying almost exclusively on glucose for its metabolism.

Lactose is the principal carbohydrate in human milk and provides approximately 50% of the energy content. Just as the two other major components of human milk have dual roles, so, too, does the carbohydrate component. Human milk carbohydrates have been shown to enhance infant immunity and brain development.

Dietary carbohydrates that resist intestinal enzymes are the main sources of carbon and energy for colonic bacteria. *Lactobacillus bifidum*, a strain of bifidobacteria, requires oligosaccharides from human milk for growth in the infant colon. This bifidobacteria represents 99% of total bacterial counts in the exclusively breast-fed infant by the end of the first week of life (Rasic & Kurmann, 1983). The lowering of pH in the gut aids in excluding enteropathic bacteria such as *Escherichia coli*. In contrast, the fecal flora of the bottle-fed infant resembles that of older children and adults, with less than 70% bifidobacteria and a higher intestinal pH.

Sialic acid (a monosaccharide residue) appears to play an important role in brain development. Approximately half of the 130 or so oligosaccharides present in human milk are sialylated (Sabharwal, Sjoblad, & Lundblad, 1991). Animal studies have revealed a significant proportion of this monosaccharide in the developing brain, with decreased concentrations of sialic acid during this early period being associated with irreversible impaired learning behavior (Morgan, Oppenheimer, & Winick, 1981). Investigators have shown that a high concentration of sialic acid exists in human milk in the first week of lactation, coinciding with a time of rapid synthesis of brain sialylated glycoproteins (Miller, Bull, Miller, & McVeagh, 1994). Additionally, lactose is a readily available source of galactose,

which is essential to the production of the galactolipids, including cerebroside. These galactolipids are essential to the development of the central nervous system.

Water and Electrolytes

Water represents the constituent in the largest quantity in human milk, providing approximately 89 mL of preformed water in each 100 mL of milk consumed. Water is required by the infant to replace evaporative losses of water from skin and lungs and excretory losses from feces and urine. The first priority for water expenditures is for evaporative loss, and the second for urinary water necessary for the excretion of solutes. Estimated nonrenal water expenditures by full-term infants in a thermoneutral environment are presented in Table 33-2.

In the case of healthy full-term infants receiving adequate fluids, water intake is greatly in excess of requirements and diluted urine is excreted. At the same time, the amount of water excreted in the urine is determined by the renal solute load and renal concentrating ability. The sum of solutes that must be excreted by the kidney is termed the **renal solute load**. The renal solute load is of considerable importance in circumstances such as low fluid intake; abnormally high losses of water, for example, as those occurring with fever; hyperventilation; and diarrhea (Foman, 1993).

Sodium and chloride are major solutes of extracellular water, and potassium is a major solute of cellular water. The movement of water across cellular membranes and compartments occurs only as a result of the movement of these solutes. Absorption of amino acids and monosaccharides depends on absorption of sodium, and the intestinal secretions necessary for digestion of food are dependent on the secretion of chloride. Potassium is required for the transmission of nerve impulses and control of skeletal muscle contractility.

Estimates of requirements for sodium, chloride, and potassium (Table 33-3) are based on estimates of what is

Table 33-3 Recommended Daily Dietary Intake of Electrolytes for Healthy Infants

Age (mo)	Weight (kg)	Sodium (mg)	Chloride (mg)	Potassium (mg)
0–5	4.5	120	180	500
6–11	8.9	200	300	700
12	11.0	225	350	1,000
24	16.0	300	500	1,400

National Academy of Science. Food and Nutrition Board (1989) *Recommended Dietary Allowances*. Washington, D.C.: National Academy Press.

needed for growth and replacement of obligatory losses. These amounts depend on the rate at which extracellular fluid volume expands, a rate that varies with age.

The electrolyte compositions of human and bovine milks are given in Table 33-4. Human milk contains 7 mEq/L of sodium (range, 3 to 19 mEq/L) (Foman, 1993). Consumed at a rate of 750 mL/d, this provides the infant with an average of 120 mg/d (1.16 mEq/d per kilogram of body weight) from birth to 2 months of age and 0.8 mEq/d per kilogram of body weight from 3 to 5 months, which is considered more than sufficient. The potassium requirement for growth averages 65 mg/d for infants. An increase in lean body mass is a major determinant of potassium needs. Between 60 and 80 mEq are required for each kilogram of weight gained. The recommended dietary intake of chloride throughout the first year of life is 120 mg/d. The chloride intake of an infant consuming 750 mL/d of milk, providing 330 mg/L of chloride, is 248 g/d (Allen, Keller, Archer, & Neville, 1991).

Minerals

Calcium (Ca), phosphorus (P), and magnesium (Mg) homeostasis in the newborn involves hormonal influences that regulate the concentrations of these minerals in the infant. Most of the mineral content of the body is in tissues, with less than 1% of Ca, P, and Mg in the circulation.

Table 33-2 Nonrenal Water Expenditures of Full-Term Infants Under Thermoneutral Conditions at Different Ages

Route of Loss	Water expenditures (mL/d)		
	1 Mo	4 Mo	12 Mo
Evaporative loss	210	350	500
Fecal loss	42	70	105
Growth	18	9	6

Component (mg/dL)	Human	Bovine
Sodium	15	58
Chloride	43	103
Potassium	55	138

Table 33-5 Serum Concentrations of Minerals in Neonates

Mineral	Normal Range (mg/dL)
Calcium	8–11
Magnesium	2.1 ± 0.3
Phosphorus	4–7.1

Data adapted from Itani, O., & Tsang, R. C. (1991). Calcium, phosphorus, and magnesium in the newborn: Pathophysiology and management. In W. W. Hay (Ed.). *Neonatal nutrition and metabolism*. St. Louis, MO: Mosby.

However, serum concentrations are useful because fluctuations from normal ranges often are associated with clinical symptoms. Normal serum concentrations of these minerals are presented in Table 33-5.

Blood calcium concentration is maintained within very narrow limits by the interplay of several hormones (1,25-dihydroxycholecalciferol, parathyroid hormone, calcitonin, estrogen, and testosterone), which control calcium absorption and excretion as well as bone metabolism. The 1% of calcium not found in the bone is essential in nerve conduction, muscle contraction, blood clotting, and membrane permeability. These extra skeletal levels of calcium are maintained at the expense of bone in the face of inadequate calcium intake or absorption. In the event of such circumstances, resultant demineralization of bone and reduction in strength occur.

Calcium homeostasis is closely linked with that of P and Mg. Longitudinal studies measuring Ca and P in human milk and maternal and infant sera show progressive increases in infant serum Ca in association with decreasing P content in breast milk and infant serum (Greer et al., 1982). In addition, progressive increases in serum Mg levels were seen in breast-fed infants in association with decreasing P content of the milk. Ca and P decrease over time during lactation (Anderson, 1992). Human milk provides optimal Ca, P, and Mg content for bone mineral-

ization in term newborns. Cow's milk-based formulas generally have higher Ca content than does human milk to compensate for the poorer absorption rates of the formulas. Infants receive an average of 240 mg of Ca from 750 mL of human milk, approximately two thirds of which they retain. The retention of Ca from infant formulas based on cow's milk is less than one half. These differences in retention are reflected in the recommendations for Ca, P, and Mg for breast-fed and formula-fed infants outlined in Table 33-6.

Trace Elements

Whereas the macronutrients (protein, fat, carbohydrates, and major minerals) are essential components of body structure, energy sources and micronutrients provide protection against oxidative damage during cellular metabolism and have major roles in immune function. **Macronutrients** are any of the chemical elements, such as carbon, required in relatively large quantities for growth. **Micronutrients** are any of the chemical elements, such as iron, required in minute quantities for growth.

Iron, zinc, copper, manganese, selenium, molybdenum, chromium, and iodine are generally considered to be the essential trace minerals. Table 33-7 outlines the recommended daily intake of trace elements for infants.

Iron is a powerful oxidant and a constituent of hemoglobin, myoglobin, and a number of enzymes and, therefore, an essential nutrient for the infant. With stored iron, the term infant can maintain satisfactory hemoglobin levels from human milk without other iron sources during the first 4 months of life. After 6 months of age, infants should consume iron-fortified foods or iron-fortified formula to ensure adequate iron stores (Haschke et al., 1993). The recommended daily allowance (RDA) from 6 months to 3 years of age is set at 10 mg/d per kilogram of body weight for healthy infants and should not exceed a maximum of 15 mg/d. Iron deficiency anemia has been associated with impaired mental and motor development and should be prevented (Scheard, 1994).

Table 33-6 Recommended Dietary Intake of Calcium, Phosphorus, and Magnesium for Breast-Fed and Formula-Fed Infants

Age	1–6 mo		6–12 mo	
	Breast-Fed (mg)	Formula-Fed (mg)	Breast-Fed (mg)	Formula-Fed (mg)
Mineral

Zinc is an essential component of many enzymes and plays a role in cellular immune function (Prasad, 1991). Because full-term infants exclusively breast-fed rarely show signs of zinc depletion, requirements must be satisfied by maternal milk levels. During the first month of life, breast-fed infants consume an average of 2 mg/d of zinc (Casey, Neville, & Hambidge, 1989). The dietary zinc requirement of infants consuming formula is higher than that of breast-fed infants because of lower bioavailability of the formula (Lonnerdal, Cederblad, Davidsson, & Sandstrom, 1984). Assuming an intake of 750 mL/d of formula, the recommended intake for formula-fed infants is 5 mg/d of zinc.

The remaining trace elements have received less investigation but are no less important in the enzymatic activity of the body. One consistent finding from studies of levels of trace elements in human milk is their variability between individuals and stages of lactation.

Water-Soluble Vitamins

The water-soluble vitamins (B and C vitamins) are, for the most part, present in the serum and, as the name implies, the fluid compartments of the body. With the exception of vitamin B₁₂, these vitamins are typically excreted in urine when blood concentrations are too high. The RDAs for water-soluble vitamins for infants are presented in Table 33-8.

Vitamin C (ascorbic acid) functions primarily as an **antioxidant** and a **reducing agent**. An **antioxidant** is a substance that slows down the oxidation of hydrocarbons, oils, fats, and so on, thus helping to check deterioration. A **reducing agent** is a substance that reduces another one, or brings about reduction, and is itself oxidized in the process. As a reducing agent, vitamin C serves as a cofactor for a number of essential enzymatic reactions

Table 33-8 Recommended Daily Dietary Allowances for Water-Soluble Vitamins for Infants

Vitamin	0–6 Mo	6–12 Mo
Vitamin C	30 mg	35 mg
Thiamin	0.3 mg	0.4 mg
Riboflavin	0.4 mg	0.5 mg
Niacin	5 mg NE	6 mg NE
Vitamin B ₆	0.3 mg	0.6 mg
Folic acid	25 µg	35 µg
Vitamin B ₁₂	0.3 µg	0.5 µg

National Academy of Science. Food and Nutrition Board (1989). *Recommended Dietary Allowances*. Washington, D.C.: National Academy Press.

(Hornig, Moser, & Glatthaar, 1988). In addition, vitamin C enhances iron absorption from the GI tract. Human milk is a rich source of vitamin C, containing approximately 43 mg/100 mL. Concentrations of ascorbic acid in human milk are generally considered to average approximately seven times those in plasma (Cummings, 1981). It is recommended that infant formulas contain at least 8 mg/100 kcal of vitamin C, providing approximately 30 mg/d.

Thiamin primarily serves as a cofactor for three enzyme complexes involved in carbohydrate metabolism (Moran & Greene, 1987). RDAs for thiamin are based on the mean thiamin concentration in human milk plus 2 standard deviations, which is 0.3 mg/L, or 0.4 mg/1,000 kcal.

Riboflavin serves as an essential component of flavoproteins. Flavoproteins function as hydrogen carriers in a number of critical oxidation-reduction reactions, such as energy metabolism, glycogen synthesis, erythrocyte production, and the conversion of folate to its active coenzyme (Moran & Greene, 1987). Requirements for riboflavin are related to nitrogen intake. The dietary allowance from birth to 6 months of age is set at 0.4 mg/1,000 kcal.

Niacin is converted in the liver to the active cofactors that play central roles in body metabolism in a wide range of oxidation-reduction reactions, including glycolysis, electron transport, and fat synthesis (Moran & Greene, 1987). Human milk contains approximately 1.5 mg of niacin and appears to be adequate to meet the niacin needs of the infant. The niacin RDA for formula-fed infants up to 6 months of age is 8 NE (niacin equivalent) per 1,000 kcal.

Vitamin B₆ serves as a cofactor for a large number of reactions involved in the synthesis, interconversion, and catabolism of amino acids and neurotransmission (McCormick, 1989). Most of the vitamin B₆ in human milk is in the form of pyridoxal (Hamaker, Kirksey, & Borschel, 1990). There is 12 to 15 µg/100 mL of vitamin B₆ in human

Table 33-9 Recommended Daily Dietary Allowances for Fat-Soluble Vitamins for Infants

Age (mo)	Vitamin A ($\mu\text{g RE}$)*	Vitamin D (μg)**	Vitamin E (mg)	Vitamin K (μg)
0–6	395	7.5	3	5
6–12	375	10	4	10

*1 retinol equivalent (RE) of vitamin A equals 3, 33 IU.

**10 μg of vitamin D equals 400 IU.

milk and 64 $\mu\text{g}/100\text{ mL}$ in cow's milk. The RDA for infants under 6 months of age is 0.30 mg.

Folates function metabolically as coenzymes that transport single carbon fragments from one compound to another in amino acid metabolism and nucleic acid synthesis. Human and cow's milk both contain about 50 $\mu\text{g}/\text{L}$ of folate. The needs of infants are adequately met by milk from humans and cow's milk.

Vitamin B₁₂ functions as an enzyme in amino acid metabolism. The minimum RDA for infants is 0.3 $\mu\text{g}/\text{d}$ the first year of life, when growth is rapid.

Fat-Soluble Vitamins

Vitamins A, D, E, and K are the fat-soluble vitamins, differing from the water-soluble vitamins in several ways. Fat-soluble vitamins are found in the fat component of milk and other foods and tend to move into the liver and adipose tissue and remain there, rather than being excreted as are water-soluble vitamins. Table 33-9 outlines the RDAs for the fat-soluble vitamins.

Vitamin A is essential for vision, growth, cellular differentiation, reproduction, and the integrity of the immune system (Goodman, 1984; West, Rombout, Van der Zijpp, & Sijtsma, 1991). In vitamin A deficiency, a keratinizing metaplasia of the mucus-secreting epithelial surface occurs and can result in overgrowth of bacteria and secondary infections (Sommer, 1994). The RDAs made by various groups are 350 to 400 $\mu\text{g}/\text{d}$ (Joint Food and Agriculture Organization/World Health Organization Expert Committee, 1988, Food and Nutrition Board, 1989, Scientific Review Committee, 1990).

Vitamin D is essential for proper formation of bone and mineralization. The metabolite of vitamin D, 1,25-dihydroxyvitamin D, in concert with parathyroid hormone, is responsible for the mobilization and absorption of calcium, thereby promoting mineralization of the skeleton. Vitamin D is unique among nutrients because the body can synthesize it with exposure to sunlight. The level of 40 IU/100 mL, or 1.00 $\mu\text{g}/100\text{ mL}$, may provide adequate amounts in the fully breast-fed infant to meet the requirements of 400 IU, or 10 $\mu\text{g}/\text{d}$. The exception would be in-

fants whose mothers are not exposed to sunlight. It is recommended that these infants receive a daily supplement of 5 to 7.5 μg .

Vitamin E is an antioxidant similar in function to vitamin C but is fat-soluble. Its primary function is as a scavenger of free radicals, thereby protecting cellular membranes against oxidative destruction (Kelleher, 1991). Because the requirement for vitamin E is closely related to the intake of polyunsaturated fatty acids, the RDA of 3 mg for infants from birth to 6 months of age is based on the tocopherol concentration of human milk (Jansson, Akesson, & Holmberg, 1981).

Client Education

Bottle-Feeding the Neonate

- The bottle should be prepared (see Client Education: Preparation of Infant Formula) and allowed to come to room temperature, either by sitting out for half an hour or running warm water over the bottle.
- The neonate should be held in a comfortable position with the head elevated.
- The bottle should be held so the formula fills the nipple and no air is in the neck of the bottle (Figure 33-2).
- The infant should be burped at least twice during the feeding:
 - The infant may be upright on the shoulder.
 - The infant may be placed in a sitting position, with one hand supporting the chin and the other gently rubbing the back. This is the preferred position as it allows one to watch for regurgitation.
- After a few minutes, resume feeding.

A.

B.

Figure 33-2 Proper bottle position for feeding. A. The baby should be held in a comfortable position with the head elevated. B. The bottle should be angled so that the nipple is completely covered with milk, preventing the baby from sucking air.

Vitamin K is a group of compounds essential for the formation of prothrombin and other proteins involved in the regulation of blood clotting. Owing to the low concentrations of vitamin K reported in human milk ($2 \mu\text{g/L}$), it is recommended that exclusively breast-fed infants receive a supplement at birth. Additionally, infant formulas should contain $4 \mu\text{g}/100 \text{ kcal}$ of vitamin K (AAP, 1985).

BREAST-FEEDING

As previously stated, breast-feeding is the optimal choice of infant feeding by all major societies and agencies, including the AAP, American Dietetics Association, and WHO (Figure 33-3). These groups base their recommendations on the strong scientific evidence of decreased infant

mortality in developing countries and decreased morbidity in developed countries seen in exclusively breast-fed infants compared with those fed human milk substitutes.

Lactation is a complex physiologic process under neuroendocrine control, whereas breast-feeding is the process by which milk is transferred from the maternal breast to the infant. Understanding the difference in these two interrelated processes is important when counseling the mother. Most lactation and breast-feeding problems are preventable and can be overcome with proper knowledge and technical skills (see Chapter 30). Prenatal visits should include discussion about infant feeding issues to provide an opportunity for parents to make an informed choice by gaining information. Allowing for open discussion of the facts helps diffuse the guilt that lack of knowledge or lack of support

Figure 33-3 Breast-feeding is the method of choice for many new mothers.

from a physician or nurse about breast-feeding may cause. Studies have demonstrated that prenatal education and breast-feeding support from family, friends, and especially the infant's father, are associated with the mother's choice of breast-feeding, regardless of maternal age, ethnic group, educational level, or marital status. Prenatally, mothers are intensely focused on readiness for the birth experience, therefore breast-feeding instruction and information will need to be reviewed after delivery. The office and clinic environment can send a strong message to parents about the priorities of the clinician and staff. A clinic or hospital environment replete with formula advertisements in the form of posters, pads, and pencils gives a message that may undermine any verbal "lip service" paid to breast-feeding.

Critical Thinking

Bottle Propping

Feeding the infant by propping the bottle as the infant lies in the crib is not recommended. What are some of the reasons that this is not a good idea?

- The infant may regurgitate and aspirate the formula.
- Infants who nurse from propped bottles may develop bottle mouth syndrome.

Which other negative effects can you think of that are related to this manner of feeding?

COMMERCIAL INFANT FORMULA

No commercially processed infant formula has been developed that reproduces the immunologic properties, nutrient **bioavailability** (rate at which a nutrient enters the blood stream and is circulated to specific organs or tissues), digestibility, and nutritional effects of human milk. The composition of infant formula, however, has improved tremendously in the past 50 years as a result of a greater understanding of infant nutrient requirements, absorption, and metabolic activities. Continual research is under way to qualitatively enhance infant formulas (Lo & Kleinman, 1996).

When used as the sole source of infant nutrition, infant formula must meet all the energy and nutrient requirements for the healthy term infant. The AAP Committee on Nutrition has developed infant formula standards. The Food and Drug Administration regulations for infant formula are based on these standards. Additionally, the In-

Client Education

Preparation of Infant Formula

- The equipment should be gathered:
 - Bottles may be made of plastic or glass, or have plastic liners.
 - Nipples should allow a steady flow of formula but should not be so large as to cause the infant to swallow too fast.
 - Formula may be in ready-to-feed, concentrate, or powder form.
- The label should be checked to make sure the formula is in ready-to-feed or concentrate form.
- When powder or concentrate forms are used, they must be mixed according to the directions on the bottle.
- Either the ready-to-feed formula is poured directly into the bottles, or the concentrated or powdered formula is mixed in a clean container and then poured into the bottles.
- Once prepared, the formula may be stored in the refrigerator for up to 48 hours; if not used in 48 hours, it should be discarded.
- Formula may be left at room temperature for up to an hour and then should be discarded.

Research Highlight

Mothers' Ideas About the Infant Feeding Process

Purpose

To describe how mothers of preterm infants who were learning to nipple feed viewed their own as well as their infant's role in the feeding process.

Method

A descriptive, comparative study was undertaken in two neonatal intensive care units in the Midwest. A convenience sample of 22 mothers of very low-birth-weight infants was obtained. Interviews were undertaken in which mothers were rated on a 6-point scale concerning their thinking about their co-regulatory role in their infant's feeding. Videotapes also were obtained of the feeding procedure.

The instrument used for data collection was the Working Model of Feeding developed by Pridham, Schroeder, Van Riper, Thoyre, Limbo, & Mylnarczyk in 1999. It is a scale describing infant behaviors and maternal expectations concerning infant participation in feeding. The variables range from 1 in which infant participation in feeding is not regarded as a necessary or valued condition of feeding (the mother does not take the infant's perspective), through 6, in which the mother views the infant's participation as essential for the feeding to progress. Mothers with a score of 6 believed in being proactive during feeding to prevent distress and fatigue.

Findings

Scores ranged from 1 to 6, with a mean of 3.3 (SD = 1.4). Mothers with higher scores were more likely to be significantly older and their infants were at a younger gestational age at birth.

Understanding feeding from the maternal perspective may assist clinicians in developing strategies for teaching feeding skills. Rather than beginning teaching with how to feed, it may be more prudent to begin with examination of maternal ideas about learning to feed the infant at high risk.

Nursing Implications

Many times it is the nurse who has the initial contact with the mother who needs to begin feeding her infant who is at high risk after many days or weeks of alternative feeding methods. To discuss maternal attitudes before the onset of this process may eliminate significant barriers to the process.

Thoyre, S. M. (2000). Mothers' ideas about their role in feeding their high-risk infants. *Journal of Obstetric, Gynecologic, and Neonatal Nursing*, 29, (6), 613-624.

infant Formula Act mandates adherence to standards and quality control and requires that quantitative label declaration be made for 38 nutrients. The amount of each nutrient is added in formulas at higher concentrations than human milk to compensate for the lower bioavailability of nutrients from infant formula.

Commercially available infant formulas fall into several categories: 1) Standard cow's milk-based formulas; 2) soy-based and lactose-free formulas; 3) elemental, hydrolyzed protein, and free amino acid formulas; 4) premature infant formulas; and 5) specialty infant formulas, including those for metabolic disorders (Table 33-10). These formulas

come in powder, concentrate, or ready-to-feed forms. Health care providers should make sure that parents understand how to mix these formulas correctly to avoid hyperosmolar or overly dilute preparations, which can be dangerous (Wilcox, Florello, & Glick, 1993). When using a ready-to-feed formula after the infant is 6 months of age or living in an area with nonfluorinated water, a fluoride supplement may be required (AAP, 1985).

Standard cow's milk-based formula is the formula of choice for routine feeding when human milk or breastfeeding is not available (Klish, 1990) (Figure 33-4). These formulations modify whole cow's milk to reduce protein

Table 33-10 Commercial Infant Formula Selection

Formula	Criteria
Standard, cow's milk-based	Human milk not available
Soy, lactose-free	Galactose deficiency Vegan
Elemental, protein hydrolysate	Cow's milk allergy Intestinal malabsorption
Premature	Premature, low-birth-weight infants
Specialty	Metabolic disorders

and renal solute load. There are two categories, namely, casein predominant and whey predominant. Cow's milk is 80% casein and 20% whey, and the formulas derived from this are called casein predominant. Whey predominant formulas have been developed to provide a protein composition like that of human milk, 40% casein and 60% whey.

Figure 33-4 One of the benefits of bottle-feeding is that other family members, including siblings, can share in the responsibility of feeding the baby.

Nursing Alert

CLEAN BOTTLES

It is important to make sure that the bottles are clean and contain no dried milk before sterilization, because this can contaminate the formula. Bottles can be washed in the dishwasher.

These “humanized” formulas are prepared by combining nonfat cow's milk with demineralized whey, a by product of cheese. In both types of standard formulas, lactose is added to provide a more appropriate energy ratio. Vegetable oils, as long-chain triglycerides, are added next as a fat source. To ensure adequate essential fatty acid intake, formulas should provide a minimum of 1% to 3% linoleic acid per kcal (ESPGN, 1991). Formulas have yet to include cholesterol or long-chain polyunsaturated fatty acids. At one quart of intake, 100% of the RDA can be met for vitamin and minerals. Iron-fortified standard formulas generally are well tolerated (Nelson et al., 1988) and should be used to provide adequate iron. With a caloric density of 67 to 70 kcal/dL (20 kcal/oz) these formulas should be offered as needed. The usual intake of 150 to 200 mL/d per kilogram of body weight provides 100 to 130 kcal/d per kilogram of body weight, resulting in a goal target weight gain of 20 to 30 g/d.

Soy-based, lactose-free formulas (ProSobee, Mead-Johnson; Bristol-Myers Isomil, Ross) originally were made from soy flour. Currently, manufacturers use a water-soluble soy protein isolate, which is purified to over 90% protein. Methionine is added to complete this protein. Corn syrup or sucrose is used as the carbohydrate source. These formulas are recommended to be used for their lactose-free status in infants with galactosemia lactose intolerance or vegetarian practices (AAP, 1983). However, these formulas are not designed for infants with cow's milk allergy because 30% of these infants also will be allergic to the soy protein. These formulas also are not recommended for preterm infants because the phytate fiber in the soy com-

Nursing Tip

COST OF FORMULA

Powdered or concentrated formula is less expensive than the ready-to-feed form.

Nursing Alert

WATER FOR FORMULA

If the water supply is not purified or there is any question about cleanliness, then:

1. Bottled or boiled water should be used to prepare the formula.
2. The equipment should be sterilized.

promises nitrogen and mineral balance for babies at high risk (Shenai et al., 1981). Calorie, protein, vitamin, and mineral needs can be met for infants consuming 1 qt/d. Also available is Lactofree (Mead-Johnson; Bristol-Myers) which is a lactose-free, protein formula from cow's milk.

Elemental, protein hydrolysates (Nutramigen and Pregestimil, Mead-Johnson Bristol-Myers; Alimentum, Ross) are designed to meet the needs of infants with documented cow's or soy protein allergy (Kleinman, Bahna, Powell, & Sampson, 1991; AAP, 1989; Lee & Heiner, 1986).

These formulas also have been used for infants with malabsorptive problems (Schwartz & Maedak, 1985). Manufacturers enzymatically hydrolyze the casein protein to remove large proteins that will be allergenic. The goal is to contain proteins of less than 1,200 molecular weight to be truly hypoallergenic. Free amino acids (L-cysteine, L-tyrosine, and L-tryptophan) are added to compensate for those removed in processing. A whey hydrolysate, i.e., Good Start (Carnation), is available but may contain proteins with molecular weights higher than 2,000 and may not be truly hypoallergenic. Infants that continue to exhibit bloody stools or cow's milk intolerance on the hydrolysate may benefit from free amino acid infant formulas (Vanderhoof et al., 1997). Neocate is a powdered infant formula composed of free amino acids, maltodextrins, long-chain triglycerides, medium-chain triglycerides, vitamins, and

minerals that has been found to provide a safe, hypoallergenic source for infants who are allergic to the hydrolysates (Sampson, James, & Bernhisel-Broadbert, 1992).

The casein protein hydrolysates (Pregestimil and Alimentum) contain the carbohydrate source as glucose polymers and the fat source as a blend of long- and medium-chain triglycerides. The medium-chain triglycerides are added to enhance absorption because they do not require pancreatic lipase or bile salts for digestion. The formulas Nutramigen and Good Start do not contain medium-chain triglycerides. Vitamins and minerals are added to provide

Client Education

Methods for Infant Formula and Equipment Sterilization

Bottles must be sterilized if there is any question about the cleanliness of the water. There are two methods of bottle sterilization

Terminal Method

- The equipment is washed with soap and water.
- The formula is prepared according to directions.
- Bottles are filled; nipples are inverted, with caps loosely applied.
- Bottles are placed in a large pan, with 2 to 3 inches of water or in a bottle sterilizer.
- The pan is covered, and the water is boiled for 25 minutes.
- The bottles are allowed to cool, the lids screwed on, and the bottles stored in the refrigerator.

Aseptic Method

- The equipment is washed in soap and water and placed in a large pan or sterilizer.
- The equipment is boiled for 5 minutes.
- The water for mixing the formula is boiled separately for 5 minutes.
- The equipment is removed with tongs, and the formula is mixed in the sterilized pitcher.
- The prepared formula is poured into the bottles, lids applied, and stored in the refrigerator.

Nursing Alert

FOOD ALLERGY SYMPTOMS

1. Skin symptoms, such as swelling, hives, and skin rashes.
2. Colicky behavior, diarrhea, and blood in the stool.
3. Stuffy nose, and breathing difficulties.
4. Swelling of the mucous membranes of the mouth.
5. Anaphylactic shock.

100% of the RDAs for infants when intake is approximately 32 oz/d. Refer back to Table 33-1 for nutrient components.

Specialty formulas are made for infants with severe nutrient sensitivities (e.g., 3232A), or specific inborn errors of metabolism (e.g., phenol-free for infants with phenylketonuria). These products should only be used in consultation with a metabolic dietician and are beyond the scope of this review.

Premature formulas (Enfamil Premature Formula, Mead-Johnson; Similac Special Care, Ross) are designed specifically for the immature infant at high risk (Figure 33-5). Low-birth-weight infants are born without the benefit of the last trimester's supply of fat, minerals, and trace elements; therefore, requirements for intake are specialized to meet their needs (Neu, Valentine, & Meetze, 1990). Protein is more concentrated (2.2 to 2.4 g/dL) and contains 60% whey and 40% casein to provide enhanced digestibility and a better amino acid pattern. The carbohydrate source is a blend of 40% to 50% glucose polymers, with the remainder as lactose. Replacing half the lactose as glu-

cose polymers allows the formula to have an isosmolar formulation. Oil made up of long- and medium-chain triglycerides enhances digestibility. These 24 kcal/oz formulas with iron are recommended at an intake of 150 mL/d per kilogram of body weight to provide 100% of the RDAs of vitamins and minerals for preterm infants weighing less than 2,000 g and less than 35 weeks' gestation.

INTRODUCTION OF SOLID FOODS AND WEANING

Weaning is generally the term used to describe the introduction of semisolid or solid foods to the breast-fed or formula-fed infant. Several factors influence the introduction of solid foods and the weaning process, including the nutritional requirements of the infant, development and maturation of the infant, and foods available to supply the nutrients (Stordy, Redfern, & Morgan, 1996).

The introduction of semisolid foods should not take place too early for several reasons. Developmentally, the infant has an extrusion tongue reflex until 4 to 6 months of age, making solid feeding inappropriate. This protective reflex results in the infant pushing out with the tongue any semisolid or solid bolus of food. The practice of solid additions to the bottle, or so-called infant feeders, should also be avoided. In addition, solid foods add to the renal solute load and may contribute to higher plasma concentrations of sodium and urea (Wharton, 1996). As a result the infant will either reduce milk intake, which will compromise normal growth and development, or consume more calories than are needed, increasing the risk of childhood obesity. Some parents have started solids early believing that this practice will help the infant sleep through the night. However, feeding infants solids at bedtime is not related to nighttime sleeping patterns. Several well-controlled studies found that infants who receive solids before bedtime have the same sleep patterns as those who do not receive solids (Keane, Charney, Straus, & Roberts, 1988; Macknin, Medendorp, & Maier, 1989).

Conversely, the introduction of solids should not be delayed much beyond 6 months of age (AAP, 1980). For the breast-fed infant, mother's milk alone may be insufficient to meet the recommended energy and nutrient

Figure 33-5 Special formulas are available for premature and high-risk infants.

Nursing Alert

CHOKING PREVENTION

Avoid small items that can easily lodge in infant's airway, such as grapes, nuts, popcorn, watermelon, and seeds. Hotdogs also should be avoided.

VITAMIN SUPPLEMENTS

Generally, routine vitamin supplements are not necessary for the fully breast-fed or formula-fed infant drinking 32 oz/d. Breast-fed infants receiving a limited amount of sunshine may require 400 IU/d of vitamin D. After 4 to 6 months, both breast-fed and formula-fed infants need iron; however, this need can be met by an iron-enriched diet or iron-fortified formula. Fluoride supplementation at 0.25 mg/d should be started once the teeth erupt (Foman and Ekshard, 1993) if the infants does not receive an adequate source of fluorinated water (AAP, 1986). Parents and caregivers should call their local water service to check how much fluoride is in the water.

needs, particularly in terms of vitamin D, iron, zinc, and copper. In addition, some infants who have not started to take food from a spoon by 6 months of age subsequently show considerable delay in adapting to the chewing and tongue-rolling action of the weaning from the milking action of the suckling.

Most mothers initially use manufactured weaning foods because of their convenience and their physical and nutritional properties. Because of the infant's need for iron at 6 months, iron-fortified rice cereal should be introduced first in quantities of 1 to 2 tablespoons/d mixed with breast

milk or formula (Poskitt, 1983; AAP, 1980). One food at a time should be introduced, waiting at least 3 days between each new food to watch for allergic reactions (e.g., hives, wheezing, gas, and blood in the stool). Oatmeal and barley cereal can then be introduced into the diet, again with portion sizes of 1 to 2 tablespoon per day. Orange, yellow, and green vegetables should be used next to provide increased vitamin A and C. Fruits can then be initiated, avoiding citrus fruits (e.g., oranges and orange juice) until after 9 months of age. At 8 months of age, egg yolks and meats can be added to the diet. Avoid egg whites and fish until after 1 year of age because these foods can be highly allergenic. See Table 33-11 for a suggested schedule for introducing solid foods.

Foods based on the parents' meals usually are introduced next. Care should be taken to ensure food is small or mashed into pieces suitable for the baby. Cultural differences can play a role in the diet. Thus, caution should be observed when using home-prepared dishes that often are high in fat, carbohydrates, and sodium and low in iron and vitamin D (Stordy, Redfern, & Morgan, 1995; Mills & Tyler, 1992).

Careful attention to food preparation is essential when using commercially prepared foods to avoid exposure to botulism or lead from cans. Honey should be avoided because botulism spores tend to contaminate this product and can make the infant very ill. Other foods to avoid include nuts, grapes, popcorn, hard chopped carrots, celery, white bread (which can be very sticky), hard candy, and seeds. Cow's milk is recommended to begin after 1 year of age (AAP, 1992). Infants that begin too early are found to be iron deficient. Cow's milk also is inadequate source of folate, copper, linoleic acid, and vitamin C.

Infants on vegan diets should be assessed by a nutritionist because energy, protein, vitamins D, vitamin B₁₂, calcium, and zinc can be limited in their meals (Nutrition

Critical Thinking

Infant Nutrition

You are asked to attend medical rounds in the neonatal unit. Infant nutrition is discussed. Several of the nurses, doctors, and residents have questions about the comparison of human milk and prepared formulas. How will you prepare for a continued discussion of this topic the next week?

- When comparing the constituents of human milk and formula, what are the benefits of human milk?
- What are some of the specialty formula preparations, and how do they differ from standard infant formula?
- What are some of the reasons that prepared formula would be used or recommended?

Table 33-11 Recommended Timetable for Introducing Solid Foods

Age (mo)	Goal Intake
6	1–2 tablespoons/d of iron-fortified rice cereal, increase to 4–5 tbsp/d, rice, oatmeal, or barley
7	Add 1–2 tbsp/d of yellow, green, or orange vegetables
8	Add 1–2 tbsp/d of strained meats or egg yolk
12	Add whole cow's milk Egg whites Seafood Orange juice

Box 33-1 Sample Menu for a 7-Month-Old Infant

A.M.	6 oz of milk
10 A.M.	2 oz of apple juice
Noon	1–2 tbsp of rice cereal 1–2 tbsp of apple juice mixed in cereal 6 oz of milk
3 P.M.	1–2 tbsp of banana
Dinner	1–2 tbsp of rice cereal 1–2 tbsp of strained squash or pumpkin
Evening	6 oz of milk

Standing Committee of the British Pediatric Association, 1988). Menus and supplements should be provided to the caregivers to help them plan adequate nutrition. A sample menu for a 7-month-old infant is presented in Box 33-1.

NURSING IMPLICATIONS

The nurse needs to assess the particular nutritional needs of the infant. Prematurity, metabolic disorders, or sensitivities may require a specialized formula. The nurse also needs to assess the parent's choice of feeding. It is important to discuss this decision because the mother may have made the decision without adequate knowledge. Once these data have been gathered, the nurse may formulate nursing diagnoses regarding the infant's intake and the

mother's knowledge and ability to feed the infant. Interventions may involve using a variety of techniques to deliver formula and trying different types of formula preparations. One of the most important interventions is to teach the mother to safely feed the infant, whether breastfeeding (covered in Chapter 30) or formula feeding. The nurse must monitor the infant feeding to ensure the infant is receiving adequate nutrition. The nurse can determine if the mother is able to prepare and properly feed her infant.

Web Activities

- Visit the websites of some of the formula manufacturers mentioned in this chapter. Compare the nutrient values they advertise for the different types of formula they offer, such as soy, nonfortified, and the like.
- Find a La Leche League contact or support group in your geographic area by first visiting their web site.
- Go to www.tdh.state.tx.us/lactate/ position. Discuss your findings.
- What sources are available on the web that provide information about W.I.C.?

Key Concepts

- There are significant differences related to growth and development when comparing breast-fed and formula-fed infants.
- The nurse is expected to be able to assess adequate milk intake in the exclusively breast-fed infant during the first few weeks of life.
- Parents need to know how to assess early hunger cues in their newborn infant.
- Infant formulas are designed to meet the energy and nutrient requirements based on human milk as the gold standard or attend to particular needs such as prematurity and allergies.

Review Questions and Activities

1. Scientific evidence is emerging that relates the early diet of infants with long-term consequences. Which of the following are found in human milk but not in formula?
 - a. Glucose
 - b. DHA (docosahexaenoic acid)
 - c. Sodium
 - d. Magnesium

The correct answer is b.
2. The milk protein whey is much easier to digest than is casein. In comparing human milk with bovine milk (the base for many formula preparations), the whey-to-casein ratio is different. Which ratio of whey to casein is best representative of human milk?
 - a. 70:30
 - b. 50:50
 - c. 18:82
 - d. 40:60

The correct answer is a.

3. Which of the following statements about fat content in human milk is true?
 - a. The fatty acid DHA is not dependent on maternal diet.
 - b. Cholesterol levels are low in human milk.
 - c. The fat content in human milk is consistent across feedings and individual mothers.
 - d. Long-chain fatty acids in human milk have been related to cognitive function and vision.

The correct answer is d.

4. Infants need adequate carbohydrate intake for the following reasons with the exception of which?
 - a. Energy for metabolism
 - b. Energy for colonic bacteria
 - c. Brain development
 - d. Protein catabolism

The correct answer is d.

5. What are the fluid and electrolyte consequences of feeding an infant concentrated formula?

Newborns at Risk Related to Birth Weight and Premature Delivery

Nursing care of infants who are at risk for health problems related to low or high birth weight or to prematurity present unique nursing challenges. Although advances in care have improved survival, these infants are medically fragile. To work with these fragile infants, the nurse must be an advocate for neonates who cannot speak for themselves. Caring for these infants means being sensitive to the family unit as a whole. Use the following questions to examine your personal feelings about issues that may affect your response to the infant and family.

- ❖ How do I feel about caring for an infant with potential long-term morbidity related to complications of prematurity?
- ❖ How can I facilitate the development of parent-infant bonding when an infant is severely ill?
- ❖ How do I feel about caring for an infant who has extremely low birth weight?
- ❖ Which ethical considerations should be considered in caring for a premature infant?
- ❖ How small is too small?

Key Terms

Air-block syndrome	Gavage feeding	Low birth weight (LBW)	Prematurity
Apnea	Hyaline membrane disease (HMD)	Necrotizing enterocolitis (NEC)	Preterm birth
Asymmetric intrauterine growth restriction	Hyperglycemia	Nephrocalcinosis	Postconception age
Auditory brain evoked response	Hyperkalemia	Neutropenia	Respiratory distress syndrome (RDS)
Bilirubin	Hypernatremia	Opsonization	Retinopathy of prematurity (ROP)
Bronchopulmonary dysplasia (BPD)	Hypoglycemia	Osteopenia	Short bowel syndrome
Containment	Hypokalemia	Patent ductus arteriosus (PDA)	Small for gestational age (SGA)
Disseminated intravascular coagulation (DIC)	Hyponatremia	Perinatal asphyxia profound	Symmetric intrauterine growth restriction
Dysmotility	Intrauterine growth restriction (IUGR)	Periventricular leukomalacia (PVL)	Total parenteral nutrition (TPN)
Extremely low birthweight (ELBW)	Intraventricular hemorrhage (IVH)	Persistent pulmonary hypertension in the newborn (PPHN)	Ventricular peritoneal shunt (VPS)
Gastroesophageal reflux (GER)	Jaundice	Plethora	Very low birth weight (VLBW)
	Large for gestational age (LGA)	Pneumatosis intestinalis	

Competencies

Upon completion of this chapter, the reader should be able to:

1. Compare the clinical characteristics of the infant who is small for gestational age with those of the premature infant.
2. List the problems that frequently affect the preterm infant.
3. Develop a plan of care for the infant who is small for gestational age.
4. Develop a plan of care for the infant who is large for gestational age.
5. Discuss parental challenges related to caring for their premature infant.
6. Illustrate the techniques and strategies that can be used to facilitate parent-infant bonding.
7. Discuss alternative care modalities for the premature infant.
8. Understand the ethical issues that may arise when providing care for the premature infant.
9. Review the long-term medical needs of infants who are small for gestational age or premature.
10. Discuss the rationale for thorough discharge planning to meet the needs of these infants.

This chapter highlights infants who are at risk as a result of low birth weight (LBW), birth weight higher than expected for a given gestational age, and prematurity. Infants who are born at birth weights below or above normal for their **postconceptional age** (age from conception described in weeks) are referred to as having intrauterine growth restriction (IUGR), being

small for gestational age (SGA), or being large for gestational age (LGA). These conditions place the infant at risk for health problems, particularly when the infant also is premature. Although alterations in birth weight and prematurity may affect the same infant, the concepts are discussed separately for clarity.

THE SMALL FOR GESTATIONAL AGE INFANT

Infants termed **small for gestational age (SGA)** are those whose birth weight is lower than expected for the infant's gestational age. These infants are at high risk for multiple problems, including growth delays, feeding problems, thermoregulatory problems, respiratory problems, developmental delays, vision disturbances, and hearing impairment. The potential also exists for disruption of parent-infant bonding (Bernstein, Heimler, & Sasidharan, 1998). Nurses caring for mothers and their newborns should understand the unique challenges these infants and their families face.

Low birth weight often is linked to prematurity (post-conceptual age of less than 37 weeks). Infants who are premature have a number of risk factors related to gestational age (Figure 34-1). They also may have risks associated with birth weight that have long-term effects on the infant's health and the family unit. A group of infants at risk for problems separate from and often in conjunction with prematurity are those who are SGA. The infant who is SGA has not met the expected growth parameters for the gestational age at birth. The term implies that some intrinsic or extrinsic factor has affected the ability of the fetus to meet usual growth parameters.

It is important to recognize that the infant who is SGA is at risk for stillbirth, perinatal morbidity, and adverse effects in adulthood (Gardosi, 1997). These infants often require early delivery secondary to a hostile uterine environment. The fetus is compromised by deprivation of adequate nutrients and oxygen and is at risk for intrauterine death (Schaap et al., 1997).

Figure 34-1 These male triplets were delivered before 37 weeks' gestation; now, at 6 weeks of age, they are each showing different rates of growth and weight gain.

The term **low birth weight (LBW)** can be defined as a birth weight less than 2,500 g. Each year, 20 million term infants are born with birth weights under 2,500 g (de Onis, Blossner, & Villar, 1998). The infant who is SGA has not achieved his genetic growth potential (Goldenberg & Cliver, 1997). Other terms used interchangeably with SGA are dysmaturity, fetal growth restriction (FGR), and intrauterine growth restriction (IUGR).

Intrauterine Growth Restriction

The term **intrauterine growth restriction (IUGR)** generally is reserved for infants who are at less than the 10th percentile at birth on standardized graphs in weight, length, and head circumference. Each year 30 million newborns are born who have growth restriction (de Onis, Blossner, & Villar, 1998). IUGR is classified as symmetric and asymmetric.

Symmetric Intrauterine Growth Restriction

The term **symmetric IUGR** is used when the measurements of the head, weight, and length are less than the 10th percentile. Symmetric IUGR implies that the cause of the growth restriction occurred early in pregnancy and was genetic or intrinsic in nature. Symmetric IUGR is more likely to result from an intrinsic cause, that is, something that affects the fetus from within and starts early in gestation. A poor prognosis is associated with major chromosomal disorders and congenital infection.

Asymmetric Intrauterine Growth Restriction

The term **asymmetric IUGR** is used when the measurements of the head circumference and length are in a higher percentile than is the measurement for weight. This growth pattern occurs later in pregnancy than does symmetric IUGR and may be caused by placental insufficiency, maternal malnutrition, or other extrinsic factors. Extrinsic factors are those that affect the fetus from the outside, such as maternal hypertension and low caloric intake. Outcomes are better in infants who have asymmetric IUGR compared with those who have symmetric IUGR. Asymmetric IUGR is more likely to be caused by extrinsic factors than is symmetric IUGR.

Factors Associated with Fetal Growth Restriction

A number of factors may affect fetal growth, including fetal, maternal, and placental factors. Some of these factors

are listed in the Nursing Alert. FGR may affect perinatal mortality and the infant's short and long-term morbidity.

Fetal Factors

Fetal factors are those that affect the genetic growth potential of the fetus. This potential may be affected by normal variations, such as race and gender. Multiple gestation also is associated with FGR (Goldenberg & Cliver, 1997; Sherear & Devon, 1997).

Infants with chromosomal anomalies such as trisomy 13 (Patau syndrome), trisomy 18 (Edward syndrome), trisomy 21 (Down syndrome) may be SGA. Congenital malformations such as anencephaly, gastrointestinal (GI) atresia, renal agenesis, and some cardiovascular defects may be implicated in LBW. Congenital infection may be implicated in infants who are SGA. Rubella may cause damage during organogenesis and may cause a decrease in cell number. Cytomegalovirus is associated with cytolysis and localized necrosis (Naeye, 1967). Inborn errors of metabolism, such as transient neonatal diabetes, galactosemia, and phenylketonuria, are associated with small fetal size.

Maternal Factors

Maternal factors include maternal hypoxemia, such as sickle cell disease, respiratory disease, cardiovascular disease, and living in a high-altitude environment. Other maternal factors include short stature, young maternal age, low socioeconomic status, primiparity, grand multiparity, and low pregnancy weight. Maternal exposure to teratogenic agents, such as alcohol, cigarette smoke, and anticonvulsant medications also may be implicated.

Placental Factors

Placental insufficiency is the leading cause of infants who are SGA because of the delivery of inadequate nutrients for appropriate fetal growth. Other physical attributes of the placenta and placental circulation also may affect fetal growth. Multiple infarcts, aberrant cord insertions, and small placental size may affect fetal growth.

Complications Associated with the SGA Infant

Infants who are SGA are at risk for many problems that range from perinatal asphyxia to hypoglycemia. Knowing that an infant is SGA can help anticipate, prevent, or provide early intervention for problems the infant may face. To determine whether an infant is at risk for the complications of the SGA infant the gestational age must be determined.

Assessment

Information from ultrasonography can be useful in establishing the predelivery diagnosis of IUGR. The fetal bipari-

etal diameter, abdominal circumference, and femur length provide the obstetrician with information to determine appropriate fetal growth. Information from ultrasonography regarding placental morphology and amniotic fluid assessment and Doppler evaluation of blood flow through the umbilical vessels may contribute to determining the cause of the FGR and assessing the well-being of the fetus before delivery. Fetal lung maturity studies may identify potential respiratory problems at birth.

At birth the infant must be weighed and measured carefully. These measurements are then used to plot the infants' growth against standardized charts. The Colorado Growth Chart frequently is used in the United States (Battaglia & Lubchenco, 1967). Calculating the ponderal index is another way of determining appropriate growth (weight in grams divided by length to the third power). When the gestational age is in question the Ballard or New Ballard Score (Figure 34-2), which has been expanded to include extremely premature infants, may be used to help determine gestational age.

Care

Once the infant has been determined to be SGA, steps may be taken to anticipate problems and provide early intervention. Complications may include prematurity, birth asphyxia or birth depression, thermal instability, metabolic imbalances, and hematologic concerns. Birth depression encompasses infants who have low HR at birth. These infants may require intervention from caregivers to establish adequate HR and respirations.

At birth the infant is at risk for hypoxia from perinatal asphyxia profound, persistent pulmonary hypertension, and meconium aspiration syndrome. **Perinatal asphyxia profound** is metabolic acidosis at birth associated with

NEWBORN MATURITY RATING & CLASSIFICATION

ESTIMATION OF GESTATIONAL AGE BY MATURITY RATING

Apgar scores of 3 or less that persist after 5 minutes, multi-system organ dysfunction, and neurologic manifestations. **Persistent pulmonary hypertension in the newborn (PPHN)** is a condition in which abnormally elevated vascular pressures result in continuation of flow through fetal

blood pathways such as the ductus arteriosus and foramen ovale. These infants should be delivered in a location where immediate access to resuscitation equipment and personnel who are expert in the resuscitation of high-risk newborns are available.

Once born, the infant should be stabilized and complications such as hypothermia, hypoglycemia, hypocalcemia, polycythemia, and hyperviscosity should be anticipated, screened for, and corrected early. The infant who is SGA should be observed for respiratory distress and care rendered as needed. Prevention of heat loss is essential. Blood glucose levels should be checked and hypoglycemia corrected promptly. A central hematocrit measurement also is important.

A physical examination should be performed to screen for congenital anomalies. When present, the family should be referred to appropriate specialty services, such as cardiology or genetics. Screening for congenital infection also may be indicated.

Outcome and Follow-up

The mortality risk is significantly higher for the infant who is SGA compared with the infant who is appropriate for gestational age. The infant who is SGA shows more gross motor and minor neurologic dysfunctions over time. Cognitive function also is lower for the infant who is SGA than for the infant who is appropriate for gestational age (Kok et al., 1998). The infant's outcome is determined by the cause of the growth restriction.

An association of cardiovascular and metabolic disorders in adulthood has been made with the infant with IUGR. More research is needed to improve the understanding of the pathophysiology, background, and long-term effects of the intrauterine environment (Barker, 1997; Westgren, Lingman, & Persson, 1997).

THE LARGE FOR GESTATIONAL AGE INFANT

In addition to infants who have low birth weights, those born at birth weights greater than expected for that gestational age may be at significant risk for complications. These complications may occur in utero, during delivery, or postnatally. Infants who are **large for gestational age (LGA)** have birth weights greater than the 90th percentile or 2 standard deviations above the mean weight for gestational age.

Associated Factors

Infants who are LGA are associated with diabetic mothers, are born to parents who are large, congenital syndromes such as Beckwith-Wiedemann syndrome or fetal complications such as hydrops fetalis. Mothers who have diabetes or Beckwith-Wiedemann syndrome produce hyperinsulinemic states in utero, thereby causing increased glucose levels in the fetal environment and resulting in increased weight gain by the fetus.

Complications

Infants who are LGA are at risk for macrosomia and resultant cephalopelvic disproportion. Cephalopelvic disproportion may result in difficult vaginal delivery secondary to the inability of the infant to pass through the birth canal, resulting in birth asphyxia or birth trauma. Birth trauma may include brachial plexus injury, a fractured clavicle, facial palsy, shoulder dystocia, or subdural hemorrhage. Postnatally, infants who are LGA are at risk for hypoglycemia, polycythemia, hyperbilirubinemia, respiratory distress, and cardiac and congenital anomalies.

Assessment and Care

Nursing care of the infant who is LGA includes assessment for birth injury or respiratory difficulty, monitoring of glucose levels and other laboratory values, and management of any of these potential medical problems. Parents should be apprised of the potential complications and informed of changes in the infant's condition. Allowing parents to participate in the care of their infant assists in the bonding process.

THE PREMATURE INFANT

Preterm birth or **prematurity** is defined as delivery before 37 weeks' gestation. Approximately 8% of all births in the United States are preterm (AAP, ACOG, 1997).

Neonatal care has changed dramatically over the past two decades. In the 1980s, viability in infants was defined as those born at 28 weeks' gestation or later. In the 1990s, infants born at 24 to 25 weeks' gestation were surviving with less morbidity. These changes are due to technical advances in ventilatory management, better understanding of the needs of the preterm infant, and improvement in neurodevelopmental care.

Factors Associated with Preterm Delivery

Care of the preterm infant continues to be a challenge in the health care arena. Prematurity continues to be the leading cause of perinatal mortality in the United States (AAP, 1999). Many risk factors are associated with preterm labor and delivery. Some of these risk factors can be attributed to previous maternal history of a preterm birth, a spontaneous abortion, an incompetent cervix, or other uterine anomalies. Factors that occur during the pregnancy that put a woman at risk for preterm labor and delivery include multiple gestation (Figure 34-3), infection, premature rupture of membranes, adolescent pregnancy, polyhydramnios, and oligohydramnios (AAP, 2000).

Figure 34-3 Multiple gestation is one risk factor for preterm delivery.

The lack of prenatal care also plays a role in preterm labor and delivery. Maternal habits, such as cigarette smoking, substance abuse, and poor diet, and social status also are areas in which we can change and improve outcomes.

Assessment of the Preterm Infant

Assessment of the high-risk infant is an important role of the bedside nurse. A systematic approach to the physical assessment of high-risk infants allows the neonatal nurse to determine the infant's condition and approximate gestational age quickly and efficiently. Continued evaluation reveals subtle changes that allow the caregiver to anticipate and manage problems early. It is important to determine the gestational age of the infant because doing so will provide valuable information in interpreting the physical examination and planning age-appropriate care. The physical examination also is important in the assessment of a premature infant. A careful head-to-toe assessment is important to determine the infant's condition. Ongoing observation allows the nurse to quickly recognize problems before they compromise the infant's well-being.

Gestational Age Assessment

Knowing the infant's gestational age assists the caregiver in anticipating problems that may occur after delivery. Gestational age must be considered in evaluating posture

muscle tone. Many details go into the assessment of an infant's gestational age. The results of the infant's examination may be compared with charts developed by Dubowitz and Ballard, who use a scoring sheet to evaluate neurologic characteristics, such as posture, and physical characteristics, such as skin thickness, to estimate the infant's gestational age (Ballard et al., 1991).

Neurologic Assessment

Neurologic assessment of the newborn includes evaluation of tone, activity, and reflexes. Tone develops by way of a caudalcephalic route. Knowing how reflexes mature with progressing gestational age can aid the nurse in developing a plan of care. For example, an infant's sucking reflex is evident at about 32 weeks postconception; however, a coordinated suck-swallow-breath pattern may not develop until about 34 weeks postconception. Encouraging nonnutritive sucking at 32 weeks postconception and introducing oral feedings at about 34 weeks postconception would be included in the care plan of an infant born at less than 32 weeks' gestation.

Physical Characteristics

The skin of a premature infant can be a clue to gestational age. Thin gelatinous skin is associated with infants who are less than 26 weeks' gestation. The skin becomes thicker and less translucent with increased gestational age. The presence or absence of lanugo, plantar creases, breast tissue, and ear cartilage provides other clues to the infant's gestational age (Figure 34-4). Eyes are fused before 24 weeks' gestation. Eyelashes and eyebrows appear at 20 to 23 weeks' gestation. Hair is fine and woolly and sticks together at 28 to 34 weeks' gestation. Before 28 weeks' gestation, the preterm female infant may have a prominent

Figure 34-4 This preterm infant still has excess hair on the face, back, and arms.

REFLECTIONS FROM A NURSE

"As I wheeled the neonatal transport incubator into the recovery room I mentally prepared myself. I knew it would be a difficult first meeting for this baby and her mother. The mother had been in the hospital for 3 weeks now because of premature labor. It had seemed that the contractions were controlled, at least until tonight. The delivery was very fast; Dad didn't even have time to get to the hospital before the baby was born.

The baby was born at just 26 weeks' gestation, but smaller than expected. So many problems can affect a baby this size. We had to take her to the stabilization area right away; there was no time to show her to her mother. She needed to be warmed, to get oxygen, to be placed on a ventilator, to have IV access—these things are critical in the first minutes of a premature infant's life.

As I looked down at the baby I sighed. Even to me she looked tiny and helpless. A tube in her mouth was secured with tape, almost obscuring her face. Wires attached to electrodes were attached to her chest; a temperature probe was taped to her abdomen. An umbilical artery line for monitoring blood pressure and drawing blood for

laboratory tests and an umbilical venous line for administering intravenous fluids and medications were inserted into her umbilical cord and secured with tape. She was curled into the fetal position in a nest of blankets. The constant whoosh of the ventilator and beep of the cardiac monitor accompanied us.

I rolled the incubator to the mother's bedside and positioned it next to the mother's bed. Tears rolled down her face.

'She's so tiny,' she said.

'What's her name?' I asked.

'Sara,' she answered.

'Would you like to touch Sara?' I offered.

'I'm afraid I will hurt her,' she cried.

After assuring the mother that she would not hurt the infant and that in fact, Sara needed her touch, the mother agreed to touch her. I helped the mother to place her hand though the incubator porthole and touch Sara's hand. Sara's tiny fingers curled around her mother's finger. I saw a tiny smile shine through the tears, the first step of a long journey."

clitoris with small separated labia and the preterm male infant will have nondescended testes. Preterm males are prone to develop hydrocele and inguinal hernias and should be evaluated for these regularly.

Physical Assessment

The physical examination provides an opportunity for early recognition of problems. The nurse must be skilled in assessing the newborn for nonverbal cues. An experienced nurse can process multiple observations while examining individual systems. The nurse should develop a consistent approach to examination of the neonate that

covers all major systems. The sequence of the examination should be from least invasive to most invasive, for instance, observation would precede palpation.

A basic physical examination of a preterm infant should include the infant's color and skin condition. The baby's posture, activity, and state of arousal indicate his neurologic status. The respiratory rate and effort, heart rate, and presence or absence of murmurs, pulses, and perfusion are important information in assessing the infant's respiratory and cardiovascular status. The presence or absence of abdominal distension and bowel sounds are indicative of feeding tolerance. Prompt attention should be given to abnormalities observed during assessment.

Examination techniques used with the premature infant include inspection, auscultation, palpation, and transillumination. Observation requires patience and is an important skill to cultivate. Auscultation includes listening to sounds produced by the body that can be heard with the naked ear or a stethoscope. Palpation is examining by touch. Transillumination requires use of an instrument with an intense but cool light source. The light is placed against the infant's skin. Illuminated skin indicates the presence of air or fluid rather than solid matter.

When examining an infant, timing is important. The caregiver must know the infant's baseline values to evaluate changes in condition. The infant must be warm and positioned comfortably. The examination should be clustered with other caregiving activities to provide adequate rest intervals between care and before feedings.

Continuity of care is important in recognizing subtle changes in the infant's physical examination. Parents who visit frequently may be the first to note that something is different about their baby, and their observations should be viewed as important contributions to the evaluation database.

Because all systems are immature, premature infants are at risk for a number of complications. A head-to-toe physical examination includes a number of observations that may attest to the fact that the infant is immature. These observations in and of themselves may not be concerning. Putting a number of observations together, however, may indicate the need to assess an infant more closely for a specific condition common to premature infants. Complications commonly associated with premature infants are discussed in the systems review that follows.

Review of Systems

Potential alterations associated with prematurity are discussed by body system.

Cardiovascular System

The premature infant is at risk for a number of problems associated with the cardiovascular system. Two common problems encountered in the preterm infant are patent ductus arteriosus (PDA) and systemic hypotension.

Patent Ductus Arteriosus

A **patent ductus arteriosus (PDA)** results from the failure of the ductus arteriosus to close or from its reopening after closure. The ductus arteriosus is an artery that extends from the pulmonary artery to the aorta. It is part of the fetal circulation, allowing blood to bypass the lungs in utero. The ductus normally closes after birth. When the ductus arteriosus remains open after birth, a left to right shunt through the ductus may occur, which may lead to

pulmonary edema. PDA with left to right shunt is associated with necrotizing enterocolitis (NEC), bronchopulmonary dysplasia, and intraventricular hemorrhage (IVC) (Davis et al., 1995).

A PDA is common in premature infants. The more premature an infant is, the more likely it is the infant will have a PDA. If left untreated the infant may require extended oxygen and ventilator therapy and may have difficulty gaining weight.

The nurse caring for a premature infant should be aware of the risk of a PDA and monitor the infant for symptoms. These symptoms include a murmur best heard in the second or third intercostal space at the left sternal border, a hyperactive pericardium, bounding peripheral pulses, and a widened pulse pressure.

A PDA is diagnosed by echocardiography. Treatment may be surgical ligation, or closure may be attempted using a prostaglandin inhibitor. The prostaglandin inhibitor commonly used is indomethacin (Davis et al., 1995).

Hypotension

Hypotension is a complication often seen in premature infants. It usually is associated with vasodilation after rapid rewarming or a response to an illness, such as sepsis. Morphine used for sedation may produce hypotension in the preterm infant. Hypotension is seen with hypovolemia after abruptio placenta, cord accidents, and internal bleeding. Hypotension is seen secondary to fluid shifts from intravascular to extravascular spaces in infants who have sepsis or who have had surgery. Cord accidents can occur due to rupture of cord, cord strippers, cutting without clamping, or knot in the end. Symptoms include tachycardia, pallor, poor capillary refill, poor peripheral pulses, and poor urine output. Treatment may be with volume expansion using 5% normal saline, albumin, or blood products. Vasopressor may be used to maintain the blood pressure at levels that will maintain renal perfusion and circulation.

Central Nervous System

The premature infant is at risk for a number of problems associated with the neurologic system. Common problems associated with prematurity are intraventricular hemorrhage, posthemorrhagic hydrocephalus, Periventricular leukomalacia (PVL), developmental delays, and hearing impairment.

Intraventricular Hemorrhage

An **intraventricular hemorrhage (IVH)** is an intracranial hemorrhage frequently associated with prematurity. The more premature the infant, the more likely it is the infant will have an IVH. The bleeding usually occurs within the first 3 days of life.

Nursing Alert

CLINICAL FACTORS ASSOCIATED WITH INTRAVENTRICULAR HEMORRHAGE

- < 34 weeks' postconceptual age
- Low Apgar score at 5 min
- Pneumothorax
- Low birth weight
- Infusion of hyperosmolar solutions
- Asphyxia
- Rapid volume expansion
- Acidosis
- Hypertension
- Hypotension
- Patent ductus arteriosus
- Hypercarbia
- Rapid sodium bicarbonate infusion
- Seizures
- Abnormalities of coagulation

The site of origin frequently is the subependymal germinal matrix (Bernstein, Heimler, & Sasidharan, 1998). This area of the brain is rich in capillary blood vessels. As the infant grows, the number of blood vessels decreases in size until about 36 weeks' gestation. The premature infant's body is unable to regulate blood flow in this area. Thus, changes in blood flow related to asphyxia, trauma, hypercarbia, or rapid fluid infusion may place a strain on the delicate vessels, causing them to rupture and bleed. Clinical factors associated with IVH are listed in the Nursing Alert.

Hypertension has been implicated as a factor in IVH. Sudden increases in blood pressure are associated with caregiving, such as suctioning, performing abdominal examinations, lumbar puncture, and starting an intravenous (IV) infusion. Rapid increases in blood pressure also may occur after correction of hypotension. The increased blood pressure may stress the vessel walls in the germinal matrix areas of the ventricles of premature infants.

Prevention of preterm delivery and use of antenatal steroids may reduce the incidence of IVH. Prompt resuscitation in the delivery room is an important factor in the prevention of IVH. Premature infants should be delivered in a location that has equipment and personnel available for expert resuscitation. The nurse caring for an infant who is at risk for IVH should take care to avoid activities that

Box 34-1 Classification of IVH

- Grade I: Subependymal germinal matrix hemorrhage
- Grade II: Intraventricular extension without ventricular dilation
- Grade III: Intraventricular extension with ventricular dilation
- Grade IV: Intraventricular and intraparenchymal hemorrhage

are likely to provoke rapid or excessive changes in the infant's blood pressure. Dim lighting, low noise levels, minimal handling, and care in the administration of fluids and medications are important. The head of the bed should be slightly elevated; the legs of the infant should not be raised higher than the head.

Infants who are at risk for IVH should be monitored for symptoms. These symptoms include a sudden deterioration in condition, oxygen desaturation, hypotension, bulging anterior fontanel, and hyperglycemia.

Diagnosis of IVH generally is made with portable ultrasonography using the anterior fontanel as a viewing window. The degree and extent of the IVH are classified from Grades I to IV. The grade describes the location and size of the bleed (Box 34-1). No increase in morbidity or mortality is associated with a Grade I or II IVH. Grade III may be associated with severe developmental delay. Infants with Grade IV are at high risk for death or severe developmental delay.

Nursing Alert

SIGNS OF INTRAVENTRICULAR HEMORRHAGE

- Sudden decrease in oxygen saturation
- Sudden deterioration in condition
- Hypotonia
- Hyperglycemia
- Bradycardia
- Hypovolemia
- Metabolic acidosis
- Tense, bulging anterior fontanel
- Significant decrease in hematocrit level
- Seizures
- Apnea

Intraventricular hemorrhage occurs in 15% to 40% of infants born at less than 32 weeks' gestation and who weigh less than 1,500 g at birth. Approximately 35% of infants with IVH develop posthemorrhagic hydrocephalus. In 65% of these infants the progression of ventricular enlargement will arrest spontaneously (Hansen & Snyder, 1998). The long-term outlook for these infants depends more on injury to the parenchyma than on the IVH and hydrocephalus.

Posthemorrhagic Hydrocephalus

After IVH, posthemorrhagic hydrocephalus may develop as a result of obstruction at the level of the ventricles or at the aqueduct of Sylvius. IVH also can impair absorption by way of the arachnoid villi owing to an inflammatory obliteration process in the posterior fossa (Hanson & Snyder, 1998). The obstruction results in overaccumulation of cerebrospinal fluid (CSF).

The daily care of a premature infant who has had an IVH should include keeping the head of the bed slightly elevated and assessing the fontanels and sutures (Roland & Hill, 1997). Head circumference measurements should be done weekly. Ventricular enlargement is monitored by serial ultrasonography.

Posthemorrhagic hydrocephalus may be associated with increased intracranial pressure. Signs of increased intracranial pressure include bulging fontanels and separated cranial sutures. Vomiting may be seen and may be forceful. An increase in the frequency and severity of apnea and bradycardia may be noted. Eyes may deviate downward.

Management of posthemorrhagic hydrocephalus depends on the rapidity of progression. A diuretic, such as acetazolamide, may reduce CSF production and is usually used in conjunction with furosemide. Infants treated with either diuretics or routine removal of CSF should be monitored closely for electrolyte imbalance and metabolic acidosis. Preliminary studies evaluating the use of fibrinolytic therapy have shown promise in the prevention of posthemorrhagic hydrocephalus (Roland & Hill, 1997). Surgical placement of a temporary draining device may be needed until the infant is ready for a **ventricular peritoneal shunt (VPS)** (a tunneled internal drain that empties into the peritoneal cavity). A ventricular to subgaleal shunt also may be used as a temporary device or until a VPS can be placed for long-term management (Roland & Hill, 1997; Hansen & Snyder, 1998).

Before discharge, parents of infants with VPSs should be taught to watch the infant for signs of increased intracranial pressure that could indicate shunt failure. Parents of infants with arrested posthemorrhagic hydrocephalus should also be taught the signs of increased intracranial pressure because late progression of hydrocephalus can occur (Hanson & Snyder, 1998).

Periventricular Leukomalacia

Periventricular leukomalacia (PVL) is a symmetric non-hemorrhagic lesion within the periventricular white matter of the brain. The pathogenesis of PVL is complex and not entirely understood. One possibility is that blood vessels in the periventricular white matter of the brain have limited capacity to expand during episodes of hypotension, allowing poorly perfused areas of the brain to develop areas of infarction. Secondary hemorrhage into areas of infarction may occur with reperfusion. Another theory is that chemically mediated injury may occur with subclinical infection owing to an association between chorioamnionitis and positive blood cultures in the infant who subsequently develops PVL (Perlman, Risser, & Broyles, 1996).

Although PVL affects only 3% of preterm infants, it is associated with long-term neurologic morbidity, including seizures and spastic motor dysfunction (Perlman, Risser, & Broyles, 1996; Bernstein, Heimler, & Sasidharan, 1998; Volpe, 1997). Parents should be connected with resources for follow-up and treatment of associated neurologic sequelae and support groups.

Diagnostic techniques such as near-infrared spectroscopy may provide insights into the cause of PVL (Volpe, 1997). Once the pathophysiology is known, strategies to prevent PVL can be devised.

Hearing Loss

Cognitive development and social development are important aspects of developmental care. Because premature infants are at risk for otic nerve damage, resulting in hearing loss, it is important to assess the infant's ability to hear.

Nursing Alert

RISK FACTORS ASSOCIATED WITH HEARING IMPAIRMENT

- Asphyxia
- Congenital infection
- Hyperbilirubinemia
- Ototoxic drug administration
- Prolonged mechanical ventilation
- Persistent pulmonary hypertension
- Hydrocephalus
- Acidosis
- Sepsis
- High noise levels
- Bacterial meningitis
- Craniofacial anomalies

NOISE IN THE NICU

You can be instrumental in minimizing noise in the neonatal intensive care unit. Modifications such as using plastic trash cans, padding the top of the incubator, and keeping voices low help limit noise in the nursery (Figure 34-5).

Infants who are born prematurely are physiologically immature and at risk for a number of complications of prematurity, some of which are associated with the risk of hearing impairment. Some of the therapies used in the care of preterm infants are associated with the risk of hearing loss. Risk factors for hearing impairment include asphyxia, congenital infection, hyperbilirubinemia, administration of ototoxic drugs, prolonged mechanical ventilation, hydrocephalus, acidosis, sepsis, and noise levels in the neonatal intensive care unit (NICU).

Figure 34-5 A pad wrapped around an incubator can help block light, cold, and noise to minimize environmental stimulation for the newborn.

The nurse should be alert to the infant's responses to sounds. If the infant does not respond to auditory stimuli, a hearing screening test should be performed. Automated oto-acoustic devices are used to screen infants for hearing impairment. An **Auditory Brain Evoked Response** test can be performed as well. It is a hearing test designed to screen newborns that records electrical potentials arising from the auditory nervous system. If the infant does not pass the test, follow-up with an audiologist is warranted.

To facilitate cognitive, social, and language development, an infant with hearing deficits may be fitted with hearing devices. The family should be taught communication skills, which will enhance the interactive process (Kenner, Amlung, & Flandermeyer, 1998).

Hematologic System

Nurses caring for preterm infants must have an understanding of the normal and abnormal conditions associated with the hematologic system. Acute and physiologic anemia, polycythemia, and coagulopathy often are found in the premature infant.

Anemia

Anemia can be defined as hemoglobin less than 13 g/dL in the first 28 days of life. Anemia may be present at birth or develop postnatally. It can be associated with blood loss, hemolysis, or decreased erythrocyte production.

Acute Anemia. Acute anemia is common and also may be associated with hypovolemia. Acute anemia may be caused by intrapartum events or frequent blood sampling for laboratory tests. Conditions related to blood loss in the fetus are fetomaternal transfusion or obstetrical bleeding from abruptio placenta, placenta previa, and abnormal insertion of the umbilical cord. After birth, blood loss may occur from a torn umbilical cord or internal hemorrhage in the newborn. Internal hemorrhage may include IVH or rupture of the liver or spleen during a traumatic delivery. Anemia also may result from hemolysis owing to chronic infection, isoimmune hemolytic disease, or inherited defects in the red cell membranes.

Acute anemia should be treated immediately. Symptoms include pallor, tachycardia, hypotension, and shock. The cause should be identified and treated, if possible. Laboratory evaluation may be helpful in identifying the cause when the maternal history does not include intrapartum bleeding.

Laboratory evaluation includes measuring hemoglobin and hematocrit levels. The hematocrit may be normal if blood is drawn immediately after an acute episode of bleeding; the true level of hemoglobin is masked because the blood loss is so rapid. As blood volume is restored (3 to 6 hours), the erythrocytes may be less dense and the

hematocrit may be decreased. When large doses of volume are given to correct suspected hypovolemia, the hematocrit may be diluted.

Other laboratory evaluation includes a reticulocyte count. The reticulocyte count indicates if the anemia is chronic, such as in erythroblastosis fetalis, which is a hemolytic disease related to Rh incompatibility between mother and infant. In a chronic anemia the fetus rapidly replaces erythrocytes, which results in an increased reticulocyte count.

Erythrocyte morphology may give a clue to the cause of the anemia. For instance, an increased number of spherocytes may indicate an ABO incompatibility, or an increased number of erythroblasts may suggest hemolytic disease.

Direct and indirect Coombs tests on the infant is important to evaluate for maternal antigens to the infant's blood. These antigens may be seen in Rh disease, ABO incompatibilities, and minor blood group incompatibilities. The mother's blood may be tested to see whether fetal cells are present as seen in fetomaternal transfusions.

Physiologic Anemia. A physiologic anemia may develop from physiologic changes associated with the change from the production of fetal hemoglobin in utero to that of adult hemoglobin after birth. Physiologic anemia often is seen in the stable premature infant. The hematocrit reaches a natural low point as the infant's body transitions from the production of fetal hemoglobin to that of adult hemoglobin. The decrease in fetal hemoglobin prompts the postnatal increase in erythropoietin (Kenner, Amlung, & Flandermeyer, 1998). Erythropoietin then stimulates the production of erythrocytes.

The hematocrit reaches a low point at about 6 to 8 weeks in a premature infant. The infant may be pale but usually maintains a heart rate within normal range. Physiologic anemia does not require treatment unless the infant is dependent on oxygen, is having frequent blood drawn for monitoring, or is symptomatic of anemia. If decreased activity, poor feeding, tachycardia, dyspnea, tachypnea, or poor weight gain are present, the anemia is considered to be symptomatic (Chen, Wu, & Chanlai, 1995). Treatment generally consists of transfusion of packed erythrocytes. Human erythropoietin also may be used for treatment of anemia (Chen, Wu, & Chanlai, 1995; Kenner, Amlung, & Flandermeyer, 1998).

Polycythemia

Infants with polycythemia will have a peripheral hematocrit value of more than 75% or a central hematocrit value of more than 65%. Infants at risk are those with trisomy 13 (Patau syndrome), trisomy 18 (Edward syndrome), trisomy 21 (Down syndrome), twin-to-twin transfusion syndrome, and those who receive placental transfusion at birth. In-

fants whose mothers have diabetes also are at risk. Symptoms of polycythemia include lethargy, hypotonia, irritability, tremors, poor feeding, and **plethora** (deep rosy-red skin color). Cyanosis with crying, tachypnea congestive heart failure, hepatomegaly, cardiomegaly, and jaundice is indicative of polycythemia. Polycythemia may be associated with hypocalcemia, hypoglycemia, and jaundice. When the hematocrit value is less than 70% and no symptoms are observed, the infant should be monitored. Complications of hyperviscosity are associated with infarcts in major organs. When the infant is symptomatic the hematocrit may be reduced by a partial exchange transfusion.

Coagulopathy

Clot formation requires an interaction between clotting proteins, platelets, and damaged blood vessels. Many conditions in the premature infant are associated with prolonged clotting times. Thrombocytopenia is one such condition that may occur with infection, isoimmune disorders, thrombotic disorders, necrotizing enterocolitis, and birth asphyxia. Maternal or infant medications may prevent clot formation by interfering with platelet function. Infection and asphyxia may be associated with **disseminated intravascular coagulation (DIC)**. This condition involves coagulation in the microvasculature that results in prolonged bleeding owing to the consumption of available clotting factors during the coagulation process.

Symptoms of coagulopathy include petechiae, ecchymosis, prolonged bleeding at puncture sites, pulmonary hemorrhage, and intracranial bleeding. Complications include anemia and hyperbilirubinemia related to breakdown of erythrocytes in entrapped hemorrhage. Management of coagulopathy includes identifying and treating the cause. Supportive measures include maintaining a normal blood pressure and provision of blood products if needed. Fresh frozen plasma, packed erythrocytes, and platelets may be transfused as needed.

Hepatic System

The liver of the preterm infant also is immature. Common hepatic problems associated with prematurity include hyperbilirubinemia and alterations in the metabolism of medications.

Hyperbilirubinemia

Hyperbilirubinemia implies excessive serum **bilirubin** (product of erythrocyte destruction that may be a result of a natural or a hemolytic process) and therefore is associated with a pathologic cause or outcome (Schwoebel & Sakraida, 1997). The physiology and etiology of bilirubin are discussed in Chapter 32.

Premature infants are prone to potentially high levels of bilirubin and may have **jaundice** (yellow tint to the skin

related to increased bilirubin levels). Bilirubin levels increase earlier, reach peaks later (5 to 7 days) and remain elevated longer than in the term neonate as a result of several factors. These factors are low levels of the enzymes that bind to bilirubin, more rapid erythrocyte breakdown, and decreased albumin levels. The preterm infant also is at increased risk for reabsorption of bilirubin from the GI tract owing to poor GI motility, inability to feed, feeding intolerance, and delayed stooling.

Phototherapy is the treatment of choice for the management of hyperbilirubinemia in the preterm infant (Figure 34-6). Early intervention is recommended. Phototherapy may be started early on infants who have multiple bruises from delivery because serum bilirubin will increase as the blood in the bruise is broken down.

Issues of importance to the nurse caring for a preterm infant under phototherapy include maintenance of normal body temperature, ensuring eye patches are in place, monitoring of strict intake and output, managing IV fluid, monitoring bilirubin levels, assessing for signs of neurodevelopmental consequences, and educating the parents. Premature infants requiring phototherapy need increased maintenance fluids secondary to an increase in insensible water losses (IWLs).

The premature infant is at increased risk for neurologic injury because of immaturity of the blood-brain barrier and propensity for delayed clearance owing to delayed maturation of the normal physiologic mechanisms (Schwoebel & Sakraida, 1997). In addition, the potential for central nervous system (CNS) hemorrhage, hypoxia, and hypoglycemia increase the potential for bilirubin-related kernicterus. There is not a consensus on what bilirubin levels are dangerous to the preterm infant, but cautious management is necessary.

Gastrointestinal System

In utero, the GI tract processes large volumes of amniotic fluid, which aid in maturation. By 20 weeks' gestation the anatomic development of the GI tract is complete; functional capabilities develop later in gestation. Although some GI function is present at birth, regardless of gestational age, premature infants may have limitations in overall GI function. Common problems related to the immature GI tract include dysmotility, NEC, and gastroesophageal reflux (GER).

Dysmotility

The onset of peristalsis is at 28 to 30 weeks' gestation. Once feedings are initiated the infant must be monitored closely for **dysmotility**, or a slow rate of GI peristalsis. Environmental factors affect the development of the GI tract: colonization of bacteria and introduction of enteral feedings help to stimulate maturation.

Digestion and absorption of nutrients vary according to gestational age. Protein is remarkably well handled by the preterm infant, whereas carbohydrate absorption is

A.

B.

Figure 34-6 A. Infant warmer with phototherapy light. B. Eye patches and phototherapy equipment.

limited because of lactase deficiency. Malabsorption of dietary fat is common secondary to a lack of small bile pools and pancreatic lipase. Early low-volume feedings have been shown to increase gut hormones thought to be important in intestinal maturation.

Motility of the GI tract changes during gestation and after birth. The gastroesophageal sphincter pressure increases from 28 weeks' gestation through the first week of life, and peristalsis of the small intestine improves during the third trimester (Merenstein & Gardner, 1998). Gastric emptying is decreased in preterm infants. The more premature the infant the greater the delay in passage of stool. Enteral feedings promote gastric emptying and the release of hormones that may improve peristalsis (Merenstein & Gardner, 1998).

Necrotizing Enterocolitis

Necrotizing enterocolitis (NEC) is a devastating disease process most commonly seen in premature infants but occasionally seen in compromised term infants. NEC is characterized by necrosis of the mucosal and submucosal layers of the GI tract. The exact pathogenesis remains unclear. Mucosal injury is thought to be the initial stage of this disease. The risk of mucosal injury in the neonate is associated with perinatal hypoxia; asphyxia; hypovolemia and rapid reperfusion; viscous blood with decreased flow to the GI tract, such as in polycythemia; and hypotension, with resultant decrease in blood flow.

Although prevention of NEC is of primary importance to the practitioner, the lack of a clear cause limits attempts to avoid the disease altogether. Prevention is aimed at preventing factors associated with NEC. Certain factors predispose infants to NEC; they are listed in the Nursing Alert. Changes in blood flow patterns to the GI tract are the most common cause of mucosal injury. Once mucosal injury has occurred the bowel lining becomes edematous. Hemorrhage and ulceration then occur followed by formation of a false membrane. Introduction of enteral feedings and overgrowth of normal GI flora (bacteria) cause an invasion in this already damaged bowel wall. Gas production occurs, which further weakens the mucosa, and gas becomes trapped in the interspace of the bowel wall. This trapped air is called **pneumatosis intestinalis** and is a hallmark of the disease process.

The infant may have subtle signs and symptoms or may deteriorate rapidly. The signs and symptoms can be divided into early onset, second stage, and late onset. Early symptoms include abdominal distention, gastric residuals, vomiting, and bloody stools. Lethargy, temperature instability, apnea, and bradycardia also may be present. When these conditions occur, delay in feedings is necessary and the infant should be monitored closely.

As the disease process worsens, fluid shifts from damaged intestinal mucosa into the abdominal cavity. Hypo-

Nursing Alert

RISK FACTORS FOR NECROTIZING ENTEROCOLITIS

- Asphyxia
- Hyperosmolar feedings
- Polycythemia, hyperviscosity
- Rapid increase in the volume of feedings
- Enteric pathogenic microorganisms

volemia results, with a decrease in blood pressure and urine output. Late signs include erythema, edema, and abdominal tenderness. Thrombocytopenia occurs as platelets are consumed to help repair damaged bowel mucosa. The infant should be monitored for prolonged bleeding.

Management of this disease process should be begun at the earliest signs of difficulty. Management includes stopping feedings and starting IV fluids, gastric decompression with an orogastric tube, antibiotic therapy, strict measurement of intake and output, and replacement intravascular volume with blood or plasma. Resuscitation may be necessary. The infant should be monitored frequently for changes in clinical status. Radiographic views of the abdomen should be reviewed every 6 to 8 hours to assess for pneumatosis intestinalis. Laboratory evaluation includes complete blood count (CBC) with differential and platelet count, blood culture, serum electrolytes, blood urea nitrogen (BUN), creatinine and glucose, and a lumbar puncture for culture if the infant's condition permits.

If the infant's condition does not worsen in the first 3 days, feedings may be initiated slowly. If symptoms worsen, the infant should not be fed to rest the bowel. Total parenteral nutrition (TPN) with intralipids for nutrition and to promote healing will be initiated and IV antibiotics will continue for 7 to 14 days when indicated.

The infant is monitored closely for signs of perforation, leading to air in the peritoneal cavity. Surgical intervention is indicated when perforation occurs. Necrotic bowel is resected, and primary anastomosis or stoma is established. All efforts are made to preserve the length of the bowel. When perforation occurs, the mortality rate is 20% to 40%.

Complications of NEC include lactose intolerance, malabsorption, fungal infection, metabolic bone disease, cholestasis, and liver dysfunction. Late complications of NEC include strictures, fistulas, and abscesses. Recurrent signs and symptoms include chronic electrolyte imbalances and failure to thrive. **Short bowel syndrome** also

may occur in NEC as a result of extensive resection of the GI tract, resulting in loss of absorptive surface that, in turn, results in diarrhea, dehydration, and poor growth.

Gastroesophageal reflux

Gastroesophageal reflux (GER) is defined as the return of gastric contents into the esophagus. The premature infant is at great risk for GER secondary to immature muscle tone, poor sphincter control, delay in gastric emptying, and increased intraabdominal pressure. Common signs of GER are vomiting, small wet burps, poor weight gain, apnea and bradycardia, esophagitis, and recurrent aspiration. Collaborative management is essential in GER. Nursing may include positioning the infant with the head elevated (Figure 34-7), frequent small-volume feedings, frequent burping during feedings, monitoring for apnea, and thickening formula. Medical management includes the use of agents to increase gastric emptying time and improve GI motility.

Immune System

Many factors put the preterm infant at high risk for infection. Two mechanisms are responsible for the infant's un-

Figure 34-7 Elevating the head is one way of managing care for the infant with gastroesophageal reflux.

derdeveloped immune system: qualitative and quantitative neutrophil deficiency and impaired opsonization (Lott, 1994).

Neutropenia (decreased number of neutrophils) commonly is seen in infection from decreased neutrophil marrow progenitor cells and a decreased marrow neutrophil storage pool (Lott, 1994). Neutrophils also are less effective than they normally are during times of stress in the newborn.

Opsonization (the action of opsonins facilitating phagocytosis) is impaired secondary to lower immune complement and antibody levels. Maternal antibodies are the only source available and do not cross the placenta in large quantities before 32 weeks' gestation.

Infection

The most common risk factor for infection in the preterm infant is exposure to infections in utero. These infections are sometimes linked to the onset of preterm labor and delivery. Maternal risk factors for infection include health practices related to substance abuse, maternal illness, colonization with infection, active bacterial or viral infection, and fever during labor and delivery. Neonatal risk factors include prematurity, male gender, multiple gestation, and congenital abnormalities.

Infection is suspected in all infants born prematurely without a clear cause for the early delivery. Evaluation for infection may include a CBC with differential, blood culture, evaluation of tracheal aspirate (if intubated), gram stain culture, and a lumbar puncture for culture. Broad spectrum antibiotic therapy is initiated until the organism is identified. Length of treatment may vary from institution to institution.

The premature infant also is at risk for late-onset infection, which is one that occurs after the first 5 to 7 days of life. These are commonly nosocomial infections. Underlying illness, poor skin barrier, and immature immune status make the premature infant more susceptible to infection.

Prevention of late-onset infection is an important aspect of neonatal care. Nurses caring for premature infants must be diligent in good hand-washing technique and in instructing parents and other health care personnel to wash their hands thoroughly. Equipment should be cleaned before and after use to prevent spread of infection. Each infant should have his or her supplies to prevent cross-contamination. Overcrowding in a nursery also increases the risk for infection. Once an infant is admitted to the nursery, the infant's bed space should not be changed without careful deliberation. The nurse caring for a premature infant also should try to ensure that caregivers and family members avoid contact with the infant when they are ill. Screening siblings for illness when they visit the nursery with their parents is especially important (Figure 34-8).

Figure 34-8 The triplet's big sister is allowed to hold only the infant who is showing the best growth rate and adaptation to extrauterine life.

The evaluation for late-onset infection is the same as for an early infection; suprapubic needle aspiration of urine for culture, a bladder tap also may be indicated. Increased incidences of meningitis and urinary tract infection also are seen in infants who have late-onset infections.

The infant may have varying signs and symptoms. Generalized symptoms are common, such as poor feeding, irritability, lethargy, and temperature instability. Signs of infection often include the following: respiratory symptoms, such as grunting, nasal flaring, retractions, increased

Critical Thinking

Protecting Infants from Illness

Calling in sick is discouraged in hospitals. It is especially difficult in a neonatal intensive care unit because the unit may be left short-handed or substitute staff will be provided that cannot provide the level of care a staff nurse is trained to deliver. Even an expert neonatal nurse cannot complete the variety of tasks expected of full time personnel. Thus, calling in sick places an extra burden on co-workers.

You have read that infants who have low birth weights are susceptible to infection. In balancing personal pressure with the infants and co-workers' needs, what should you do if you wake up one morning with a fever? What should you do if you have had two previous absences and the third means a verbal counseling? What should you do if you know the unit is short-staffed?

respirations, and apnea; cardiovascular symptoms, such as bradycardia or tachycardia, decreased blood pressure, cyanosis, and mottling; and GI disturbances, such as diarrhea, abdominal distention, emesis, and increased residuals.

As in all pregnancies, mothers delivering premature infants must be screened for sexually transmitted diseases. If the mother has not been tested or if the prenatal chart is not available, the mother must be screened once hospitalized. Follow-up by nursery personnel is essential. Sexually transmitted diseases are treated the same way in preterm infants as they are in term infants.

The preterm infant also is at increased risk for fungal infections for several reasons. Prolonged treatment of the mother with antibiotics may increase yeast colonization in the mother's vaginal canal, thereby increasing the infant's exposure at delivery. These infants have multiple intravascular catheters in place for long periods of time, multiple courses of antibiotic therapy, and an immature immune response. Treatment with antifungal agents is common. These agents have effects on the renal and hematologic systems. Careful monitoring of potassium, BUN, creatinine, hematocrit, and platelet count is essential for early intervention should side effects occur.

Nursing Tip

SOAP FOR BATHING

The natural acid mantle of the skin helps keep bacterial growth at a minimum. Nonalkaline soaps should be used for bathing the preterm infant to protect the acid mantle.

Integumentary System

Skin care is an important aspect of care (Gordon & Montgomery, 1996). Skin functions as a barrier to infection and controls temperature and insensible water loss (Dollison &

Beckstrand, 1995). At less than 34 weeks' gestation a preterm infant's skin is immature. Once the infant is born the skin matures over the first couple of weeks and begins to resemble that of a term infant. Because a premature infant's skin is fragile, it is subject to injury. Epidermal stripping, absorption of chemicals applied to the skin, and IV fluid infiltrates are common.

Epidermal Stripping

The skin of a preterm infant is more permeable because of its thin stratum corneum. The epidermis remains thin until 32 weeks' gestation. Collagen, which provides support to dermal structures and allows the skin to stretch, is unstable. Decreased cohesion between the dermis and epidermis exists. Epidermal stripping occurs easily because the adhesive of bonding agents may be greater than the bond between the epidermis and dermis. When the dermis is stripped, increased chemical absorption and increased fluid loss occur along with the potential for bacterial exposure. The use of pectin-based barriers helps prevent epidermal stripping. Placing the barrier under tape decreases the amount of epidermal stripping (Dollison & Beckstrand, 1995). Pectin-based barriers come in thin sheets that can be cut to the desired size and shape. The sheets stick to skin when warmed. Tape will pull on the barrier rather than the infant's skin.

Absorption of Chemical Agents

The thin skin of a premature infant allows chemicals to be readily absorbed through the skin. Nursing care includes avoidance or limitation of the use of adhesives and adhesive removers. Table 34-1 lists some chemicals that can be absorbed through the skin. Absorbable chemical agents should be removed from the skin with water.

Intravenous Fluid Infiltrates

Intravenous infiltrates are of particular concern in preterm infants because many solutions and medications can cause sloughing of the skin. Infection and scarring also can occur. Many premature infants require IV therapy because

of medical conditions that prevent full enteric nutrition or the need for pharmacologic therapy. Properly cleaning the site and protecting the IV to prevent infiltration necessitating multiple IV starts are important considerations. It is important for the nurse to remember that each needle puncture is a break in the integrity of the infant's skin and a potential source of infection.

The IV site should be checked at least every hour. When an IV infiltrate is detected, the IV should be discontinued immediately and the area of infiltrate elevated, if possible. Hyaluronidase may be used to limit sloughing in some cases. Phentolamine may help prevent tissue necrosis in dopamine solution infiltrates.

When the skin breaks down over a joint, scarring and development of a contracture may limit joint mobility in the future. A consultation with plastic surgery often is required for evaluation of the area and for recommendations on steps to take to minimize long-term sequelae.

Ophthalmologic System

As with other body systems, the eyes of a premature infant are still developing. The premature infant therefore is at risk for the development of vision problems.

Historically, premature infants developed retrolental fibroplasia (RLF), which resulted in blindness, as a result of exposure to high levels of oxygen. Changes in treatment modalities and development of sensitive monitoring equipment have essentially eradicated this illness; however, it is important for nurses caring for premature infants to be aware of the potential harm of indiscriminate use of oxygen.

With improved methods of treatment and equipment, smaller premature infants are surviving. These infants are at risk for retinopathy of prematurity. We now know the infant also is at risk for other eye problems.

Retinopathy of Prematurity

One of the most prevalent problems seen in premature infants is **retinopathy of prematurity (ROP)**. Before 32 weeks' gestation, vascularization of the retina is incomplete (Shapiro & Askin, 1999). The younger the infant the less vascularization has occurred. Once an infant is born, the vessels in the eye continue to grow and extend to the periphery of the retina. As these vessels grow there is risk for abnormal development of the eye vessels. This proliferation of blood vessels in the eye is known as ROP, which can lead to limited vision or even blindness if not detected and treated early. In severe ROP, treatment includes cryotherapy or laser photocoagulation to limit the development of the abnormal blood vessels. When these treatments fail the infant may require eye surgery to preserve some sight.

Infants who have birth weights less than 1,500 g or who are born at less than 28 weeks' gestation should be

Table 34-1 Effects of Absorbable Chemical Agents	
Absorbable Chemical	Potential Effect
Isopropyl alcohol	Sloughing
Betadine	Transient hypothyroidism
Hexachlorophene	Central nervous system damage
Adhesive remover	Increased blood alcohol levels

screened by a pediatric ophthalmologist for ROP at 4 to 6 weeks of life and then regularly until vascularization is complete. ROP occurs in 25% to 35% of surviving premature infants having up to 35 weeks' gestation. Blindness occurs in 3% to 5% (Bossi & Koerner, 1995; Bernstein, Heimler, & Sasidharan, 1998).

Other Eye Problems

Infants who have developed ROP at any stage are at risk for late retinal detachment and should be followed closely. Premature infants also are at risk for myopia, amblyopia, glaucoma, and strabismus (Bernstein, Heimler, & Sasidharan, 1998). Parents should be encouraged to keep postdischarge eye appointments so that vision problems can be identified early to preserve sight. The long-term implications on the quality of life of the infant and family are clear.

Renal System

The kidneys are responsible for elimination of toxins and regulation of fluid, electrolytes, and arterial blood pressure (Seaman, 1995). In utero the placenta acts as the organ of excretion, removing excess fluid and waste products from the fetus. The fetal kidney has a low glomerular filtration rate (GFR) that increases with gestational age. The GFR remains low until nephrogenesis is complete, at about 36 weeks' gestation. Infants born at less than 36 weeks' gestation have underdeveloped structures and decreased renal function. Renal function increases during the first week of life because of decreased renal vascular resistance and an increase in systemic blood flow. Increased renal function results in diuresis at about 5 days of life as the GFR increases and the infant excretes excess extracellular fluid. Although the GFR increases in the first week of life, it is lower in the preterm infant than in the term infant owing to a decreased number of nephrons (Seaman, 1995).

Careful monitoring of the renal status of premature infants is important so that problems are identified early and thus early intervention can be provided. Renal problems common to premature infants include oliguria, glucosuria, and nephrocalcinosis.

Oliguria

Urine flow depends on fluid intake. Normal urine output is 1 to 2 mL/h per kilogram of body weight (mL/kg/h). Oliguria can be defined as less than 1 mL/kg/h. Oliguria may be a symptom of inadequate fluid intake or acute renal failure. Acute renal failure in premature infants may be associated with perinatal asphyxia and multisystem organ failure. Urine output may be affected by hypoxemia, hypovolemia, acidosis, and mediations that impair renal blood flow. Sepsis sometimes is associated with renal failure.

An accurate urine output measurement is extremely important in monitoring renal well-being in infants; how-

ever, accurate measurements may be difficult to obtain. Nurses who care for premature infants have developed creative methods of checking output. One method involves weighing a dry and a wet diaper on a balance scale (Figure 34-9). The difference between the two weights is roughly the urine output.

In severe cases of oliguria a bladder catheter may be required for accurate measurement. In addition to urine output, renal function is evaluated by monitoring serum creatinine and hydration by monitoring BUN.

Glucosuria

Term infants may have a trace of glucose in the urine. Glucosuria is seen more frequently in premature infants in whom minor elevations in serum glucose allow spillage into the urine. Glucose in the urine sometimes is seen in premature infants who have an infection IVH, and in those receiving steroids.

An increased frequency of yeast dermatitis has been observed in infants with glucosuria. Keeping the skin area that comes into contact with wet diapers clean and dry is important in preventing cutaneous yeast infections. The nurse caring for the premature infant should consider each diaper change an opportunity to observe the area for rash and skin breakdown. Yeast infections in the diaper area generally appear as redness in the creases with a papular rash, frequently with satellite lesions, that is, lesions extending beyond the reddened area. The treatment for yeast dermatitis is antifungal cream.

Nephrocalcinosis

Nephrocalcinosis is the formation of renal calculi, usually calcium oxalate (McCormick, Brady, & Keen, 1996). A hospitalized premature infant with a complicated medical history is at risk for nephrocalcinosis. Risk factors include prematurity and hypercalciuria, resulting from furosemide administration and calcium supplementation.

Diuretics often are used in the premature infant to treat congestive heart failure associated with PDA and to improve lung function in infants with certain lung diseases. A commonly used diuretic is furosemide. Premature infants need increased doses because of their low GFRs. Furosemide is associated with increased excretion of calcium and therefore may be associated with renal calcifications. When an infant is on long-term furosemide therapy, it is important to monitor renal function regularly. Ultrasonography of the kidneys may be done periodically to evaluate for the presence of renal calculi.

Fluid restriction, alkaline urine, and metabolic acidosis may contribute to the formation of nephrocalcinosis (McCormick, Brady, & Keen, 1996). Many preterm infants who are receiving diuretic therapy also will receive formula for premature infants that contains higher levels of calcium

A.

B.

C.

Figure 34-9 Urine output can be measured by first weighing a clean diaper (A) and then a wet diaper (B); the difference is the infant's urine output. (C) The diaper of a premature infant is so small that this method of measuring urine output may prove a challenge.

and other minerals than does formula for term infants. Infants who are receiving diuretics because of a chronic lung condition may have fluid restrictions, placing them at an even higher risk for developing nephrocalcinosis.

When nephrocalcinosis is present, other diuretics also may be used, such as chlorothiazide and spironolactone. Chlorothiazide has a lesser effect on the infant's electrolyte values than does furosemide, and spironolactone is a potassium-sparing diuretic; however, electrolyte levels should be monitored, and replacement salts provided as required.

Respiratory System

Before birth the infant's lungs are filled with fluid and underperfused. The placenta acts as the organ of respiration for the fetus, providing for gas exchange. Most right ventricular output is shunted from the pulmonary artery across

the ductus arteriosus into the aorta, bypassing the pulmonary circulation. (Kenner, Amlung, & Flandemeyer, 1998). Approximately 10% of blood flow goes to the fetal lung in utero.

Fetal lung fluid begins to be absorbed before birth, and the alveolar fluid secretion decreases near term. During labor this process accelerates. When the cord is clamped and with the first breaths, the alveoli are able to fill with air. Thus, lung volume is established. The lung fluid then moves to the interstitial space and is removed by the lymphatic and pulmonary blood vessels. Interruption of this process may result in a respiratory disease process in the newborn infant. Delivery of a preterm infant interrupts this process and may result in a respiratory disease state.

The most common problem in premature infants is respiratory distress. Premature infants may have respiratory distress syndrome (RDS), transient tachypnea of the

newborn (TTN), retained fetal lung fluid, bronchopulmonary dysplasia (BPD), apnea of prematurity, air-block syndrome, pneumonia, or meconium aspiration syndrome. Respiratory problems may occur alone or in combination, or the premature infant may have one respiratory problem early in the course of treatment and another or others later.

Respiratory Distress Syndrome

Also called **hyaline membrane disease (HMD)**, **respiratory distress syndrome (RDS)** is the most common cause of respiratory disease in the preterm neonate. In rare cases, this disease also may be seen in infants of mothers with diabetes or term neonates with asphyxia. The disease manifests as surfactant deficiency characterized by collapsed alveoli and low lung volume.

Each year RDS is seen in over 40,000 infants and approximately 65% are infants of 30 weeks' gestation or less (Farrell & Wood, 1976). The disease process worsens with decreasing gestational age.

The premature lung is deficient in surfactant. Surfactant is essential in maintaining surface tension and preventing alveolar collapse. As surfactant is used up the premature lung becomes progressively atelectatic and underperfused, resulting in intrapulmonary shunting and hypoxia. Efforts to reduce the incidence and severity of RDS include the use of antenatal steroids and surfactant replacement therapy. Administering steroids to the mother prenatally seems to accelerate lung growth and maturity. The use of surfactant replacement helps to diminish the severity of RDS once the infant is delivered (Moise & Hanson, 1998; Casey, 1999).

Typical radiographs of the preterm infant with RDS reveal low volume lungs, with a granular appearance to the lung fields and air bronchography. Common forms of treatment include continuous positive airway pressure, positive end expiratory pressure to prevent lung volume loss during expiration, mechanical ventilation, high-frequency oscillatory ventilation, and surfactant replacement therapy (Kenner, Amlung, & Flandemeyer, 1998).

Transient Tachypnea of the Newborn

Transient tachypnea of the newborn (TTN) is not a common disease in the preterm infant. TTN lasts approximately 5 to 7 days, and the main symptom is tachypnea. Often, no underlying cause is identified.

Retained Fetal Lung Fluid

Retained fetal lung fluid is a disease process seen in term, near term, and preterm neonates resulting from the inability or failure to completely clear the lungs of fluid at birth. Retained fetal lung fluid often is mistaken for TTN. The lungs usually are mature.

The medical history often reveals a rapid vaginal delivery or delivery by cesarean section. The most common

symptom is tachypnea; however, grunting, nasal flaring, and retractions also may be noted. The clinical course may be as short as 4 hours or up to 24 hours of age. Breath sounds generally are coarse on auscultation. Treatment includes oxygen therapy and fluid restriction. Occasionally, continuous positive airway pressure is needed (Figure 34-10).

Bronchopulmonary Dysplasia

One of the most common complications of respiratory disease in the preterm infant is **bronchopulmonary dysplasia (BPD)**. Infants who are born prematurely and require mechanical ventilation and oxygen therapy for a prolonged period of time are at risk for damage to the alveoli and lung tissue. Whereas the pathogenesis of BPD is multifactorial, the primary cause is immature pulmonary development with surfactant deficiency. Treatment of this pulmonary disease requires the use of mechanical ventilation, resulting in barotrauma to the small and large airways, interstitial damage, inflammation, fibrosis, and cystic changes.

Northway et al. (1967) described the pathology of BPD in four stages of progressive chronic changes in the lung, starting as early as the second to third day of life with patchy loss of cilia and advancing to necrosis of alveolar epithelium and severe bronchiolar metaplasia by 1 month of age. Toce et al. (1984) described a clinical and radiographic scoring system for preterm infants at 28 days of life or 36 weeks' postconceptual age. The scores range from normal to severe disease. Respiratory rate, retractions, oxygen requirement, carbon dioxide retention, and growth rate are evaluated. Radiographic changes range from cardiovascular abnormalities to lung hyperexpansion and fibrosis.

In the 1990s, an increase in the occurrence of BPD was seen. This increase is primarily a result of surfactant

Figure 34-10 Premature infant receiving oxygen therapy through an oxygen hood.

replacement therapy and the ability to manage smaller preterm infants than in the past. These infants weigh as little as 500 g and are delivered from 23 to 24 weeks' gestation.

Prevention of BPD is directed toward prevention of RDS by using prenatal steroids, managing preterm labor, and using ventilation strategies designed to reduce the effects of barotrauma. Other management strategies include closure of patent ductus arteriosus, fluid management, early diuretic therapy, and good nutrition. More recent strategies, including vitamin A supplementation, antioxidant therapy, and high-frequency oscillation, have reduced the severity of BPD.

Treatment strategies include a combination of modalities and require a multidisciplinary team approach. Fluid restriction in combination with diuretic therapy while providing adequate nutrition are tremendous challenges for all caregivers. Use of bronchodilators, steroids, and vasodilators is essential in controlling disease progression and managing symptoms.

Nursing care is aimed at providing a stable, developmentally sound environment to ensure optimal outcomes. Prevention of hypoxic episodes and close monitoring of the infant's tolerance to procedures and handling are essential. Clustering of care, use of containment during procedures, and sedation often are used to conserve energy expenditure. Energy conservation is extremely important to ensure adequate weight gain and optimal use of calories. Consistent caregivers are important both to the infant's social development and in order to be attuned to subtle changes in the infant's condition that can become serious if early intervention is not provided.

It is essential to have family involvement in the care of these infants who are developing socially and cognitively. Having family members provide routine care promotes attachment and allows the infant social contacts that are not medically oriented. Families must learn to provide the infant's care because many of these infants will go home with monitoring equipment and therapy that may be stressful for the family. A successful transition to home care is dependent on supporting the family structure while the infant is in the hospital.

The management and care of these fragile infants with chronic conditions present an ongoing challenge to neonatal caregivers. Research is needed to continue to improve outcomes in this population.

Apnea of Prematurity

Apnea is defined as the cessation of respirations for more than 20 seconds. Color changes and bradycardia may accompany apnea. Periodic breathing frequently is seen in the premature infant and is described as three or more pauses in respirations, with less than 20 seconds of respirations between pauses.

Nursing Tip

MAINTAINING AN APPROPRIATE THERMAL ENVIRONMENT

Maintenance of a neutral thermal environment is extremely important in the management of all aspects of caring for a premature infant.

Apnea may be classified as central or obstructive. Central apnea results secondary to the immature myelination of the neurons in the CNS. The chest wall in the premature infant is highly compliant, resulting in inadequate tidal volume. Obstructive apnea occurs when chest wall movement is evident but no airflow occurs in the nares.

Nursing management is directed toward control of the physical environment through temperature regulation and positioning. When positioning the preterm infant, it is extremely important to avoid neck flexion and thus airway obstruction. A good way to position an infant is prone, with neck and shoulder support to decrease flexion.

Exact documentation of the frequency of episodes, duration, severity, resolution, and intervention required is extremely important to determine a pattern, a cause, and adequacy of therapy. Many episodes of apnea may resolve on their own; however, others will require intervention. Intervention may include gentle tactile stimulation, such as stroking the foot. More vigorous stimulation may be needed and can be provided by rubbing the infant's back or soles of the feet. Use care not to rub vigorously enough to bruise the infant. Other interventions include oxygen therapy or positive pressure ventilation with bag and mask.

Medical management of apnea of prematurity includes treatment of the underlying disease process, supportive oxygen therapy, continuous positive airway pressure to increase end expiratory volume. Pharmacologic support is used to stimulate the chemoreceptors in the respiratory center of the CNS, relax bronchial smooth muscle, increase respiratory drive, and increase respiratory muscle activity. The most commonly used methylxanthines are aminophylline, theophylline, and caffeine.

Air-Block Syndrome or Pneumothorax

A complication of ventilation in the preterm infant is pneumothorax or **air-block syndrome**. Caused by alveolar overinflation and rupture, air enters the perivascular sheath and dissects along the blood vessels or along the trachea and bronchial tree. Maldistribution of air leads to overdistention in some alveoli and atelectasis in others. There are five types of air leakage: pneumomediastinum, pneumopericardium, pneumothorax, pneumoperitoneum,

and subcutaneous emphysema. Air that enters the pulmonary interstitial tissue may lead to pulmonary interstitial emphysema (PIE).

Air leaks are caused by rapid changes in alveolar pressure and ventilation. In pulmonary disease the lung is stiff and noncompliant. The premature infant requires mechanical ventilation because of this disease process, thereby, increasing the risk of pneumothorax. The incidence of pneumothorax is decreased by minimizing inspiratory and mean airway pressures. Treatment of respiratory disease with surfactant and high-frequency ventilation has decreased the occurrence of air leakage in the preterm population (Carroll, 1991).

Signs and symptoms of pneumothorax in the preterm infant include decreased breath sounds on the affected side, changes in blood pressure, tachypnea, grunting, cyanosis, bradycardia, distant heart sounds, and irritability. It is more difficult to appreciate signs and symptoms of pneumothorax in the preterm infant because of resonance, chest wall compliance, and other disease processes.

Treatment requires evacuation of the extra pulmonary air and usually is an urgent surgical procedure. Nursing care requires continuous monitoring of blood pressure, heart rate, and oxygenation.

Pneumonia

The incidence of pneumonia in the preterm infant is greater than 10% (Lott, 1994) owing to immature immune response, extended hospitalizations, and prolonged ventilatory support. The mortality rate for perinatally acquired pneumonia is approximately 20%; for postnatal infections the rate increases to almost 50% (Lott, 1994).

The causes of neonatal pneumonia can be divided into three categories: transplacental infections that are mostly viral, such as cytomegalovirus, syphilis, tuberculosis, and listeria; perinatal infections that include group B

Streptococcus, *Haemophilus influenzae*, *Escherichia coli*, *Klebsiella*, and *Chlamydia*; and postnatal infections, such as *Pseudomonas*, *Serratia*, *Staphylococcus aureus*, CMV, and respiratory syncytial virus (RSV).

Medical treatment requires broad spectrum antibiotics until the organism is identified. At that time antibiotic therapy is adjusted to suitable drugs for that organism.

Respiratory syncytial virus is the major cause of bronchiolitis and pneumonia in infants during the first 3 years of life (Lott, 1994) and is the most common cause of re-hospitalization for the preterm infant. RSV is most prevalent during the months from winter to spring. Treatment in the infant who is mildly infected is aimed at supportive and symptomatic therapies. Ribavirin occasionally is used in infants with severe disease. Prophylactic immunization is available with palivizumab (Synagis) for infants most at risk for developing severe illness. Synagis is an intramuscular (IM) injection given once a month for 6 months and may be given in conjunction with other immunizations (AAP, 1998).

Meconium Aspiration Syndrome

Meconium aspiration is similar to RDS in presentation and radiographic findings and is caused by aspiration of meconium-stained amniotic fluid in utero or at delivery. Meconium aspiration syndrome rarely is found in premature infants of less than 36 weeks' gestation (Casey, 1999). Meconium aspiration results in a chemical pneumonitis, airway obstruction, and hyperinflation. Pneumonia, pulmonary hypertension, and pneumothorax are common complications.

SPECIAL CONSIDERATIONS IN CARING FOR THE INFANT AT HIGH RISK

Nurses in the NICU are in a position to provide physical care to infants and psychosocial care to families. This care involves facilitating parent-infant bonding, providing parent education, and serving as advocates for their patients—infants who cannot speak for themselves. Controlling the physical environment, meeting infants' physical and medical needs, and maintaining client records used in medical decision-making are important aspects of the nursing role (Figure 34-11).

Of particular importance in the NICU is alleviating parental anxiety and providing insights into the family's values and cultural preferences for the health care team. The nurse serves as the infant's protector when the parents are not at the bedside and as an interpreter for medical terminology. The following section addresses considerations that affect ill infants whether they are premature, have IUGR, or have other medical conditions.

CHEST TUBE ASSESSMENT

1. Assess the chest tube insertion site: an occlusive dressing is used as a barrier to infection.
2. Assess chest tube patency: fluctuation of the water column may indicate patency.
3. Assess output: drainage should be minimal; drainage should not be bloody.
4. Evaluate the water seal: excessive bubbling indicates an air leak in the system.

Figure 34-11 Documenting all care given to the high-risk infant is an important nursing responsibility.

Parental Anxiety

The birth of a premature infant is a challenge to parents who anticipated having an uneventful pregnancy, a normal delivery, and a healthy infant. Instead, the infant is ill, very small, and in a place filled with strange sounds and highly technical equipment (Figure 34-12). Hospital personnel are brisk, professional, and efficient; they speak rapidly, using medical jargon. It is easy for parents to feel as if they are unable to care for their infant and to experience a sense of isolation from the staff.

The technical component of care for the preterm infant is intimidating and often overwhelms parents. They may feel helpless because of the fragility of the infant. With support and education, parents become familiar with the equipment, staff, and routines. Once this occurs, parents are able to begin participating in the infant's care.

It is important for nurses who care for premature infants to promote family-centered care. The parent is the constant in the baby's life. The nurse should support the individuality and coping mechanisms of each family and should make each visit to the baby as pleasant as possible.

Information given to parents should be complete and clear. Specialized medical terms should be avoided, and any written materials should be provided in lay terms.

Figure 34-12 The nurse must remember the critical role that parents play in the at-risk infant's high-tech world.

The developmental needs of the infant should be discussed. Teaching parents to recognize the unique personality of their infant and the infant's distress signals will foster parent-infant interaction and help provide confidence in parenting skills. Involving parents in the infant's care is very important (Figure 34-13).

Personalization of the infant's bedside, use of the infant's name, and a permissive visitation policy foster family involvement. Comfortable chairs, subdued lighting, and a quiet atmosphere may calm and soothe the baby and the parents.

Ethical Considerations

The goals of neonatal care are to preserve life, decrease morbidity, and relieve pain and suffering. Technologic advances have been a benefit to many and have allowed for

Figure 34-13 Parents will learn the cues to their infant's needs at each visit to the NICU.

the mortality and morbidity of premature infants to improve. These advances also have resulted in ethical dilemmas for all parties involved. How small is too small? Whose decision is it to resuscitate an infant born at 23 weeks' gestation? Should infants with lethal anomalies be resuscitated? These are just a few of the questions that face neonatal caregivers.

Nurses are the primary caregivers in the NICU. They need to maintain expertise and objectivity, while providing the family with a supportive and caring environment. These competing obligations make caring for the client more difficult. The role of the nurse should first be as client advocate, to ensure that the care the client is receiving is what is best for that client and the family.

In general, all infants at 24 weeks' gestation and above are considered viable. State and federal laws exist that mandate viability. In all instances, the parents should be given the information that is needed to make informed decisions about therapy and procedures. Most tertiary care centers have ethics committees that can be called on to assist in decision-making processes. The parents or anyone involved in the infant's care can request a committee meeting in which client information is presented, discussion of options occurs, and a collective decision can be made. The caregivers, social services, and support persons of their choice support parents through this process. Of utmost importance is to ensure that the decision is one the parents are comfortable with.

Thermoregulation

Maintenance of a normal body temperature is an extremely important aspect of nursing care of the preterm neonate. A healthy term infant is able to initiate temperature regulation by heat production within a few hours after birth. Term and preterm infants who are ill do not have this ability. The newborn can produce heat through four mechanisms: metabolic processes, voluntary muscle activity, peripheral vasoconstriction, and nonshivering thermogenesis (Kenner, Amlung, & Flandemeyer, 1998). The preterm infant is limited in the ability to produce heat as a result of decreased

glycogen stores in the liver, decreased brown fat availability, small muscle mass, and increased body surface area.

The infant can lose heat by four modes of heat transfer: evaporation, conduction, convection, and radiation. It is important for nurses caring for premature infants to understand these concepts to prevent cold stress in infants (Box 34-2).

Evaporation is the loss of heat as water is lost from the skin to the environment. It is important to dry an infant rapidly after birth to prevent evaporative heat loss and cold stress. *Conduction* is the transfer of heat from one object to another when in direct contact. For example, placement on a cold scale to weigh the infant will result in heat from the infant's body being transferred to the scale. Placing a warm blanket on the scale first, and returning the dial to zero, before weighing the infant helps prevent conductive heat loss. Electronically warmed scales are available to help maintain the infant's temperature.

Convection is the loss of heat from an object to the environment. The use of servo-controlled incubators and neutral thermal temperature charts determines the best incubator temperature to prevent heat loss and minimize oxygen and calorie consumption so important in the care of the premature infant. When caring for an infant, use of portholes instead of opening the incubator door prevents rapid heat loss from the incubator. Open only the portholes of the incubator on one side at a time to prevent cross-ventilation and heat loss from the incubator. When nursed in a bassinet or on a warmer, the infant should be protected from drafts.

Radiation is the loss of heat between objects that are not in direct contact. A cold window near the infant's incubator would allow the wall of the incubator to cool. The infant would then lose heat to the cool incubator wall. The use of double-walled incubators and incubator covers helps prevent heat loss by radiation.

Once these conditions are controlled in the environment of a preterm infant, maintenance of body temperature is easier. Signs and symptoms of hypothermia and hyperthermia are outlined in Box 34-3. The consequences of hypothermia include hypoglycemia, pulmonary vasoconstriction, altered surfactant production, metabolic acidosis,

Box 34-2 Preventing Cold Stress in the Premature Infant

Evaporation

- Dry at delivery.
- Dry after bathing
- Keep linens dry.
- Use plastic-wrap blankets.
- Use heat shields.
- Use humidified air.

Conduction

- Prewarm the bedding.
- Use a warmed scale.
- Cover X-ray plates.
- Warm the diapers.
- Warm the water and cleansers.

Convection

- Warm the environment.
- Avoid drafts.
- Cover up the infant.
- Use head caps.

Radiation

- Avoid windows.
- Use incubator covers.
- Use a double-walled incubator.

Box 34-3 Signs of Thermal Stress**Hypothermia**

- Mottling, pallor
- Acrocyanosis
- Cyanosis
- Bradycardia
- Tachypnea
- Apnea
- Lethargy
- Hypotonia
- Poor feeding or feeding intolerance

Hyperthermia

- Flushing
- Hypotension
- Diaphoresis
- Tachycardia
- Tachypnea
- Apnea
- Irritability

hypoxia, and weight loss or poor weight gain (Blackburn & Loper, 1992).

When rewarming an infant who has been stressed by cold, it is important to increase the temperature gradually. Increase the ambient air temperature by 1 to 1.5 degrees until the infant's temperature is stable. Rapid rewarming may result in hypotension from peripheral vasodilation and apnea.

Consequences of hyperthermia include an increased metabolic rate, leading to increase oxygen consumption and dehydration from increased insensible water loss. Peripheral vasodilation may result in hypotension (Kenner, Amlung, & Flandemeyer, 1998). Seizures and apnea also may occur (Merenstein & Gardner, 1998).

All types of warming devices used in the care of preterm infants have benefits and risks. Shown in Figure 34-14 are a radiant warmer and one type of incubator. Heat shields, plastic-wrap blankets, hats, warming pads, and skin protectors are useful tools in temperature regulation. Skin-to-skin holding also is of benefit in heat conservation for infants and is discussed subsequently.

Nutrition and Fluid Management

Fluid and nutrition are essential to life. In the newborn who is ill, fluid and nutrition take on added importance because of the infant's large surface area, limited storage, and increased metabolic needs to maintain thermal homeostasis and for growth and development.

Fluid Management

The management of fluids in the preterm infant may become very complicated. Owing to their small size, large surface area, and immature skin barrier the premature infant may have large evaporative losses (insensible water losses). The preterm infant's total body water is 85% to

90%, whereas the term infant's is 80%. The extracellular fluid of the preterm infant is 50% to 55% compared with 45% in the term infant. The major routes of water losses are evaporative from the skin and lungs and excretory

A.

B.

Figure 34-14 A. Radiant warmer. B. Covered incubator with portholes.

from the urinary tract. Mechanisms that increase **insensible water loss (IWL)** include use of radiant warmers and phototherapy.

Fluid losses are inversely proportional to weight and gestational age. The smaller the infant the greater the fluid losses (Table 34-2). Measures to aid in decreasing IWLs include humidified air, which decreases IWL by 30%, and use of plastic blankets or shields, which decreases IWL by 50% (Costriano & Baumgart, 1986).

The overall goal of fluid management is threefold: to maintain normal body fluid composition and volume, to prevent overhydration and dehydration, and to replace ongoing water losses. Fluid needs in the first few days of life usually are higher in infants who have LBW than in larger premature infants or term infants. For example, an infant weighing less than 1,000 g initially may have a fluid requirement of 100 mL/kg/d, whereas an infant weighing 1,500 g would need only 80 mL/kg/d.

Strictly monitoring fluid intake and output is essential. Monitoring the infant's urine output by weighing diapers is necessary to assess fluid status. Evaluating laboratory values also is helpful. The following laboratory tests can assist in maintaining the delicate balance of fluids: serum electrolytes, BUN, and creatinine. Elevated sodium and BUN levels generally indicate a need for fluid. Elevated creatinine indicates renal dysfunction often owing to prematurity.

Weight loss is necessary and expected in the first few days of life (Figure 34-15). Generally, term infants may lose from 10% to 15% of their birth weights, whereas preterm infants may lose from 15% to 20% of their birth weights. This weight loss is caused by natural diuresis. It is essential to provide adequate nutrition during this time to prevent excess weight loss in an already compromised infant.

Because fluid balance is so important in premature infants and because very small amounts of fluid may add up to a significant volume, strictly measuring fluid intake and urine output is essential. All fluids are recorded and considered, including fluids that medications are mixed with and fluids used to flush IV lines and catheters. When

Figure 34-15 At 2 weeks of age, this preterm infant is starting to gain weight.

blood, blood products, and other volume-expanding fluids are used, the measurements also must be included in the infant's daily intake. Electronic pumps designed to administer fluid to a tenth of a milliliter are used to avoid overhydrating an infant. Failing to include medications and blood products in the intake, miscalculating fluid needs, entering an erroneous IV rate, or failing to adjust to decreased urine output in a timely manner can lead to fluid overload. Complications of fluid overload in the premature infant include pulmonary edema, PDA, congestive heart failure, IVH, and BPD.

Fluid management may be divided into short-term and long-term management. Those infants requiring IV fluids for the first few days of life generally are managed on a glucose solution, with the addition of electrolytes and calcium supplements. Very premature and acutely ill infants may require IV fluids for a prolonged period of time. These infants will need a **total parenteral nutrition (TPN)** solution that meets the requirements of carbohydrates, protein, electrolytes, vitamins, and minerals generally received through feedings. These needs generally are

Table 34-2 Fluid Losses in Incubator

Weight (g)	Insensible Water Loss (mL/kg)	Urine (mL/kg)	Total (mL/kg)
<1,000	65	45	110
1,001–1,200	55	45	100
1,251–1,500	38	45	83
>1,500	17	45	62

met through TPN with intralipids for essential fatty acid requirements.

Various routes are available for parenteral fluid administration in the preterm infant. For short-term access, peripheral lines may be adequate. The nurse generally inserts a small-gauge Teflon catheter into a scalp or peripheral vein. Long-term access is necessary for **very low birth weight (VLBW)** infants, that is, infants weighing 1,500 g or less at birth; **extremely low birth weight (ELBW)** infants, that is, infants weighing 1,000 g or less at birth; and infants who are acutely ill. Long-term access may be achieved with umbilical venous catheters, percutaneous central venous catheters, or central venous catheters. Use of indwelling catheters increases the infant's risk for infection, bleeding, clot formation, and microemboli. Careful monitoring and aseptic technique are necessary.

Electrolyte Management

Electrolyte supplementation usually is not required in the first 24 hours of life and should not be given until urine output is established. The fluid losses from skin, lungs, and urine contain small amounts of electrolytes. By the second day of life maintenance electrolytes are required. At this time, 2 to 4 mEq/kg/d of sodium, potassium, and chloride may be added.

The infant who has VLBW lacks the ability to conserve sodium and potassium. Therefore, sodium requirements may be as high as 9 mEq/kg/d, and potassium requirements 8 to 10 mEq/kg/d.

Hyponatremia (serum sodium less than 125 mg/dL) occurs secondary to sodium wasting with diuretic therapy, GI and renal tubular losses, fluid overload, syndrome of inappropriate antidiuretic hormone, sepsis, and congenital adrenal hyperplasia. **Hypernatremia** (serum sodium greater than 155 mg/dL) is most likely from dehydration or excessive sodium intake (Zenk, Sills, & Koepfel, 2000).

Hyperkalemia (serum potassium greater than 7 mg/dL) occurs as a result of low urine output and immature renal function, specifically distal tubular dysfunction. This condition is life-threatening. Preterm infants may present with electrocardiographic changes. Acidosis with a shift of potassium from the intracellular to the extracellular compartment is noted. Treatment includes discontinuation of potassium administration, increase in serum glucose levels, and insulin administration to shift the potassium into the intracellular compartment.

Glucose Homeostasis

Glucose is the main substrate necessary for energy, brain metabolism, and CNS integrity. During fetal life, glucose crosses the placenta and is the main source of energy for the growing fetus. After birth, neonates must maintain glucose homeostasis on their own.

Hypoglycemia

Owing to immaturity, the preterm infant's metabolism may not be capable of producing and regulating glucose. The preterm infant is at high risk for hypoglycemia secondary to rapid depletion of already low glucose stores and inability to produce and regulate glucose. **Hypoglycemia** is defined as serum glucose less than 40 mg/dL. Signs and symptoms of hypoglycemia include jitteriness, irritability, cyanosis, seizures, and apnea.

In term infants who are asymptomatic and nonstressed early feedings can be attempted. This option is less likely for a premature infant because of the inability to suck and lack of substrate for food absorption. At times, it may be appropriate to provide the early feeding by gavage, retesting 30 minutes after feeding. Infants who are symptomatic and most premature infants will require IV glucose followed by maintenance fluids. Glucose requirements for term and preterm infants weighing more than 1250 g initially begin at 6 to 8 mg/kg/min. is provided by 10% dextrose at 80 mL/kg/d. Preterm infants have a greater demand for glucose because of their large brain to body-weight ratio compared with term infants and older children (Haymond, 1989). Glucose levels are monitored until stable. Treatment of the underlying pathology is essential.

Hyperglycemia

Hyperglycemia is defined as a blood glucose greater than 125 mg/dL in the term infant and greater than 150 mg/dL in the preterm infant. Hyperglycemia is commonly seen in the premature infant. These infants are not able to tolerate a glucose infusion at the same rate as would a more mature infant. This intolerance is due a decrease in insulin release in response to glucose.

Sepsis, specifically gram-negative sepsis, also increases the risk for hyperglycemia. Certain drugs may cause an increase in glucose levels, including high levels of methylxanthines, which are used in the treatment of apnea of prematurity. Hyperglycemia may be a stress response as seen

Nursing Alert

RISK FACTORS FOR HYPOGLYCEMIA

- Decreased substrate availability
- Endocrine disorders
- Increased utilization
- Sepsis
- Central nervous system abnormalities

in neonates postoperatively. Steroid therapy also produces a hyperglycemic state in preterm infants.

In the infant who has LBW glucose infusions are initiated and increased gradually. Initial fluids are started at 2 to 4 mg/kg/min and gradually increased to 8 to 12 mg/kg/min, depending on the infant's tolerance and needs. The basal metabolic rate in preterm infants is higher than that in term infants and may require higher concentrations of glucose to meet these needs. If the preterm infant is unable to tolerate high glucose concentrations, insulin may be added to the fluids or given as a separate IV drip until levels are under control. In the first few days of life frequent monitoring of glucose levels is extremely important.

Feeding

Nutritional needs for premature infants often are complex. Accelerated needs for calories and minerals cannot always be met through the use of human milk or standard formulas. Approximately 50 to 60 kcal/kg/d are necessary for infants to maintain weight. The term infant may require 100 to 110 kcal/kg/d and the preterm infant from 110 to 140 kcal/kg/d for weight gain.

Formula Feeding

Formulas are available specifically designed for the preterm infant to provide high calorie intake per ounce and extra protein, vitamins, and minerals needed for growth and development (Figure 34-16). Human milk remains the feeding of choice for premature infants. Because of the infant's size and limitations related to the medical conditions, enteral intake may be restricted. Standard formula and human milk at the volumes tolerated by the infant may provide inadequate calories to sustain rapid growth and high metabolic needs. At limited volumes these feedings do not provide adequate minerals for bone mineralization, and **osteopenia** (bone mass below normal levels) may occur.

There are commercial formulas designed for premature infants and commercially prepared fortifiers available to add to expressed human milk that increase the calorie and mineral content of the milk. As the infant grows and is able to tolerate larger volumes of feedings, the formula may be changed to formula designed for term infants or to nonfortified human milk.

Breast Milk Feeding

Mothers who decide to provide breast milk for their infants need encouragement and support. Mothers must be educated on the correct expression and handling of breast milk. Many hospitals have nurses who specialize in lactation support available to assist these mothers. These lactation consultants are available to provide support to the

Figure 34-16 This preterm infant receives a specially designed formula to meet his nutritional needs; note placement of a nasogastric tube.

mothers during the transition from gavage feedings to breast-feeding when needed.

Initiating Feedings

Determining when to initiate feedings is dependent on several factors: the infant's clinical status, assessment of GI

PARENT EDUCATION

When teaching parents how to check orogastric feeding tube placement, teach them to place the end of the tube in a glass of water after checking placement. The water will bubble with each breath if the tube is in the trachea rather than the stomach. Being able to double-check placement may give parents more confidence in their ability to perform this skill.

motility, and nutritional needs. Once the infant's condition is stable and stooling has begun, enteral feedings usually may be introduced.

The feeding regimen may vary but generally depends on gestational age and weight. Preterm infants less than 31 week's gestation are unable to coordinate sucking and swallowing with respirations. Therefore, orogastric tube feedings are necessary (Figure 34-17). They may be given as a continuous hourly drip or by intermittent **gavage feedings**, usually every 2 to 3 hours, depending on the infant's tolerance (Box 34-4).

Very premature infants may be started on sterile water, human milk, or half-strength premature formula for the first feedings. These feedings are minute and are used to stimulate GI motility. Larger infants and premature infants who are more mature may be started on human milk or full-strength formula. Once the feedings have been initiated and tolerated, the caloric density and volume of feedings are gradually increased to full-strength 24-cal/oz formula, or fortifiers are added to human milk to increase caloric density to 24 cal/oz. Volume is gradually increased by 15 to 25 mL/kg/d until full feedings are established. A full enteral feeding for a premature infant is 150 to 160 mL/kg/d of premature formula or fortified human milk. Once the infant transitions to 20 cal/oz or nonfortified human milk, the infant must receive at least 180 mL/kg/d.

It is essential for the nurse to be aware of the infant's tolerance to feedings and changes in tolerance resulting from an increase in calories or volume. Signs and symptoms of feeding intolerance include increasing gastric residuals, bile in gastric aspirate, blood in gastric contents or stools, abdominal distention, change in bowel pattern or diarrhea, visibly dilated loops of bowel emesis, temperature instability, apnea and bradycardia, and hypoxia.

Infants between 32 and 35 weeks' gestation are generally assessed for readiness to feed by mouth. These include infants born at a younger gestational age and who

are now 32 to 35 weeks by postconceptual age and infants who have just been born at this gestational age. If the infant does not demonstrate the ability to coordinate oral feedings (an adequate suck-swallow reflex and breathing) or does not have the stamina to feed orally, gavage feedings are indicated. As discussed in previously, volume is increased as tolerated by the infant.

During gavage feedings the infant will require oral stimulation to improve coordination and facial muscle tone. Offering a pacifier during gavage feeds may aid in the development of oral feeding skills (Figure 34-19). Non-nutritive sucking also may be achieved by suckling at the breast once the mother has manually expressed milk.

Occasionally, alternative formulas may be necessary. Because infants who have experienced bowel injury may not tolerate standard or premature formulas, use of elemental or basic formulas may be required. While an important adjunct for feeding high-risk infants, these formulas are not as high in calories and protein as are the premature formulas. When alternative formulas are used, supplementation with carbohydrates and protein is necessary to ensure optimal nutrition.

Pain Management in the Neonate

In 1979, the International Association for the Study of Pain defined pain as an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage (Merskey et al., 1979). Pain is a very subjective experience. It is extremely difficult to identify the degree of pain of infants because of their inability to express pain. This inability of the infant to tell caregivers of their pain has led to failure of caregivers to recognize and treat pain in the neonatal population. According to Anand (1998), preterm and term infants demonstrate similar or even exaggerated physiologic and hormonal responses to pain compared with those observed in older children and adults.

The American Academy of Pediatrics (AAP) and the Canadian Pediatric Society (CPS) (AAP & CPS, 2000) jointly promoted a document to address the issue of pain management and prevention in neonates. In the past, the focus has been centered on treatment of pain rather than a systemic approach to reduce or prevent pain.

We now know that neonates have the neurologic capability to experience pain. The peripheral and spinal structures necessary for pain information transmission are present and functional between the first and the second trimesters. Therefore, infants born as early as 24 weeks' gestation are capable of feeling pain.

It has been proposed that untreated pain has adverse physiologic consequences and probable short-lived and long-term consequences (Shapiro, 1993). Adverse physio-

Figure 34-17 Premature infant with orogastric feeding tube.

Box 34-4 Oral Gastric Tube Placement

A. Indications: Provision of enteric feedings when oral feedings are not possible.

1. Immature suck-swallow reflex
2. Abnormal gag reflex secondary to neurologic disease
3. Inability to take full enteric feeding orally
4. Abnormal respiratory pattern
5. For gastric decompression

B. Contraindications

1. Recent repair of esophageal fistula or perforation

C. Equipment

1. Cardiac monitor
2. Suction equipment and catheter
3. 5- or 8-F feeding tube
4. 3- or 5-mL syringe
5. Stethoscope
6. Gloves
7. 1/2-in tape, Elastoplast, skin barrier

D. Procedure

1. Wash hands.
2. Put on gloves.
3. Position infant on back.
4. Monitor heart rate, oxygen saturations, and respiratory rate.
5. Gently suction nares and oropharynx.
6. Measure length for insertion by placing catheter tip from nose to stomach and estimating distance (Figure 34-18). Mark length on tube with tape.
7. Moisten end of tube with sterile water.
8. Place finger on anterior portion of tongue. Stabilize head.

Figure 34-18 Measurement for a nasogastric feeding tube.

9. Insert tube along finger into oropharynx.

10. Gently advance tube to predetermined length.

11. Use pacifier to stimulate suck-swallow if able.

a. Do not advance if resistance is met.

b. Stop procedure if signs of respiratory distress occur.

12. Determine correct placement

a. Inject 1 mL of air into catheter while auscultating over stomach.

b. Aspirate contents; note amount and type.

13. Secure catheter to infant's face using pectin-based skin barrier under tape.

E. Complications

1. Apnea or bradycardia
2. Hypoxia
3. Perforation of posterior oropharynx, esophagus, stomach, or duodenum
4. Aspiration or esophagitis
5. Interference with suck reflex

logic consequences such as alterations in blood pressure and glucose may affect the development of IVH. More immediate effects may be feeding intolerance, inability of infants to interact with parents, and interruption of sleep-wake cycles. Potential long-term consequences include impairments of neurodevelopment, learning, and memory (Shapiro, 1993).

As caregivers, bedside nurses are the best advocates for neonates. Nurses must be aware of behavioral and physical signs neonates use to indicate pain. Behavioral changes include crying, facial changes, and gross motor

movement (see the Nursing Tip). Physiologic and autonomic changes also occur that can indicate when infants are in pain. These changes may be subtle, or they may also indicate early signs of illness. These changes include increased heart and respiratory rates that when left untreated may advance to apnea and bradycardia, increased blood pressure, and palmar sweat. The very immature neonate may not show a response to pain and later have changes in heart rate, blood pressure, and oxygen saturation.

Several tools are available to aid the nurse in assessing neonatal pain. These tools use behavioral and physiologic

Figure 34-19 This premature infant sucks on a pacifier during his gavage feeding.

responses to pain or noxious stimuli. They are CRIES (Crying Requires Increases Expression Sleepless (Krechel & Bildner, 1995), the Premature Infant Pain Profile (PIPP) (Stevens, 1996), and the Neonatal Infant Pain Scale (NIPS) (Lawrence et al., 1993).

Pain management is an area of research on which neonatal caregivers have focused. Prevention or avoidance of noxious stimuli, use of nonpharmacologic measures,

Nursing Tip

NONPHARMACOLOGIC MANAGEMENT OF PAIN

- Group blood draws
- Central venous access
- Noninvasive monitoring
- Expert staff for inserting IV lines and drawing blood

and pharmacologic treatment are integral parts of caring for our clients.

Changes in environment such as dim lighting and decreasing noise levels help decrease noxious stimuli and stress. Simple comfort measures aid in the neonate's ability to cope with painful interventions. These measures include containment, swaddling, nonnutritive sucking on a pacifier, and positioning to midline. These interventions may aid in the control of pain for minor procedures; they are not enough for moderately to severely painful procedures.

With the advances in neonatal care have come advances in anesthesia and training of personnel that have increased the safety and efficacy of anesthesia for neonatal procedures. The use of opioids has become more common in the NICU. Thus, caregivers must be aware of the potential for adverse effects on the respiratory, cardiovascular, and renal systems in neonates.

The goals of pain management are to minimize the intensity, duration, and physiologic cost to the neonate.

Drug Metabolism and Excretion

The liver and the kidneys are the major organs responsible for removal of drugs from the body. Whereas the metabolism and excretion of therapeutic drugs is well studied in healthy adults, the use of drugs in neonates is not well understood. Drug therapy must be carefully monitored for its tolerance and effect. In discussing drug metabolism absorption, distribution, clearance, and elimination must be considered.

Many factors affect drug absorption in the neonate. The route by which the drug given plays an important part. For example, for oral administration, the surface area of the intestinal tract is relatively small and the gastric emptying time is prolonged. The bile salt pool size is decreased, and bacterial colonization is not conducive to absorption. IM injection is not feasible long term owing to small muscle mass, poor peripheral perfusion, and decreased muscle activity. IV drug therapy is best tolerated

Nursing Tip

BEHAVIORAL SIGNS OF PAIN IN NEONATES

- Cry: change in frequency or pitch
- Facial changes: brow bulging, vertical furrows, eye squeezing, nasolabial furrow, and open lips
- Gross motor: attempt to withdraw from painful stimuli (near term infants),
- Limpness or flaccidity (preterm infants)

by the neonate but in most cases requires prolonged IV placement with increased risk for infection.

Factors affecting drug distribution include increased body and extracellular water, decreased amount of plasma protein available for binding, decreased serum pH, and altered cardiac output.

In the preterm infant the liver and all other systems are immature. Hepatic function is decreased in neonates. There are varied hepatic pathways that mature at different points in gestation. Drug metabolism and elimination in the liver therefore depend on gestational age.

Renal elimination is directly correlated with the GFR. Extreme caution must be used in administering and monitoring drugs in premature infants. Drug therapy is tailored to the infant and may change daily.

Drug metabolism and elimination must be carefully monitored. Monitoring for therapeutic levels is essential to ensure that treatment is adequate and toxic levels are not reached. Standardized dosing regimens are common in neonates and calculated daily based on the infant's weight.

COMPLEMENTARY THERAPY

Neonatal nurses must be prepared to provide holistic family-centered care to the infants in their charge. Nurses can nurture clients and families by their caring and insight. There are nonpharmacologic therapies to enhance the experience of the infant and the family. Some are described in this section. The emphasis is on the premature infant and the infant's family because these infants are the ones hospitalized for long periods of time.

Developmental Care

Developmental care is a philosophic approach to the care of the premature infant. Premature infants may be hospitalized for a prolonged period of time and are subjected to many tests, procedures, and therapies during hospitalization. Developmental care is an approach designed to support the infant's efforts toward self-regulation.

Interventions include positioning, modification of the environment, and promotion of self-regulatory behaviors such as nonnutritive sucking (Engebretson & Wardell, 1997).

The reflexes and responses of a premature infant are consistent with postconceptual age. The infant continues to grow and develop postnatally. A need exists for early awareness and intervention to ensure normal musculoskeletal and developmental growth. Premature infants are prone to developing contractures and malposition of the extremities. Many infants require periods of sedation or paralysis owing their medical condition or require prolonged immobilization of a limb or extremity for medical interventions, such as percutaneous central lines. By being

aware of the potential for contractures to develop, the nurse can take measures to minimize risks.

Premature infants have undeveloped muscle tone. The more premature the infant the more hypotonic the infant will be. Tone will develop in the same sequence as in the term infant; however, flexor tone will not develop to the same degree. When premature infants are allowed to lie in a frog-legged position for long periods of time, with elbows flexed and shoulders abducted, the forward rotation of the shoulder may be limited (Figure 34-20). This limitation may interfere with the development of hand-to-mouth orientation. Prolonged positioning with the hips flexed, abducted, and externally rotated may cause hip dislocation or interfere with weight bearing later in life.

The infant's position should be changed regularly and frequently, about every 2 to 3 hours. Position changes should be documented to ensure a full range of positions. Gentle passive range-of-motion exercises may be provided as tolerated. Proper body alignment is essential. When turning, arms and legs should be held close to the infant's body.

Modifications of the infant's environment include indirect, soft, or dimmed lighting. A quiet environment is important. Padded incubator covers can help block out excess light and muffle noise. The inside of the cover should be dark and patterns limited to avoid overstimulation. Containment boundaries can give the infant a feeling of security, and soft bedding can aid in comfort.

Promoting self-regulatory behaviors includes clustering care to prevent fatigue and nonnutritive sucking. Nonnutritive sucking can provide infants who have LBW an opportunity to organize their behavior (Engebretson & Wardell, 1997). Nonnutritive sucking can be provided when the infant is irritable or receiving gavage feeds and after procedures to calm the infant (Figure 34-21). Once the infant is stable, nonnutritive breast-feeding can be introduced.

Figure 34-20 Frequent position changes for the premature infant will aid in development of good muscle tone.

Research Highlight

Development of a Pacifier for Low-Birth-Weight Infant's Nonnutritive Sucking

Purpose

As advances in neonatal care have improved the survival of smaller and smaller infants, nurses have had to modify care practices and equipment to accommodate the infant's size and level of development. The authors of this study developed and tested a pacifier specifically designed for infants who have very low birth weight.

Methods

Two aspects of pacifier design were addressed: size and shape. A natural approach was used to develop a pacifier similar to the infant's thumb. It was thought this shape would promote stimulation of the oral cavity and perioral region. Plaster molds of a preterm infant's palate and thumb were made and found to match. The model of the thumb was chosen as the pacifier design.

To determine the appropriate size for the pacifier, the sizes of thumbs, the infants' weights, head circumferences, and facial dimensions of 49 infants were obtained; thumb size was found to be proportional to weight. The mean values of these measurements were used to determine nipple length and circumference of the pacifier prototype. The addition of an angle upward was included to simulate the angle of the thumb.

Clinical trials were conducted in two phases to test the pacifier design. The first phase was to test a prototype nipple, which was attached to a commercial guard. The second phase was to test the completed nipple. The completed nipple was attached to a soft guard.

Infants who were average for gestational age, less than 2,500 g at birth, and free of anomalies that would interfere with sucking were included in the study; 36 infants were randomly assigned to either a prototype or a commercial pacifier. They were offered a pacifier while awake. Nurses in the neonatal intensive care unit served as clinical experts for the study. A nurse offered the pacifier and remained with the infant throughout the 30-minute observation time. Observation was of behavioral states using the 12-category Anderson Behavioral State Scale. Sucking patterns were noted, and the heart rate was measured and charted every 2 minutes. The pacifier was removed from the infant's mouth when signs of distress were observed.

Findings

In phase I, infants who received the prototype pacifier were found to be in a state of alert inactivity (a state suitable for feeding) significantly more often than were those in the group receiving the commercial pacifier. In the phase II clinical test, convenience samples of 20 infants were tested. The findings were positive for the acceptance of the pacifier: 100% of the infants sucked on the pacifier, 65% sucked vigorously, and 85% were in a sleep state after 20 minutes.

Nursing Implications

The infants in the clinical trials spent significantly more time in alert behavioral states associated with better feeding than did infants using the control pacifier. This increased alertness is an indication of behavioral organization. The pacifier is cost-effective and can be used successfully by parents to provide comfort to their infants. Use of this pacifier may contribute to earlier and better feeding patterns and improved growth.

Engebretson J. C., & Wardell D. W. (1997). Development of a pacifier for low-birth-weight infant's nonnutritive sucking. *Journal of Obstetric, Gynecologic, and Neonatal Nursing*, 26, (6), 660-664.

Figure 34-21 Nonnutritive sucking on a Wee-Thumbie pacifier helps this infant who has low birth weight remain calm and conserve energy.

All developmental interventions should consider the infant's gestational age. Older infants who are chronically ill should be provided with developmentally appropriate toys and activities. Parents should be involved as much as possible. A multidisciplinary team that includes physicians, primary nurses, infant occupational therapist, developmental specialists, and a speech pathologist may be needed to ensure the infant's developmental needs are being met. At discharge, preparing the infant for entry into society should be addressed in addition to the medical needs.

Early childhood intervention programs are federally funded programs designed to aid parents and infants in the transition from being hospitalized to going home. Team members include occupational therapists, physical therapists, and social workers. Infants are assessed for progression of developmental milestones, and parents are taught approaches to care to aid in the infant's development.

Therapeutic Touch

The newborn infant's sense of touch, temperature, and pressure are well developed. The major methods of communication are through touch and cry. The NICU environment and therapies consist of noxious stimuli, and the neonate may develop an aversion to touch. Noncaregiving touch is necessary and should be provided by parents and professionals. Parents should be taught to observe their infant's signals. Thus, they gain confidence in parenting skills and come to know and understand their infant's signals regarding what is and what is not tolerated.

Infant Massage

As the preterm infant matures, head-to-toe massage may be initiated. Infant massage consists of stroking at a rate of 12

to 16 strokes per minute and is thought to soothe the infant and stimulate respirations, circulation, and GI function. Varying the touch pattern maintains the infant's interest.

Containment

Containment is use of the hands to support the infant in a midline position during painful or noxious procedures. Also referred to as facilitated touch or gentle human touch, containment consists of a caregiver placing one hand on the infant's head and the other on either the infant's bottom or legs in a tucked position, and providing firm but gentle pressure (Figure 34-22). Containment has been shown to increase the infant's tolerance of procedures; provide faster return to baseline levels of vital signs on completion; cause less hypoxia, tachypnea, and tachycardia; and result in less energy expenditure.

Any of these forms of gentle touch help the preterm infant adapt to the environment and tolerate uncomfortable procedures. Therapeutic touch is needed during procedures to comfort the infant. Therapeutic touch is used at other times to provide the infant with pleasurable sensations and is especially effective when parents are involved. The infant may associate pleasurable sensations with the parents, facilitating attachment.

Kangaroo Care

Kangaroo care originated in Bogota, Columbia, as a necessity for providing preterm infants with warmth and

Figure 34-22 Containing the preterm infant in a midline position.

nutrition. Kangaroo care consists of a parent holding an infant, unclothed except for a diaper, upright on the mother's or father's chest. The parents are instructed to wear a shirt that opens in the front. This technique also is called skin-to-skin holding (Figure 34-23).

The benefits for the parents include feelings of well-being, feeling a part of their infant's care, enhanced parent-infant attachment, and self-confidence and self-esteem. The benefits for the infant include better weight gain, temperature regulation, decreased apnea, improved oxygenation, earlier discharge, increase in breast-feeding and increased supply, and earlier time to oral feeding. Kangaroo care, once viewed as an alternative therapy, is now common in most NICUs (Victor & Person, 1994).

Co-Bedding of Twins

Placing newborn twins together may provide support for the infants during transition to extrauterine life. Twins may be born with unique expectation of what constitutes a normal habitat, and their transition to extrauterine life may be facilitated by maintaining contact each other. This contact is thought to be supportive in nature (coregulating) (Nyquist & Lutes, 1998). Co-bedding is based on the premise that extrauterine adaptation of twin neonates is enhanced by

Figure 34-23 Kangaroo care, or skin-to-skin holding, has many benefits for the parent and infant.

continued physical contact with the other twin rather than the sudden deprivation of such stimuli (Nyquist, 1998).

An improvement in temperature regulation and behavioral states has been observed in co-bedding. Co-bedding may facilitate the development of similar circadian rhythm patterns and sleep-wake cycles. The effects of co-bedding and the value of supporting synchronized behavior in twins require additional evaluation (Nyquist, 1998).

NEONATAL TRANSPORT

Because care of small and premature infants requires specialized equipment and highly trained personnel, many infants require transport to regional centers where the needs of the infants can be met. Moving these infants requires an well-integrated system of assessment and perinatal transport.

Perinatal centers are designated according to their ability to handle complicated maternal and neonatal conditions. A level I center generally is a community hospital that is designed to care for the normal pregnant woman and delivery of a well newborn. A level II center is designed to handle more complex pregnancies and deliveries, and the nursery is prepared to care for infants with mild and intermediate conditions. A level III center is one that cares for the most complex obstetric and neonatal complications and conditions. A level III center also has the latest diagnostic techniques and the subspecialists necessary to care for infants with uncommon illnesses.

Maternal Transport versus Neonatal Transport

When a pregnancy is determined to be at high risk, plans can be made early to deliver the infant in a tertiary center. Mothers who go into premature labor may have no problems before the onset of labor. Transport of the pregnant mother to a center equipped to care for both her and the infant is the preferred method of transport.

When an infant is transported inside the womb there is no risk of exposure to cold stress or hypoglycemia, which are serious potential risks of neonatal transport. Transferring the pregnant woman who is in preterm labor allows the possibility of stopping labor on arrival at the tertiary care center.

Because high-risk deliveries may follow uneventful pregnancies, all hospitals must be set up to resuscitate and stabilize newborn infants. The American Heart Association and the American Academy of Pediatrics have developed a program called the Neonatal Resuscitation Program that addresses the needs of neonatal patients in the delivery room (AHA, AAP, 2000).

When a premature or infant at high risk is born at a level I or II perinatal center, a transport team with specialized equipment and training is required to move the infant to a regional center. Problems that develop during neonatal transport may be serious. Thermal stress, equipment failure, and other unexpected events may occur.

Neonatal Transport Team

Neonatal transport teams were developed to provide access to limited health care resources. They are composed of highly trained personnel experienced in the care of premature and infants at high risk. These teams extend the care of the level III perinatal center to the community with their expertise and specially designed equipment (Figure 34-24).

Members of the neonatal transport team assist the referring unit with stabilization of infants before transport. Infants must have the following before being transported: normal temperature, normal blood sugar level, and blood pressure within the normal range; stable airway, either breathing easily on their own or with an endotracheal tube in place; normal blood gas values, normal electrolyte values, and acid-base balance. When infection is suspected, treatment must begin before transport.

Parents should have the opportunity to see and touch their infant before transport. Small mementos of the infant are important. A lock of hair, the infant's footprints, or a picture may be given to the mother. Mothers should be encouraged to continue with plans for breast-feeding if that was their intent before delivery. Mothers should be encouraged to begin expressing breast milk as soon as possible after delivery and be referred to a lactation consultant or support group if the infant will not be able to breast-feed shortly after birth.

Figure 34-24 Transport incubator.

Back Transport

Level III nurseries often are located far from the parent's home. The location may make access difficult for some parents. Distance, traffic, weather, and parking costs are barriers to the nursery. When the infant no longer needs the expertise and support services offered by the level III nursery return transport should be considered as the infant's condition improves.

Return transport, or back transport, refers to transporting the infant back to the referral hospital for care until the infant is ready to go home. Return transport provides a number of advantages. The costs incurred at a community hospital are frequently lower than those at a tertiary center. If the infant is nearer the parents' home, they may have the opportunity to visit more frequently. Close proximity facilitates parent teaching and increases parents' familiarity with the care of their infant. The infant's pediatrician can assume primary care and facilitate discharge planning.

DISCHARGE PLANNING

Preparations for discharge of a high-risk preterm infant should begin on admission to the ICU. Many factors must be considered, and the discharge process often can be traumatic for the family. Providing a smooth transition for the infant and the parents is essential (Figure 34-25).

Criteria to be met before discharge include the infant's ability to maintain temperature in an open crib, steady weight gain, ability to breast-feed or bottle-feed, and absence of apnea or appropriate monitoring devices available at home. In some instances the infant may be discharged before being able to take all feedings orally. In these cases, the parents must be able to demonstrate the ability to provide alternate feeding strategies.

The parents must be educated in the proper care of their infant. To ensure proper caloric density the nurse caring for the infant should review feeding schedules, volumes, and preparation of formula. The nurse should teach the parents how to give medications needed by the infant after discharge, including dosing, accuracy, and administration. Parents who are taking their infant home on a cardiac, apnea, or saturation monitor need equipment training and training in cardiopulmonary resuscitation. Parents should be educated in infant safety. Parents also need to be taught to recognize signs of illness, when to call the pediatrician, and what to do in an emergency. Parents need a written record of the infant's diagnosis, any surgeries, and all discharge instructions, including treatments and medications.

The discharge process is a multidisciplinary team effort. Involvement of the primary nurse or advanced practice nurse, neonatologist, social services, respiratory services, occupational therapists, physical therapists, and appropriate consultants is essential for a smooth transition.

Figure 34-25 Parents need to develop comfort and confidence with their newborn before discharge.

Follow-up needs should be reviewed and their importance emphasized.

Resources are available in the community for parents of infants at high risk. Early childhood intervention pro-

grams provide for many of the follow-up services needed and are generally available nationwide. These programs also provide for transition from one stage of development to another. Support programs are common in urban areas, often through tertiary care centers and religious organizations. Financial planning must be addressed with the family early in the clinical course. Owing to advances in technology, smaller and sicker infants are surviving. Insurance provision often are used up while the infant is hospitalized. Assisting the family with the process of obtaining financial aide is critical, and social services play an integral part in this process. See Chapter 38 for further community services available to families of critical infants.

The most common causes of re-admission to the hospital include infection, specifically RSV; failure to thrive; profound apnea; and aspiration pneumonia.

Case Study/Care Plan

INFANT WITH IUGR

Daniel is a premature second twin born to a 34-year-old, gravida 3, para 2. Maternal prenatal laboratory results are A-positive blood type; nonreactive rapid plasma reagin testing; and negative results on testing for human immunodeficiency virus, hepatitis B surface antigen, and group B *Streptococcus*. The pregnancy was complicated by pregnancy-induced hypertension and twin gestation. His mother was treated during the pregnancy with apresoline and magnesium sulfate for control of her hypertension and with betamethasone (Celestone), a steroid that aids in the development of the fetal lung.

Daniel was delivered by cesarean section for severe IUGR at 33 weeks' gestation. He was assigned an Apgar score of 7 at 1 minute and 8 at 5 minutes. Daniel weighed 1,180 g at birth, his head circumference was 27 cm, his length was 38 cm. All parameters were less than the 10th percentile. He was vigorous at birth, cried at delivery, and then developed mild respiratory distress during the first few minutes of life.

Daniel was given whiffs of oxygen for cyanosis after delivery. He was placed in an oxygen hood for 2 days for treatment of TTN. For the first 2 weeks of life, Daniel had one to two episodes of apnea daily. He has had no apnea for the past 3 weeks.

Daniel's initial glucose level was 28 mg/dL. A glucose test was repeated after Daniel received an IV bolus of D₁₀W and then was started on a continuous drip of D₁₀W. The repeated level was 57 mg/dL. Daniel was started on feedings of expressed breast milk on the second day of life. Human milk fortifier was later added to increase the caloric density of Daniel's feedings because of slow weight gain. Oral feedings were started at 1 week of life, corrected gestational age 34 weeks.

Daniel's parents live in a small town about 50 miles from the hospital where the NICU is located. His mother was transported to the obstetrical unit 3 weeks before his delivery. Daniel's parents were involved in his care as much as possible during his hospital stay. Daniel went home at 6 weeks of age.

Assessment

Daniel is at risk for a number of problems related to prematurity and fetal growth restriction. Not all complications affect all infants who are born early and smaller than expected for gestational age. All infants in this category, however, should be screened and monitored to be sure these complications are diagnosed early and appropriate steps taken to prevent or manage the problem. In addition, Daniel's family is at risk for problems related to separation anxiety, feelings of inadequacy to care for an ill infant, fear that he will not survive, and concerns for the financial strain this illness and hospitalization will place on the family.

Nursing Diagnosis

Impaired gas exchange related to retained fetal lung fluid or to surfactant deficiency as evidenced by increased oxygen requirement and work of breathing.

Expected Outcomes Daniel will exhibit adequate gas exchange as evidenced by respiratory rate 40–60 breaths per minute; oxygen saturation greater than or equal to 92%; clear and equal breath sounds; mild to no retractions; and lack of nasal Raring and expiratory grunt.

Planning

Assure that trained medical healthcare team is available to care for infant, and that proper equipment and supplies are available and in working order. Anticipate potential for worsening of infant's condition requiring escalation of care.

(continued)

Nursing Interventions

1. Place on radiant warmer with ISC control.
2. Place on cardio-respiratory monitor and pulse oximeter.
3. Obtain arterial blood gas and chest x-ray if ordered.
Report abnormal results.

Rationales

1. To minimize metabolic demands and oxygen consumption which are increased in temperature regulation.
2. To monitor vital signs and oxygen saturation.
3. Monitors levels of O₂ and CO₂ in the blood; monitors for potential respiratory complications due to fluid build-up in the lungs.

Evaluation Monitor and record response to oxygen if used.

Nursing Diagnosis

Ineffective thermoregulation related to inadequate fat stores, large surface areas, and inability to shiver as evidenced by the need for assistance with temperature control.

Expected Outcome Infant will maintain temperature within accepted range of 36.5 to 37.2. Infant will be free of apnea and bradycardia, and maintain adequate oxygenation.

Planning Assure availability of equipment to provide a proper thermal environment for the infant. Assure availability of health care providers who are trained in the recognition of thermal stress and the use of equipment to provide thermal support for premature and ill infants.

Nursing Interventions

1. Place infant on a radiant warmer with ISC control or into a preheated incubator set at a temperature appropriate for gestational age and weight.
2. Monitor temperature on admission then hourly until stable. Continue to monitor temperature at regular intervals.
3. Observe for apnea, bradycardia, and color changes associated with temperature instability.
4. Use caps and swaddling once temperature is stable.
5. Avoid placing infant on cold surface such as scales without insulation.
6. Avoid drafts during care giving activities.
7. Dry infant promptly following bathing.

Rationales

1. Prevents hypothermia.
2. Provides baseline and monitors changes.
3. Respiratory and cardiac alterations require immediate attention; color change may be indication of significant temperature fluctuation.
4. Helps infant maintain normal temperature.
5. Prevents hypothermia.
6. Reduces heat loss.
7. Reduces chance of heat loss through evaporation.

Evaluation Document temperature on nursing flow chart. Document interventions used to maintain temperature, and infant's response. Notify primary care provider of any abnormal temperatures.

Nursing Diagnosis

Risk for impaired parent-infant attachment related to separation as a result of illness.

Expected Outcomes Parents will visit on a regular basis and demonstrate an interest in caring for their infant. They will ask appropriate questions about their infant's condition and express understanding, while participating in decisions about their infant's care.

(continued)

Planning

Assure health care providers are available who are trained in facilitation of parent-infant attachment and in crisis intervention. Provide a family-friendly environment to support attachment and family function.

Nursing Intervention**Rationales**

- | | |
|--|---|
| 1. Introduce parents to health care providers and to the nursery environment. | 1. Will foster increased comfort level. |
| 2. Avoid use of medical jargon when giving information. | 2. Understanding is enhanced when information is presented at a level consistent with the current knowledge base. |
| 3. Update parents on a regular basis regarding the condition of their infant. | 3. Helps alleviate parental anxiety. |
| 4. Encourage parents to name their infant and call the infant by name. | 4. Emphasize the infant's individuality. |
| 5. Encourage parents to bring in toys and pictures. | 5. Personalizes the infant's bedside. |
| 6. Offer the opportunity for parents to provide skin to skin holding of their infant. | 6. Promotes bonding and attachment; gives infant feeling of security. |
| 7. Encourage parents to participate in the care of their infant. | 7. Helps parents assume ownership of their new roles. |
| 8. Assure that appropriate referrals are made to Social Services, Psychological Services, etc. | 8. Ensures that parents are aware of available resources. |

Evaluation

Document family visits and phone calls, parent education and discharge planning, and any referrals made. Chart observations of family interactions with infant.

Key Concepts

- The smallest of changes in the care and management of infants who are preterm and have low birth weights may have profound effects on health.
- The American College of Obstetricians and Gynecologists (ACOG) and the World Health Organization report improvements in the management and prevention of preterm labor throughout the 1980s.
- The percentage of preterm births in the United States rose from 8.9% in 1980 to 10.2% in 1990.
- Prematurity is the cause of approximately 75% of neonatal deaths, and the costs of hospitalization and care have soared over the past decade.
- In addition to the technical care responsibilities of the nurse caring for infants at high risk is the responsibility of educating the parents and family and helping them to bond with their infant.
- In addition to the technical care of the preterm infant, it is the responsibility of the bedside nurse to educate

the parents and family. It is also the nurse's responsibility to aid the parents in bonding with their infant.

- The preterm infant's status may change very rapidly, therefore it is the nurse's assessment skills and ability to recognize changes in the infant's behavior that are crucial in identifying the disease process early in the course.
- Over the past decade we have seen remarkable changes in the management of preterm infants. Improvement in mortality and morbidity has been seen in infants as early as 24 weeks gestation.
- Neonatology encompasses the care of the very fragile preterm infant, and also caring for the ill term infant. The bedside nurse may care for an infant as small as 500 grams or an infant as large as 4000 grams.
- The nurse must be able to recognize the cues of a preterm infant that is stressed in order to prevent long term complications for that infant. These cues

include but are not limited to crying, frowning, finger splay, decreased tone, and irritability. The cues may also be autonomic: variability in heart rate, respiratory rate and blood pressure are common.

- ✿ It is extremely important for the bedside nurse to differentiate between the complications that may occur in the asymmetrical and symmetrical growth retarded infant, and in the large for gestational age infant.

- ✿ The survival of smaller and younger gestation infants brings with it many ethical dilemmas that the caregivers and family must face. It is important for the nurse to identify and come to terms with these issues in order to assist the family in adjusting to the reality of their preterm infant.

Review Questions and Activities

1. Identify non-reassuring fetal heart rate patterns using electronic fetal monitoring and discuss the physiology and nursing interventions for each pattern.
2. What are the characteristics of a reassuring fetal heart pattern?
3. What is the difference between a screening test and a diagnostic test? Provide examples of each type of test used in care of the pregnant woman.
4. What are the indications for a non-stress test and how are the results interpreted?
5. Compare and contrast the non-stress test with the biophysical profile.
6. What is the purpose of a contraction stress test?
7. What are the goals of short-term fluid therapy?
 - a. Prevention of hypoglycemia, limitation of negative fluid balance, and provision of protein sparing carbohydrates
 - b. Prevention of hypoglycemia, provision of enough fluids to give a positive fluid balance, and to provide carbohydrates
 - c. Provision of adequate glucose and fluids to prevent dehydration
 - d. Replacement of insensible water losses

The correct answer is a.
8. The major routes of water losses include:
 - a. urine and stool
 - b. Gastrointestinal losses
 - c. evaporative from skin and lungs
 - d. answers a and c

The correct answer is d.
9. To be classified as symmetric IUGR, what must the infant must be?
 - a. less than the 10th percentile in birth weight
 - b. less than the 10th percentile in birth weight and length
 - c. diagnosed in utero by doppler ultrasonography

- d. less than the 10th percentile in birth weight, length and head circumference

The correct answer is d.

10. What is the purpose of serial x-rays in clients with necrotizing enterocolitis?
 - a. Assessment of lung volume
 - b. Assessment for pneumotosis or free air in the bowel
 - c. To irradiate the infant
 - d. To check for pneumonia

The correct answer is b.

11. How is late onset infection defined?
 - a. As onset of symptoms after day of life 14
 - b. As onset of symptoms after day of life 5 to 7
 - c. As onset of symptoms in the first few days of life
 - d. As any infection occurring in the neonatal period

The correct answer is b.

12. What are three common organisms of early onset infection?
 - a. pseudomonas, staphylococcus epidermidus, and Escherichia Coli
 - b. staphylococcus aureus, Klebsiella, and pseudomonas
 - c. streptococcus pneumoniae, Escherichia Coli, and group B Streptococcus
 - d. Haemophilus influenzae, staphylococcus epidermidus and candida albicans

The correct answer is c.

13. What are the consequences of overhydration in the ELBW infant?
 - a. Increased blood pressure, poor perfusion, and alkalosis
 - b. Patent ductus arteriosus, hyperglycemia, bronchopulmonary dysplasia, and necrotizing enterocolitis
 - c. Hyponatremia and acute renal failure
 - d. Hypoglycemia and elevated heart rate

The correct answer is b.

- 14.** What causes compromise of the respiratory system of an infant born at 26 weeks' gestation?
- The infant's chest wall is stiff and very compliant
 - The infant's ribs have flexible cartilage
 - The infant's intercostal muscles are underdeveloped
 - The infant's skin is translucent

The correct answer is b.

- 15.** Which are the common signs and symptoms of a patent ductus arteriosus in preterm infants?
- Murmur, widened pulse pressures, and increased heart size
 - Weak pulses, normal blood pressure, and deterioration in ventilatory status
 - Murmur, narrowed pulse pressure, and pulmonary edema
 - Clammy skin and thready pulse

The correct answer is a.

- 16.** Which is the most common form of lung disease in the newborn?
- Meconium aspiration
 - Retained fetal lung fluid
 - Hyaline membrane disease
 - Asthma

The correct answer is b.

- 17.** Which intervention is utilized to keep oxygen consumption to a minimum during the re-warming process? Adjust the incubator:
- 1 to 1.5 degrees higher than the infant's temperature
 - at 37 degrees
 - at least 2 degrees higher than the infant's desired temperature
 - at least 2 degrees lower than the infant's desired temperature

The correct answer is a.

Newborns at Risk Related to Congenital and Acquired Conditions

*D*uring a pregnancy, a family dreams of giving birth to the perfect child (or what they consider to be a normal child) both physically and mentally. The birth of a child with a congenital or acquired anomaly challenges those dreams and forces families to deal with a crisis for which they may be completely unprepared. As a nurse, you must tend to not only the physical needs of the infant and the family's need for knowledge, but also the psychological needs of the family as they strive to control the emotional upheaval that may result from this birth. You must also closely examine your own feelings and attitudes toward birth anomalies, so that you can effectively and sensitively guide families through the adaptation process.

Key Terms

ABO incompatibility	Extracorporeal	Hypocalcemia	Omphalocele
Acquired disorder	membrane	Hypoglycemia	Pathologic jaundice
Anencephalus	oxygenation (ECMO)	Hypospadias	Phototherapy
Brachial palsy	Encephalocele	Imperforate anus	Physiologic jaundice
Choanal atresia	Epispadias	Infant of a diabetic	Polycythemia
Cleft lip	Erythroblastosis fetalis	mother (IDM)	Rh incompatibility
Cleft palate	Esophageal atresia	Intracranial hemorrhage	Sepsis
Clubfoot (talipes	Exstrophy of the bladder	Jaundice	Spina bifida
equinovarus)	Facial palsy	Kernicterus	STORCH titer
Congenital disorder	Gastroschisis	Macrosomia	Subarachnoid
Congenital heart defect	Genetic disorder	Maternal sensitization	hemorrhage
Developmental dysplasia	Hydrocephaly	Meningocele	Subdural hemorrhage
of the hip (DDH)	Hydrops fetalis	Microcephaly	Tracheoesophageal
Diaphragmatic hernia	Hyperbilirubinemia	Myelomeningocele	fistula

Competencies

Upon completion of this chapter, the reader should be able to:

1. Identify the incidence, risk, anatomic anomalies, pathophysiologic markers, clinical manifestations, and potential complications of congenital or acquired defects in the neonate.
2. Develop a plan of care with specific nursing diagnoses and appropriate interventions for the neonate who is born with a congenital or acquired anomaly.
3. Design an educational plan to meet the needs of the parents and family of a neonate with a congenital or acquired anomaly.
4. Develop a therapeutic relationship to better meet the needs of the family of a neonate who is born with a congenital or acquired anomaly during this crisis.
5. Identify the incidence, risk, clinical manifestations, and potential complications of acquired disorders in the neonate.
6. Develop a plan of care with specific nursing diagnoses and appropriate interventions for the neonate with an acquired disorder.

The hope and expectation of every pregnant woman is to deliver a healthy, normal infant who will grow and develop into a mature adult who will someday make a contribution to society. Numerous factors, including heredity and the environment, can affect the outcome of a pregnancy. Some abnormalities or disorders can occur in a single or a few genes from either parent, from factors influencing the intrauterine environment, or from a combination of these.

A **congenital disorder** is an anomaly that results from genetic, prenatal, or environmental factors, or a combination of these, and is present at birth. A **genetic disorder** is an inherited defect that is transmitted from genera-

tion to generation. An **acquired disorder** is a condition that results from environmental factors rather than genetic circumstances.

This chapter describes the most common congenital and acquired disorders in the neonate and the immediate nursing care that is required, using the nursing process. In addition, the psychosocial impact of the disorders on the parents and family are presented. Both the perinatal and the neonatal team must anticipate and be ever cognizant of the needs, not only of the compromised neonate, but also of the infant's family. Parents should always be kept informed of their infant's condition and involved in care as soon and as often as possible.

CONGENITAL ANOMALIES

Congenital anomalies are abnormalities present at birth as a result of either genetic or prenatal environmental factors or both. Genetic anomalies are the result of hereditary factors and are transmitted from generation to generation. (See Chapter 13 for a detailed discussion of genetic disorders.)

Congenital defects occur in 3% to 4% of all live births (Wardinsky, 1994) but this number increases if one includes congenital defects that may not be diagnosed until later in childhood, such as developmental dysplasia of the hip (DDH). Major congenital defects are the leading cause of death in infants less than 1 year of age in the United States and account for 20% of all neonatal deaths.

Central Nervous System Anomalies

As one of the most complex systems of the body, the central nervous system (CNS) is subject to a multitude of congenital anomalies. The stages in the development of the nervous system must proceed in a predetermined order or a defect occurs. These stages can be affected by both genetic and environmental factors, or a combination of both.

The most common anomalies of the CNS occur during the primary neurulation period, which is during the first 3 to 4 weeks of gestation. These anomalies, termed “neural tube defects,” occur as a result of failure of the neural tube to close. There has been steady decline in the number of children with all forms of neural tube defects as the result of prenatal diagnosis and termination of affected pregnancies (Golden, 1998). Recent evidence suggests that the nutrient folic acid promotes neural tube closure. Therefore, women considering conception are encouraged to begin taking folic acid supplements before conception and to continue with them until 12 weeks’ gestation (Rayburn, Stanley, and Garrett, 1996). In 1993, the American Academy of Pediatrics recommended that folic acid be administered to all women of childbearing age (Rowe, 1995).

Encephalocele

Encephalocele is a herniation of the brain and meninges through an opening in the skull (Figure 35-1). This neural tube defect is readily visible at birth. Skin generally covers the encephalocele, but it may break open, increasing the risk for infection. Treatment consists of surgical intervention to replace brain contents and repair the defect. If hydrocephalus or enlargement of the head without enlargement of the facial structures is present, a ventricular shunting procedure is generally performed 7 to 10 days after the encephalocele has been repaired. The shunt is formed by placing a flexible tube into the ventricular sys-

Figure 35-1 Infant with encephalocele.

tem of the brain, which diverts the abnormal accumulation of cerebrospinal fluid (CSF) into another area of the body, most often the abdominal cavity, where it can be absorbed. (Refer to the section on hydrocephaly in this chapter for nursing care of the infant with a shunt.)

Anencephaly

In **anencephaly**, there is a complete or partial absence of the cerebral hemispheres and skull. The exact cause of anencephaly is unknown; it occurs in 1 of 1000 live births (Paidas & Cohen, 1994). These infants are frequently still-born or die within the first few days of life because they do not have any cerebral function. Nursing interventions are directed toward providing comfort measures until the infant dies from respiratory or cardiac failure. The families require a great deal of emotional and spiritual support in grieving the impending death of their newborn.

Microcephaly

Microcephaly is the condition in which there is a normal-sized head that contains a small brain. This condition can be either congenital or acquired. Congenital microcephaly may be seen in conjunction with a chromosomal abnormality; an intrauterine infection, such as rubella, cytomegalovirus, or toxoplasmosis; and maternal exposure to x-rays. The acquired form of microcephaly may result from maternal herpes, ischemic insults, or hypothyroidism. Diagnostic evaluation includes a **STORCH** titer, for syphilis, toxoplasmosis, other infections, rubella, cytomegalovirus, and herpes, and skull x-rays films. There

is no treatment for this disorder, which generally results in mental retardation. Nursing care is predominantly supportive. The parents must be supported while they learn to cope with and accept this disorder in their newborn.

Hydrocephaly

Hydrocephaly is a condition that results from an excess accumulation of CSF in the ventricles of the brain and the subarachnoid space as a result of an imbalance between CSF production and absorption (Figure 35-2). Normal growth and development of the brain is altered because of the increased intracranial pressure (ICP) from the CSF fluid. This condition occurs in 3 to 4 of 1000 newborns (Shiminski-Maher & Disabato, 1994). Cesarean section may be necessary because of the enlarged head. This disorder is readily apparent at birth. The infant is born with an enlarged head, bulging fontanelles, separated skull sutures, and a prominent forehead with depressed eyes that are rotated downward, causing the “setting sun” sign.

Nursing care includes continuous observation and assessment of neurologic status of the infant. Ongoing observations must be carefully documented. The head should be supported while holding, turning, or positioning the infant. A flotation mattress or sheepskin is used under the infant to prevent skin breakdown and infection. Signs of increased ICP should be continuously assessed, and serial head circumference measurements should be plotted.

Surgical intervention includes the placement of a shunt from the ventricle in the brain to the peritoneum to allow for drainage of excess CSF. Postoperatively, the infant is positioned on the side opposite the shunt to prevent pressure and kinking of the shunt. The infant's bed is left in a flat position to prevent rapid loss of CSF and decompression. The long-term prognosis depends on the cause of hydrocephalus, the extent of tissue damage, and the success of the shunt procedure. Parents should be taught the care of the infant and shunt, including positioning and skin care, before discharge. They need to be edu-

Nursing Alert

CLINICAL MANIFESTATIONS OF INCREASED INTRACRANIAL PRESSURE

- Widening sutures
- Bulging anterior fontanelle
- Lethargy
- Irritability
- High-pitched, shrill cry
- Poor feeding
- Poor sucking
- Decreased level of consciousness
- “Setting sun” sign
- Opisthotonos

cated on the signs of increased intracranial pressure, shunt malfunction, skin breakdown, and infection.

Spina Bifida

Spina bifida is a common CNS defect that results from failure of the spinal cord to close. There are two categories: spina bifida occulta and spina bifida cystica. Spina bifida occulta is the failure of the spinal column to close when neither the cord nor the meninges herniate through the defect (Figure 35-3). This condition occurs in 10% to 30% of all live births (Kenner, Amlung, 1998).

Spina bifida cystica, which includes meningocele and myelomeningocele, has an incidence of 1 in 1000 live births (Kenner, Amlung, 1998). In a **meningocele**, there is an external sac that protrudes through the defect that contains meninges and CSF. However, the spinal cord and nerve roots are in their normal position. **Myelomeningocele** is the most common form of spina bifida cystica and occurs in 1 of 500 live births (Milhorat & Miller, 1994). In a myelomeningocele, the sac contains both meninges and

SIGNS OF INFECTION

Observe for signs of infection, such as fever, a decrease in responsiveness, poor feeding, and seizures.

Figure 35-3 Spina bifida. A. Normal spine; B. spina bifida occulta; C. spina bifida with meningocele; D. spina bifida with myelomeningocele.

CSF, as in meningocele, but it also contains neural tissue. Myelomeningocele may arise at any point in the vertebral column from C1 to the coccyx but is most common in the lumbar, lumbosacral, and sacral segments.

Spina bifida may be diagnosed in utero through the testing of amniotic fluid. Elevated levels of alpha-fetoprotein (AFP) found in the amniotic fluid confirm the diagnosis of an open neural tube defect, such as spina bifida. The open defect allows leakage of CSF into the amniotic fluid, causing the elevated AFP levels. An ultrasound examination may also be performed to visualize the defect. If the diagnosis of spina bifida is not made in utero, it is usually apparent at birth. The head should be carefully examined for signs of hydrocephalus, and serial head-circumference measurements done. A computerized tomographic (CT) scan or magnetic resonance imaging (MRI) study may be performed to define the type and severity of hydrocephalus. Electromyography may assist in assessing the motor function of the lower extremities. In addition, an abdominal sonogram or intravenous pyelogram may be performed to rule out hydronephrosis (Milhorat & Miller, 1994).

Whenever possible, the spinal lesion should be closed within the first few hours of life. Prompt surgery is performed to prevent infection and halt any further loss of existing neurologic function. Since a high percentage of infants with neural tube defects develop hydrocephalus, a ventriculoperitoneal shunt is placed after the neural tube defect has been repaired.

Immediate nursing care includes placing the infant in a prone or side-lying position with rolled towels to prevent pressure on the sac and to protect the sac from tearing. Change the infant's position every hour to prevent

pressure on a specific area. The sac should be covered with a moist, sterile gauze dressing, and the skin around the defect should be cleansed and dried to prevent skin breakdown. The nurse should administer prescribed prophylactic antibiotic agents. The infant's bladder should be emptied, using Credé's method, at regular intervals to prevent stasis of urine in the bladder resulting from the loss of normal nerve innervation.

Postoperatively, nursing care involves assessing the infant for signs and symptoms of infection, increased ICP, and bowel and bladder assessment. The infant is placed in a prone or lateral position to keep pressure off the incisional area. Manual emptying of the bladder to stimulate urination is continued. Passive range of motion (ROM) exercises should be performed with the lower extremities; a physical therapist should be consulted for appropriate exercises. A number of orthopedic problems, such as foot deformities, dislocated hips, and kyphoscoliosis, can occur. Therefore, orthopedic status must be continually monitored and vigorous physical therapy must be initiated.

Assessing Newborn Urinary Elimination

1. Newborns usually void during delivery or immediately following delivery.
2. Urinary function may be suppressed for several hours after birth.
3. Newborns usually void 10–15 times each day by 2–3 days of life.

Warning signs

- failure to void within 24 hours
- concentrated, red, or rusty reddish brown urine

Assessing Newborn Intestinal Elimination

1. Newborns usually pass their first stool (meconium) by 8–24 hours. Meconium is passed for the first few days and is typically black or green in color, sticky, and tarlike.
2. By the second and third day the newborn passes transitional stools which are of thinner consistency than meconium, greenish-brown to yellowish-brown in color, and less sticky.
3. By the 5th day of life, the newborn typically passes 4–6 stools per day (frequency may vary from one stool per 2 days to 10 stools per day).
4. Breastfed newborns have yellowish (sometimes greenish) stools which are more liquid in consistency and frequent, while bottlefed infants tend to have more formed, pale stools.

Warning signs

- If no stool in 24 hours, consider imperforate anus
- Watery, green, excessive mucous, foul odor, and flatus may be evidence of intestinal problems or infection.

Respiratory System Anomalies

The upper respiratory system begins forming early in the fourth week of gestation; formation of the lower respiratory system begins in the middle of that week. Malformations in the respiratory system can be life-threatening; therefore, recognition of these anomalies in the delivery room is imperative for proper treatment. The first few minutes of life are the most crucial, so ensuring adequate oxygenation during this period is necessary to the long-term positive outcome for the newborn.

Choanal Atresia

Choanal atresia is a condition in which there is a bony or membranous separation between the nose and the pharynx (Figure 35-4). Ninety percent of atresias are bony, and 10% are membranous. The incidence of choanal atresia is 1 in 5,000 to 7,000 births (Guzzetta, Anderson, Eichelberger, Newman, Rouse, Schmitzer, Boyajian, & Tomaski, 1994). Unilateral atresia is much more common than bilateral atresia, and the female-to-male ratio for affected infants is 2:1. Twenty to fifty percent of clients with choanal atresia have other anomalies; therefore, genetic consultation for these clients is recommended, along with a thorough search for additional anomalies (Miller, Fanaroff, & Martin, 1997). The most common anomalies are colobomata of the eyes, heart defects, renal anomalies, growth and mental retardation, ear deficits and gastroesophageal

Figure 35-4 Choanal atresia, separation between the nose and pharynx.

reflux (referred to by the acronym “CHARGE”) (Coniglio, Manzione, & Hengerer, 1988).

Infants are nose breathers for the first 3 months of life. Choanal atresia may be immediately recognizable at birth by signs of respiratory distress, especially if the atresia is bilateral. One method that may be used in the delivery room to assess the infant for choanal atresia is passing a catheter through each nostril to check for patency. If the catheter does not pass bilaterally, the diagnosis of choanal atresia is made. Infants with choanal atresia may be cyanotic at rest, but their color improves when they open their mouth to cry. Nasal discharge is present.

If it is determined that the infant has bilateral choanal atresia, surgical intervention is an immediate necessity. Prognosis is excellent if there are no other concomitant related medical conditions. Unilateral choanal atresia is often not detected until the infant's nostril becomes occluded with secretions, such as during a cold.

Diaphragmatic Hernia

Congenital **diaphragmatic hernias** occur during gestational life when the diaphragm fails to close during the seventh or eighth week. The defect allows the abdominal organs to be displaced into the left side of the chest through an opening in the diaphragm (Figure 35-5). It occurs in 1 in 3,000 live births (Guzzetta, Anderson,

Figure 35-5 Diaphragmatic hernia.

Eichelberger, Newman, Rouse, Schmitzer, Boyajian, & Tomaski, 1994) with equal frequency in male and female infants.

Prenatal diagnosis of congenital diaphragmatic hernia (CDH) may be made using an antenatal ultrasound technique as early as 26 weeks' gestation (Miller, Fanaroff & Martin, 1997). Surgical repair in utero has been completed at some perinatal centers, but this has not markedly changed the outcome (Holland et al., 1998). The presence of abdominal contents in the thoracic cavity during the embryonic period may prevent the normal development of lung tissue on the affected side. At birth, most affected newborns present with severe respiratory distress, because at least one of the lungs is unable to expand, or may not have fully developed (i.e., hypoplastic lungs). The respiratory distress progressively worsens as the stomach and bowels fill with air. Breath sounds are usually diminished or absent on the affected side and, instead, bowel sounds are audible in the chest. In 85% to 90% of cases, the hernia is on the left side because the liver fills the defects on the

right side (Holland, 1998). Physical examination of the newborn reveals a large or asymmetric chest and a flat relatively small abdomen.

Before surgery to repair the hernia is attempted, the infant's medical condition must be stabilized. Medical measures are taken to reverse hypoxia, hypercarbia, and metabolic acidosis. A nasogastric tube is inserted for gastric decompression. Mechanical ventilation with 100% oxygen is used to maintain functional respiratory status. If the infant's respiratory status does not improve, extracorporeal membrane oxygenation (ECMO) therapy may be required before the hernia repair (Guzzetta, Anderson, Eichelberger, Newman, Rouse, Schmitzer, Boyajian, & Tomaski, 1994). **ECMO** is a cardiopulmonary bypass therapy that allows the infant's lungs to rest and heal by exchanging blood gasses through a membrane oxygenator outside the body.

Preoperative nursing interventions include: positioning the newborn on the affected side with the head and chest elevated to allow for better expansion of the normal lung; placement of a gastric tube and connection to continuous low suction to keep the stomach and intestines decompressed; maintenance of oxygen and ventilatory support; and medication administration. Close and careful monitoring is essential at all times.

Once the infant is medically stable, surgical repair is performed. Postoperatively, maintenance of respiratory function is a high priority. Ventilatory support continues with careful monitoring for possible complications, such as pneumothorax and acid-base imbalances. Prognosis depends on the degree of pulmonary development and success of the closure. If the infant required mechanical ventilation during the first 18 to 24 hours of life, the survival rate is approximately 50%. If the infant with a diaphragmatic hernia did not experience any respiratory distress within the first 24 hours of life, survival rates reach 100% (Holland et al., 1998).

Cardiovascular System Anomalies

By the end of the third week of gestation, a functional cardiovascular system is in place to support further development of the embryo. Partitioning of the heart, a complex process, is completed by the end of the seventh week of gestation. Many women are not even aware that they are pregnant during this period. Formation of the cardiovascular system can be altered as a result of the presence of many factors, including genetic and environmental factors and some maternal medical conditions. A thorough maternal history and careful physical examination are important in the diagnosis of congenital heart disease (Figure 35-6).

Patent Ductus Arteriosus

The patent ductus arteriosus is a vascular connection that, during fetal life, short-circuits the pulmonary vascular bed and directs blood from the pulmonary artery to the aorta. Functional closure of the ductus normally occurs soon after birth. If the ductus remains patent after birth, the direction of blood flow in the ductus is reversed by the higher pressure in the aorta.

Ventricular Septal Defects

A ventricular septal defect is an abnormal opening between the right and left ventricle. Ventricular septal defects vary in size and may occur in either the membranous or muscular portion of the ventricular septum. Due to higher pressure in the left ventricle, a shunting of blood from the left to right ventricle occurs during systole. If pulmonary vascular resistance produces pulmonary hypertension, the shunt of blood is then reversed from the right to the left ventricle, with cyanosis resulting.

Truncus Arteriosus

Truncus arteriosus is a retention of the embryologic bulbar trunk. It results from the failure of normal septation and division of this trunk into an aorta and pulmonary artery. This single arterial trunk overrides the ventricles and receives blood from them through a ventricular septal defect. The entire pulmonary and systemic circulation is supplied from this common arterial trunk.

Subaortic Stenosis

In many instances, the stenosis is valvular with thickening and fusion of the cusps. Subaortic stenosis is caused by a fibrous ring below the aortic valve in the outflow tract of the left ventricle. At times, both valvular and subaortic stenosis exist in combination. The obstruction presents an increased work load for the normal output of the left ventricular blood and results in left ventricular enlargement.

Coarctation of the Aorta

Coarctation of the aorta is characterized by a narrowed aortic lumen. It exists as a preductal or postductal obstruction, depending on the position of the obstruction in relation to the ductus arteriosus. Coarctations exist with great variation in anatomical features. The lesion produces an obstruction to the flow of blood through the aorta, causing an increased left ventricular pressure and work load.

Tetralogy of Fallot

Tetralogy of Fallot is characterized by the combination of four defects: 1) pulmonary stenosis, 2) ventricular septal defect, 3) overriding aorta, and 4) hypertrophy of right ventricle. It is the most common defect causing cyanosis in patients surviving beyond two years of age. The severity of symptoms depends on the degree of pulmonary stenosis, the size of the ventricular septal defect, and the degree to which the aorta overrides the septal defect.

Complete Transposition of Great Vessels

This anomaly is an embryologic defect caused by a straight division of the bulbar trunk without normal spiraling. As a result, the aorta originates from the right ventricle and the pulmonary artery from the left ventricle. An abnormal communication between the two circulations must be present to sustain life.

Atrial Septal Defects

An atrial septal defect is an abnormal opening between the right and left atria. Basically, three types of abnormalities result from incorrect development of the atrial septum. An incompetent foramen ovale is the most common defect. The high ostium secundum defect results from abnormal development of the septum secundum. Improper development of the septum primum produces a basal opening known as an ostium primum defect, frequently involving the atrioventricular valves. In general, left to right shunting of blood occurs in all atrial septal defects.

Tricuspid Atresia

Tricuspid valvular atresia is characterized by a small right ventricle, large left ventricle, and usually a diminished pulmonary circulation. Blood from the right atrium passes through an atrial septal defect into the left atrium, mixes with oxygenated blood returning from the lungs, flows into the left ventricle, and is propelled into the systemic circulation. The lungs may receive blood through one of three routes: 1) a small ventricular septal defect, 2) patent ductus arteriosus, and 3) bronchial vessels.

Anomalous Venous Return

Oxygenated blood returning from the lungs is carried abnormally to the right side of the heart by one or more pulmonary veins emptying directly, or indirectly through venous channels, into the right atrium. Partial anomalous return of the pulmonary veins to the right atrium functions the same as an atrial septal defect. In complete anomalous return of the pulmonary veins, an interatrial communication is necessary for survival.

Figure 35-6 Congenital heart abnormalities. (Used with permission of Ross Products, Division of Abbott Laboratories, Columbus Ohio.)

Congenital Heart Defects

Congenital heart defects (CHD) are anatomic abnormalities in the heart that are present at birth. The incidence of CHD is approximately 1% of births (Hoffman, 1995). There are more than 100 different types of cardiac anomalies; ventricular septal defects are the most common and constitute more than 20% of all CHDs. Transposition of the great arteries and coarctation of the aorta are the most common life-threatening anomalies. CHDs are the second major cause of death in the first year of life (premature birth, is the first).

The causes of CHDs are unknown, but both genetic and environmental factors are thought to influence their development. Infants with Down, Marfan, or Turner's syndromes frequently have related cardiac anomalies. Other factors linked to CHDs include maternal alcoholism; maternal rubella infection; maternal diabetes mellitus; maternal use of certain medications, including anticonvulsants, estrogen, progesterone, lithium, warfarin (Coumadin), or isotretinoin (Accutane); and exposure to x-rays. Prematurity, low birth weight, and congenital infections can also increase the risk for CHDs.

Major types of congenital cardiac defects are illustrated in Figure 35-6. CHDs are now categorized physiologically rather than as cyanotic or acyanotic (Wong & Perry, 1998). The four physiologic signs and the associated defects are listed in Table 35-1.

Assessment begins with a thorough review of the maternal history for risk factors that could predispose the infant to a congenital heart defect. The admitting nurse must carefully assess the infant's cardiovascular and respiratory functions and promptly report any abnormal findings. The infant is assessed for signs and symptoms of respiratory distress, including cyanosis, and congestive heart failure (CHF). In addition, a thorough assessment of the cardiac

Client Education

Congenital Heart Defects

Teach parents about the heart condition:

- Provide pictures and diagrams of the heart and then demonstrate the defect
- Provide written material on the specific heart defect

Instruct parents on medication administration:

- Provide a written schedule of times when the medication(s) should be administered
- Instruct on the purpose, dose, correct administration, and side effects of the medication(s). Inform parents about when to notify the physician.
- Allow parents to demonstrate their knowledge of medication administration (after instructions have been provided) to validate their understanding.

Educate parents about detecting these signs and symptoms and reporting them to the physician:

- Increased respiratory rate
- Breathing difficulties (such as nasal flaring or retractions)
- Excessive sweating
- Poor sucking
- Weight loss
- Poor feeding
- Cyanosis

Table 35-1 Physiologic Signs of Cardiac Defects

Physiologic Sign	Cardiac Defect
Increase in pulmonary blood flow	Atrial septal defects Ventricular septal defects Patent ductus arteriosus
Obstruction to pulmonary blood flow	Coarctation of aorta Subaortic stenosis
Decrease in pulmonary blood flow	Tetralogy of Fallot Tricuspid atresia
Mixed blood flow	Complete transposition of great vessels Anomalous venous return Truncus arteriosus

rate, rhythm, and sounds should be conducted. Signs of CHF to look for include: tachycardia, tachypnea, gallop rhythm, diminished peripheral pulses, diaphoresis, edema, and hepatomegaly. Newborns exhibiting these signs require prompt diagnosis and appropriate therapy in a neonatal intensive care unit. Diagnostic tests used to obtain specific information about the defect and the need for surgical intervention include arterial blood gas analysis, chest x-ray studies, electrocardiogram (ECG), echocardiogram, and cardiac catheterization.

Nursing interventions include continuous monitoring of the infant's cardiac and respiratory status, maintaining a thermoneutral environment, administering oxygen as ordered, administering medications as prescribed, offering comfort measures to minimize crying when it precipitates cyanosis, and gavage feeding of the infant if necessary to

decrease the workload of the heart. In addition, the nurse should inform the parents of the newborn's condition and management.

Before discharge, parents need experience in providing care and detailed instruction. Parents should be taught about their infant's heart defect, medication administration, and how to observe for signs and symptoms. In addition, home-based care should be instituted.

Gastrointestinal System Anomalies

Proper formation of the gastrointestinal (GI) system is necessary for the infant to support adequate nutrition and growth after delivery. During the fourth week of gestation, a primitive gut is formed. Many intricate steps are involved in the development of the complete GI tract, during which it is exposed to the possibility of formation of various anomalies. These malformations can occur anywhere in the GI tract and may be simple or complex. Knowledge of the signs and symptoms of GI anomalies is crucial because the nurse is often the first person to detect a problem.

Cleft Lip and Palate

Cleft lip or **palate** are terms that signify a congenital opening in the lip or palate, or both, that results from failure of the maxillary and premaxillary processes to fuse during the seventh to twelfth week of intrauterine life. This

facial malformation is frequently seen in conjunction with other syndromes that occur in relation to avitaminosis or viral infections during the first trimester. Clefts of the lip or palate occur in approximately 1 in 600 to 700 Caucasian newborns. The incidence is double that rate in Asians and half that rate in African Americans. Cleft lip occurs more often in males and is generally located on the left side (Guzzetta, Anderson, Eichelberger, Newman, Rouse, Schnitzer, Boyajian, and Tomaski. 1994). The cleft deformity ranges from minor notching to complete separation of the entire lip and nasal floor (Figure 35-7). The defect may involve the lip, both the lip and palate, or only the palate, and may be unilateral or bilateral. Rarely is the defect located in the midline. The defect tends to occur more often in families in which a close relative also has the anomaly. Environmental factors, such as exposure to radiation or toxic substances, also play a part in contributing to the multifactorial nature of the defect.

Diagnosis of cleft lip may be made from physical appearance of the infant at birth. To determine if a cleft palate is present, the examiner inserts a gloved finger inside the newborn's mouth to feel the soft and hard palate.

Initial care of the child with a cleft lip or palate focuses on feeding. Feeding problems arise because of the infant's inability to create adequate suction and difficulty in swallowing. The infant with a cleft lip, is unable to hold onto and form a seal around the nipple. When feeding the infant, the bottle should be held while the infant's cheeks are grasped together to close the cleft. The infant should

Cleft Lip

be bubbled or burped at frequent intervals, because air may be swallowed. If a cleft palate is present, the infant is unable to form a vacuum to maintain the suction necessary for feeding. The infant must be fed in an upright position, and the flow of milk should be directed to one side of the mouth to avoid choking. The degree of feeding difficulty depends on the size and type of defect; it is greatest in the child with a cleft palate. Newborns with less severe defects and intact lips can often successfully breastfeed because the breast may fill the cleft. Devices available for use with infants with cleft lip and palate include special nipples, compressible bottles, and syringe feeders.

Education, counseling, and emotional support for the parents is an important aspect of nursing care. This defect can be quite disfiguring. Parents need to be encouraged to ask questions and verbalize their anxieties and fears. Provide the parents with pamphlets that show photographs of infants both before and after surgical repairs. Parents must be taught to feed their infant in an upright position and to aim the nipple towards the intact part of the palate, while gently squeezing the bottle.

Surgical repair of the cleft lip is performed at approximately 3 months of age. Repair of the cleft palate is generally postponed until the infant is between 9 and 12 months of age. This delay allows time for the anatomic changes that normally occur in the palate contour (increase of the palate arch). Early surgery of a cleft palate seems to have a negative effect on facial growth, but the trend is toward closure during infancy because improved speech results. Preoperative teaching with parents should include information about the type of surgery being performed, postoperative care that the child will require, and how to use any appliances the infant needs. These children require multidisciplinary care through adolescence, including nursing care and specialist care, such as a pediatrician, audiologist, speech pathologist, otolaryngologist, plastic surgeon, orthodontist, and social worker (Guzzeta, Anderson, Eichelberger, Newman, Rouse, Schnitzer, Boyajian, & Tomaski, 1994).

Esophageal Atresia and Tracheoesophageal Atresia

Esophageal atresia (EA) and tracheoesophageal fistula (TEF) are uncommon anomalies in which the esophagus and trachea do not separate in a normal way. **Esophageal atresia** is a condition in which the esophagus ends in a blind pouch or narrows into a thin cord and is not connected to the stomach. During the 34th to 36th days of gestation, the trachea and esophagus ordinarily separate into two distinct tubes. Failure of this separation causes a **tracheoesophageal fistula** (TEF). TEF occurs in 1 in 4,500 births (Holland, Price, & Bensarb, 1998). The exact cause is unknown. These may be life-threatening anom-

alies of the esophagus and may occur together or singly. Figure 35-8 illustrates esophageal atresia.

Atresia is the congenital absence or closure of a normal body opening. EA can occur with or without a fistula (TEF) into the trachea. The most common esophageal atresia is a fistula between the distal esophagus and the trachea, which occurs in 86% of newborns born with *an esophageal defect*. Other types include esophageal atresia without a fistula (7.7%), H-type tracheoesophageal fistula without esophageal atresia (4.2%), esophageal atresia with a proximal fistula (0.8%), and atresia with proximal and distal fistulae (0.7%) (Holland, Price, & Bensard, 1998) (Figure 35-9). Infants born with this anomaly must be examined for other congenital anomalies, because 30% to 70% of affected infants have other malformations. CHD is the most common accompanying anomaly. Other potentially accompanying anomalies include vertebral malformations, atresias of the small intestine, imperforate anus, and genitourinary defects; the acronym for this syndrome is VATER, which stands for vertebral, anal, tracheoesophageal atresia or fistula, and renal anomalies. Some experts use the acronym VACTERL to delineate the same group of symptoms. The “C” stands for congenital heart defect and the “L” for limb deformities (Kenner, Lott, Flandermeier, 1998).

Infants with EA and TEF may appear to be well immediately after birth. However, soon afterward, they present with copious oral secretions or are unable to swallow oral feedings. Signs and symptoms of esophageal atresia (with or without TEF) include drooling, choking, coughing, cyanosis, and regurgitation of food. Abdominal distention is a prominent feature in an infant with a distal fistula, because air is forced into the stomach.

Figure 35-8 A. Normal esophagus; B. tracheoesophageal fistula (esophagus ends in blind pouch, connects to trachea by fistula); C. congenital esophageal atresia (esophagus has two blind pouch ends with no communication to the trachea).

Figure 35-9 Imperforate anus. A. Anal opening is present but constricted; B. anus and rectum are normal but the anal opening is covered by a thin membrane; C. rectum ends in a blind pouch; D. rectum and anal canal are present but not connected.

Diagnosis of esophageal atresia is confirmed if a nasogastric catheter cannot be passed any further than 10 centimeters past the infant's nares, through the esophagus, and into the stomach. If a radiopaque catheter is used, an x-ray film reveals that the tube coils in the blind end (pouch) of the esophagus.

If the infant is stable, immediate primary surgical repair is done. If the infant is medically unstable, surgery is delayed until the infant's clinical status is stable and he or she can tolerate the surgical procedure.

After diagnosis is made and before surgery, nursing care of these infants includes positioning the infant in a 30-degree upright position to prevent gastroesophageal reflux; these infants should not be given anything orally. A catheter is placed in the upper esophageal pouch and connected to continuous low suction to remove secretions and prevent aspiration. The infant needs intravenous fluids to maintain fluid and electrolyte balance. Supplemental oxygen and intubation may be required if the infant experiences respiratory distress. Parents must be educated about the defect, the management plan, supported during this acute period, and kept informed about the care of the infant before and after surgery. Clarify and reinforce the physician's explanations about the malformation and the impending surgical repair. Encourage parents to ask questions and explain that the surgery is done in staged repairs. The first repair is provision of a gastrostomy and ligation of the fistula; the second is repair of the atresia, done several days later.

Surgery consists of closure of the fistula and anastomosis of the esophageal segments. Postoperative care involves the careful and continuous monitoring of the infant's cardiovascular and respiratory status and assessing for any potential complications. If the infant has a gastrostomy, feeding may be started in 48 hours. Oral feedings may be started in 5 to 10 days after the repair. The overall survival rate is 85% to 90%, with a good prognosis for a normal life.

Omphalocele and Gastroschisis

Omphalocele and gastroschisis are congenital defects in the abdominal wall. The incidence of omphalocele is 1 in 4,000 live births; gastroschisis occurs much less often than omphalocele, perhaps 1 in 10,000 births (Cunningham et al., 1997). The cause of these defects is unknown. An **omphalocele** is a defect covered by a peritoneal sac, located at the base of the umbilicus into which portions of the abdominal organs herniate. The peritoneal sac may contain both the small and large intestine, stomach, liver, spleen, and bladder. The peritoneal sac covering the defect may rupture during or after birth. Omphalocele develops during the 10th to 12th weeks of gestation and are often seen in conjunction with other cardiac, genitourinary, neurologic, or chromosomal anomalies.

This defect may be detected on an antenatal sonogram. If omphalocele is present, a vaginal delivery is still permitted, because the outcome is not any different than if the infant is delivered by cesarean section. If the diagnosis has not been made by sonogram, the defect is easily recognizable at the time of birth.

Gastroschisis is a condition in which the bowel herniates through an abdominal wall defect to the right of the umbilicus. In contrast to omphalocele, the contents are not contained in a sac, but instead the contents lie openly on the abdomen. Gastroschisis occurs in 1 in 4,000 to 10,000 live births (Quirk J. G. Jr, Fortney J, Collins H. B. 2nd, West J, Hassad S. J., Wagner C. 1996). This condition is often seen in small-for-gestational-age and preterm newborns and is rarely associated with other anomalies. Generally, there is a greater loss of fluid in the infant with gastroschisis than in the infant with omphalocele, unless the omphalocele is not covered by a layer of peritoneum. In utero, the intestine was allowed to float freely in amniotic fluid, so it may appear edematous and may be covered with black necrotic tissue.

Surgery is indicated for both omphalocele and gastroschisis. Preoperative care is similar for infants born with

either defect. Immediate care is directed toward maintaining body heat and fluid and electrolyte balance and protecting the exposed abdominal organs. The exposed organs should be covered with a warm, sterile, saline-soaked gauze, which, in turn, should be covered with plastic wrap to contain body heat and prevent further trauma. The newborn should be positioned in the lateral position; the bowel should be supported to prevent injury. A nasogastric tube is inserted for gastric decompression. Intravenous fluids, volume expanders, and antibiotics should be ordered by the physician.

The surgical procedure to replace the organs in the abdominal cavity varies, depending on how large the defect is. If the defect is large, the surgery may need to be done in stages. A staged repair is done with a polymeric silicone (Silastic) pouch, which is used to suspend the viscera above the infant. Daily reduction maneuvers are done to return the suspended organs to the abdominal cavity. This staged reduction is generally done over 7 to 10 days. The infant then returns to surgery for closure of the abdominal wall (Kenner, Lott, Flandemeyer, 1998). If the defect is small, surgery to return the organs back into the abdominal cavity is performed as soon after birth as possible. With surgical treatment and nutritional support, the survival rate is more than 90% in affected infants (Rowe, 1995).

Parental support is extremely important. Parents need to be encouraged to hold their infant's hand and have as much physical contact as possible. The parents may experience a great deal of difficulty in accepting these disfiguring anomalies and in bonding with their newborn. The nurse must keep the parents informed about their newborn's condition, prognosis, physical appearance, and management plan. The nurse should assist and counsel parents who are trying to cope with this crisis.

Imperforate Anus

Imperforate anus refers to a group of congenital anomalies involving the rectum and anus. These anomalies result when the membrane separating the rectum from the anus fails to absorb during the seventh or eighth week of gestation. The condition occurs in 1 in 5,000 births and is 57% more common in males (Holland, Price, & Bensard, 1998). The anomalies are classified by location, either high or low. In the low type, there may be stenosis of the anal opening or a thin transparent membrane may cover the normal anal opening. In the high type, the rectum ends in a blind pouch or there is no connection between the anus and the rectum (Figure 35-9). The necessary treatment and the prognosis are determined by the type of defect.

Approximately 20% to 75% of infants with an imperforate anus have accompanying anomalies. These anomalies are of the VATER or VACTERL variety (i.e., vertebral abnormalities, anal atresia, tracheoesophageal fistula with

esophageal atresia, cardiac abnormalities and renal or radial limb abnormalities) (Kenner, Lott and Flandemeyer, 1998).

Visual inspection of the anal opening may lead the examiner to the diagnosis of imperforate anus. Additional clinical findings may include failure to pass a meconium stool and the inability of the rectum to allow insertion of a thermometer or a gloved small finger.

Surgery is done in stages if the anomaly is the high type. The infant requires a temporary colostomy in the interim. If the anomaly is of the low classification and a thin transparent membrane covers the anal opening, treatment consists of membrane excision, followed by daily dilation. Parents should be taught the dilation procedure.

Genitourinary System Anomalies

The urinary system begins to form during the fourth week of gestation, whereas first indications of the genitals appear during the fifth week. Defects in the genitourinary system are often not life-threatening but may be of great concern to the family, especially if the defect has involved formation of the genitalia. The anomalies can be surgically repaired with varying outcomes in regard to function and appearance. Some of the malformations may be a symptom of a much more complex disease.

Hypospadias

Hypospadias is a congenital anomaly in which the urethral meatus is located on the ventral surface of the glans penis instead of at the tip (Figure 35-10). This anomaly is

REFLECTIONS FROM A FATHER

"When my first son was born, I was absolutely on 'cloud nine'. The pregnancy, the birth, and our growth together as a couple had all been more than I could have ever hoped for. But when I looked at my son more closely, I noticed that his penis did not look right, because the opening was on the top rather than at the tip. I must admit that I was quite relieved to learn that this condition is easily repaired and will have no lasting negative effects on my son's growth and development."

Figure 35-10 Hypospadias. (Courtesy of Dr. James Mandell, chief surgeon, Urology Department, Albany Medical College, Albany, NY.)

fairly common, occurring in approximately 8 of 1000 male births (Angel, 1996). The exact cause is unknown, but it may be that hypospadias is inherited as a multifactorial problem. The sibling of an affected infant has an increased risk (14%) of also having this anomaly (Kaplan, 1994). Surgical repair is generally completed during the first year of life. The infant should not be circumcised before surgical repair because the foreskin is used, if necessary, for plastic surgery.

Epispadias

In **epispadias**, the urethral meatus is located on the dorsal surface of the penis (Figure 35-11). This is a rare anomaly, which occurs in only 1 of 100,000 live births (Kaplan, 1994). This condition often occurs with exstrophy of the bladder. Surgical repair is necessary and, as in infants with hypospadias, circumcision should not be done before the repair.

Exstrophy of the Bladder

Exstrophy of the bladder is an anomaly in which the anterior wall of the bladder and the lower portion of the abdominal wall are absent, causing the bladder to lie open and exposed on the lower abdomen. This defect is rare and occurs in only 1 of 25,000 live births (Kaplan, 1994). At birth, the bladder is visible in the suprapubic area and is red. Urine enters the bladder and can be seen draining onto the infant's skin. The exposed bladder should be kept

Figure 35-11 Epispadias. (Courtesy of Dr. James Mandell, chief surgeon, Urology Department, Albany Medical College, Albany, NY.)

moist until surgical closure is completed. However, there is a difference of opinion on whether to cover the bladder or not; some physicians prefer to keep the bladder exposed, although others prefer to use a moist, sterile covering. Nursing care during this period before closure is aimed at preventing infection. Meticulous skin care around the bladder is required to prevent excoriation from the constant dripping of urine onto the infant's skin.

Surgical reconstruction is often done in two stages. The first stage is done within the first few hours after birth. The bladder and abdominal wall are surgically closed. The second surgical procedure involves creating a urethra, which is performed before the child goes to school, if possible.

Parents need support and education. They need understanding and guidance on how to accept their infant with such an obvious anomaly. They must be taught how to care for their infant at home until the final stage of the surgery is completed.

Ambiguous Genitalia

Even though parents may know the probable gender of their fetus from an ultrasonographic examination, gender is not certain until birth occurs. In rare cases, the gender of the newborn remains unclear at the time of birth. In these situations, it is imperative for the staff and physicians to be extremely cautious but to reassure the parents that the gender of their infant will be determined as soon as possible. Evaluation of the newborn with ambiguous genitalia must be treated as a medical emergency for many reasons. First, the ambiguous genitalia may be the result of several

types of congenital adrenal hyperplasia that are life-threatening. Second, if the uncertainty of gender assignment is handled poorly, it can provoke long-term consequences for both the parents and the child (Moshang & Thornton, 1994).

Gender assignment should be achieved as soon as possible, preferably no later than age 2. However, gender determination within 3 to 6 months after birth is helpful in cases in which reconstructive surgery is necessary (Kenner, Lott, & Flandermeyer, 1998). Gender determination should only be done after careful review and consideration. The process of review should be initiated with a thorough maternal and family history, physical examination of the infant, and laboratory and radiographic studies. The mother should be asked about drugs that she took during the pregnancy, family history of a previous sibling who died during the first 10 days of life, or siblings who experienced precocious puberty. Positive responses from these questions might indicate congenital adrenal hyperplasia (Moshong & Thornton, 1994). The laboratory and radiographic evaluation consists of measurement of circulating hormones, analysis of the chromosomes (results are usually available in 2 to 3 days), and visualization of the internal organs (Kenner, Lott, & Flandermeyer, 1998).

Parental involvement is a critical consideration that the nurse must include in her plan of care. Parents require a great deal of support as they learn to deal with this situation. The nurse is responsible for coordination of care to ensure that the parents understand all the information they are given by various members of the health care team. Knowledge and understanding of basic neonatal embryology and sexual ambiguity can be beneficial to the nurse in identifying newborns with this disorder (Kenner, Lott, & Flandermeyer, 1998).

Musculoskeletal System Anomalies

Similar to many of the other systems, formation of the musculoskeletal system begins in the fourth week of gestation. This system includes development of the joints, muscles, and skeleton. Malformations are often relatively minor and, with proper recognition and treatment, the outcome is usually favorable.

Developmental Dysplasia of the Hip

Developmental dysplasia of the hip (DDH) was previously termed “congenital hip dislocation.” DDH includes malformations of the hip involving varying degrees of deformity that may be present at birth, ranging from subluxation to complete dislocation. There are two basic types of DDH: developmental dislocation and teratogenesis. The

more common of the two is the developmental dislocation, which is embryologically normal but is the result of mechanical forces in utero and the influence of maternal hormones, mainly estrogen, which relaxes tissues in preparation for birth. The infant’s hip is generally dislocated in the perinatal period. The less common type of DDH, in which the hip is dislocated in the embryologic period of gestation has a teratogenic cause, seen in conjunction with malformation of the pelvis and hip (Griffin, 1994). Some affected infants show normal hip movement at birth, so the initial examination may be normal, but they later demonstrate abnormal hip development. Therefore, dysplastic hip screenings should be done at 2 weeks and 2, 4, 6, 9, and 12 months of age (Kenner, Lott, & Flandermeyer, 1998).

DDH occurs in 10 of 1,000 live births (Bennett, 1998). The cause is considered to be multifactorial, with genetic, hormonal, and environmental influences that predispose the hip joint to dislocation. The condition is approximately six times more common in girls than in boys. It is usually, but not always, unilateral, with the left hip being more commonly involved.

DDH must be detected in the neonatal period to enable early treatment and prevent complications. Ortolani’s maneuver and Barlow’s test are useful in making the diagnosis of DDH. These tests should be completed only by an experienced practitioner. Ortolani’s maneuver determines whether one or both hips are dislocated (Figure 35-12). A positive result on Ortolani’s maneuver is elicited when the hip is flexed at a 90-degree angle the leg is gently abducted, and an audible clunk is heard. In infants with DDH, Ortolani’s maneuver elicits positive results until 8 weeks of age or longer (Griffin, 1994). Barlow’s test determines whether the hip can be dislocated on manipulation. Positive results on Barlow’s test occurs when the examiner flexes both hips and knees and slightly adducts the hips; a posterior-directed force on the knees causes the hip to dislocate (Bennett, 1998).

Secondary signs of DDH develop after 6 weeks of life, when the hip migrates laterally and superiorly (Figure 35-13). These signs are asymmetrical gluteal folds (higher on the affected side); limited abduction of the affected hip; and a femur that appears to be shorter on the affected side (Galeazzi’s sign) (Griffin, 1994).

Treatment should be started as soon as possible after diagnosis to prevent any further deformity. Regardless of the type of hip dysplasia, the hips must be maintained in a flexed and abducted position. Methods used to maintain this position include triple diapering and an orthopedic splint, such as the Pavlik harness (Figure 35-14). The harness may be worn for the first 1–2 months of life. Frequently, a spontaneous relocation of the hip will occur in 3 to 4 weeks as a result of wearing the Pavlik harness (Cooperman & Thompson, 1997). The harness is effective

A.

B.

Figure 35-12 Ortolani's maneuver. A. Hand placement; B. hip abduction.

in 90% of cases. However, if the harness is ineffective in attempting to stabilize the hip, a spica cast may be applied to the hip or surgery may be necessary.

Parental support and teaching is an important part of the treatment plan. Parents must be educated about the

REFLECTIONS FROM FAMILIES

"Having our daughter in a Pavlik harness was a real challenge at first—especially the positioning, the diaper and clothing changes, and handling questions from curious observers. But then our 7-year-old son said, 'Hey, it looks like a slingshot to me,' and since then, we've had a more light-hearted view of the treatment and a more positive outlook about our daughter's future."

disorder, treatment management, and care of the infant in a harness or cast. Care should be directed toward preparing the parents for home care and assisting them in feeling comfortable holding and caring for their infant in an orthopedic device. The infant requires extensive follow-up with the orthopedist, and the nurse should stress keeping these follow-up visits.

Clubfoot

Clubfoot (talipes equinovarus) is the most common congenital deformity of the foot, in which portions of the foot and ankle are twisted out of a normal position (Figure 35-15). The foot is fixed in plantar flexion (downward) and is deviated medially (inward). Clubfoot is a musculoskeletal disorder that occurs twice as often in boys as in girls, with an overall incidence of 1 in 1,000 births (Coop-

Figure 35-14 Infant in a Pavlik harness, used to treat developmental dysplasia of the hip.

erman & Thompson, 1997). The exact cause is unknown. This is a structural deformity that is easily recognized by its resistance to manual correction (Griffin, 1994).

Treatment is most successful when begun soon after birth, before the muscles and bones of the leg develop abnormally, causing shortening of the tendons. Nonsurgical treatment consists of gentle repeated manipulations of the foot, with serial castings done every few days for the first 1 to 2 weeks, then every week or two until correction of the foot is satisfactorily completed. Correction is usually completed in 6 to 8 weeks. To maintain the correction from serial castings, braces are usually worn for another 6 months, or longer. If conservative measures are unsuccessful in correcting the foot, surgical intervention is required during infancy.

Infants with this deformity are frequently placed in a cast while they are still in the newborn nursery. Nursing care is aimed toward supporting and educating the parents about this anomaly; nursing interventions include teaching the parents cast care, how to assess the toes to ensure ad-

equat vascular circulation, how to handle the infant in a cast, and adhering to the follow-up treatment plan.

ACQUIRED DISORDERS

Conditions that result from environmental factors are referred to as acquired disorders. Although some disorders may be detected soon after birth, others may not become evident for several days. The longer an acquired disorder goes undetected and untreated, the greater the possibility of complications or long-term sequelae. Neonatal admission nurses must learn to carefully screen the maternal history for risk factors and must maintain up-to-date assessment skills. In addition, the nursing staff must remember to keep the parents of these neonates informed about the condition, treatment modalities, prognosis, and possible outcomes for infants with the disorder.

Trauma and Birth Injuries

In a difficult or traumatic delivery, certain birth injuries may occur. The injuries range from mild to life-threatening. A complete and thorough assessment of the neonate soon after birth allows the nurse to identify injuries sustained and develop an appropriate plan of care. In addition to meeting the specific needs of the neonate with a birth injury, nurses must also see to parental needs. The parents should be informed of their infant's condition, his or her special needs during the hospital stay and after discharge, and the possible outcomes.

A review of mortality rates indicates a steady decline in fetal deaths caused by birth injuries. Between 1981 and 1993, injury-related deaths decreased from 23.8 to 3.7 per 100,000 live births. Despite the significant decrease in mortality rates, birth injuries still rank as an important risk factor for neonatal morbidity (Fanaroff & Martin, 1997).

Fractures

Fractures often occur as the result of a difficult labor, breech deliveries, or large infants or when fetal distress is present and a rapid delivery is necessary. Common sites of fractures include the clavicle; long bones, such as the humerus and femur; and the skull. Fractures may not be detected immediately after birth because the infant may not display any signs of pain or the deformity may not be apparent. Definitive diagnoses for all fractures are determined by x-ray studies. During birth, the bone most often fractured is the clavicle. Fractured clavicles occur in at least 1.7% to 2.9% of term deliveries and more frequently on the right side (Fletcher, 1994). The break often occurs in the middle third of the bone; it is usually the result of dystocia in a vertex delivery. The newborn may be asymptomatic if the fracture is not displaced, and the fracture

Figure 35-15 A. Talipes equinovarus (clubfoot); B. if the foot can be moved toward midline, the twisting is positional rather than congenital.

may not be detected until the infant is 2 to 3 weeks old. At that time, the infant develops a callus and mass over the fractured clavicle. Signs and symptoms of a fractured clavicle may include decreased mobility or immobility of the affected arm, crepitus along the involved clavicle, absence of the Moro reflex on the affected side, and crying by the infant when the arm is moved. Other than gentle handling to minimize pain, there is no medical or surgical treatment. The prognosis for complete recovery is good. Health care providers and the parents must be taught not to lift the infant up by the arms. If a fractured clavicle is suspected, the Scarf sign should not be assessed. Immobilization of the affected arm by immobilizing it close to the body (i.e., pinning sleeve to shirt or using a sling) may provide pain relief. The immobilization may be discontinued in 8 to 10 days when there is callus formation.

The second most often fractured bone is the humerus. These fractures result from a difficult delivery of the arms or shoulders during a vertex or breech delivery. The fracture is generally detected during delivery when the obstetrician hears and feels the humerus snap (Griffin, 1994). Signs and symptoms are the same as those of a fractured clavicle, with the exception that crepitus is not evident. The fractured arm should be immobilized in the adducted position with a splint or cast for 2 to 4 weeks, or until healing occurs.

Fractures of the femur also occur as the result of a difficult delivery. Deformity of the thigh, swelling, or immobility may be noted. Treatment involves traction, suspension, and casting for approximately 3 to 4 weeks (Mangurten, 1997).

The newborn's skull is extremely flexible and can withstand a great deal of molding; therefore, skull fractures are rare. The types of fractures that may occur are linear fractures and depressed fractures. Linear fractures, the most common, account for 70% of all skull fractures. This skull fracture generally has no signs or symptoms and does not require any special treatment, unless an intracranial hemorrhage has occurred. In depressed fractures, the skull becomes indented from the pressure exerted on the head by the pelvis or by forceps during delivery. Depressed fractures may require surgery if brain tissue is involved. Skull x-ray studies and CT scans are done to determine the site of fracture and to identify any potential complications.

The parents of newborns with fractures are often fearful of hurting their infant. To allay some of their fears, they should be taught how to handle and feed their infant and change diapers. Parents also should be taught the importance of follow-up care that includes additional x-rays films and CT scans, which may be necessary for several months after discharge to make sure that reunion of the bone occurs (Moe & Paige, 1998).

Facial Palsy or Paralysis

Facial palsy or paralysis results from pressure exerted on the seventh cranial nerve during a difficult vaginal delivery or from pressure of forceps, which causes paralysis on one side of the infant's face. The incidence of facial palsy in the newborn varies from 0.05% to 1.8% (Eng, 1994). In 75% of cases, the facial paralysis occurs on the left side (Moe & Paige, 1998). Usual signs of facial paralysis include inability to close the eye on the affected side, absence of wrinkles in the forehead during crying, and drawing of the mouth to one side when crying. No medical treatment is required, and the condition usually resolves within 3 weeks.

Brachial Paralysis or Palsy

Brachial palsy is a paralysis of the muscles involving the upper extremity that occurs as a result of injury to the brachial plexus during a prolonged and difficult labor, followed by a traumatic delivery. Brachial plexus injuries are estimated to occur at a rate of 0.5 to 1.9 per 1000 live births (Moe & Paige, 1998). The most common site of injury is at the fifth and sixth cranial nerve and is called Duchenne-Erb paralysis. This type of injury causes paralysis in the upper arm. Erb's paralysis usually results from the pulling or stretching of the shoulder away from the head during a difficult vertex or breech delivery. Clinical manifestations include a flaccid arm with the elbow extended and the hand internally rotated, an intact grasp reflex, absent or weak Moro reflex on the affected limb, and diminished or absent deep tendon reflexes on the affected arm.

Another type of injury that can occur from C8 to T1 is called Klumpke's palsy. This injury causes paralysis to the lower arm and hand. The incidence of Klumpke's paralysis is less than 2% of all cases. Treatment of brachial plexus injuries may include immobilization for 1 to 5 days, passive ROM exercises, and proper positioning of the affected arm and hand. In 88% to 92% of cases, full recovery is seen during the first year of life. Parents must be taught how to do passive ROM exercises and must be informed that these exercises are done to prevent further complications caused by contractures (Moe and Paige, 1998).

Intracranial Hemorrhage

Intracranial hemorrhage (ICH) is a collection of blood within the cranium. It results from birth trauma and is more likely to occur in the large, full-term newborn and spontaneously in the premature newborn, who is at highest risk for the development of ICH. There are different types of hemorrhage; the newborn can have one or more of these types. The most common types are subdural and subarachnoid hemorrhage.

Subdural hemorrhage (hematoma) is a collection of blood in the subdural space of the brain that results from lacerations of the large veins and sinuses that are frequently seen in conjunction with a tear in the dura. Subdural hemorrhages occur less frequently now than in the past; they now account for less than 10% of all ICHs in the newborn because of improvements in obstetric monitoring and care. Subdural hemorrhages are a life-threatening condition because of their inaccessibility for aspiration by subdural tap (Fanaroff & Martin, 1997). Surgical evacuation of subdural clots may be necessary on an emergency basis.

Signs and symptoms include a decreased level of consciousness, seizures, and asymmetry of motor function. Diagnosis depends on results of a CT scan of the brain. If a subdural hemorrhage is confirmed, the prognosis is poor if the laceration is of the tentorium or falx; this diagnosis carries a mortality rate of 45%. The majority of infants with this type of laceration develop other complications, such as hydrocephalus. If the hemorrhage is of a lesser degree, 50% of the infants are neurologically normal at follow-up visits (Hill & Volpe, 1994).

Subarachnoid hemorrhage is the most common type of neonatal ICH. This type of hemorrhage in the full-term newborn is usually the result of trauma; in the premature infant, the hemorrhage results from hypoxia. Bleeding is of venous origin and is the result, more commonly, of smaller hemorrhages rather than massive ones. Diagnosis is confirmed by results of lumbar puncture and a CT scan of the brain. Signs of a subarachnoid hemorrhage include irritability, decreased level of consciousness, and seizures. Seizures are treated with anticonvulsant medications (Moe & Paige, 1998).

The nursing care of the newborn with ICH is generally supportive. Care includes monitoring of ventilatory and neurologic status; intravenous therapy to maintain fluid and electrolyte balance; observation and management of seizures; and prevention of increased ICP. The newborn should be handled minimally to promote rest and reduce stressors (Wong & Perry, 1998).

Because follow-up care varies, depending on the type and extent of hemorrhage, parent teaching must be individualized according to the prognosis for the infant's condition. Referral to local support groups may be beneficial.

Infants of Diabetic Mothers

Diabetes mellitus and gestational diabetes mellitus is increasing throughout the population. Gestational diabetes occurs in approximately 2% to 3% of pregnant women (Sills & Rapaport, 1994).

The **infant of a diabetic mother** (IDM) presents with a number of clinical problems. A better understanding of maternal and fetal metabolism, resulting in stricter meta-

bolic control, improved fetal surveillance, early delivery, and neonatal intensive care, has increased the survival rates for IDMs over the past few years (Kalhan & Saker, 1997). In recent years, perinatal mortality rates have decreased by 6% in IDMs, from more than 10% to less than 4% (Coustan, 1997).

The fetus is at risk for many problems when the mother has diabetes mellitus. Alteration in glucose metabolism affects the infant in utero and immediately after birth. One factor that determines how the fetus is affected is the severity and duration of the maternal diabetes. A positive outcome for the health of the fetus requires maintenance of normoglycemia in the pregnant woman with diabetes. Even with good control of the mother's glucose levels, problems can occur. Common problems observed in infants of diabetic mothers include macrosomia, respiratory distress syndrome, hypoglycemia, hypocalcemia, hypomagnesemia, hyperbilirubinemia, polycythemia, and congenital anomalies.

Macrosomia

Macrosomia is defined as a fetal weight above the 90th percentile for gestational age or a birth weight of more than 4,000 g (8 lb, 12.8 oz). Macrosomia is a common characteristic of infants of diabetic mothers. The probability of insulin-dependent women giving birth to a macrosomatic infant is 20% to 30% (Ogata, 1994). Women with gestational diabetes have the same likelihood of bearing a macrosomatic infant as a woman with preexisting diabetes. The macrosomatic infant has a round chubby face, chubby body, and a plethoric appearance, which is related to polycythemia. The infant's internal organs (liver, spleen, and heart) are enlarged and amount of body fat is greater than normal. Much of this fat is deposited in the shoulders and intrascapular area. The IDM has normal brain growth, and the characteristic disproportion between head and shoulder size greatly contributes to dystocia and trauma during birth (Ogata, 1994).

Insulin is the hormone central to the development of macrosomia. Late in pregnancy, when the mother's pancreas does not release enough insulin to meet the increasing needs, she becomes hyperglycemic. These high levels of maternal blood glucose cross through the placenta to the fetus, and the fetal pancreas responds by releasing large amounts of insulin. This increased production of insulin by the fetus stimulates the growth of insulin-sensitive tissues (i.e., adipose, muscle, and connective tissue), which causes macrosomia (Fanaroff & Martin, 1997).

Respiratory Distress Syndrome

IDMs are at greater risk of developing respiratory distress syndrome (RDS) than normal full-term newborns. Fetal

hyperinsulinemia adversely affects fetal lung maturation by inhibiting the development of enzymes necessary for the synthesis of the phospholipid components of surfactant. Fetal lung maturity in the normal full-term infant is evidenced by a lecithin-sphingomyelin (L/S) ratio of 2:1. But in the mother who has diabetes mellitus or gestational diabetes mellitus, it is recommended that the L/S ratio be 3:1 or more, or the amount of phosphatidyl glycerol in the amniotic fluid should be more than 3%, to confirm adequate lung maturity.

Hypoglycemia

The most common problem in an IDM at birth is **hypoglycemia** (i.e., blood glucose levels of less than 40 mg/dL). The infant's blood glucose level is high at the time of birth because of maternal hyperglycemia. Because of this elevated level of fetal blood glucose, the fetal pancreas responds by producing large quantities of insulin, causing a state of hyperinsulinemia. Even though there is a cessation of the maternal glucose supply when the cord is clamped, the infant is still in a hyperinsulinemic state. Hypoglycemia usually occurs during the first 3 hours after birth. The blood glucose level in the newborn is checked by heel stick after birth and again at frequent intervals, especially during the first 24 hours of life. Most IDMs are asymptomatic. Signs of hypoglycemia can include jitteriness and tremors, apnea, cyanosis, a high-pitched cry, lethargy, and tachypnea. Treatment includes providing early feedings (within 30 minutes after birth if bowel sounds are present) or the administration of intravenous glucose.

Hypocalcemia and Hypomagnesemia

Hypocalcemia and hypomagnesemia are metabolic problems seen in IDMs. **Hypocalcemia** is a blood calcium level of less than 7 mg/dL. It is one of the most common clinical problems that affect IDMs. Approximately 10% to 20% of IDMs experience hypocalcemia during the neonatal period. The cause is believed to be related to decreased concentrations of parathyroid hormone during the first four days of life (Ogata, 1994). Many infants with hypocalcemia are asymptomatic, but some may exhibit jitteriness, a high-pitched cry, irritability, seizures, and twitching. These symptoms may be indistinguishable from those of hypoglycemia, except that they generally occur between 24 and 36 hours after birth versus hypoglycemia, which occurs during the first 1 to 3 hours of life. To restore normal calcium levels, therapy is initiated by providing early feedings, intravenous calcium, or oral calcium supplements.

Reduced serum magnesium levels may occur in pregnant diabetic women and their infants. Hypomagnesemia in the newborn is believed to result from increased maternal losses of magnesium in the urine, which are character-

istic of diabetes. Magnesium deficiency may inhibit fetal parathyroid hormone secretion, which is associated with hypocalcemia (Barron, Lindheimer, & Davison, 2000).

Hyperbilirubinemia and Polycythemia

Hyperbilirubinemia, an elevated level of direct bilirubin in the blood, is a common finding that occurs in 20% to 25% of IDMs (Ogata, 1994). Many infants also have **polycythemia**, which results from an increased number of red blood cells, and plays a significant role in hyperbilirubinemia. An increased rate of erythrocyte breakdown results from changes in erythrocyte membrane composition, which, in turn, result from changes in maternal glucose availability (Ogata, 1994). This increased red blood cell breakdown, along with bruising suffered by the macrosomatic infant at birth, may contribute to high bilirubin levels.

Congenital Anomalies

The incidence of congenital malformations is two to four times higher in IDMs than in infants born to mothers who do not have diabetes (Ogata, 1994). The most common anomalies are cardiac and skeletal malformations and neural tube defects. In most anomalies related to diabetic pregnancies, the structural abnormalities have occurred before the eighth embryonic week. This reinforces the importance of women with diabetes monitoring their glucose levels before conception and delaying pregnancy until their glycosylated hemoglobin level is within the normal range (Coustan, 1997).

The incidence of congenital heart lesions in IDMs can be as much as five times that of infants of normoglycemic mothers. The most common lesions in the IDM are atrial or ventricular septal defects, transposition of the great vessels, and coarctation of the aorta (Fanaroff & Martin, 1997).

Skeletal malformations may include delayed ossification, osseous defects, caudal regression syndrome, and femur agenesis or hypoplasia. CNS anomalies include hydrocephalus, meningomyelocele, and anencephaly (Kenner, Amlung, Flandermayer, et al., 1998).

These infants may also present with abdominal distention, failure to pass meconium stool, and bile-stained vomitus, caused by a transient delay in the development of the left side of the colon. This condition is known as neonatal small left colon, or lazy colon syndrome. Normal bowel function develops in early infancy (Fanaroff & Martin, 1997).

Hyperbilirubinemia

Hyperbilirubinemia, or jaundice, is a common finding in all newborns. Hyperbilirubinemia is an excess of bilirubin in the blood, which causes jaundice. Bilirubin is formed

from the breakdown of hemoglobin in the red blood cells. Jaundice results from deposits of the yellow pigment in bilirubin. Excess amounts of bilirubin are evidenced by a yellowish discoloration of the neonate's skin, mucous membranes, and sclera, termed **jaundice**. Jaundice proceeds in a cephalopedal progression, first appearing on the head and face and then progressing to the trunk and extremities. If jaundice is present, it may be observed by blanching the skin on the infant's forehead or over the bridge of the nose. If the skin blanches to a yellow hue, jaundice is present. In dark-skinned infants, the nurse may more easily detect jaundice by observing the color of the sclera and the buccal mucosa.

Hyperbilirubinemia may result from either physiologic or pathologic factors. Even though hyperbilirubinemia is a common clinical finding in the newborn, the normal physiologic jaundice process must be distinguished from the abnormal pathologic jaundice condition.

Physiologic Jaundice

Physiologic jaundice occurs in approximately 50% to 60% of full-term newborns and up to 80% of preterm newborns during the first week of life. It is a transient elevation of unconjugated bilirubin, which occurs after 24 hours of age, and is a normal physiologic process. The mean unconjugated bilirubin level in cord blood is 1.8 mg/dL. The full-term infant reaches peak bilirubin concentration levels of 6 to 7 mg/dL between 48 and 72 hours after birth. Increased bilirubin levels resolve without any intervention, declining to less than 2 mg/dL by 6 to 7 days after birth. Ethnic variability may also influence bilirubin levels during the first week of life. Asian and Native Americans have average peak serum bilirubin levels that are twice the level of other ethnic groups.

Pathologic Jaundice

Jaundice that is evident in the first 24 hours of life, a bilirubin level that rises more than 0.5 mg/dL per hour, or true hemolysis is considered **pathologic jaundice**. The most common cause of pathologic jaundice is blood group incompatibility, specifically ABO and Rh incompatibility. Other less common situations that may be seen in conjunction with pathologic jaundice in the newborn are maternal or fetal infections, swallowed maternal blood, maternal diabetes, fetal enzyme deficiencies, fetal enclosed hemorrhage (e.g., cephalhematoma or bruising), fetal polycythemia, fetal small-bowel obstruction, and fetal hypothyroidism.

Kernicterus

A possible complication of pathologic jaundice is kernicterus, also termed "bilirubin encephalopathy." **Kernicterus** is the excess accumulation of unbound, unconju-

gated bilirubin, which is deposited in brain tissues, particularly the basal ganglia. The excess bilirubin crosses the blood-brain barrier, causing yellow staining of the brain tissue, similar to its effect on the skin. Kernicterus causes varying degrees of neurologic damage. There is not a direct correlation between serum bilirubin levels and the severity of brain tissue damage. However, in the full-term healthy infant whose total serum bilirubin exceeds 25 mg/dL, the risk for kernicterus increases. Premature infants or infants with other medical complications are at risk for kernicterus at much lower serum bilirubin levels. Perinatal conditions can also influence the bilirubin-binding capacity of hemoglobin and increase the risk for kernicterus at lower serum bilirubin levels; these include hypoxia, acidosis, hypothermia, hypoglycemia, sepsis, and administration of certain medications (e.g., salicylates, sodium benzoate). Kernicterus usually becomes evident during the first 6 days of life. Early signs, which may be absent or present, include lethargy, poor feeding, temperature instability, hypotonia, and a high-pitched cry. Permanent neurologic sequelae in these children include ataxia, opisthotonos, deafness, seizures, and mental retardation (Blackburn, 1995).

ABO Incompatibility

ABO incompatibility occurs as a result of the mother and fetus having different blood groups. The mixing of maternal and fetal blood leads to hemolysis of fetal red blood cells. ABO incompatibility is the most common and mildest type of hemolytic disease; it rarely causes severe hemolytic problems, which would require an exchange transfusion. The incompatibility occurs when the fetal blood is type A, B, or AB and the mother is type O. The incompatibility arises because the mother does not have the fetal red blood cell antigen A or B and produces antibodies that cross the placenta to the fetus. This problem may occur in the first pregnancy, because mothers with type O blood already have naturally occurring anti-A and anti-B antibodies in their blood. There is no way of preventing ABO incompatibility.

Laboratory studies may be helpful in establishing a diagnosis of ABO incompatibility. Positive results on direct Coombs' test occurs in 3% of cases, but positive results in both direct and indirect Coombs' test occur in 80% of cases. The direct Coombs' test measures the presence of antibodies on the red blood cell surface, and the indirect test is a measurement of antibodies in the serum (Kenner, Amlung, & Flandermeyer, 1998).

Rh Incompatibility

Rh incompatibility is a hemolytic disease caused by the incompatibility of Rh factors in maternal and fetal blood. Rh incompatibility, or isoimmunization, occurs when the

woman is Rh-negative and the fetus is Rh-positive. If both parents are Rh-negative, there is no hemolytic incompatibility with the infant and the infant is Rh-negative. Isoimmunization occurs when fetal blood cells escape and pass through the placenta into the maternal circulation. The fetal blood cells may pass into the maternal circulation as early as 8 weeks' gestation or during an abortion, amniocentesis, ectopic pregnancy, hydatidiform mole, abdominal trauma, or when the placenta separates during delivery. The woman may form protective antibodies against the fetal blood cells. The process by which the maternal immunologic system forms antibodies against fetal blood cells is termed "**maternal sensitization.**" Usually, the woman becomes sensitized during the first pregnancy but does not form enough antibodies to adversely affect the infant. However, during subsequent pregnancies, antibodies form rapidly, resulting in lysis or destruction of fetal red blood cells.

Erythroblastosis fetalis is a condition in which there is vast destruction of fetal red blood cells by maternal antibodies, resulting in fetal anemia and hyperbilirubinemia. The severity of this condition depends on how well the infant can compensate for the destruction of red blood cells. However, the destruction of fetal red blood cells may be so severe that a marked hemolytic anemia develops and the blood does not have sufficient capacity to carry oxygen to the tissues. Fetal death or birth of an infant with hydrops fetalis may result from this condition (Ensher & Clark, 1994). **Hydrops fetalis** is the most severe form of fetal hemolytic disease: there is severe anemia resulting in hypoxia, cardiac decompensation, and hepatosplenomegaly.

The signs of Rh incompatibility in the newborn are jaundice, pallor, and enlargement of the liver and spleen. Jaundice becomes evident within the first 4 to 5 hours after birth and peaks when the infant is 3 or 4 days old (Blanchette, Doyle, Schmidt, & Zipursky, 1994).

Management of Rh incompatibilities focuses on prevention of the disease by administering Rh₀ (D) immune globulin (RhoGAM) to the mother after delivery or abortion, if the infant was Rh-positive. This agent should be administered within 72 hours after delivery; this treatment should prevent the woman from producing antibodies to the fetal blood cells that entered her bloodstream during the delivery.

Management of Newborn Hyperbilirubinemia

The goal of managing the newborn with jaundice is to keep the serum bilirubin below neurotoxic levels. The most common treatment modalities are phototherapy and exchange transfusions.

Phototherapy is the use of ultraviolet light in the treatment of jaundice in the newborn (Figure 35-16).

A.

B.

Figure 35-16 A. Phototherapy, set-up for jaundiced newborn; B. phototherapy equipment including bilateral eye patches.

Phototherapy works by encouraging the liver to excrete bile in the form of unconjugated bilirubin. Blue or fluorescent bulbs are commonly used in phototherapy. The adverse effects of using phototherapy include dermal rash, lethargy, abdominal distention, possible eye damage, dehydration, thrombocytopenia, hypocalcemia, secretory diarrhea, and “bronze baby” syndrome (Kenner, Amlung, & Flandermeyer, 1998).

The prolonged exposure to ultraviolet light may cause retinal damage; therefore, it is extremely important to keep the infant’s eyes shielded with eye patches when under the light. However, try to keep as much of the infant’s skin exposed as possible. During oral feedings, the light and eye patches can be removed to provide sensory stimulation and interaction with the parents or care provider.

Infants undergoing phototherapy require close monitoring of their body temperature, fluid and electrolyte balance, and serum bilirubin concentration (lights should be turned off while drawing blood). The serum bilirubin levels must be checked frequently to ensure that phototherapy is effective.

If the infant is to receive phototherapy at home, the nurse is responsible for teaching the parents to record the infant’s temperature, weight, and fluid intake; to weigh diapers; and to note the frequency of stools. Another method of phototherapy uses a fiberoptic blanket and is more convenient for home use.

If phototherapy is ineffective and the serum bilirubin level is rising to a level that may be neurotoxic, an exchange transfusion may be necessary. Exchange transfusions should lower the bilirubin level by 50% to 60%. During an exchange transfusion, the infant’s antibody-coated red blood cells and excess bilirubin are removed and replaced by donor blood that contains noncoated red blood cells. Only small amounts of the infant’s blood are removed and replaced at a time. The procedure is repeated until the infant’s total blood volume has been diluted with the fresh blood. Exchange transfusions are considered safe, but complications may arise. The nurse must be alert for the following complications: bradycardia, arrhythmias, infection, thrombosis, hypocalcemia, and fluid overload.

NEONATAL INFECTIONS

Neonatal infections cause more than 30% of all neonatal deaths. Approximately 50% of neonatal mortalities that occur during the first 24 hours of life are attributed to infection (Kenner, Lott, Flandermeyer, 1998). Infection in the neonate can be caused by a variety of agents. Infection may be passed through the placenta to the baby during pregnancy or from exposure to organisms present in the vagina during birth or from the environment. Organisms that initially infect the mother and then are passed on

transplacentally to the fetus are referred to by the acronym TORCH (toxoplasmosis, other [gonorrhea, syphilis, varicella, parvovirus, HBV, and HIV], rubella, cytomegalovirus, and herpes simplex virus. (See STORCH, Chapter 21.) Major complications from infections include respiratory distress, shock, acidosis, disseminated intravascular coagulation (DIC), and meningitis (Kenner, Lott, & Flandermeyer, 1998).

Sepsis

Sepsis is a systemic bacterial, viral, or parasitic infection that invades the bloodstream of the newborn. It occurs either during or after birth in approximately 1 of 1000 full-term births (Ensher & Clark, 1994). Bacterial sepsis in the newborn is divided into two categories: early onset or late onset. Early onset sepsis occurs during the first few days of life and is generally caused by obstetric complications, such as prolonged or premature rupture of membranes, chorioamnionitis, peripartum maternal fever, fetal distress, or aspiration by the newborn. The microorganisms that usually cause the early-onset infection are from the maternal vaginal tract and include group B *Streptococcus species*, *Haemophilus influenza*, *Listeria monocytogenes*, *Escherichia coli*, and *S. pneumoniae*. Infants with early-onset sepsis have a high mortality rate.

Late-onset sepsis generally occurs after the first week of life. Bacteria that causes the late-onset sepsis include organisms acquired either from the mother’s genital tract or by contact from humans and equipment (Merenstein, Adams, & Weisman, 1998). The bacteria that commonly cause late-onset sepsis include *Staphylococcus aureus*, *S. epidermidis*, *Pseudomonas* organisms, and group B beta-hemolytic Streptococci. The most common organisms for causing sepsis in the newborn is the group B *Streptococcus species*, which are acquired from the mother.

It is often difficult to distinguish sepsis in the neonate from other medical conditions because the symptoms of both early- and late-onset sepsis are vague and nonspecific. Because of the high mortality rate of sepsis, it is imperative for the nurse to observe and report to the physician any subtle changes that occur in the neonate’s status.

The most accurate method of confirming bacterial sepsis is isolation of the bacteria from either the blood, CSF, or urine. Generally, the CSF is tested in the symptomatic newborn, because meningitis is a frequent cause of sepsis (Merenstein, Adams, & Weisman, 1998). Other tests include a complete blood cell (CBC) count with differential, C-reactive protein, erythrocyte sedimentation rate, total platelet count, and cultures (blood, urine, or CSF). A chest x-ray study detects pneumonia.

After obtaining the appropriate laboratory samples, antibiotic therapy is initiated. A broad-spectrum antibiotic, such as ampicillin in combination with an aminoglycoside,

is commonly administered, pending culture and sensitivity results. Once the causative organism is determined and the antibiotic sensitivities are known, the least toxic antibiotic is administered for an appropriate period of time (Merenstein, Adams, & Weisman, 1998).

Before the advent of antibiotic therapy, the mortality rate from bacterial sepsis was 95% to 100%, but now, with antibiotics, the mortality rate has been reduced to less than 50%. The most common complications of bacterial sepsis are meningitis and septic shock. Bacterial meningitis affects 1 in 2,500 live births (Wong & Perry, 1998). The outcome of neonatal sepsis is influenced by early recognition, antibiotic therapy, and supportive care (Merenstein, Adams, & Weisman, 1998).

FAMILY EXPERIENCES

The nursing care of the family with a newborn who has a congenital disorder is extremely demanding and must involve a multidisciplinary team approach, including such specialists as nurse practitioners, surgeons, social workers, dietitians, physical therapists, and neurologists. The care must address the surgical and rehabilitative needs of the infants and the educational, psychosocial, and financial needs of the family.

In the early postpartum period, it is particularly challenging to work with the parents. At this time, parents are going through the shock and disappointment of having had a “less-than-perfect” child. They must first be given the time, opportunity, and support to go through the grief process. This process involves the parents experiencing shock, denial, anger, and depression before accepting the newborn and reorganizing the family. Nurses can best facilitate parental passage through the process by being accessible and keeping the lines of communication open between the parents and staff. Nurses should educate the family about the disorder and their infant’s present and future health care needs. When they are ready, parents should be encouraged to touch and become involved in their infant’s care.

NURSING PROCESS

Although not all congenital disorders can be predicted in the perinatal period, the nursing process provides a framework for nurses caring for families after the birth of an infant with an anomaly.

Assessment

Nursing assessment begins with a thorough review of the mother’s history, including the family, past medical, psychosocial, previous obstetrical, and present prenatal his-

tory. Histories are reviewed to identify potential risk factors that alert the health care team to the possibility of a disorder in the fetus. As soon as the infant is delivered, the neonatal team must perform a physical assessment of the infant and its adaptation to extrauterine life. Initially, care is directed toward stabilization of the newborn and transport to the neonatal intensive care unit (NICU). Once the neonate with a disorder is stabilized in the NICU, attention is turned toward assessing the needs of the parents and family. Certain variables that may influence a family’s ability to cope with the birth of a infant with a congenital or acquired disorder include age of the parents, culture, religion, and the support systems available to them. The nurse formulating the plan of care should assess the effect of these variables on the family and use that knowledge when providing information and communicating.

Nursing Diagnosis Newborn

Care is individualized based on the disorder, the threat to survival, and family structure and coping abilities, but several general aspects of nursing care are common to most cases. Initially, nursing care is directed toward the stabilization and maintenance of life support. At this time, potential nursing diagnoses are:

- Ineffective thermoregulation related to stress of condition and or birth defect

- Infective breathing pattern related to oral pharyngeal secretions and/or structural anomalies

- Decreased cardiac output related to decreased circulating oxygen secondary to a congenital cardiovascular defect

Should the infant survive the initial neonatal period, surgical correction of the birth defect is scheduled as soon as the infant’s condition is stabilized. Postoperatively, potential nursing diagnoses are:

- Risk for infection related to the immature immune system, lack of normal flora, environmental hazards, and open wounds

- Impaired skin integrity related to structural anomalies and immobility

- Imbalanced nutrition: less than body requirements, related to NPO status that is required by the structural anomaly

- Pain related to procedures and treatments

Parents and Family

- Grieving related to realization of present or future loss for family and or child and birth of a newborn with a defect

- Ineffective coping (depression) related to perceived parental role failure and loss of a “perfect infant”
- Deficient knowledge related to cause, management, and care of a newborn with a birth defect
- Anxiety related to unpredictable outcomes or prognosis of impaired infant
- Impaired parenting related to inadequate bonding, secondary to parent-child separation or failure to accept impaired child

Outcome Identification

Newborn

Sample targeted outcomes for the infant born with an anomaly might include:

- Maintaining a core body temperature of 97.7°F to 99.5°F (36.5°C to 37.5°C)
- Maintaining adequate gas exchange to support life
- Demonstrating signs of adequate circulating oxygen
- Exhibiting no signs of infection
- Maintaining and/or demonstrating no further breakdown in skin integrity
- Receiving adequate nutrients to support growth
- Remaining free of, or displaying less frequent signs of, episodic pain.

Parents and Family

Anticipated outcomes of nursing care for the family might include that parents will:

- Verbalize their feelings and concerns regarding their newborn’s medical problems, prognosis, and outcome
- Demonstrate an understanding of their infant’s needs while participating in care
- Show the beginnings of attachment and the development of a parent-infant bond

Planning

Newborn

After delivery, the infant born with a congenital or acquired anomaly is cared for in an NICU. There the infant is placed under a radiant heater, connected to a cardiac monitor, and oxygen is administered to maintain respiratory function. Care is directed towards stabilization and preparation for surgery if indicated.

Parents and Family

In addition to meeting the infant’s needs, the nurse must also recognize and deal with the educational, emotional, and psychosocial needs of the parents and family. The

nurse must function as educator, support person, and facilitator to the parents and family during all aspects of care for the infant born with a defect or disorder. The parents’ feelings and reactions are carefully assessed, as is their ability to absorb and understand information regarding their infant’s condition. Families need constant information, guidance, and support from the nursing staff to make decisions regarding the course of action to be taken.

Nursing Interventions

Preoperative interventions for the infant include temperature regulation, maintenance of respiratory and cardiovascular function, and management of fluid and electrolyte balance. Depending on the type of defect present, other potential nursing interventions may include the management of open lesions and gastric decompression with the insertion of an oral gastric tube.

Postoperatively, the infant returns to the NICU and must be continuously monitored and frequently assessed for changes in condition or the development of complications. Vital functions are maintained with oxygen or mechanical ventilation and monitored with a pulse oximeter and measurement of arterial blood gas levels. Other nursing interventions include maintaining a neutral thermal environment, administration of intravenous fluids and strict measurement of intake and output, daily weight, hourly vital signs, and blood glucose monitoring. The nurse also provides care of the surgical site, administers antibiotics, and provides pain relief for the promotion of comfort.

It is crucial that the nursing staff encourage and facilitate parent-infant bonding by encouraging parental involvement in the care of the infant. Touching, talking to, and holding the infant during visitation should be encouraged by the nurse.

Another important aspect of nursing care is the referral to appropriate community and national agencies for financial and psychological support. Nurses should familiarize themselves with available community services that provide support, assistance, and education to families with special needs or problems.

Evaluation

Newborn

The effectiveness of nursing interventions is determined by continuous assessment of the infant’s condition and the evaluation of care. The following guidelines provide the basis by which to evaluate care and measure the degree of accomplishment of the expected outcomes.

- Assess and monitor vital signs including body temperature hourly. Measure blood glucose levels at frequent intervals.

Case Study/Care Plan

INFANT OF A MOTHER WITH GESTATIONAL DIABETES

Rudy is a 4200 g (9 lb, 4 oz) male infant born via cesarean section at 38 weeks' gestation. His mother is a 27-year-old gravida 1, para 0, in whom gestational diabetes was detected at 28 weeks' gestation. His Apgar scores were: 7 at 1 minute (1 point off each for color, tone, and irritability); and 8 at 5 minutes (1 point off each for color and tone). Initial physical examination reveals the following: large for gestational age; blood glucose level, 38 mg/dL; heart rate, 156; respirations, 64/min with nasal flaring; gestational age, 37 weeks by Dubowitz scale; and apparent congenital anomalies or birth trauma, none.

Assessment

- 4200 g male
- Apgar 7, 8
- IDM, LGA
- HR 156, R 64

Nursing Diagnosis

Risk for injury related to hyperinsulinemia, secondary to gestational diabetes as evidenced by hypoglycemia.

Expected Outcome Infant will maintain blood glucose levels that are within normal limits.

Planning Discuss preferred feeding methods with parents.

Nursing Interventions

Rationales

- | | |
|--|--|
| 1. Monitor glucose levels: at birth, on admission to the nursery, every 2 hours for the first 8 hours, and then every 4 hours for 24 hours. If glucose levels are abnormal, the testing should be repeated every 30 to 60 minutes until the infant has been stabilized | 1. Hypoglycemia may be present without any observable signs. |
| 2. Observe for signs of hypoglycemia (i.e., jitteriness and tremors, lethargy, apnea, cyanosis, tachypnea, and high-pitched cry). | 2. These signs may indicate hypoglycemia, which generally develops 1 to 3 hours after birth. |
| 3. Feed newborn early by providing glucose, breast milk, or formula. | 3. Prevents or treats hypoglycemia that may develop 1 to 2 hours after birth. |
| 4. Provide a neutral thermal environment. | 4. Avoids cold stress, which increases metabolism, thereby causing rapid consumption of glucose. |

Evaluation Blood glucose levels are stabilized and remain above 40 mg/dL. No signs of hypoglycemia are evident. Axillary temperature remains between 97.6°F and 98°F (36.4°C and 36.7°C).

Nursing Diagnosis

Impaired gas exchange related to immature pulmonary system, secondary to maternal gestational diabetes.

Expected Outcome Infant will demonstrate a normal respiratory status as evidenced by: a normal respiratory rate, rhythm, and depth; normal clear breath sounds; and arterial blood gas levels within the normal range.

Planning Explain assessments and care to parents so that they will know what to expect.

(continued)

Nursing Interventions	Rationales
1. Observe for signs of respiratory distress (i.e., nasal flaring, grunting, retractions, apnea, cyanosis).	1. IDMs are at greater risk of developing respiratory distress because fetal hyperinsulinemia adversely affects fetal lung maturity.
2. Assess respiratory rate and effort and suction nasopharynx as needed.	2. Maintaining a clear airway will facilitate respiratory efforts.
3. Position infant on side with a rolled towel to the back.	3. Facilitates drainage of mucus.
4. Auscultate breath sounds every 3 to 4 hours as needed, assess infant for cyanosis, noting its relationship to activity.	4. Breath sounds and effectiveness of perfusion will indicate potential respiratory distress.
5. Provide a neutral thermal environment.	5. Prevents cold stress, which can increase the consumption of oxygen, leading to respiratory distress.

Evaluation Respiratory rates are within normal limits (30 to 60 breaths per minute). No signs of respiratory distress are evident.

Nursing Diagnosis

Risk for injury related to hypocalcemia, secondary to maternal gestational diabetes.

Expected Outcome Infant will maintain a calcium level between 7 mg/dL and 11 mg/dL.

Planning Help parents understand the relationship between maternal gestational diabetes and the newborn's condition and required care.

Nursing Interventions	Rationales
1. Monitor serum calcium levels.	1. Approximately 10% to 20% of IDMs experience hypocalcemia.
2. Observe for signs of hypocalcemia (i.e., muscle twitching and jitteriness, irritability, seizures, and vomiting).	2. Hypocalcemia, generally occurs between 24 and 36 hours after birth.
3. Administer calcium supplements as ordered by physician.	3. Treats or prevents hypocalcemia.

Evaluation No signs of hypocalcemia are evident and serum calcium levels remain above 7 mg/dL.

Assess respiratory function at frequent intervals: respiratory rate, breath sounds, skin color, and signs and symptoms of respiratory distress (nasal flaring, grunting, retractions).

Continuous pulse oximetry and frequent blood sampling for arterial blood gas (ABG) values provides valuable information about the oxygenation and ventilation status in the newborn.

Assess cardiovascular function and perfusion at frequent intervals: heart rate, blood pressure, rhythm, pres-

ence of murmur, capillary refill, skin color, and peripheral pulses.

Observe for signs and symptoms of infection.

Assess for signs of skin breakdown.

Strictly monitor infant's intake and output of fluids, maintain patency of infant's peripheral lines, and take body weight daily.

Observe infant's response to pain and pain relief interventions.

Parents and Family

Document all phone calls from parents and family received in the unit regarding infant's condition and progress.

Observe and document all visits from parents and family to the NICU.

Observe and document parent-infant interactions (i.e., talking to, holding, touching).

Document all parent teaching done (including CPR training).

Assess level of understanding of teaching done (i.e., return demonstration, question-and-answer).

Web Activities

- Search the Internet under some of the disorders discussed in this chapter, such as spina bifida. Are there support groups for families experiencing these conditions? What type of information is available? Do they also direct information to health care professionals?
- Search the Internet for government statistics on survival rates and quality-of-life issues for infants with the anomalies discussed in this chapter.

Key Concepts

- Genetic disorders are inherited defects passed down through generations; acquired disorders result from environmental factors.
- The most common anomalies affecting the CNS occur during the first 3 to 4 weeks' gestation, and many are detectable through prenatal diagnosis.
- Respiratory system anomalies are often life-threatening and require immediate intervention in the delivery room.
- There are more than 100 types of congenital heart defects, many with no known cause.
- Families need explicit instructions in feeding and caring for a newborn with a gastrointestinal anomaly, because special equipment, formulas, or techniques may be required.
- Many musculoskeletal anomalies, once detected, can be aggressively treated and have good prognoses.
- Birth injuries or trauma are often not evident at birth but are detected in the first few hours or days following delivery.
- Macrosomatia, or fetal weight above the 90th percentile, is a common characteristic of infants born to mothers with diabetes.
- Jaundice, or an elevated serum bilirubin level, occurs in more than half of all full-term newborns during the first week of life.
- Neonatal infections can have many causes and many characteristic complications, including respiratory distress, shock, acidosis, DIC, meningitis, and death.

Review Questions and Activities

Match the terms in Column I with a definition or statement from Column II.

Column I

- _____ congenital disorder
- _____ spina bifida
- _____ meningocele
- _____ myelomeningocele
- _____ gastroschisis
- _____ intracranial hemorrhage
- _____ subdural hemorrhage
- _____ phototherapy

Column II

- a. Collection of blood within the cranium
- b. Collection of blood in the subdural space of the brain
- c. Results from genetic or prenatal environmental factors, or both
- d. Contains meninges and CSF
- e. Results from failure of the spinal cord to close
- f. Exposure to an ultraviolet light
- g. Abdominal wall defect to the right of the umbilicus, through which the abdominal organs herniate
- h. Contains meninges, CSF, and neural tissue

Identify the following statements as true or false:

1. Hypocalcemia is defined as a calcium level of more than 7 mg/dL.
2. Hypoglycemia is defined as a blood glucose level of less than 60 mg/dL.
3. Physiologic jaundice generally occurs during the first 24 hours after birth.
4. Ortolani's maneuver and Barlow's test are useful in detecting clubfoot.
5. Hypospadias is a congenital anomaly in which the urethral meatus is located on the ventral surface of the glans penis.
6. Prenatal diagnosis of congenital diaphragmatic hernia can be made by antenatal ultrasound examination as early as 26 weeks' gestation.
7. Myelomeningocele is the most common form of spina bifida cystica.
8. Clinical manifestations of increased ICP include: widening sutures; bulging anterior fontanelle, high-pitched shrill cry, and the "setting sun" sign.

Study questions:

1. Differentiate physiologic from pathologic jaundice.
2. Provide four planning and implementation nursing actions for the infant at risk for injury related to hyperinsulinemia.
3. List five signs of respiratory distress in the newborn.
4. List seven signs of hypoglycemia in a newborn.
5. Describe the nursing care for an infant who is receiving phototherapy.

Developmental Care of the Infant at Risk

Understanding the needs of high-risk neonates and their families is the first ingredient to providing effective and sensitive nursing care. Ask yourself the following:

- *How can I know if a baby is in distress if it cannot cry?*
- *Do I think all babies respond in the same ways, or are they as individual as are adults?*
- *Have I ever been in a neonatal intensive care unit (NICU)? How did it make me feel?*
- *How important do I think it is for parents to be fully involved in the care of their hospitalized infant?*
- *The NICU is a very high technology environment. How does that make me feel?*
- *Have I ever been in the presence of a critically ill infant? How did I feel?*
- *What do I know or believe about an infant's experience of suffering and pain?*
- *What are my ethical questions about aggressive technologic support of the critically ill infant?*

Standards of care

Competencies

Upon completion of this chapter, the reader should be able to:

1. Discuss the history and philosophy of developmental care.
2. Explain the relationship of infant behaviors to the theories underlying developmental care.
3. Identify the elements of developmental care.
4. Apply the principles of developmental care to diverse clinical situations.
5. Use current standards of practice in the implementation of developmental care.
6. Discuss the research basis for developmental care.
7. Discuss the role of the family in the developmental care of the high-risk infant.

The premature birth of an infant continues to be a major challenge to the health care delivery system and families affected by this experience. The preterm birth rate in the United States increased in 1998 to 11.4% overall, with the rate for African Americans at 17.6% (Ventura et al., 2000). Despite major scientific breakthroughs in prenatal care and the technologically advanced care of the prematurely born infant, the U.S. infant mortality rates remain high compared with other developed countries (7.2 infant deaths per 1,000 births) and are disproportionately high for the African American population (14.3 infant deaths per 1,000 births) (Ventura et al., 2000). Prematurity or low birth weight is the second highest cause of infant mortality overall and the leading cause of infant death in the African American population (Ventura et al., 2000). In addition, as major advances in the medical care of these infants have resulted in the increasing survival of infants having very low and extremely low birth weights, the incidence of complications or morbidities secondary to premature birth has increased. Researchers and clinicians alike have focused attention on the environment of the intensive care nursery and caregiving practices surrounding the hospitalization period in an effort to provide optimal support for the healthy development of these infants. This focus has led to the development of new approaches to the care of the preterm infant aimed at improving developmental outcomes adapted to the individual infant, and emphasizing the inclusion of the family as a whole in their infant's care.

The term **developmental care** is used broadly to describe any infant care protocol designed to promote opti-

mal physical, cognitive, and emotional development in the first weeks or months of life. Whereas the protocols described as developmental care differ from one setting to another, they generally address issues of environmental light, sound, and temperature levels; infant position, containment, and handling strategies; nonnutritive sucking; feeding; and pain management. This chapter includes discussions of each of the individual developmental care strategies in common use, the effectiveness of a comprehensive developmental approach to infant care, and the role of families in the care of the infant at risk.

HISTORICAL DEVELOPMENT

Historically, the approach to the care of the infant at risk has evolved through three stages (Figure 36-1).

Figure 36-1 Historical overview of developmental care.

Stage 1

Before the early 1960s the standard of care for these infants was to maintain the infant in strict isolation, with minimal handling and little emphasis on the kind or amount of stimulation the infant received. The major concerns in infant care were protection of the infant, prevention of infection, and maintenance of a warm environment. Parents typically had little access to their infants for prolonged periods of time, and infants received little handling or interaction other than that necessary to provide care.

Stage 2

In the 1960s two concerns emerged related to the effects of these infant care practices. First, nurses and other caregivers began to be concerned about the effects of the long-term separation of the parent and infant on the baby's growth and development and on the development of the parent-infant relationship. Second, caregivers began to be concerned about the lack of sensory stimulation the hospital environment provided for the developing infant. This second concern was based on the observation that the sterile hospital environment did not provide the same richness of visual stimulation (pictures, toys, color), sound (music, mother's voice), touch (cuddling, caressing), or movement (rocking, walking with infant) that the home environment could offer. As a result, caregivers during this period began to focus on two things: increasing the involvement of parents by increasing visiting hours and encouraging them to participate in care, and enriching the infant's environment by placing pictures in the incubators, playing music for the baby, taping the parents' voices to play for the baby, and experimenting with the effects of touch through interventions such as infant massage. Research in this period emphasized issues of parent-infant attachment, the effects of early and prolonged separation on the development of the attachment relationship, and the effects of added stimulation on infant growth and development (Klaus & Kennell, 1982; Brazelton & Cramer, 1990).

Stage 3

The concept of the neonatal intensive care unit (NICU) began to evolve in the early 1970s, with the introduction of the continuous positive airway pressure (CPAP) technique (Gregory et al., 1971). The use of CPAP had the potential to dramatically increase the survival of the very premature infant but required specialized 24-hour care. This requirement provided the impetus for the development of the NICU. By the late 1970s, as CPAP and other life-saving technologies in hospital nurseries had begun to improve the survival rates of the very premature infant

(those weighing less than 1,500 g or born earlier than 32 weeks postconceptional age), the population of the intensive care nursery became increasingly younger and smaller. Caregivers of these vulnerable infants began to question how the intensive care environment affected the infants in their charge. They became aware that, rather than providing too little stimulation, the intensive care nursery was an environment of excessive and often inappropriate stimulation. For these babies, the high-technology intensive care nursery was characterized as an environment of continuous bright lights; loud, unexpected, and random sounds; and noxious, often painful, stimuli. The effort to provide developmentally appropriate care now focused on the need to protect the youngest and most vulnerable infants from excessive and often overwhelming environmental stimulation and to support their efforts to cope with those stimuli. The concept of individualized developmental care, as expressed in today's NICUs, has evolved from these concerns.

THEORETICAL FRAMEWORK FOR DEVELOPMENTAL CARE

One of the earliest proponents of modifying and individualizing the care of the premature infant to support optimal development was Heidelise Als. Als proposed a framework, or way of looking at infant development, which she identified as the synactive theory of neurobehavioral development (Als, 1986). This theory is based on four principles. First, infant development occurs in a way that is designed to best ensure the survival of the infant in the specific environment in which it exists. For example, healthy infants are born with a strong sucking reflex and need to suck, which supports their survival as a mechanism through which they are able to take in nutrition. Premature infants may not yet have developed a strong sucking reflex because the uterine environment in which they are developing does not require a sucking mechanism for the fetus to receive nutrients. In both cases the development of the fetus-infant is designed to support optimal functioning in the appropriate environment.

The second principle is that infants develop in continuous interaction with the environment around them. Before birth the fetus develops in interaction with the surrounding uterine environment. After birth, the infant continues to develop in interaction with the extrauterine environment. Therefore, prematurely born infants in hospital nurseries are developing in interaction with environments very different from the uterine environment in which they normally would be found.

The third developmental principle proposes that development occurs from global to discrete or from simple to

complex. For example, as the infant's limbs develop, the arms develop as buds emerging from the body (global or simple development). As these arm buds grow they begin to differentiate into hands at the distal end, and finally, the fingers develop (discrete or complex development).

The fourth principle underlying Als' theory postulates that the developing organism (infant) seeks to maintain physiologic stability or balance in the presence of two powerful competing physiologic impulses, to explore or move out and to withdraw or avoid. Older infants exhibit these impulses, as they will eagerly explore their environment until a stranger comes too close, then will withdraw and move closer to their caregivers. Very immature prematurely born infants also actively respond to their external environment. Widening the eyes, raising the eyebrows, and softening the face are behaviors that may indicate interest and readiness to respond in the premature infant. If the stimuli become too powerful, the infant may withdraw by averting or closing the eyes or turning away from the stimuli. A prematurely born infant who is overwhelmed by environmental stimuli may show more extreme aversive reactions such as hiccupping, spitting up, hyperextending the extremities, or demonstrating a brief period of apnea or bradycardia. Thus, Als postulates that infants develop in adaptation to their environment and in interaction with that environment. This development proceeds from global or undifferentiated states to discrete or differentiated states. As development occurs, the organism strives to maintain stability while both reaching out to explore and interact with the environment, and withdrawing or avoiding excessive stimuli.

INDIVIDUALIZED DEVELOPMENTAL CARE

Individualized Developmental Care refers to the modification of the nursery environment and caregiving practices to support the infant's optimal development. This approach to care includes the reduction of excessive environmental stimuli by lowering light and sound levels in the NICU; organizing caregiving activities to provide periods of rest and recovery for the infant; positioning the infant in a flexed, contained position; modifying caregiving practices based on an assessment of what the individual infant finds least distressing; and supporting the infant's efforts to provide self-comfort and maintain physiologic stability and organization.

In her theory, Als (1986) also proposes that infant neurobehavioral development occurs within five interrelated and interdependent subsystems and that through assessment of these subsystems the developmental status of the infant can be evaluated. These five subsystems are the autonomic, motor, state, attentional-interactive, and self-regulatory subsystems. The development of each of these subsystems includes infant behaviors that provide insight into the development of that subsystem. The first subsystem to develop is the autonomic subsystem. The stability and integration of the autonomic system can be assessed through respiratory patterns, heart rate responsiveness, skin color, and visceral responses (Als, 1986). The motor subsystem includes muscle tone, posture, and patterns of movement. The state subsystem refers to the infant's level of consciousness, ranging from deep sleep to awake and agitated. The attentional-interactive subsystem depends on the infant's ability to maintain a robust alert state and refers to the infant's readiness for social interaction. Finally, the self-regulatory subsystem refers to the infant's ability to maintain behavioral stability in the other subsystems or to initiate efforts to regain stability if it has been lost.

STANDARDS OF CARE

The term **standards of care** refers to formal guidelines for the care of clients developed by professional organizations. These guidelines describe or recommend the content, scope, and sequence of care activities that are considered appropriate, necessary, and sufficient for the care of a particular client population. Standards of care also may focus on a specific issue such as emergency transport of the high-risk infant. In general, formal standards of care should be viewed as a baseline or minimum criteria for directing care with the recognition that practice standards will change rapidly in some cases as new knowledge is generated. The American Nurses Association (ANA) has established general guidelines for clinical practice based on the nursing process (American Nurses Association, 1998). These guidelines direct practice in every area of nursing, focusing on the nursing process, nursing diagnosis, outcomes identification, nursing intervention, evaluation, and revision. In addition, in specialized areas of nursing practice, such as neonatal nursing, specialized professional groups may provide more specific practice guidelines.

In the 1990s, several professional groups began to focus on the need for formal guidelines to direct the implementation of developmental care. In 1999, the National Association of Neonatal Nurses (NANN) developed guidelines for the prevention, recognition, and management of neonatal pain. These guidelines reflected growing concern regarding the lack of appropriate pain management in the neonate, and represent an early and important step for-

ward in changing practice in this area. In 2000, nursing care guidelines related to infant and family-centered developmental care also were developed by NANN. These guidelines include suggestions for interventions to facilitate the adaptation of the infant and family; modifications of the physical surroundings, including light and noise; and recommendations for handling the infant. In addition, the Physical and Developmental Environment of the High-Risk Infant Project (a national interdisciplinary project begun in 1993 and directed by Stanley Graven of the University of South Florida) began developing recommendations related to NICU light and sound levels and infant sleep, touch, and feeding practices for the very premature or high-risk infant. As these guidelines are developed, they are presented to major professional groups involved in the care of the high-risk infant for review and endorsement. When completed, these guidelines will represent the most definitive standards available for the developmental care of high-risk infants. In addition, Dr. Graven's group sponsors an annual conference for clinicians and researchers presenting the work of the study groups and related research.

In addition to guidelines specific to caregiving activities, professional organizations have developed standards of care for nursery design that have implications for developmental care activities. Guidelines related to the structural design of NICUs have been developed by the 4th Consensus Committee to Establish Recommended Standards for Newborn ICU Design (1999) developed under the auspices of the Physical and Developmental Environment of the High-Risk Infant Project, these guidelines have made recommendations specifically related to sound and light management in the NICU and have direct implications for the implementation of developmental care.

The specific recommendations from all of these guidelines are included in this chapter with the discussion of specific aspects of developmental care. It is important for the nurse beginning practice in the neonatal area to be aware of these guidelines and their contents and for all nurses in the neonatal area to ensure that their own practice is congruent with the best professional standard available.

ELEMENTS OF DEVELOPMENTAL CARE

The elements considered part of developmental care can and do vary somewhat among clinical sites. In general, however, these elements can be divided into those related to the total nursery environment, such as light and sound (macro-environment), and those related to the individual infant's environment or care experiences, such as positioning and handling (micro-environment). Each of the components discussed in this chapter has been studied individually and found to have important effects on infants.

In addition, the effectiveness of these components combined into comprehensive developmental care protocols will be discussed.

Macro-environment Components

The **macro-environment** of the high-risk infant is considered to be all of those elements that define the caregiving milieu, that is, the conditions that define the surrounding space in which caregiving occurs. This macro-environment has been found to have a major impact on the development of prematurely born and high-risk infants. The macro-environment is one aspect of the infant's neonatal experience in which nursing has a major responsibility. In this chapter the macro-environmental components to be discussed include the levels and patterns of NICU light and sound and temperature control.

Light

One element common to many developmental care protocols is the control of light levels in the infant's environment. Some protocols prescribe consistently dim lights throughout the 24-hour day, whereas others recommend regularly scheduled times when the lights are dimmed. The recommendation to dim environmental lighting in the NICU as part of a developmental care protocol is based on research related to the effects of light on the infant. NICU light levels and lighting patterns (i.e., same light level, random changes in light levels, and structured patterns of light-dark cycles over the 24 hour period) have been studied in terms of the effects of light levels on the incidence of retinopathy of prematurity (ROP); light patterns on the development of infant biologic rhythms; and on infant growth, behavior, and physiologic responses.

Nursery Light Levels and Patterns

Early articles related to light in the NICU focused on descriptions of the levels of lighting commonly found in these areas, sources of light, and patterns of lighting over time. The first studies describing lighting levels typically found in the NICU were published in the mid-1980s through 1990. Surveys of illumination levels in the NICUs of that time reported light levels of approximately 240 to 900 lux (approximately 24 to 90 ft-c) in the United Kingdom and illumination levels of 285 to 1485 lux (28 to 148 ft-c) in the United States (Robinson, Moseley, & Fielder, 1990; Landry, Scheidt, & Hammond, 1985; Glass et al., 1985). Peak light exposure for the infant was found to be associated with supplementary light sources such as phototherapy lamps (300 to 400 ft-c), treatment lamps (200 to 300 ft-c), and most dramatically, extensive direct window exposure supplementing artificial lighting (levels of up to

Critical Thinking

Light Patterns

The effects of light on human health have been the subject of much research. When you are thinking about the effects of lighting levels and patterns in the NICU, ask yourself how light affects you. Which kind of lighting is restful or quieting? When you are ill or tired, which kind of lighting do you prefer? What do you know about the effects of continuous lighting on adults? How do you think light levels affect sound levels?

1,024 ft-c have been reported) (Hamer, Dobson, & Mayer, 1984). Within hospitals, illumination levels were found to be highest in the areas of highest infant acuity and perhaps greatest infant vulnerability to negative effects of excessive illumination.

Nursing Alert

NICU DESIGN STANDARDS FOR LIGHT

Advocates for developmentally appropriate care for the hospitalized infant have long emphasized the importance of reduced light levels in the NICU; however, standard recommendations for NICU light levels have not been available. In 1999, the Consensus Committee to Establish Recommended Standards for Newborn ICU Design issued recommendations based on an analysis of existing research.

Recommendations for NICU lighting (Standards 14-16) include the following requirements: environmental light levels in the infant care areas should be adjustable from 1 to 60 footcandles; natural and artificial light sources should include a way they can be immediately darkened if necessary; artificial light sources should have visible spectrum distribution similar to daylight; and NICUs should be able to maintain environmental lighting in the 10 to 20 ft-c range, unless higher light levels are considered necessary for care delivery. (In 10 to 20 ft-c of light, the room would appear dim, all of the contents of the room would be clearly visible, and reading would be uncomfortable.)

*footcandle is a unit of illumination equal to 1 lumen per square foot.

In addition to documenting high levels of illumination, all of these studies indicated that the lighting levels within units tended to be consistent over time, demonstrating little structured diurnal variation (Robinson, Moseley, & Fielder, 1990; Landry, Scheidt, & Hammond, 1985). Documented temporal variability in illumination levels within units appeared to occur in a random pattern, with little or no predictability or temporal pattern. Some seasonal variability in illumination levels was noted as a function of direct window exposure (Landry, Scheidt, & Hammond, 1985).

A recent study by Lotas et al. (2001), surveyed 69 NICUs in the Southeastern United States to describe current lighting practices and assess changes in practice since the original research appeared. Nurse managers of the units were asked to describe their unit light levels as dim, moderate, or bright. A subset of NICUs in 18 surveyed hospital was then selected to be site visited for direct measurement of NICU lighting levels. For this subset, hospitals were grouped by their self-reported lighting group: low, moderate, and high lighting levels. Lighting levels obtained by direct measurement were then combined to provide a profile of lighting patterns within each of these groups. Light levels varied widely within each group, with little relationship between reported levels and measured levels. In fact, the lowest average daytime light levels were recorded in the group of hospitals self-identified as having high light levels. Overall, light levels ranged in all visited units from 25 to 68.05 ft-c throughout the 24-hour period of direct measurements. This represents a reduction in average light levels from those reported in earlier studies but demonstrates that many units still have lighting in excess of recommended levels.

Two limitations in all of these studies should be noted. The data are limited by variation in the instrumentation used in their collection and the calibration of those instruments. Many or most available light meters demonstrate a $\pm 5\%$ random error factor, and calibration processes usually include a $\pm 10\%$ random error factor. The potential cumulative error therefore is fairly high. The level of illumination for any particular infant in a nursery also may vary accord-

Nursing Tip

LUX

Lux is a metric unit of illumination equal to 1 lumen per square meter. Lumen refers to the unit of light flux emitted by a uniform source of one candela. Lux values can be converted to approximate footcandles by dividing by 10.

ing to placement of the incubator in relation to windows, overhead lighting, and other nursery equipment. The total light exposure of an infant also depends on factors such as the use of eye shields, frequency with which the fluorescent tubes are changed in both the phototherapy unit and rooms of the unit, and use of additional lighting for instrumentation and other procedures. The position of the infant's head also can influence light exposure. When the infant is in a side-lying position, the lower eye receives less light exposure than does the upper eye. The potential exists for infants lying in a supine position to be staring directly into the overhead lights. Therefore, illumination levels described for a NICU may or may not be representative of the conditions experienced by an individual infant, and comparisons between nurseries are difficult to make.

Effects of Nursery Light on the Visual System

Much of the concern about excessive light levels in the NICU environment has focused on the potential for damage to the developing visual system, most specifically regarding the incidence of ROP. ROP is a retinal neovascular disorder found commonly in prematurely born infants (Palmer et al., 1991). ROP varies in severity inversely with the gestational age of the infant, with infants over 31 weeks' gestation rarely developing the disease except in its mildest form. The condition usually heals with few or no sequelae; however, its most severe forms can lead to serious vision loss or, most extremely, complete blindness secondary to retinal detachment or severe retinal scarring. The primary factors associated with the development of ROP have been widely accepted to be the combination of retinal immaturity in the preterm infant and the high oxygen levels that may be part of the infant's treatment through the increase in oxygen free radicals in the retina (Hepner, Krause & Davis, 1949; Riley & Slater, 1969; Glass et al., 1985). However, excessive and precocious exposure of the immature retina to intense and continuous light in the NICU has been proposed as an important contributing factor. It has been hypothesized that energy from light striking the immature retina may cause a further increase in oxygen free radicals and, subsequently, an increase in retinal injury (Glass, 1988; Phelps & Watts, 1997). Some early clinical studies supported this hypothesis, reporting a significantly decreased incidence of ROP in infants who had been shielded from environmental light by dimming the room lights or shielding the incubators with thick covers (Glass et al., 1985; Ackerman, Sherwonit, & Williams, 1989). However, a meta-analysis completed in 1997 (Phelps & Watts, 1997), reviewed all randomized or quasi-randomized controlled trials that examined the effects of reduced light exposure to prematurely born infants on the incidence or severity of ROP. Only three studies qualified for this analysis (Locke & Reese, 1952; Lopes et al., 1997; Seiberth et al., 1994). The results of these three studies did not support

the hypothesis that reducing the preterm infant's exposure to environmental light would reduce the incidence of ROP. An additional six studies were reviewed that did not meet the inclusion criteria for the meta-analysis (Ackerman, Sherwonit, & Williams, 1989; Glass et al., 1985; Hepner, Krause, & Davis, 1949; Hommura et al., 1988; Locke & Reese, 1952; Repka et al., 1995). Even with the addition of these studies, no significant reduction in the incidence of ROP secondary to shielding the infant from environmental light could be documented.

Although current research does not document a relationship between nursery light levels and ROP incidence or severity, the samples in the existing studies are small and the data cannot be considered conclusive. Large controlled clinical trials are needed to definitively demonstrate the relationship of light exposure in the preterm infant and the development and severity of ROP. Other issues not well explored in the current research literature include the effects of excessive light levels or eye shielding on the subsequent development of visual processing and the relationship between gestational age and light levels optimal for infant visual development.

Nonvisual Effects of Nursery Light

In addition to concerns about the effects of excessive and precocious exposure to light on the developing visual system, caregivers also have explored the effects of light levels and patterns on other aspects of the functioning of the preterm infants. One major concern focuses on the effects of continuous lighting or random variation of lighting levels (both common NICU patterns) on the development of biologic rhythms (circadian or ultradian) in the infant. Biologic rhythms are controlled by the suprachiasmatic nucleus in the anterior hypothalamus, are thought to exist in all living beings, and serve the purpose of synchronizing and coordinating compatible physiologic functions and separating incompatible ones (Reppert, 1992; Moore-Ede, Sulzman, & Fuller, 1982). The dominant organizer of biologic rhythms in humans is the day-night cycle, with feeding patterns as additional organizers in the infant (Arendt, Minors, & Waterhouse, 1989). Physiologic functions considered to have a circadian pattern include heart and respiratory rates; temperature; sleep-wake cycles; and secretion of several hormones, including cortisol, adrenocorticotrophic hormone (ACTH), and endorphins (Arendt, Minors, & Waterhouse, 1989; Moore-Ede, Sulzman, & Fuller, 1982). In addition, growth hormone, which does not exhibit a true circadian cycle, is strongly influenced by sleep-wake cycles, which are thought to have a circadian function.

In the human infant, early development of biologic rhythms occurs in the fetus and is thought to be determined predominantly by maternal biologic rhythms (Reppert, 1992). After birth, the development of circadian

functions continues under the influence of the infant's environmental cues with light-dark cycles and feeding cycles. Circadian patterns in heart rate, body temperature, and sleep begin to emerge after the 3rd week of life (Hellbrugge, 1974; Tenreiro et al., 1991; Glotzbach, Edgar, & Ariagno, 1995). It is this development that may be disrupted if the preterm infant in the NICU environment receives inadequate or inappropriate environmental cues to develop normal circadian function.

A small number of studies have compared the effects of light-dark-cycled light with the effects of continuous bright lighting on the physiologic functioning of infants in the NICU (Mann et al., 1986; Blackburn & Patterson, 1991; Lotas & Medoff-Cooper, 2001). Six studies have compared infants maintained in a light-dark-cycled environment with infants maintained in continuous lighting (Mann et al., 1986; Blackburn & Patterson, 1991; Lotas & Medoff-Cooper, 2001; Miller et al., 1995; Shiroyiwa, Kamiya, & Uchibori, 1986; Tenreiro et al., 1991). In four studies, the outcome variables included activity, heart rate, and respiratory rate (Blackburn & Patterson, 1991; Lotas & Medoff-Cooper, 2001; Shiroyiwa, Kamiya, & Uchibori, 1986; Tenreiro et al., 1991). Blackburn and Patterson (1991) studied 18 infants cared for in continuous light compared with a light-dark environment and reported a significant reduction in heart rate and activity level, with longer periods of quiescence, although no differences in respiratory rate were noted. Lotas and Medoff-Cooper (2001) compared 18 infants assigned to either a nursery maintaining routine lighting or one maintaining light-dark cycles. These authors found a consistent decrease in heart and respiratory rates during the dark cycle in infants maintained in a light-cycled nursery; however, these findings were apparent only after infants had been in the light-cycled nursery for 3 weeks. The third study of 10 preterm infants achieved a decrease in illumination to the retina by blindfolding each infant for 10 hours in a 24-hour period. A reduction in infant movement and lower heart and respiratory rates were seen while the infants were blindfolded (Shiroyiwa, Kamiya, & Uchibori, 1986). Although these findings should not be interpreted as support for the practice of routinely blindfolding infants, they do provide support for the premise that the intensity of nursery lighting may be an added stressor for infants and that reducing this stressor may contribute to increased physiologic stability.

Tenreiro et al. (1991) examined the effects of continuous light initially, when infants were in the intensive care setting, followed by light-dark cycling, when infants were transferred to intermediate care areas. These authors reported increasing circadian rhythm development in temperature and heart rate once infants were placed in the light-cycled environment. It was noted, however, that all emerging biorhythms were unreliable. In addition, the timing of the light-cycled treatment coincided with concep-

tional ages when such rhythms might be expected to emerge.

Other studies focused on the effects of environmental light patterns on the development of infant sleep and activity patterns and on weight gain (Mann et al., 1986; Miller et al., 1995). Mann et al. (1986) studied the effects of light-dark cycles in the NICU on 41 healthy preterm infants. The 20 infants assigned to the light-cycled nursery were exposed to 12 hours of bright lighting and 12 hours of dim lighting. Infants in the control group were exposed to continuous bright lighting, which was the nursery routine. In the postdischarge follow-up, infants from the light-dark-cycled nursery were found to spend significantly more time sleeping (mean difference of 2 hours per day) and less time feeding (mean difference of 1 hour per day) and gained more weight (mean difference 0.5 kg) than did infants in the nursery with continuous light. Significant differences between the groups continued through the first year of life.

A recent study by Miller et al. (1995) examined 41 infants assigned to one of two intensive care rooms with either a continuous or day-night-cycled lighting pattern. Infants in the light-cycled group had greater weight gain, spent less time on assisted ventilation and under phototherapy, began oral feeding sooner, and had enhanced motor coordination as measured by the Brazelton Neonatal Behavioral Assessment Scale completed at discharge by an evaluator blind to the infant's lighting treatment. Whereas these studies use different methods, somewhat different lighting treatments, different populations of infants, and somewhat different outcomes and times for evaluation, they demonstrated similar findings in relation to significantly increased infant weight gain in the light-dark-cycled group.

These studies provide findings that are suggestive but not conclusive of the benefits of a light-cycled environment, at least for infants of 29 weeks' gestation or greater. Although these studies provide some contrast in findings, these differences are not necessarily contradictory. All report behaviors (i.e., increased alertness, sleep-wake organization, and improved physiologic stability) that may indicate an increase in infant neurobehavioral organization with reduced lighting. Some of the apparent contradictions in the findings of these studies may be related to the differences in lighting conditions used and in the timing and pattern of data collection; however, the extremely small sample size in each study makes data interpretation difficult. Changes in lighting levels also may have influenced other aspects of the environment, such as noise levels and staff activity, which were not documented. Furthermore, it should be emphasized that no studies have compared a light-dark-cycled nursery environment with a nursery environment with continuously dim lighting. These studies are further limited by lack of randomization in some and

variations in light levels. Additionally, few data are available for extremely low birth weight infants.

Much research remains to be done to understand the effects of environmental light on the developing preterm infant. Although studies have shown that infant outcomes improve when light levels are reduced, at this time researchers have not documented the level of light that is most appropriate for the preterm infant, or whether the optimal light level varies for infants of different gestational ages. Definitive work on the effects of light-dark cycles compared with continuous light levels also remains to be done.

Recommendations for Practice

In the past, continuous lighting levels of 60 to 100 ft-c (approximately the light level in an office or classroom) were thought to be necessary to allow adequate evaluation of the infant's skin color and perfusion from any area of the NICU. Although, at this time there is no established standard for light levels in the NICU, within the concept of developmental care lower light levels (± 20 ft-c) are recommended. Current standards for NICU lighting recommend that light levels be adjustable over a range of 1 to 60 ft-c (Consensus Committee to Establish Recommended Standards for Nursery ICU Design, 1999). At this time no recommendation can be made for the implementation of light-dark cycles in the nursery. Specific strategies for reducing the effects of lighting on the infant in the NICU include the following:

- Avoid the use of overhead lights unless necessary. Use individual lighting at the infant's bedside for caregiving.
- Incubator covers can be used during times when the infant is at rest. Small, thin receiving-type blankets may not provide optimal light shielding for the infant. Opaque covers that cover the top and the sides of the incubator are preferable.
- Outside windows often are the source of the highest light levels in the NICU. When outside windows are present, opaque shades of some type should be available to allow modifications of light levels, and incubators should be placed away from direct sunlight.
- When overhead phototherapy lights are used, ensure that the infants in adjacent incubators are screened from any increase in light levels.
- Shield the infant's eyes when using treatment lights for procedures or caregiving. Place a screen between the treatment light and adjacent incubators to protect those infants from random light exposure.
- When the infant is placed in a supine or side-lying position with the face upward, ensure that the infant

is not directly under an overhead light. Preterm infants may not have the ability to turn their heads away from the light or to adequately shield their eyes by closing them.

- Education of the family about the infant's development and caregiving needs should include explanations of the concerns about light levels and the precautions taken to protect the baby from excessive light. The nurse may help the family reflect on their own practices in relation to light levels in an infant's environment. Do they darken the room in which an infant is sleeping? Do they protect a baby's eyes from bright sunlight?

Sound

Over the past 3 decades researchers have repeatedly documented consistent sound levels of 50 to 90 dB in the NICU, with excursions to as high as 120 dB (Anagnostakis, Petmezakis, & Matsaniotis, 1980; Robertson & Philbin, 1996; Long, Lucey, & Philip, 1980; Thomas, 1989). For the purpose of comparison, 50 dB is about the sound level of light traffic and 90 dB is about that generated by light machinery (Figure 36-2). According to the Occupational Safety and Health Administration standards, 80 dB is the highest sound level that does not produce measurable damage, regardless of the duration of the sound, and 90 dB is the limit imposed in industrial standards as the highest safe level for an 8-hour period for adults. The NICU noise level also has been found to demonstrate little diurnal variation and fluctuations in sound; when fluctuations do occur, they are unpredictable (Thomas, 1989).

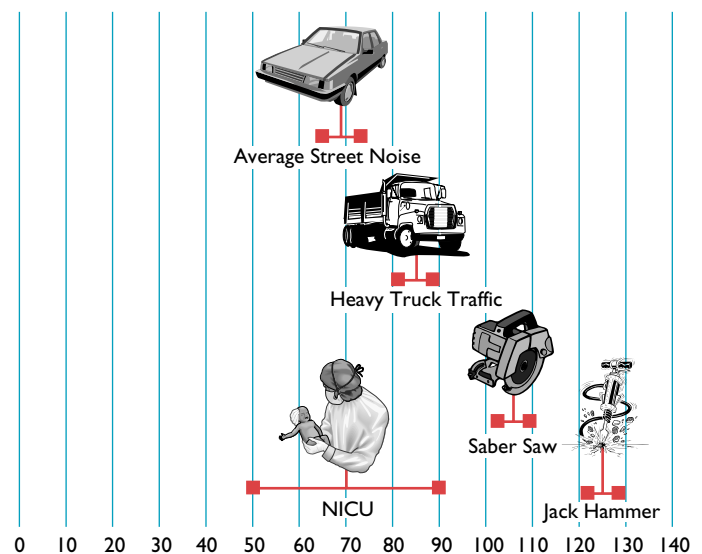

Figure 36-2 NICU sound levels (in dB) relative to other common environments.

Critical Thinking

Effects of Sound

Sound levels or sharp unexpected noises can negatively affect the sick or immature infant.

- How do you respond when you hear an unexpected sharp noise such as a car backfiring nearby or a door slamming? Do you startle?
- What happens to your heart rate and breathing?
- How do you feel when you have been in a very noisy environment for several hours?
- Do you think a premature or sick baby will respond differently or in the same way as you do?

Nursery Sound Levels and Patterns

In studies exploring the sources of sound in the NICU environment, researchers have identified both anticipated and unanticipated components of nursery sound. As expected, much of the sound present in the NICU is generated by the equipment used in the care of the infants, including incubators, oxygen monitoring devices, ventilators, and infusion pumps (Thomas, 1989). Furthermore, monitor alarms and telephones, as expected, contributed significantly to the high-amplitude sound excursions. Less expected, however, were findings demonstrating that most of the high-amplitude sound excursions, 70 dB or higher, were related to staff activities, including closing doors,

trash can lids, incubator ports or drawers; laughter; and conversation (Long, Lucey, & Philip, 1980).

Effects of Nursery Sound on Hearing

At this time no studies exist which definitively demonstrate that sensorineural hearing loss is associated with nursery noise levels. Approximately 8% to 9% of low birth weight infants develop clinically significant hearing loss (Pettigrew et al., 1988). This incidence has been attributed to multiple risk factors, including significant intraventricular hemorrhage, prolonged oxygen therapy, hyponatremia, the use of aminoglycoside antibiotics, incidence of asphyxia, and elevated serum bilirubin levels (Taeusch & Ballard, 1998). The toxic effect of excessive nursery noise levels has been proposed as another risk factor but has not been studied systematically in human infants. It should be noted, however, that the hearing loss found in these infants has been described as usually most marked in the high-frequency range (Pettigrew et al., 1988) and that much of the equipment-related sound in the infants environment, such as that from ventilators, incubators, and alarms, often is also in the high-frequency range (Thomas, 1989). It also is worth noting that infants with the greatest number of risk factors associated with sensorineural hearing loss are also likely to have the longest exposure to the ambient noise of the NICU.

A second area of concern related to the long-term effects of NICU noise on the low birth weight infant is whether, even in the absence of impairment of functional hearing, there may be some alteration in the infant's processing of auditory stimuli. The following may permanently influence the way in which auditory stimuli are processed and understood by the infant: the high level of continuous sound, or white noise, experienced by the infant in the incubator; lack of predictability or rhythmicity of NICU sound; and limited ability of the infant to associate a source, face, or event with the sounds heard. Certainly, the animal data describing developmental changes in the sensory and motor cortex secondary to altered sensory input support such a speculation, although the relationship has not been examined in human infants (Spinelli, 1990).

Effects of Nursery Sound on Infant Responses

The final group of studies examining the issue of sound in the NICU has focused on what the long-term and short-term outcomes of such sound may be for the infant in that environment. Researchers have examined the immediate responses of infants to noise in the nursery. Long et al. (1980) documented a repeated pattern of decreased transcutaneous oxygen tension, increased intracranial pressure, and increased heart and respiratory rates in two infants in response to sudden loud noise in the nursery. Gorski et al. (1983) described mottling, apnea, and bradycardia in preterm infants exposed to sharp excursions in sound such as telephones, monitor alarms, and conversa-

Nursing Alert

OTOTOXIC DRUGS IN THE NICU

Sound levels in the NICU have not been proved to have a negative effect on the development of hearing in the hospitalized preterm infant. Particular concern, however, is focused on the interaction of excessive ambient sound levels with ototoxic drugs the infant may receive while hospitalized. These drugs include but are not limited to the aminoglycosides, such as gentamicin, kanamycin, streptomycin, and tobramycin, when used for more than 5 days. An additional ototoxic effect may occur when loop diuretics (diuretics acting on the loop of Henle), such as furosemide, ethacrynic acid, bumetanide and others, are given with aminoglycosides. Nurses should be alert to the possible risks posed to infants by these drugs alone or in interaction with the NICU environment.

tion during medical rounds. Both studies provide support for the notion that nursery noise levels are a disorganizing influence on the neurologically immature low birth weight infant and raise speculation regarding the energy cost to the infant that these episodes represent.

Gaedki et al. (1969), in a related study of the effects of noise on the sleep patterns of term infants, reported that sound levels of greater than 70 dB were incompatible with infant sleep and sound levels of 55 dB aroused an infant from light sleep. Although this study has not been replicated with low birth weight infants, the reported sound levels are similar to those present in the NICU, suggesting that NICU noise may, in fact, interfere with the development of sleep and rest patterns in these infants. Alternatively, low birth weight infants in the NICU may be able to adapt to some degree to the continuous noise levels of their environment and therefore develop and maintain a pattern of sleep and rest.

Finally, a limited amount of research exists that suggests a relationship among ambient noise levels, infant stress, and endocrine responses. Early research using a rat model demonstrated measurable increases in ACTH secretion with increased stress, including sound levels as low as 68 dB (American Academy of Pediatrics Committee on Environmental Hazards, 1974). More recent research by Schanbert and Field (1987), using growth hormone secretion as a physiologic index of stress, reported that low birth weight infants stressed by handling manifested decreased growth hormone levels. Taken together these studies suggest that excessive noise levels may produce a stress response in infants, including alterations in endocrine function, and that one stress-related endocrine change in infants is a likely decrease in serum growth hormone levels. Certainly, each of these relationships is complex, measurement in human infants is difficult, and great caution must be used in extrapolating findings from animal studies to human infants. The premise that excessive noise in the NICU may contribute to poorer growth outcomes in infants, however, is worthy of further exploration.

Recommendations for Practice

A review of the research related to the effect of nursery sound on the developing low birth weight infant does provide support for realistic concern and justification for the modification of sound levels where possible, although it does not provide definitive evidence of any long-term effects of excessive sound. Several suggestions for sound reduction can be made:

- Some, though certainly not all, of the noxious noise is generated by staff activities that can be modified. NICU staff can begin to monitor activities, such as carrying on conversations with people across the room and loud laughing, to keep the associated noise levels to a minimum.
- Caregivers and families alike could be encouraged, when possible, to conduct conversations with one another away from the incubator or out of the caregiving area completely (Figure 36-3).
- Opening and closing doors and drawers and manipulating equipment can be done in ways that keep noise to a minimum. One source of noise could be minimized simply by depressing the latch on the incubator ports before closing them or applying some felt stripping around the incubator doors.
- Where possible, metal equipment such as wastebaskets could be replaced with plastic to reduce the associated noise level.
- Radios, intercoms, and other extraneous sound could be eliminated from the NICU.
- Equipment used in the nursery could be modified where possible to reduce the sound reaching the baby. Computer printers could be equipped with soundproofed covers. Telephones could be placed away from the caregiving area or equipped with flashers rather than ringers. Monitor alarms could be replaced with quieter audible alarms or flashing alarms.
- The use of carpeting and acoustical ceilings where possible can significantly reduce noise levels.
- When considering new or replacement equipment or other items for the nursery, the noise level generated by those items or equipment should be a primary consideration. Sound levels inside the incubator certainly are determined in large part by the noise of the machinery itself, and such noise levels should become part of the selection criteria.
- Specific guidelines for acceptable noise levels should be established for the NICU. These could be used as a standard when selecting nursery equipment and would serve to encourage manufacturers to design

Figure 36-3 Many NICUs have a separate room in which families can spend quiet time with their newborn.

and develop quieter equipment for use in the NICU. Such guidelines also could be used to evaluate care-giving procedures.

Temperature

One of the earliest interventions known to improve survival in premature infants was maintaining them in a warm environment (Silverman, Sinclair, & Agate, 1966). Early strategies for keeping the infant warm included keeping the baby physically close to the parent and keeping the infant close to a heat source such as an oven, stove, or hot water bottle. Today, premature infants are maintained in incubators or on radiant warmers to support stabilization of body temperature until their own temperature-regulating mechanisms are adequate. These devices are designed to maintain infants in a *thermo-neutral environment*, that is, in an ideal environmental temperature in which infants, when quiet or asleep, can maintain their body temperature without increasing the metabolic rate above resting levels (Taeusch & Ballard, 1998). For premature infants, the range of environmental temperature fluctuation tolerated may be as little as 3.0°. Several factors make premature infants especially vulnerable to the effects of environmental temperatures. These infants have very little fat tissue, particularly brown adipose tissue, which plays a major role in heat production. Their larger body surface area to body mass ratio causes them to lose heat more rapidly than do full-term infants, older children, and adults. The increased permeability of their skin causes them to lose body water and heat more quickly than do older children and adults (Taeusch & Ballard, 1998).

In addition to the particular vulnerability of premature infants to heat loss, several external mechanisms interact to modify their thermal environment. These include the heat loss mechanisms of radiation, conduction, convection, and evaporation; heat maintenance strategies such as swaddling, wrapping, or otherwise covering the baby to avoid heat loss; and use of an external heat source, such as an incubator or radiant warmer, to provide heat to the infant.

Heat loss in the high-risk infant occurs primarily through the mechanisms of radiation, conduction, convection, and evaporation. Radiation is the major form of heat loss for infants in incubators. Heat loss through radiation refers to the transfer of body heat to cooler surfaces that surround infants but do not touch them, such as incubator walls, unit walls, and windows. The infant can become cold stressed through the loss of heat to cold walls and windows even when the incubator air is warm, or conversely, can become overheated in a cool incubator when the windows or room walls are too hot. Heat loss through conduction refers to the transfer of heat from the body core of the infant to the body surface and then to objects in

direct contact with the infant such as mattresses, blankets, and scales. The colder the surface of the object is in relation to the baby, the greater the resulting heat loss. The process of convection refers to heat loss that occurs when heat generated in the body core is brought to the body surface, lost to the surrounding air by conduction, and finally, diffused away from the infant by moving air particles. The primary sources of heat loss by convection are drafts that touch the infant's skin or incubator walls. Evaporative heat loss increases as the humidity level of the air decreases. Evaporative heat loss also increases as the gestational age of the infant decreases owing to the extremely porous skin of the very immature infant. In these infants, evaporative heat loss may represent the greatest heat loss of any mechanism and presents a very real threat to the infant.

Recommendations for Practice

Understanding the sources of heat loss has enabled nurses to modify the infant's environment to minimize such losses. Some suggested interventions follow:

- ✿ Place incubators or radiant warmers away from external wall and windows and away from drafts.
- ✿ Use thermal shades on windows.
- ✿ Prewarm incubators and radiant warmers before placing the infant in them.
- ✿ Ensure use of double-walled incubators.
- ✿ Place warmed blankets on surfaces, such as scales, that will be in contact with the infant.
- ✿ Warm blankets before wrapping the infant.
- ✿ Avoid opening the incubator unnecessarily.
- ✿ Use the plastic sleeves on the portholes when caring for the baby. It also is important to teach families to use the sleeves on the portholes.
- ✿ Use side guards to protect the baby from air currents when using a radiant warmer.
- ✿ Keep infants in incubators swaddled (Figure 36-4).
- ✿ Keep the baby's head covered. Many nurseries use soft knit hats for this purpose.
- ✿ Replace wet blankets immediately with dry, warmed ones.
- ✿ Warm and humidify oxygen before administration.
- ✿ Prewarm solutions for the infant that are either applied externally or used internally such as intravenous medications.

Micro-environment Components

The second set of elements included in developmental care protocols are those specifically related to the environ-

Figure 36-4 Infants in incubators should be swaddled comfortably to prevent heat loss.

Nursing Alert

RECOMMENDATIONS FOR INFANT POSITIONING RELATED TO SUDDEN INFANT DEATH SYNDROME

Until 1992, the standard of practice for positioning was to place the infant in a prone position, particularly after feeding. The rationale was that the prone position decreased the infant's risks for aspiration of vomitus. In preterm infants, the prone position also was found to produce longer sleep periods, improved respiratory effort, and decreased heart rate compared with the supine position (Masterson, Zucker, & Schulze, 1987). In the early 1990s, studies of Sudden Infant Death Syndrome (SIDS) began to link the prone position when sleeping with a significantly increased risk for SIDS. As these data emerged, the American Academy of Pediatrics (2000) issued a recommendation that the prone sleeping position no longer be used for healthy infants under 6 months of age. Whereas these recommendations are not specific to the hospitalized preterm infant, they have raised concerns about the use of the prone position for this population. These concerns have resulted in an increased use of the side-lying position in developmental care protocols, although few data are available describing the effects of the side-lying position on heart rate, respiratory rate, sleep duration, or infant state compared with the prone or supine sleeping positions (Figure 36-5). Discharge planning for all infants including the preterm or high-risk infant should include teaching the parents about the risks for SIDS and the precautions to take.

ment or care experiences of the individual infant. As a group these components can be considered the **micro-environment** or individual sensory environment of the infant. The components of the micro-environment discussed in this chapter include positioning and containment strategies, handling and touching, nonnutritive sucking, and pain assessment and management.

Positioning and Containment Strategies

Current thought related to neonatal positioning in the NICU has evolved primarily from the study of the intrauterine posture of the fetus. The intrauterine environment is such that the fetus is aided in maintaining a position of flexion as well as midline posture. This flexed, midline position is important for normal motor development but also serves to facilitate hand-to-face and mouth behaviors, which provide opportunities for sucking and

Figure 36-5 This premature infant is sleeping in the side-lying position; the nurse is containing the infant with her hands to offer a sense of warmth and security.

Critical Thinking

Positioning and Containment

Preterm infants are growing and developing in the hospital nursery environment during a period of time when they normally still would be growing and developing in their mother's uterus. It is this uterine environment that is most appropriate for the fetus and in which the fetus will grow and develop optimally. Think about how different the NICU environment is from the uterine environment. In the third trimester, the developing fetus would maintain a curled up flexed position, held there by the uterine walls. In contrast, in the NICU infants often are put in a supine, open position, which has been thought to make caregiving easier.

In the third trimester, the developing fetus also would feel the surrounding uterine walls as barriers or boundaries. As the fetus moves or kicks, the fetus impacts the uterine wall and feels the resistance and containment of that barrier. In contrast, in the NICU infants often are positioned in the center of the incubator or warmer bed, away from any barrier that could provide a sense of containment comparable with the uterine environment.

- How can the developmental care strategies for positioning and containment provide sensory input similar to that which infants would have received if they had remained in the uterus until gestational term?
- Which behavioral changes would you expect to see in preterm infants as you implement the positioning and containment strategies that are part of developmental care?

self-calming behaviors. Increasing evidence suggests that supportive positioning and handling of preterm neonates in the NICU may promote more normal motor development and minimize the chances of developing abnormal movement patterns (Fay, 1988; Jorgensen, 1993; Perez-Woods, Malloy, & Tse, 1992).

Historically, sick neonates have been cared for in the supine position to facilitate ease of physical assessments and accommodate medical interventions such as umbilical artery catheters and respiratory support devices. However, current research suggests that prone positioning may offer advantages over supine positioning for the sick neonate in terms of oxygenation, energy expenditure, and behavioral organization. Infants cared for in the prone position compared with those cared for in the supine position demonstrate increased oxygenation, tidal volume, and lung compliance; reduced energy expenditure; increased sleep time; and decreased behavioral disorganization (Fox, & Molesky, 1990; Lioy, & Maginello, 1988; Masterson, Zucker, & Schulze, 1987).

Developmentally supportive positioning also should prevent postural disorders common to chronically ill preterm neonates. One adverse effect of improper positioning is scapular retraction. In the NICU, scapular retraction may have an immediate impact on respiration and result in decreased hand-to-face or hand-to-mouth behaviors, leading to stress and avoidance behaviors in the

Client Education

Infant Positioning

When parents are present, talk with them as you position the baby. This is an opportunity to teach them how to position their infant and to practice positioning the baby with you there to support them. Talk with them about where the baby will sleep at home and how they will be able to position the baby with the supplies available to them in the home environment. A variety of positioning aids have become available on the commercial market to assist in developmentally supportive positioning, although many of these represent a significant expense. Point out to parents that although you may use some specialized equipment in the hospital, they will be able to position their baby appropriately using blanket rolls or small receiving blankets. Also discuss some of the concerns about using pillows and loose blankets in the crib with the infant (AAP, 2000).

Nursing Tip

PRONE POSITION

Although the prone position often is preferred to enhance physiologic stability in preterm infants, you need to accustom infants to side- or supine-lying positions before discharge because these positions will be recommended to parents to reduce the risk for SIDS.

A.

B.

NICU. Failure to promote shoulder rounding in preterm infants also may result in abnormal scapular retraction that may persist into early childhood, leading to delays in the achievement of normal developmental tasks (Georgieff & Bernbaum, 1986). Possible long-term effects of scapular abduction and retraction include difficulties in sitting without support, crawling, reaching for objects, and manipulating or transferring objects between hands.

External rotation and abduction of the hips is another postural disorder with potential adverse effects on long-term development. Prolonged supine or prone positioning of preterm neonates may result in excessive hip flexion and flattened frog-legged postures, which may ultimately interfere with normal movement patterns for gait and crawling (Downs et al., 1991).

Recommendations for Practice

The primary goal of supportive positioning for the preterm infant is to encourage a balance between flexion and extension (Figure 36-6). Careful attention also should be paid to maintaining body symmetry while enhancing midline

C.

Figure 36-6 Developmental positioning of the preterm infant A. Prone, flexed (frog-legged position) B. Prone, extended position C. Supine position.

Figure 36-7 Swaddling-type bedding provides soft boundaries for the newborn.

orientation of extremities. Although sufficient research exists to promote prone positioning whenever possible in acute and chronically ill preterm neonates, the goals of developmentally supportive positioning can be accomplished in a variety of prone, lateral, and supine positions. Some developmentally supportive positioning interventions include the following:

- Provide boundaries that maintain the infant's position in flexion while allowing the infant adequate room for extension (Figure 36-7).
- Whenever possible, encourage side-lying positions for the acutely ill or recovering preterm infant.
- Provide midline orientation to facilitate hand-to-mouth activities and prevent shoulder retraction.
- To avoid head molding, use gel products or water pillows and reposition frequently.
- Use the smallest diaper available to prevent hip abduction.
- When positioning the infant in the prone position, prevent external hip rotation by placing a roll under the hips, thus supporting the pelvis and allowing the knees to be flexed and tucked in. An additional blanket roll that encircles the lower extremities and extends up to the upper thorax will provide opportunities for the infant to brace against as well as facilitate hand-to-mouth behaviors. To avoid hyperextension of the neck, the head should be kept in a neutral position or with the chin tucked slightly toward the chest.
- The side-lying position may be used to facilitate midline orientation and allow opportunities for the infant

to engage in sucking and self-calming behaviors. The infant can be properly positioned in the lateral position by placing a wedge or blanket roll behind the infant's back, with a folded sheet placed across the pelvis and tucked into the bedding. Doing so will facilitate flexion of extremities and maintain the trunk perpendicular to the bed surface. Neutral lower extremity positioning also may be facilitated by placing a soft roll between the infant's legs. Furthermore, a soft, thin blanket roll or small stuffed toy can be positioned at the anterior midline to encourage slight forward rounding of the spine and prevent of trunk arching. Finally, the head should be kept in midline or with the chin tucked slightly toward the chest.

- Supine positioning may be required for the provision of necessary medical care in the acutely ill preterm infant. In the supine position, the head, body, and feet can be supported midline, using soft blanket rolls positioned close to the infant. Lateral rolls should facilitate rounding of the shoulders by gently lifting and supporting the arms off the bed. A small roll under the knees will facilitate hip and knee flexion, thereby preventing hip abduction. Finally, a

Critical Thinking

Patterns of Caregiving

To provide optimal developmental support, any approach to caregiving must be embraced by all caregivers who come into contact with the infant. The care of the high-risk neonate involves the coordinated efforts of a full multidisciplinary team, including nurses, pharmacists, physicians, medicine, respiratory therapists, and X-ray technicians. Each member of the team has an important role in the care of the infant; however, all members may not be aware of the total demands on the infant's limited energy reserves. Neonatal nurses are in a key position to act as advocates for high-risk neonates to protect them from unnecessary handling or to structure the necessary care to provide for optimal rest and recovery.

- If you felt that the caregiving activities for an infant in your care were not allowing the infant to have periods of rest and recovery, how would you begin to modify those patterns?
- How would you work with caregivers from other disciplines in organizing the care activities of an infant?

blanket roll placed at the bottom of the feet will provide containment and improve muscle tone by providing a surface against which to flex.

Handling and Touching

Adequate rest is a primary prerequisite for optimal recovery of human beings experiencing acute and chronic con-

Client Education

Interpreting the Infant's Cues

One of the challenges for parents in caring for their preterm infant is to begin to understand the behavioral cues the baby provides. Infants born at full term provide many signals to adults around them that communicate when they are hungry, tired, or ready to interact. These babies cry robustly when hungry or uncomfortable and sleep quietly once they fall asleep. They make eye contact and maintain it, which parents may interpret variously as interest or liking. Parents often respond to such eye contact with deep wonderment and pleasure. In contrast, the preterm infant may produce behavioral cues that are much more ambiguous and difficult for parents to interpret. In the initial period, preterm infants may not be able to be either alertly awake or soundly asleep. Preterm infants often cannot produce the robust cry of the full-term infant to communicate distress. The effort to maintain eye contact with another person also may be overwhelmingly stressful to infants, causing them to avert their eyes (Figure 36-8). At times, parents may interpret this action as rejection or a lack of interest in them (the parents). They may feel that their presence is unimportant to the baby. From the parents' earliest visits to the baby, the nurse should use the opportunity to teach them about the baby's responses. Teach them the signs of stress in their baby and the ways the baby shows comfort and relaxation. For example, show them how the baby's vital signs become more stable, the extremities relax, and movements are smoother. Show them how to change their approach when the baby shows signs of stress, that is, parents' lowering their voices, touching the baby, or talking to the baby (but not doing both at the same time). By using opportunities to help parents get to know their infants throughout the hospitalization, an important part of the discharge planning process will be underway.

Figure 36-8 Finger splaying is a sign of distress.

ditions. Preterm infants in the NICU, however, often are subjected to frequent caregiving episodes. Indeed, the NICU is an environment in which the caregiving episodes are not only frequent but also intense, often painful or stressful, and involve multiple caregivers. Consistent with earlier reports, a recent study suggests that preterm infants are handled a mean of 113 times per 24 hours, with undisturbed rest periods ranging between 2 and 59 minutes (Appleton, 1997). In addition, the activity surrounding the infant may continue through the 24-hour period, with little variation in intensity.

Although most of the caregiving activities are a necessary part of medical care, some disruptions of the infant that occur daily in the NICU could be deemed unnecessary and poorly timed. For example, Appleton (1997) reported that increased infant disruptions occur surrounding the changing of nursing shifts in an attempt to “tidy” the infant’s environment and make it aesthetically pleasing for other staff and parents. Although they seem routine to caregivers, such activities can be associated with deleterious effects on critically ill neonates. Adverse physiologic changes noted with handling include hypoxemia, tachycardia,

bradycardia, tachypnea, apnea, and increased intracranial pressures (Cooper Evans, 1991; Gorski, Hale, & Leonard, 1983; Long, Lucy, & Philip, 1980; Murdoch, & Darlow, 1984; Norris, Campbell, & Brenkert, 1982; Peters, 1992; Speidel, 1978). Frequent caregiver handling also has been associated with behavioral distress and may interfere with normal sleep patterns that are important for neurologic organization and growth (Appleton, 1997; Jorgensen, 1993; Wolke, 1987). Conversely, developmentally supportive handling allows for longer periods of sleep; results in earlier transition to oral feedings; and reduces hospital stays, with improved long-term outcomes (Lotas & Walden, 1996; Mann et al., 1986).

Organization of Care

Two strategies are necessary in reducing the infant's stress with handling during caregiving. First, all routine caregiving actions should be evaluated and unnecessary ones eliminated. Another strategy used by nurses to modify this continuous activity level is to cluster or group the infant's care in a way that protects some blocks of time for the baby to rest. This effort is based on two critical components: timing of caregiving and individualization of caregiving approaches to provide optimal rest and recovery for the infant. Neonatal nurses must coordinate the infant's care to decrease the frequency of disruptive contacts while providing periods of uninterrupted rest. To accomplish this, many NICUs have implemented hands-off times during which all nonemergency procedures are postponed to ensure infants an opportunity for undisturbed sleep. Caregiving activities are grouped together and typically timed to coincide with scheduled events such as feedings (Figure 36-9). Optimally, caregiving would also coincide with the infant's awake or more alert periods. Such clustering of care activities, although providing the infant with increased

opportunities for undisturbed sleep, may not be tolerated by the acutely ill neonate. Since physiologically unstable infants may become easily stressed with handling, infant cues such as grimacing, changes in muscle tone, heart rate, respiratory rate, and color, should be used to evaluate the individual infant's tolerance for caregiving activities at a particular time. An infant's tolerance to handling may be observed through behavioral cues suggesting stress and disorganization (Table 36-1). Developmentally supportive caregiving individualizes care so that infant stress behaviors are minimized and self-regulatory behaviors facilitated.

Therapeutic Touch

Although the negative effects of excessive handling on preterm infants are well documented, several researchers have argued that certain kinds of supplemental touch therapies may be beneficial to preterm neonates. Some researchers have reported that supplemental tactile stimulation, such as infant massage, results in improved performance on developmental tests, increased growth and weight gain, early discharge, reduced behavioral distress, and improved parental bonding and attachment (Field et al., 1986; Field, Scafidi, & Schanberg, 1987; Whitley, & Cowan, 1991; Nelson, Heitman, & Jennings, 1986; Booth, Johnson-Crowley, Barnard, 1985; Harrison and Woods, 1991; Pateron, 1990; Russell, 1993; White-Traut, & Hutchens Pate, 1987). These studies were performed with medically stable preterm infants, however, and the results should be extrapolated with caution to younger, sicker preterm neonates. Research in this area continues and should be evaluated carefully for inclusion in care protocols.

Other forms of touch have been found to be therapeutic in supporting or facilitating the infant in maintaining or regaining physiologic organization or stability when stressed, for example, the use of touching to provide gentle containment of the infant's extremities during a stressful procedure and allowing the infant to hold the caregiver's finger (Als, 1986). It is important to recognize that touching is a powerful stimulus that can be both stressful and

Figure 36-9 While this infant is awake, the nurse offers him a pacifier and schedules routine activities such as diaper changes.

Nursing Tip

TOUCH THERAPIES

Therapeutic touch and healing touch are very different from infant massage because they may use very gentle tactile stimulation or even may provide no physical contact. These touch therapies may be useful in the high-risk neonate because they are less likely to cause overstimulation.

Table 36-1 Stress Signals and Self-Regulatory Behaviors for Autonomic, Motor, and State Subsystems of Functions

Subsystem	Behavior	Stress	Self-Regulatory
Autonomic	Respiratory	Irregular, slow, fast, pauses	Regular
	Color	Pale (gray), webbed, red, dusky, blue	Pink
	Instability-related patterns	Tremors, startles, twitches, yawning, sneezing	Absence of tremors, startles, twitches, yawning, sneezing
	Visceral and respiratory	Spitting up, gagging, hiccoughing, bowel movement grunting, sounds, sighing, gasping	Stable viscera as evidenced by absence of visceral and respiratory stress behaviors
Motor	General extremity and trunk	Flaccidity: arms, legs, postural hyperextension, arching, stretch-drown, diffuse squirming	Flexed, tucked arms and legs; well-regulated tone; trunk tucking; leg and foot bracing
	Face	Gape face, tongue extensions, grimacing; mouthing; frowning	Hand on face, suck searching, sucking
	Specific extremity movement	Finger splaying, airplaning, saluting, sitting on air, fisting	Hand clasping, foot clasping, hand-to-mouth, grasping, holding on
State	Sleep-Awake states	Diffuse sleep-awake states, eye floating, fussing; discharge; smiling	Clear, robust sleep states

disorganizing, or soothing and organizing. Sensitive evaluation of the infant's individual response to a specific stimulus at a particular time is the most important skill for the nurse to develop in approaching the care of the preterm infant.

Kangaroo Care

In the early 1980s a concept of early mother-infant skin-to-skin touching referred to as kangaroo care began to be described in the literature. This practice was first reported from Bogota, Columbia, where clinicians described a decrease in infant mortality, morbidity, and infant abandonment when mothers were brought into the NICU and allowed to hold their diapered infants beneath their clothing, upright, between their breasts, with direct skin-to-skin contact (Rey and Martinez, 1983). Because of the resemblance of this practice to the way in which marsupial mothers hold and nurture their young, it became known as kangaroo care. The complete practice of kangaroo care includes both skin-to-skin contact with the infant placed vertically between the mother's breasts and self-regulatory breast-feeding (infant feeding as desired). One episode of kangaroo care may last a few minutes or 1 to 2 hours. Five categories of kangaroo care have been identified based on how long after the infant's birth the intervention is begun. Late kangaroo care usually is begun several days or weeks after birth when the infant has become physiologically stable. Intermediate kangaroo care begins within the first week of life while the infant is still unstable or may still be on a ventilator. Early kangaroo care is initiated in the first

day or hours of life in the infant who can be stabilized in a warmed incubator, with intravenous fluids and oxygen if necessary. Very early kangaroo care is initiated in the first hour of life in the delivery or recovery room. Finally, birth kangaroo care refers to placing the infant skin to skin on the mother's abdomen in the first minute after delivery (Anderson, 1999).

After the initial reports of kangaroo care appeared in the literature, researchers worldwide began to study this practice and evaluate its effects in rigorously controlled studies (Anderson, 1999). In these studies, positive effects on infants and on mother's and father's satisfaction were found. Infants receiving kangaroo care had longer and deeper sleep times compared with times when they were not receiving kangaroo care (Messmer et al., 1997). A study of 33 infants found that infants receiving early and intermediate kangaroo care had greater weight gain per week, fewer days of incubator care, shorter hospital stays, and were more frequently breast-fed on discharge than infants who were similar and had not received kangaroo care (Whalberg, 1991; Wahlberg, Affonso, & Persson, 1992). In a recent study of 30 infants, researchers reported that infants receiving kangaroo care while undergoing a heel stick showed markedly reduced crying and grimacing compared with infants in the control group who experienced a heel stick without kangaroo care (Gray, Watt, & Blass, 2000). Infants in kangaroo care also did not show the dramatic increase in heart rate at the time of the heel stick that other infants commonly show. Other studies, while not documenting positive infant outcomes, have

REFLECTIONS FROM A MOTHER

"I couldn't think the first time they took me into the NICU to see my son. There were so many machines, so many people, so many other babies. All the babies were very quiet and still. When I saw my son I was terrified. He didn't look like I thought he would, like any other baby I had ever seen, or like me or like my husband. I didn't see how he could ever live or be normal. He was so small. I just felt helpless and wanted to cry. The nurses said the next time I came in I could hold him, but I didn't know if I wanted to. I knew I should feel something different—like other mothers do. I should be overwhelmed with love for him, but he didn't seem to be a part of me. I wanted to feel like a mother, but I couldn't. All I could do was cry. The nurses said that when I came back the second time I could do "kangaroo care" with him. They explained what I needed to do and said that I would hold my baby on my chest between my breasts. When I came back, the nurses had me stand by my baby's incubator while they picked him up, nestled him into my chest, and helped me sit down in a large comfortable chair. As he nestled in, they covered both of us with a soft warm blanket. He squirmed a little. I could feel him move against me—almost like when he was in the womb. Then he fell asleep. He looked very comfortable, and I wasn't afraid anymore. The nurse showed me how his heart rate, temperature, and everything else was stable—just like it should be. I just kept looking and looking at him. It was like I couldn't get enough of him. I think he has my husband's chin and my long fingers."

supported the safety of kangaroo care for the very premature infant (Bosque et al., 1995; de Leeuw et al., 1991; Ludington-Hoe et al., 1999; Moran et al., 1999). Kangaroo care has been implemented in nurseries throughout Europe, South America, and the United States.

Recommendations for Practice

Guidelines for appropriate handling of preterm infants are based on the characteristics of handling, the timing of caregiving activities, and individualizing care based on the infant's physiologic and behavioral responses to caregiving. Recommendations for handling of preterm neonates during caregiving are provided below:

Characteristics of Handling

- ✦ Use slow, gentle movements when handling the preterm infant.
- ✦ Use alerting techniques, that is, speaking softly to the infant or gently placing your hand on the infant, to prevent startling and signal the start of caregiving (Figure 36-10).
- ✦ Perform caregiving activities in an unhurried manner and allow time outs when the infant shows marked signs of stress.
- ✦ Provide extra caregiving hands or boundary support during difficult and uncomfortable procedures.
- ✦ Provide **facilitated tucking** with caregiving hands or boundary support until the infant settles after care, remaining at the bedside for at least 2 to 5 minutes after completion of any procedure.
- ✦ Bathe the infant while providing support with swaddling.

Figure 36-10 The nurse gently places a hand on the infant to signal the start of caregiving.

Research Highlight

Skin-to-Skin Contact is Analgesic in Healthy Newborns

Purpose

To determine whether skin-to-skin contact (kangaroo care) between mothers and their healthy full-term newborns reduced the pain experienced by infants during a heel stick.

Method

A sample of 30 healthy full-term newborns was randomly assigned to one of two groups. Infants in group one (experimental group) were held by their mothers in a kangaroo care protocol during a heel stick procedure. Infants in group two (control group) were swaddled in a crib during a heel stick procedure (standard protocol for the nursery). In both groups, the infants were positioned comfortably and left for 15 minutes to quiet. After 15 minutes, data collection began. The infants' faces were videotaped and heart rates monitored every 10 seconds for 2 minutes before the heel stick, during the heel stick procedure, and for a 3-minute recovery period after the procedure. Measures of pain response in the infants included heart rate changes, crying, and facial grimace.

Findings

Infants receiving kangaroo care demonstrated 82% less crying and 65% less grimacing than did infants maintained swaddled in their cribs. Infants receiving kangaroo care did not demonstrate a dramatic increase in heart rate at the time the heel was lanced as did the infants in the control group.

Nursing Implications

Kangaroo care appeared to provide a powerful analgesic effect for the infants in this study. When infants in the NICU need to have a painful procedure done, for example, an intravenous line insertion or a heel stick, arranging for the infant to be maintained in skin-to-skin contact can provide a nonpharmacologic approach to pain relief.

Gray, L., Watt, L., & Blass, E. (2000). Skin to skin contact is analgesic in healthy newborns. *Pediatrics*, 105, 1, 1–6.

- ✿ Perform caregiving with the infant in a prone or side-lying position to minimizing the need for repositioning, thereby reducing handling and stress.
- ✿ Weigh the infant while swaddled or in a containment device to maintain the infant's level of physiologic organization. The blanket or other containment device can be weighed separately so that its weight can be deducted from the infant's weight.

Timing of Care

- ✿ Time caregiving activities around the sleep-wake cycles of the infant.
- ✿ Protect periods of sleep, providing 2 to 3 hours of uninterrupted sleep.
- ✿ Use electronic monitoring devices for continuous display and routine assessment of physiologic parameters. Perform hands-on assessment of vital signs

once per shift to correlate monitor readings, thereby minimizing infant handling.

- ✿ Cluster caregiving activities as much as possible without evoking a stress response in the infant.
- ✿ Gather all necessary supplies before disturbing the infant.
- ✿ Use signs at the bedside to remind all caregivers of scheduled touch times, thereby promoting periods of undisturbed sleep.

Evaluate Infant Responses

- ✿ Assess all caregiving activities for necessity, and avoid the use of routine procedures.
- ✿ Recognize stress behaviors, and use these in organizing the infant's care according to individual tolerance levels.

- Document and communicate an individualized plan of care based on infant behavioral cues of stress and self-regulation.

Recommendations for Kangaroo Care

- Kangaroo care is an important intervention for preterm and high-risk infants (Figure 36-11). Before initiating kangaroo care with a mother and infant, it is important that the nurse be thoroughly knowledgeable about the process and that the process be explained fully to the parent.
- In nurseries in which kangaroo care has not been initiated previously, an in-depth review of the literature, which is shared by the entire multidisciplinary team, would be an important first step.
- An in-service program by a clinician experienced in the use of kangaroo care would be an important step in preparing to implement this procedure in a nursery.
- Before implementing kangaroo care, ensure that you have a comfortable chair and, if possible, arrange for some privacy for the parent. A screen around the isolette can be used to provide some sense of private space.
- Arrange the timing of the kangaroo care in relation to other caregiving activities so that it is not necessary for anyone to interrupt the mother while she holds her baby.
- If the mother is planning to breast-feed, the period of kangaroo care can be an opportunity to initiate feeding. Evaluate for this before the beginning of kangaroo care.

- Kangaroo care also has been found to be beneficial for fathers in terms of facilitating their developing relationship with the baby. Offer the opportunity for kangaroo care to fathers when possible.

Nonnutritive Sucking

Nonnutritive sucking has been associated with numerous positive outcomes for preterm neonates (Figure 36-12). Positive benefits documented from nonnutritive sucking include improved oxygenation levels during gavage feedings and at rest, enhanced weight gain, earlier transition from gavage to oral feedings, increased levels of alertness before feedings, and shorter hospital stays (Bernbaum et al., 1983; McCain, 1992; Woodson, Drinkwin, & Hamilton, 1985). The benefits of nonnutritive sucking have been well documented; however, caregivers have noted that the smallest infants in the nursery who could benefit from nonnutritive sucking have difficulty owing to the size of most available pacifiers. Pacifiers designed for the term infant, and even those appropriately sized for the older preterm infant (those born at 30 weeks' gestational age or older), may be too large for the younger preterm infant. Pacifiers, such as the Wee Thumbie, designed for very small preterm infants allow the nurse to provide important sucking opportunities for these babies. This pacifier was designed from developmental theories to simulate thumb sucking in utero. It has been tested on low-birth-weight infants (Engbretson & Wardell, 1997).

Recommendations for Practice

- Experiment with the available pacifiers to find the one best suited for an individual baby. Infants may demonstrate more effective sucking behavior with a particular size and style of pacifier.

Figure 36-11 Preterm infants and their families benefit from kangaroo care.

Figure 36-12 High-risk neonates can benefit from and find comfort in nonnutritive sucking.

Critical Thinking

Nonnutritive Sucking

Infants in utero are able to bring their hands to their mouths by the middle of the second trimester. Often, sonograms taken during the second trimester show the fetus apparently sucking its thumb. Preterm infants, however, rarely show any spontaneous thumb sucking. Unlike in the watery uterine environment in which they can move freely and their flexed position helps bring their hands to their mouths, preterm infants in the NICU rarely are able to get their hands to their mouths. Think about it. If sucking often is seen on sonography in the second trimester, it must be a common behavior. If sucking is a common behavior in the developing fetus, is it just a chance occurrence or is it, in some way, important to fetal development? If it is important to fetal development, then is it important for the development of the preterm infant in the NICU? In studying this question, researchers have found that when preterm infants were given regular opportunities for nonnutritive sucking, they demonstrated more rapid weight gain and shorter hospital stays as well as changes in infant behavioral state and activity (Bernbaum et al., 1983; Field et al., 1982; Porter, & Anderson, 1979; McCain, 1992; Gill et al., 1988; Woodson, Drinkwin, & Hamilton, 1985).

- ❖ When infants are given bolus gavage feeding, nonnutritive sucking opportunities should be provided before initiation of the feeding and continued for a few minutes after the feeding is completed.
- ❖ When infants are continuously fed, nonnutritive sucking opportunities should be offered on a regular schedule such as 20 minutes every 3 to 4 hours.
- ❖ Nonnutritive sucking opportunities should be offered to even very immature infants who are not able to demonstrate a sustained organized suck. These early sucking behaviors may be important in stimulating the neurobehavioral development of the infant.
- ❖ Offer a pacifier to the infant who is fussy, restless, or irritable. Nonnutritive sucking is one of the mechanisms infants use to calm and comfort themselves.
- ❖ Do not provide an empty nipple or one stuffed with cotton to the infant. Use only an approved pacifier that meets federal safety standards.

Pain Assessment and Management

Preterm infants who require specialized neonatal care often are subjected to painful diagnostic and therapeutic procedures. Whereas pain may contribute to immediate physiologic instability and behavioral state changes, chronic, repeated pain experiences in the NICU also may result in adverse long-term developmental outcomes such as alterations in perceptions of pain in later childhood (Blackburn & Loper, 1992; Franck & Gregory, 1993; Porter, 1993; Corff et al., 1995; Grunau, Whitfield, & Petrie, 1994).

Accurate pain assessment is the first step to optimal pain management. Because pain is a multidimensional phenomenon, pain assessment should incorporate physiologic and behavioral measures. Many physiologic measures of pain have been studied in preterm neonates. The most evidence-based measures include increased heart rate and decreased oxygen saturation (Bozzette, 1993; Craig et al., 1993; McIntosh, van Veen, & Brameyer, 1994; Stevens, & Johnston, 1994; Stevens, Johnston, & Horton, 1993). Whereas physiologic measures provide greater objectivity in the assessment of pain responses, behavioral measures have been demonstrated to offer more specificity in terms of the pain experience, particularly facial actions. Brow bulge, eye squeeze, nasolabial furrow, and open mouth are the four most common facial patterns demonstrated by both preterm and full-term neonates (Bozzette, 1993; Grunau, Johnson, & Craig, 1990; Grunau, & Craig, 1987; Stevens, Johnston, & Horton, 1993; 1994).

Critical Thinking

Pain in Neonates

In the past, it was thought that newborns were unable to experience pain sensations in the same way as do older children and adults.

- Have you ever watched a newborn when blood was being drawn through a heel stick? How did the baby respond?
- Have you ever had blood drawn or an injection? How did you respond?
- How was your response like or different from the response of the newborn infant?
- Ask yourself what you think is true about a newborn's response to pain.

Critical Thinking

Pain Management

Until just over a decade ago, myths regarding pain in neonates were pervasive in the NICU. Among the two most common myths were that the central nervous system of the preterm neonate was too immature to perceive pain that resulted from common neonatal therapies coupled with the myth that expounded the dangers of administering narcotics to neonates. Despite current evidence that neonates have the anatomic and functional capacity to perceive and respond to noxious stimuli, inadequate pain management practices continue to persist within the NICU. Think about it. Would you want to have a chest tube inserted without local and systemic analgesic? Does it make sense when medical care providers say they do not use local anesthesia to perform circumcisions on male infants because the infant cries more when immobilized on the circumcision board than when the prepuce is cut away from the glans penis?

The golden rule of pain management states that what is considered painful for older children and adults must be considered painful in neonates. Think about procedures that are commonly performed in neonates. Which strategies can you use to more effectively advocate for optimal pain management practices within the NICU?

Studies of full-term and preterm infants provide evidence that pain responses vary within the context in which pain is experienced. Therefore, the nurse also must consider contextual factors when assessing for pain in the neonate. Gestational age and behavioral state are the two most powerful contextual modifiers of the pain response in neonates (Craig et al., 1993; Grunau, & Craig, 1987; Johnston et al., 1993; Stevens, & Johnston, 1994; Stevens, Johnston, & Horton, 1993; 1994). For example, whereas term infants may respond to painful stimuli with crying and localized deliberate withdrawal responses, 26% to 90% of preterm neonates between 26 and 36 weeks postconceptional age will not cry in response to noxious stimuli (Johnston et al., 1995; Rushforth, & Levene, 1994; Stevens, Johnston, & Horton, 1994). Infants in awake or alert states also demonstrate a more robust reaction to painful stimuli than do infants in sleep states. Therefore, gestational age and behavioral state may contribute to a less vigorous response pattern, requiring the caregiver to be an astute observer. In order to provide optimal pain management

within the NICU, it must be assumed that what is painful to older children and adults is similarly painful to the preterm neonate who has limited behavioral capabilities to respond because of immaturity. It is particularly important to teach parents of hospitalized infants how to assess the pain cues of their child. Parents who are accustomed to seeing pain responses of full-term infants and older children may well not recognize the pain responses of a premature or sick baby.

Instruments for Pain Assessment in Infants

Several multidimensional instruments to assess pain in neonates have been published. The Pain Assessment Tool (PAT) is a multidimensional instrument designed for assessing postoperative pain in preterm and full-term neonates (Hodgkinson et al., 1994). The PAT includes four behavioral indicators of pain (posture and tone, sleep pattern, facial expression, and cry); four physiologic measures (respiration, heart rate, oxygen saturation, and blood pressure); color; and the nurses' perception of the neonate's pain. No psychometric properties of the instrument were reported. Bildner and Krechel (1996) developed the CRIES scale for assessing postoperative pain in preterm and full-term neonates. The acronym CRIES indicates five categories that are scored on a three-point scale (0, 1, 2) and includes crying, requires oxygen to maintain saturation greater than 95%, increased vital signs, expression, and sleepless. The tool has moderately high interrater reliability ($r = 0.72$). Scores comparing the CRIES scale with the Objective Pain Score (OPS) demonstrated a moderately high correlation ($r = 0.73$; $P < 0.0001$) (Norden et al., 1991). Furthermore, scores were significantly lower after analgesic administration ($P < 0.0001$), suggesting that the measure has some beginning construct validity. The third instrument, the Premature Infant Pain Profile (PIPP), developed by Stevens et al. (1996), includes two physiologic indicators of pain (heart rate and oxygen saturation), three behavioral variables (brow bulge, eye squeeze, and nasolabial furrow), and two contextual factors (gestational age and behavioral state). The PIPP is scored on a point scale from zero to three. Content validity was established by careful review of the literature and by a panel of experts. Because the PIPP currently is the only multidimensional instrument that incorporates contextual factors that modify the pain response, it may serve to be a very useful instrument in assessing pain in preterm neonates in the NICU (Table 36-2).

Management Strategies

In the NICU, critically ill neonates are subjected to frequent painful procedures required for clinical monitoring and intervention. A study conducted by Barker and Rutter (1995) documented the alarming frequency in which painful invasive procedures were performed on infants from admission

Table 36-2 Premature Infant Pain Profile

Process	Indicator	0	1	2
Chart	Gestational age	36 weeks and more	32–35 weeks 6 days	28–31 weeks 6 days
Score 15 seconds immediately before event	Behavioral state	Active and awake Eyes open Facial movements	Quiet and awake Eyes open No facial movements	Quiet/sleep Eyes closed No facial movements
Record baseline heart rate	Maximum heart rate	0–4 bpm	5–14 bpm	15–24 bpm
Observe infant 30 seconds immediately after event				
Record baseline oxygen saturation	Minimum oxygen saturation	0–2.4% decrease	2.5%–4.9% decrease	5.0%–7.4% decrease
Observe infant 30 seconds immediately after event				
Observe infant 30 seconds immediately after event	Brow bulge	None 0%–9% of the time	Minimum 10%–39% of the time	Moderate 40%–69% of the time
Observe infant 30 seconds immediately after event	Eye squeeze	None 0%–9% of the time	Minimum 10%–39% of the time	Moderate 40%–69% of the time
Observe infant 30 seconds immediately after event	Nasolabial furrow	None 0%–9% of the time	Minimum 10%–39% of the time	Moderate 40%–69% of the time

From B. Stevens, C. Johnston, P. Petryshen, & A. Taddio. (1996). "The premature infant pain profile: Development and validation" *The Clinical Journal of Pain*, 12, (1), 13–22. Copyright 1996, *The Clinical Journal of Pain*.

to discharge in one NICU setting. The study sample included 54 infants whose gestational ages ranged from 23 to 41 weeks, with a mean age of 33 weeks. The investigators reported 3,283 invasive procedures being performed, with increased frequency of procedures inversely related to gestational age and acuity of medical illness. One infant at 23 weeks' gestation and 560 g had 488 procedures performed during her hospital stay. Considering the long-term negative impact of frequent and prolonged pain in preterm infants, strategies to prevent pain in the NICU must be of paramount concern to health care providers in the NICU. The primary strategy to prevent pain in the high-risk neonate involves the change from protocol-based care to individualized strategic planning, which first evaluates the medical necessity of invasive procedures. This approach would promote caregiving techniques such as the minimal use of tape, use of noninvasive monitoring devices when possible, and tracheal suctioning on an as-needed basis only instead of as a routine procedure. Furthermore, for those procedures deemed medically necessary, careful coordination of painful procedures, such as grouping blood drawings, should be performed to minimize the number of heel sticks and venipunctures per day (Figure 36-13).

Another goal of pain management in infants is to minimize the intensity, duration, and physiologic cost of painful experiences. The intensity and duration of pain often can be minimized through the use of quick, efficient,

Figure 36-13 Offering a pacifier during a painful procedure, such as venipuncture, can help calm and reassure the infant.

and skilled execution of invasive procedures. This goal can be facilitated in units that routinely monitor the competence of their laboratory and nursing staff personnel or units that use only expert staff to attempt invasive procedures, such as intravenous placement, on the most unstable infants or those with a history of difficult intravenous access. Developmental care techniques discussed in this chapter may improve the infant's ability to cope with and recover from painful procedures. These techniques would include the strategies discussed to protect the infant from unacceptably high levels of noise, constant bright lights, and overstimulation and also would include clustering of care to allow the infant to rest sufficiently between procedures. For example, the physiologic cost of pain can be minimized by providing proper support to the neonate during a painful procedure. A study by Corff et al. (1995) reported that a technique known as *facilitated tucking*, which consists of generalized motoric containment of the arms and legs close to the infant's body while in a side-lying or supine position, resulted in significantly lower mean heart rates, shorter mean crying, shorter sleep disruption times, and fewer sleep-state changes after a painful heel stick procedure in infants than did motoric containment. Other interventions, such as swaddling, facilitating hand-to-mouth contact, nonnutritive sucking, and touch therapies, also may assist the infant in coping with noxious stimuli. Parents also can play an active role in relieving the stress of their infants in the NICU and should be encouraged to participate in the provision of nonpharmacologic comfort measures whenever possible.

Although the mechanism is unclear, preliminary studies suggest that sucrose may be effective in alleviating pain in certain situations. Blass and Hoffmeyer (1991) found that infants who were provided with a sucrose-flavored pacifier during heel lance and circumcision cried significantly less than did infants who did not have a pacifier or those who had a water-moistened pacifier.

Although nonpharmacologic measures may be used appropriately to manage pain in many circumstances in the NICU, pharmacologic agents should be used when severe or prolonged pain is assessed or anticipated (Agency for Health Care Policy and Research, 1993). Optimal treatment of pain in infants in the NICU often has been hindered by persistent fears of health care providers regarding safety, addiction, and respiratory depression associated with the administration of opioids. Although infants younger than 1 month of age and preterm infants generally metabolize pharmacologic agents more slowly and have prolonged elimination times of the drug from their systems, it is believed that analgesic and anesthetic agents can be administered with relative safety in the NICU. This is especially true given that equipment is present to monitor the physiologic status of the infant and equipment and personnel are immediately available for treatment with

naloxone and emergency airway management if the need arises (Agency for Health Care Policy and Research, 1993).

Opioid analgesics are considered the most effective agents to treat moderate to severe pain in neonates. A variety of analgesics is available. The most commonly used analgesics for neonates include morphine and fentanyl. Although the use of acetaminophen in neonates is limited by the constraints of the route of administration, acetaminophen may remain an option for treating mild pain in some infants. A summary of the routes of administration, recommended dosages for neonates, and side effects is provided in Table 36-3.

Although sedative and other adjuvant drugs often are used in combination with analgesics, no research is available regarding the efficacy or safety of combining these drugs in the neonatal population. It also must be remembered that sedatives have no analgesic effect and may depress the behavioral expression of pain. Therefore sedation should be used only if sedation—not pain relief—is required.

Although a few studies have reported on the efficacy of local anesthesia for invasive procedures in neonates, minimal research on the safety and efficacy of this pain management strategy is available to recommend its widespread use in the NICU. Some studies have investigated the use of a topical eutectic mixture of local anesthetics (lidocaine plus prilocaine [EMLA]) for painful diagnostic and

OPIOID USE IN INFANTS

Opioids remain the cornerstone of pharmacologic management of moderate to severe pain in neonates. Health care professionals must examine their own personal beliefs about pain management in neonates and acknowledge the prevailing myths that may persist within the NICU in which they practice. Multidisciplinary focus groups may serve as a vehicle to open dialogue and discussions about current practices and to formulate strategies to improve pain management practices within the NICU. Nurses also must continue to systematically study the effectiveness of frequently used nonpharmacologic measures (cuddling, swaddling, touch, hands off periods, and nonnutritive sucking) to comfort infants undergoing minor painful procedures. As advocates for their small, preverbal clients, nurses must continue to play a major role in conducting research in the area of pain management for preterm infants.

Table 36-3 Drugs, Routes, Recommended Dosages, and Side Effects of Pharmacologic Pain Agents in Neonates

Drug	Routes*	Dosage	Frequency	Side Effects
Morphine	Intermittent IV	0.05–0.2 mg/kg over at least 5 min	As required (usually every 4 h)	<ul style="list-style-type: none"> • Respiratory depression • Hypotension • Ileus and delayed gastric emptying • Urine retention • Tolerance with prolonged use • Seizures
	Continuous IV infusion	Loading dose 100 µg/kg over 1 h; then 0.01–0.03 mg/kg/h	Continuous	
	IM, SQ	0.05–0.2 mg/kg		
Fentanyl	Intermittent IV	1–4 µg/kg slow IV push	As required (usually every 4 h)	<ul style="list-style-type: none"> • Respirator depression • Muscle rigidity • Seizures • Hypotension • Bradycardia • Tolerance with prolonged use • Withdrawal symptoms after 5 days of continuous infusion
	Continuous IV infusion	1–5.0 µg/kg/h	Continuous IV	
Acetaminophen	PO	10–15 mg/kg	Every 6–8 h	<ul style="list-style-type: none"> • Limited data in neonates • Liver toxicity • Rash • Fever • Thrombocytopenia • Leukopenia • Neutropenia
	PR	20–25 mg/kg	Every 6–8 h	

*IV—intravenous; IM—intramuscular; SQ—subcutaneous; PO—by mouth; PR—per rectum

therapeutic superficial skin procedures, such as heel sticks in preterm infants and circumcisions in term infants (Fitzgerald, Millard, & McIntosh, 1989; Benini et al., 1993). The main potential problem with the use of EMLA in newborns younger than 3 months of age is the risk of methemoglobinemia because of the immaturity of the methemoglobin reductase enzyme in this age group (Taddio et al., 1995). Thus, until further research is performed to document the safety of using local anesthetics in high-risk neonates, systemic analgesics will remain the mainstay of therapy for pain management in the NICU.

Recommendations for Practice

The difficulty with pain measurement in preterm infants arises not from lack of empirical and clinical evidence to support that preterm infants do experience pain, but in the bedside practitioner's ability to accurately assess pain and to determine the potential impact of the experience on any given individual infant. Assessment of pain in the preverbal infant is entirely dependent on the caregiver's ability to properly evaluate pain and is a prerequisite for providing optimal pain management. Unfortunately, because of im-

maturity, clinical conditions or therapeutic programs, not all infants respond to pain with clear, robust behaviors. Thus, no single physiologic or behavioral measure should be used in isolation as an exclusive criterion to assess the presence and impact of pain in preterm infants. By combining physiologic and behavioral measures while considering contextual factors, health care providers can better assess pain in preterm infants. Better assessment can best be achieved through the use of a valid and reliable multidimensional pain instrument.

ASSESSMENT STRATEGIES IN DEVELOPMENTAL CARE

Developmental care focuses on individualizing care of high-risk neonates based on infant responses to caregiving and the environment. Healthy term infants have little difficulty in adapting to the extrauterine environment; however, high-risk neonates have a lower threshold for sensory input and often demonstrate difficulty in tolerating handling and interaction. Developmentally supportive care of the high-risk neonate involves modifying caregiving and

structuring the infant's environment to support the infant's development and improve neurobehavioral organization. Since the late 1980s, several studies have demonstrated that modifying the care of preterm infants according to behavioral cues may achieve clinical outcomes such as reduced time on ventilation, earlier transition to nipple feeding, and shorter hospital stays (Lotas & Walden, 1996).

Critical to achieving these outcomes were periodic systematic assessments throughout the preterm infant's hospitalization that were used to tailor caregiving to the infant. While giving caregivers information about the infant's neurobehavioral organization, the periodic reassessments provided caregivers with opportunities for early intervention through developmentally based care plans.

One early developmental assessment tool was the Neonatal Behavioral Assessment Scale (NBAS). The NBAS is a comprehensive protocol designed to assess behavioral capabilities of healthy newborns from 36 to 44 weeks' postconceptional age (Brazelton, 1984). Infant behaviors are viewed within the context of a dynamic relationship with the evaluator and assess the infant through the continuum of sleep, arousal, and wakefulness. In this assessment, the evaluator provides a set of prescribed stimulation, activities, or tasks for the infant and assesses the infant's ability to perform and the amount of help or facilitation the infant needs to be successful. The type and amount of facilitation needed to elicit the infant's best performance is a reflection of the infant's organizational capabilities. To obtain a clinical description of infant behavior the NBAS uses clusters of behaviors, including habituation, orientation, motor performance, range of state, regulation of state, autonomic regulation, and reflexes.

After the development of the NBAS, the need for an assessment protocol designed for use with the preterm infant was identified. In response to this need, Als adapted the NBAS for the premature infant to develop the Assessment of Preterm Infant Behavior (APIB) (Als et al., 1982). The APIB consists of six sets of tasks or maneuvers that the evaluator presents to the infant. Each set of maneuvers moves from low-intensity stimulation to high-intensity stimulation. The evaluator observes the infant for behavioral signs of stress, the ability to maintain or regain stability in the face of stimulation, and the infant's need for and ability to use support or facilitation from the evaluator to maintain or regain stability throughout the assessment process. The APIB has been used clinically and in research to provide insight into the preterm infant's response to the NICU environment and caregiving activities.

A third developmental assessment tool, designed specifically for use in the NICU, is the Newborn Individualized Developmental Care Assessment Program (NIDCAP). The NIDCAP, developed by Als (1984), is designed to assess neurobehavioral organization by using systematic, naturalistic observations, that is, observations during rou-

tine caregiving. The assessment is designed for use with high-risk neonates who cannot tolerate the systematic handling and manipulation involved with other developmental assessment instruments such as the NBAS or APIB (Als, 1982). The infant is observed before, during, and after caregiving. Infant behaviors and measures of physiologic function are recorded systematically in 2-minute increments and provide the basis for specific recommendations of modifications to the infant's physical environment and direct caregiving. The NIDCAP encourages parental involvement and assists parents to recognize their infant's behavioral cues that indicate the need for time out as well as readiness for interaction.

RESEARCH SUPPORT FOR COMPREHENSIVE DEVELOPMENTAL CARE PROTOCOLS

Each of the care strategies discussed in this chapter has been shown to have value as an individual intervention for low birth weight infants. Substantial bodies of research exist supporting each of them. Both researchers and clinicians, however, have been interested in the effects of these interventions when combined in a comprehensive approach to developmental care. Comprehensive developmental care protocols are prescribed approaches to infant care that include all or most of the individual strategies described: low light and sound levels, careful maintenance of ambient temperatures, developmentally appropriate positioning and handling, protected periods for rest and sleep, pain relief, and nonnutritive sucking. However, only a few studies have tested this comprehensive approach (Table 36-4). All of these studies compared infants cared for using comprehensive developmental care protocols (the experimental group) with infants in routine nursery care (the control group). Each study evaluated the effect of a comprehensive developmental care protocol on the overall length of the infant's stay, length of time on oxygen therapy, age at which the infant was fed completely by bottle or breast, and developmental outcomes.

In evaluating the implications of these studies for clinical practice, it is important to assess the strengths and weaknesses of the methods used for each study, similarities and differences among the studies in both the methods used and findings, comparative risks and benefits to the infant in implementing the findings, and cost to the institution or third-party payer. All these studies are limited by their very small sample sizes. Two of the studies used randomized samples and quasi-experimental designs, which is a strength (Als et al., 1994; Fleisher et al., 1995). These studies differ from one another somewhat in the way they defined and implemented their developmental

Table 36-4 Summary of Developmental Studies

care protocols. They used different instruments to measure their variables. The nurses who cared for the babies in the studies differed in the kind or amount of training or preparation they had in the use of individualized developmental care approaches. Despite these differences, however, all studies reported similar findings. All studies reported significantly shorter hospital stays, a significantly reduced need for oxygen support, earlier progression to full bottle- or breast-feeding, and improved infant behavioral regulation for infants cared for using a comprehensive developmental care protocol. Thus, these infants received important benefits when compared with infants who received routine nursery care. No detrimental effects of developmental care on the babies were noted; therefore, no apparent risks to the baby can be identified in implementing comprehensive developmental care. The cost of training personnel to use the developmental care approach can be a major institutional expense; however, two studies documented that the savings in health care dollars from the reduced hospital stays more than offsets the cost of implementing the program, including personnel training Als et al. (1994) and Fleisher et al. (1995).

In summary, an analysis of the benefits, risks, and costs of implementing a comprehensive, individualized, developmental care protocol supports the recommendation that this approach to caregiving should be incorporated into standard practice in neonatal intensive care (Lotas & Walden, 1996). At the same time, however, it is critical that researchers continue to evaluate the effects of these interventions on long- and short-term health care outcomes of the premature infant.

FAMILIES AND THE HIGH-RISK INFANT

Parents play a vital role in shaping the future outcomes of their infants. When an infant is born prematurely and requires intensive care, parents often are not encouraged and facilitated to become active partners in the care of their infant. Parents often experience grief over the loss of a full-term healthy newborn and are frequently ambivalent about establishing an attachment to the preterm infant because they fear the infant will not survive or they fear the long-term prognosis. Parents with infants in the NICU often need the assistance of the health care team to participate more actively in decisions and in assuming care of their infant. Health care providers must provide opportunities for parents to interact with and care for their infant in developmentally supportive ways. Parental aspects of caregiving for the prematurely born infant can include temperature taking, oral care, diaper changes, and hand swaddling during periods of environmental or procedural stress (Figure 36-14). As the parents gain confidence in

Figure 36-14 Parents of all newborns, especially premature or high-risk newborns, should be encouraged to bond with and care for their new baby.

carrying for their infant and the infant's behavior reflects stability, parental caregiving can evolve to include more complicated tasks, as their infant's care requires.

A key component to parental caregiving in the NICU is helping parents to understand the behavior patterns of premature infants. Parents usually need assistance in interpreting their premature infant's behavior and becoming sensitive and responsive to subtle behavioral and physiologic cues. Parents should be educated to assess their infant for both time out behaviors and behaviors that support readiness for interaction. Parental education also should include developmentally supportive techniques such as clustering of care, strategies for gentle arousal of the infant for caregiving, and hand swaddling during procedures and periods of environmental stress. Assisting parents to learn appropriate interaction techniques with their preterm infant facilitates ongoing positive social interaction with their infant, allows the parents to contribute to their infant's recovery in a meaningful way, and may set the stage for parental confidence and competence in meeting

Critical Thinking

Role of Families

When preterm, small, or sick infants are admitted to the NICU, their survival depends on a combination of complex technology and highly skilled caregivers.

- How do you think parents feel when they come into this environment?
- Do you remember the first time you walked into any intensive care unit—adult, pediatric or neonatal?
- Did you understand what all of the equipment surrounding the patient was doing?
- Did you feel comfortable approaching the patient the first time?
- How important do you think it is that parents are able to be with their hospitalized newborn?
- Does it matter to the baby?
- Does it matter to the parents?
- Has one of your family members ever been critically ill and hospitalized?
- Was it important to you to be with your family member?
- Was it important for your family member to know you were there?
- What can we do as nurses to make parents feel more welcome in the NICU?

their infant's needs on discharge to home. As parents become increasingly involved in their infant's care, they can more actively participate in devising their infant's daily plan of care.

As the infant approaches being discharged, parents should be encouraged to assume more responsibility for the infant's care. In many units a special area is set aside for families to stay at the hospital for 24 to 48 hours before discharge and care for their babies with the support of the nursing staff. This opportunity allows the family to become comfortable with caring for the infant, when they have someone readily available to answer questions, and for the nurse to identify and address possible areas of concern before the infant's discharge. A particular focus at this time should be for the nurse and parents to discuss how each aspect of caregiving will be managed in the home environment. It is important to remember that parents may need some help in adapting the caregiving procedures

CHANGING ROLE OF THE NICU NURSE

One of the gaps in the care of the preterm or high-risk infant has been in the lack of support to families in making the transition from the hospital to the home with their infants. As infants have been discharged from NICUs younger, smaller, and with more complex care needs, the challenge to families has increased. NICUs are beginning to explore the efficacy and efficiency of having nurses from the intensive care environment work with the parents in preparation for discharge and then make home visits after the infant's discharge. The nurse, who is already familiar with the infant and the infant's care needs and with the parents (and they with the nurse), can provide support, consultation, and teaching to facilitate the family's adjustment to their new circumstances.

they see in the nursery to the situation they will face at home. When possible, a home visit before the infant's discharge will be invaluable in assisting parents to make this transition.

In addition to the routine care of the infant, discharge teaching should include discussions on how to evaluate the infant's signs and symptoms of illness. The nurse may need to teach the parents how to take a temperature and ensure that the parents have a thermometer in the home. Guidelines on when to call the clinic or pediatrician and when to go to the emergency room also are helpful. It is helpful to speak with parents about who they have available as a personal support system. Are extended family members, friends, or members of a church or other religious community available? If so it may be appropriate to involve that person in the teaching process in the hospital.

Finally, as the family leaves the hospital setting with their infant, it is important that they have been referred to all appropriate community resources. Referral should include information on a NICU follow-up clinic, a well baby clinic, or a private pediatrician; Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) when appropriate; and parent support groups where available. Ideally, parents also should have access to professional advice by telephone. Many nurseries also provide routine telephone follow-up by nurses during the first few weeks after discharge.

Case Study/Care Plan

INFANT BORN AT 28 WEEKS' GESTATION

Nurses caring for preterm neonates can modify their care to facilitate the infant's growth and development by modifying the environment and initiating interventions that facilitate the infant's self regulatory action or have a calming effect on the infant. This requires careful monitoring of both the infant and the environment and continual adaptation of care. The following case study illustrates not only the nursing process, but within each diagnosis a specific illustration of the dynamic adaptation of the nursing interventions to the changes in the neonate and the environment.

At 2:08 a.m.: Kevin was born at 28 weeks' gestational age. His birth weight was 987 g and his Apgar scores were 5 (minus 1 for heart rate, 2 for color, 1 for respirations, 1 for muscle tone) at 1 minute; 8 (minus 1 for color, 1 for respirations) at 5 minutes. After being stabilized in the delivery room, Kevin was transported to the NICU in an incubator with free flow oxygen. On admission to the NICU, he was placed on a warmer bed, and oxygen therapy with nasal continuous positive airway pressure (NCPAP) was initiated. Routine cardiopulmonary monitoring and continuous pulse oximetry was begun. An umbilical venous catheter was placed to allow for the delivery of nutrients. Kevin's mother (Mrs. Jones) is a 29-year-old who had experienced two spontaneous abortions before the pregnancy with Kevin. Kevin's father, (Mr. Jones) a 32-year-old engineer was in the delivery room with his wife. Both parents deeply wanted a child and were highly anxious about Kevin's condition and prognosis.

10:00 a.m.: Kevin was lying in a supine position, wearing only a diaper. His heart rate and respiratory rate were labile, (HR 148-176 with excursions to 190+; RR 32-54 with excursions 72), with excursions in response to any loud, sharp, or unexpected noise in the environment. He also demonstrated repeated apneic periods of 15 to 20 seconds. He demonstrated frequent periodic twitching and tremors in both lower extremities. His brow was furrowed in a "frown" expression, and his color darkened and paled in response to activity around him. Kevin's parents came into the NICU. It was Kevin's mother's first time to see him, although the father was in the during the night.

Assessment

This preterm neonate is developmentally immature and unable to regulate and stabilize autonomic, motor, and sensory activity. He has exhibited signs of distress in response to environmental stimuli. Developmentally, it is crucial for him to conserve energy to maintain vital function and to grow.

Nursing Diagnosis

Inability to maintain neurobehavioral stability related to excessive environmental stimuli on the macro-environmental level.

Expected Outcomes The infant will exhibit physiologic stability as evidenced by the autonomic responses of heart rate, respirations, skin color, and a decrease in the motor signs of distress.

Planning Developmental care will be instituted. This entails careful monitoring and response to infant behavior and environmental events.

Nursing Interventions

1. The nurse will modify the environment by moving the infant to an isolette with a cover and moving the isolette to a quiet area of the nursery.

Rationales

1. This helps to isolate the neonate from some of the noise and light in the environment.

(continued)

2. The nurse will swaddle and position the infant in a flexed position if the infant shows signs of distress.
2. These positions and swaddling help the infant to self regulate and minimize the startle response that is very energy taxing.

Evaluation Vital signs will be monitored and the infant will be carefully observed for signs of distress. (The following shows the dynamic monitoring and adaptation of the nursing process related to this diagnosis).

Nursing Diagnosis

Inability to maintain neurobehavioral stability in the face of excessive environmental stimuli secondary to gestational immaturity.

Expected Outcomes The baby will increase physiologic stability as measured by: no HR excursions over 170 and no RR excursions over 60. Periodic breathing expected. No apneic pauses. No mottling is present. Skin remains pink. Reduced tremors of lower extremities. Hands remain in a relaxed posture. Face is relaxed.

Planning Environment and caregiving activities will be evaluated for stimulating effect and timing.

Nursing Interventions

Rationales

- | | |
|--|--|
| 1. Advocate for moving the infant to an isolette. | 1. To reduce environmental stimuli to the baby. |
| 2. Provide isolette cover to reduce light levels impacting the baby. | 2. To reduce bright lights. |
| 3. Create a quiet zone around the baby. Place signs around the isolette. Remind staff and visitors to lower their voices and minimize noise levels around the baby. | 3. To reduce noise levels reduces stimuli. |
| 4. Swaddle the infant to provide containment and flexion for extremities. Position the baby in a side-lying position, with limbs flexed. Provide support with blanket rolls. | 4. This is a soothing position and makes the infant feel more secure, simulating the containment of the uterine environment. |

Evaluation Infant maintained HR between 154 and 162, with no excursions above 172; RR between 36 and 48, with no excursions above 54. Oxygen saturation stable between 97% and 99%. Apneic periods decreased; no tremors of lower extremities noted. Color, pink.

Assessment

In a period of 15 hours (6:45 a.m.–9:15 p.m., Kevin was approached for multiple caregiving activities. These included an examination by the resident, morning assessments by the primary care nurse, feeding by gavage, medical rounds, and a blood draw. Kevin was being handled or receiving some care for 45 minutes of each hour of the 15 hours, with no more than 15 minutes between any two activities to allow for recovery.

Nursing Diagnosis

Inability to maintain physiological stability in response to caregiving activities secondary to fatigue.

Expected Outcomes Following caregiving events the infant will demonstrate:

- A rapid return to stable baseline HR, RR, and oxygen saturation.
- Decrease in apneic episodes.
- Continued baseline tone in the extremities and face.

(continued)

Planning

The caregiving activities will be planned and grouped to avoid non-essential stimulation and allow the infant rest periods to destabilize. Reduce unnecessary noise or activity near the infant.

Nursing Interventions**Rationales**

- | | |
|---|---|
| <ol style="list-style-type: none"> 1. The nurse will group essential caregiving activities to allow for rest and recuperative periods. This also involves negotiating with other providers who care for the infant. The nurse will modify the environment to reduce noise and activity and allow rest time after feeding. 2. Assess need and timing for each caregiving event. 3. Collaborate with the resident so that only one physical examination is performed in the early morning. 4. If infant tolerance allows based on cues exhibited, schedule feeding around the physical examination so that there is at least 1 hour of rest for the infant before medical rounds. 5. Negotiate with house staff to limit discussion at the bedside, stand away from the incubator when possible, and keep the handling of the baby to only the essentials. | <ol style="list-style-type: none"> 1. The excessive stimulation has created distress for this infant that is energy taxing and has disrupted autonomic function. The reduction of stimuli will allow the infant to restabilize vital functions. 2. Avoids unnecessary stimulation for handling. 3. Minimize unnecessary stimulation. 4. Allows for rest and energy exposure. 5. Discuss unnecessary stimuli. |
|---|---|

Evaluation

The nurse continually monitors the infant for signs of stress and autonomic functioning. The process of limiting caregiving episodes and providing rest periods between caregiving or other interventions was effective in reducing the signs of stress in the infant. Following medical rounds, Kevin's HR was 156 bpm; RR, 42 rpm; color, normal; tone, normal. No apneic episodes were noted.

Kevin's parents are obviously distressed and fearful. On further discussion, neither parent has cared for babies and had no information about understanding the developmental issues with a preterm infant.

Assessment

The infant born at 28 weeks' conceptional age differs in important ways from the full-term infant the parents may have experienced in the past and whom they were preparing to parent. The preterm infant lacks the ability to express pleasure, distress, interest, and comfort with the same robust behaviors that are available to the full-term infant. The behaviors of the preterm infant that do communicate the infant's comfort, tolerance, and distress may not be recognized by parents. From the parents' first visits to the nursery the nurse can begin to teach them to recognize their baby's individual strengths, vulnerabilities, and ways of responding.

Nursing Diagnosis

Fear (parents) related to as evidenced by uncertainty about their baby in part secondary to a knowledge deficit regarding strengths and vulnerabilities of their infant and associated inability to understand infant behaviors and cues.

Expected Outcomes

- Parents will recognize positive signs in Kevin's condition.
- Parents will identify behaviors that indicate stress or comfort and stability in Kevin.
- Parents will identify Kevin's responses to environmental stimuli.

(continued)

- Parent's will identify the importance of their role in Kevin's recovery and development.

Planning

Nurses will use the time that the parents come to see Kevin to teach them about his development, the reason for medical and nursing interventions and encourage them to begin to care for Kevin in a manner that does not overstimulate him.

Nursing Interventions

Rationales

- | | |
|---|---|
| <ol style="list-style-type: none"> 1. Stand quietly with with the parents and talk about what they are seeing. Explain some of the equipment and how you will be caring for Kevin. Talk about the purpose of swaddling, and how correct positioning can help aid breathing and improve motor stability. 2. When speaking with the parents, emphasize their importance to their baby—how much Kevin needs them. 3. Support the parents in touching the baby's hand or face gently. Talk about some of the baby's individual characteristics, emphasizing strengths and qualities the parents would identify as normal. 4. When the parents seem ready, introduce the idea of kangaroo care, emphasizing the importance of their closeness and touch for the baby. 5. When the parents are present during caregiving activities, use the opportunity to point out some of the baby's responses that indicate comfort, stress, or self-comforting behaviors used by the baby. | <ol style="list-style-type: none"> 1. Teaching the parents as care is given to Kevin allows spontaneous interaction, and the parents can ask questions. 2. Parents often feel displaced by the more knowledgeable health care professionals. 3. These activities facilitate parent-infant attachment. 4. This facilitates attachment. 5. This facilitates the parents' understanding of infant behavior. |
|---|---|

Evaluation The parents continue to express concern about Kevin's progress but also are able to identify and take pleasure in indicators that show that he is progressing, that is, weight gain, more stable vital signs, better color, more self-comforting behaviors. Parents initiate opportunities to touch or hold Kevin and begin to ask about caregiving activities. Parents begin to express preferences about how things are done for their baby.

Web Activities

- Identify and evaluate five educational and support group resources for parents of premature infants.
- Explore the website of your state department of health for statistics on premature birth, infant mortality, and infant morbidity in your area. Which factors are associated with premature birth in your state? Explore health department data related to premature birth and maternal smoking, alcohol or drug use, maternal age, geographic location (rural versus urban counties), or ethnicity.
- Compare the statistics of your state on low-birth-weight incidence, teenage pregnancy, and infant mortality and morbidity rates with the goals outlined in "Healthy People 2010."

Key Concepts

- ✿ Premature infants have special needs for care to assist with normal development.
- ✿ The environment of the NICU is a factor that can enhance or detract from development of the high-risk neonate.
- ✿ Even high-risk and preterm infants provide cues for caregivers when these infants experience stress.
- ✿ The purpose of developmental care is to support the infant's neurobehavioral development and subsystems.
- ✿ Developmental care is based on a thorough assessment of the neonate.

Review Questions and Activities

1. What are the common components of a comprehensive developmental care protocol?
2. What has research shown about the light levels in many NICUs?
3. What are the components of sound or noise in the NICU?
4. Identify three strategies for protecting infants from excessive light in the NICU.
5. Identify three strategies for reducing sound levels in the NICU.
6. Define the term *thermoneutral environment*.
7. Identify three strategies for maintaining body temperature in preterm infants.
8. Which characteristics of preterm infants make them particularly vulnerable to heat loss?
9. Define each of the four mechanisms of heat loss in the preterm infant, and identify one strategy for reducing heat loss through each mechanism.
10. What are the risks and benefits of care clustering to preterm infants?
11. What are the components of complete kangaroo care?
12. What are three benefits of kangaroo care as shown by research?
13. Identify three nonpharmacologic measures for providing pain management to preterm infants.
14. Identify three behaviors in preterm infants that may indicate pain or stress.
15. The Brazelton and the NIDCAP are two infant assessment strategies in common use. In which ways are they alike and in which ways do they differ?

UNIT IX

Special Considerations

Grief and the Family in the Perinatal Experience

The client sits alone in a darkened room. She has just been told that her baby has died in utero. As you enter, she says that she cannot believe this is happening. "This is my Christmas baby. They must be wrong. What will I do?"

As her nurse you will need to have an understanding of perinatal grief, a recognition of your own responses to death, and a knowledge of ways to best support a grieving parent.

Key Terms

Anticipatory grieving
Attachment
Chronic grief

Dysfunctional grieving
Grief
Grief work

Neonatal death
Pathological grief
Relinquishment

Reproductive loss
Sudden infant death syndrome (SIDS)

Competencies

Upon completion of this chapter, the reader should be able to:

1. Describe the phases of the perinatal bereavement process.
2. Analyze the behaviors that would be demonstrated by the bereaved mother and father.
3. Analyze assessment techniques for bereavement.
4. Describe five ways caregivers can support the emotional states of clients.
5. Compare unique aspects of gender grief, including the differences of inward and outward grief.
6. Demonstrate compassionate ways of presenting information and options to the person in crisis.

Perinatal nursing is an exciting and busy specialty that encompasses the best in working with clients as they begin their families. By definition, perinatal is the interval from about 28 weeks' gestation to about 28 days after birth (Anderson, 1998). Perinatal nurses work with clients in low- and high-risk obstetrics, at infertility clinics, and in the high-tech world of neonatal intensive care. Perinatal nurses work with clients during the physical and emotional adjustments of postpartum life.

An early miscarriage or the shattering experience of a death during the perinatal period also is part of perinatal nursing. The way in which caregivers support the client and family can make a profound difference in their grief work and their future health. The grieving parents are experiencing the death of their infant along with the end of all their hopes and dreams for that infant.

In the early 1900s, stillbirth, pregnancy loss, neonatal loss, and childhood death were commonplace. It was not unusual for a woman to lose half of her pregnancies and children. At that time, sterile technique was relatively new, and diseases and disorders that are easily controlled today by antibiotics, vaccines, and blood transfusions many times resulted in death. Family members grieving for an infant were supported by the community, and grieving mothers were supported by other women. The grieving process had a structure, for example, a particular color of clothing was to be worn and for a prescribed period. Members of the social structure knew their roles in bereavement. As science

and medicine advanced, labor and delivery moved into the hospital to be handled scientifically and the rate of perinatal death decreased dramatically. Today, it is unusual for problems to occur in pregnancy that result in the death of the infant (less than 1%). The reduced incidence of perinatal loss has, in turn, decreased the ability of clients and families to cope with this tragic event because they may never have experienced the death of a close family member.

When an unexpected death occurs, there is disappointment and loss of what could have been. A person's response to the loss results from a combination of factors: life experience, education, culture, traditions, and beliefs. The feeling of being in crisis and the need for support can depend on the type of loss being experienced and on the background and beliefs of the person.

PSYCHOLOGY OF LOSS

From the time of Freud, loss and bereavement were seen as a pathological experience. It was not until the work of David Peretz in the early 1970s that it became understood that there are different types of losses, all of which impact our lives. Losses take different forms; they may be sudden, gradual, traumatic, or not traumatic. Peretz (1970) has grouped losses into four categories:

1. The first and most obvious loss occurs through the death of a significant loved one or valued person or through separation, such as in divorce.

2. The second category is loss of some aspect of the “self”; that is, the overall mental representation or image a person has of the self is significantly altered. This type of loss includes ideas and feelings about worthiness, attractiveness, lovability, self-esteem, and status. It also includes physical aspects of the self. For example, part of the physical self can be lost by surgery, such as a hysterectomy, or in an accident, such as limb amputation. This type of loss also can be related to fantasies or expectations about a desired career or a pregnancy that failed to produce a healthy infant.
3. The third category is loss of external objects. External objects are personal possessions, such as money, property, and keepsakes. These losses can occur from, for example, difficult economic times, natural disasters, or robbery. During a pregnancy, the objects would include infant toys and clothing bought in preparation for the birth.
4. The last category of loss is loss that occurs during development. These losses are normal and occur naturally in the process of living. There is no real growth or change without loss (Simos, 1979). For example, a child loses the status of being the only child when a sibling arrives, young adults lose the close relationship with their parents when they move away from home and begin living independently, and women lose the physical ability to procreate at menopause.

The reaction to any loss is an individual one based on previous experience and shaped by traditions, culture, and spiritual beliefs. A client's perception of loss translates into grief. Because grief is an emotional rather than an intellectual or rational response the feelings often seem crazy, out of control, overwhelming, and all-consuming to the individual (Ewton, 1993). A supportive environment and an openness to discussion, about the meaning of the loss are most beneficial to parents when a perinatal death occurs.

Attachment

To understand loss, one must first understand **attachment**. British psychiatrist John Bowlby established the early work on attachment. His theory (1969) looks at how human beings create strong affectionate bonds with others and the strong emotional reaction that occurs when those bonds are threatened or broken. Bowlby believed that attachment behavior is distinct from feeding and sexual behavior; attachment behavior is seen in almost all species of mammals and has a role in survival.

Pregnancy is a maturational crisis; it is a time of loss of previous roles and a transition into new roles. Pregnancy is a time of planning for the future. Dreams, which may have had their basis in childhood, are about to be realized.

The loss of roles becomes overshadowed by the hopes for this new life and new family dynamic. At any point when the experience does not meet the expectations, there is a sense of loss, change, and transition.

Consider the four developmental tasks of pregnancy (Rubin, 1967) experienced by the mother and the emotions involved when a loss occurs at any of these stages. During the first 3 months thoughts turn inward as the pregnancy is validated. A woman's focus is on her changing body. A loss at this point can be seen as something wrong with her body, which was unable to support the pregnancy. From 4 to 6 months, a stage of fetal embodiment (a sense someone is really in there) occurs. The pregnant woman relies on her mate and reviews conflicts with her own mother. A pregnancy loss at this point may lead the woman to question her ability as a mother. Fetal distinction begins at 6 months when the mother views the baby as an individual distinct from herself. Because of this increasing sense of responsibility there is a keen interest in gathering information related to a healthy infant. When the infant dies at this point the pain of severed emotional ties is observed because, in most cases, the developed fetus is seen as a person.

Attachment begins in utero and is the basis for the emotional pain experienced by the mother regardless of whether she sees or holds her infant after the delivery. The fourth task, binding-in, occurs when she prepares to give up the baby to the birth process and usually begins at 8 to 9 months. Mothers report an empty feeling, anticipating a physical emptiness and a new set of responsibilities. When a death occurs at this stage the emptiness and pain of literally losing the baby can be devastating.

Technology has enabled parents to see the fetus at earlier stages (on ultrasonography). By talking about the meaning of the pregnancy and their hopes and plans for the child, parents exhibit signs of attachment. To experience attachment is to be vulnerable to grief. Once the delivery or procedure diagnosing the end of the pregnancy has occurred and the realization of the ending of these hopes and dreams begins, feelings of overwhelming sadness and emptiness occur.

REFLECTIONS FROM A CLIENT

"I can't believe this is true, that we've lost our baby. I want to go to sleep so that I can wake up and it will be ok. Half of my brain is screaming 'No!' while the other half is trying to list all the people to call and the things we need to do."

Grief

Grief is an intense and personal experience in response to a loss. Grief, as a response of sadness to a death, can have common characteristics, although the process is very individual. A person's response to a death or loss depends on culture, traditions, reaction to past losses, circumstances surrounding the death, and the perceived available support networks. Bowlby (1969, 1980) states that infants as young as 6 months can experience a grief reaction.

Freud's (1917) classic work was the first to connect mourning and depression. In "Mourning and melancholia," Freud separated patterns of mourning from the malignant features of melancholia, which differs from grief in that it brings with it a profound lowering of self-esteem not seen in mourning. Lindemann (1944), known best for his work with survivors of the Coconut Grove night club fire, followed the 32 survivors and the relatives of the 491 people who died in the fire. Lindemann was convinced that **pathologic grief** was a distortion of the normal bereavement process and was the first to suggest that a stoic response to death was abnormal behavior. He believed **grief work** must have three components: accepting the painful emotions involved, actively reviewing the experiences and events, and testing new patterns of interaction and role relationships. The behaviors found in normal grief work are listed in Box 37-1. Lindemann (1944) stated, "The duration of a grief reaction

REFLECTIONS FROM A CLIENT

"Seeing pregnant women or a newborn really tears me up. It should be me! Not that I wish anything bad for them, but why couldn't I be with my baby, too? I even find myself looking for babies that would be about the age of my baby having the same features, just so I could 'see' her again."

seems to depend on the success with which a person does the grief work." Lindemann's work was translated by Davidson (1979) to describe the response of the survivors-parents experiencing a perinatal death (Table 37-1).

The four stages identified by Davidson are shock and numbness, searching and yearning, disorientation, and reorganization. Shock and numbness also can occur when a prenatal diagnosis of a fatal disease or anomaly is made. Grieving parents report walking around "as if in a daze." After a birth and subsequent death, many times the mother may seem to be doing well at the wake; in reality, however, she is numb and is only responding to basic needs. According to Davidson, it is later, usually 3 weeks to 3 months, when she feels the full impact of the death and begins to realize what has occurred. By this time, the numbness has subsided and she is without the support of most family and friends.

As the shock and numbness stage comes to an end, searching and yearning begin. Davidson describes the searching and yearning phase as being characterized by restlessness, anger, guilt, and ambiguity. Searching is the need to identify what has happened and who and what was lost. There is yearning for what could have been. Every pregnant woman or infant the grieving mother sees is a reminder of what could have been. This also is a time for searching for details about the birth, diagnosis, and reasons for the death. Mothers report a physical ache in their arms from wanting to hold their infant, dreaming, and being preoccupied by "What if." The mother may be very sensitive to stimuli, restless, and impatient. Anger also is seen at this time. Anger is helpful because it is a real feeling and is a change from the numbness that was felt previously. The characteristics of searching and yearning peak around the time numbness has worn off and reappear with intensity at the anniversary of the death. The need to have questions answered and to gather mementos takes on renewed energy. It is an ideal time for parents to consider joining a group for support, to hear about the experiences of others, and to see how other parents are coping.

Box 37-1 Symptomatology of Normal Grief

- Acute grief: sensations of somatic distress occurring in waves and lasting 20 to 60 minutes
- Feeling of tightness in the throat
- Choking, with shortness of breath
- Need for sighing (recovering the oxygen level in the body)
- Empty feeling in the abdomen
- Lack of muscular power
- Intense subjective distress described as tension
- Frequent crying
- Slight sense of unreality
- Preoccupation with the image of the deceased
- Preoccupation with guilt ("If only . . .")
- Irritability and anger
- Restlessness
- Lack of energy

Lindemann, E. (1944). Symptomatology and management of acute grief. *American Journal of Psychiatry*, 101, 141–148.

Table 37-1 Normal Characteristics of Stages of Grief

Stage of Grief	Characteristics
Shock and numbness (24 h–3 wk)	<ul style="list-style-type: none"> • Resistance to stimuli and denial • Difficulty in making judgments • Impeded functioning • Emotional outbursts • Stunned feelings
Searching and yearning (3 wk–4 mo, with occasional recurrences)	<ul style="list-style-type: none"> • Extreme sensitivity to stimuli • Anger and guilt • Restlessness and impatience • Ambiguity • Testing of reality
Disorientation (intensity lifts by 7 mo)	<ul style="list-style-type: none"> • Disorganization • Depression and lowered self-esteem • Guilt • Anorexia • Awareness of reality and increasing acceptance of death
Reorganization (18–24 mo)	<ul style="list-style-type: none"> • Sense of release • Renewed energy and the ability to plan for the future • Better judgment • Stable eating and sleeping patterns • Stabilization of old relationships and formation of new ones

Davidson, G. W. (1979). *Understanding mourning*. Minneapolis, MN: Augsburg Publishing.

According to Davidson, just as the searching comes to an end, a sense of disorientation is felt. Disorientation usually occurs 5 to 6 months after the death and peaks just before the first anniversary. Clients may feel disorganized and depressed and may speak of feelings of guilt. This reaction is common; it is now that they are aware of the reality of the death and emptiness this loss has brought and no longer are testing what is true. This may be a time of weight loss or gain, difficulty with sleep patterns, and physical illness. Disorientation often diminishes after the grieving person has completed a cycle of “firsts” without the child they had expected; that is, they have experienced the first Mother’s Day or Father’s Day, Thanksgiving, birth and death anniversaries, and other significant dates. Experiencing these events is crucial to grief work and constitutes some of the most difficult moments in the grief work. If clients are in a support system at this point, the resources to help them through each of these significant dates are invaluable. During this time of disorientation, there has been a low-level sense of reorganization. The client may report a brief period of renewed energy, a “new normal.” As the first 18 months pass, there is a sense of release and a pattern of stable eating and sleeping habits. This begins to occur because clients have survived the cycle of firsts and now have life experience without their “wished for” child. At the end of the second year, the client and family begin to understand what has happened and reconcile this into their lives. By no

means are they over the death. They have only just begun to understand the impact of and will forever be changed by these events. They continually will strive to “keep it together” and at the same time understand there is something—someone—missing.

REFLECTIONS FROM A CLIENT

“When this first happened, I could not even catch my breath. I felt like I was drowning. Now I look back, and I can’t imagine how I survived. I believe I am stronger for having had her. Her life does have meaning, and it will affect the rest of my life. I will never forget her. I am a different person now, with different expectations, especially about child-bearing. I no longer believe that you get pregnant and then you have a healthy baby. I know there is so much more that happens—that can happen—and that it’s a miracle to have a healthy baby!”

REFLECTIONS FROM A CLIENT

"I felt as if a weight had been lifted. I didn't miss her any less, it just was different. I didn't think of her with sadness every moment of the day. Now when I think of her, it may be about what we might have been doing if she were here. She's always in my heart. I'll always carry her with me."

Even though Davidson's research identified trends, it is important to remember that there can be wide variations between persons. Some parents report that the numbness is gone after the first 24 hours; others say it takes a few weeks. Most parents report a feeling of reorganization after all the first anniversaries have passed (around 18 to 24 months). Most parents find relief in understanding the complexity of grief and its variable reactions as well as the emotional and physical exhaustion that often accompanies grief. Consequently, it is important to assess individual personal responses to grief and to plan nursing interventions accordingly. Davidson used his findings in combination with the vision of Sr. Jane Marie Lamb to create the basis for the first international perinatal grief support program called SHARE Pregnancy and Infant Loss Support, Inc. This program has been a model for professionals and a critical link for families since the late 1970s.

Loss of a Dream

According to Peretz (1970), loss is simultaneously a real event and a perceptual or symbolic event. Perception clearly can create intense reactions. Some women who are committed to a vaginal birth but then must deliver by cesarean section react to this birth process as a loss. The woman perceives she has lost the experience of a normal vaginal birth. Parents often develop expectations or dreams about the pregnancy and infant. Even though the parents are unclear about the appearance of the child, they have aspirations and hopes attached to the child's future. When the pregnancy is terminated or when the infant dies, all of these hopes and dreams are crushed. They never will be fulfilled, and the parents experience great sadness around what might have been. This same sadness and emptiness can occur with each milestone that would have occurred if the child had lived. For example, first steps, the first day of kindergarten, graduations, and weddings remind parents of what could have been, and they revisit the loss at these times. It is helpful to talk about these dreams.

REPRODUCTIVE LOSS

Reproductive loss can include monthly menstruation for the infertile couple, miscarriage, preterm birth, birth of a child with an anomaly, death of one or more of a multiple gestation, intrauterine fetal death, neonatal death, relinquishment, and sudden infant death syndrome (SIDS). All of these losses result in the process of grief, which varies in length and intensity. Grief can cause physical and emotional distress and is a process of remembering. The nurse's role is to create a safe environment and provide support so the client or couple can recognize how this crisis will affect their lives and thus begin the work of grieving. The term *grief resolution* is a misnomer. It is inaccurate and leads to the false assumption that parents get over the loss of an infant. They will never get over the death of their dreams for the child. Parents will talk about an infant 10, 20, and even 40 years after the death as though the event happened yesterday. The nurse in different settings, over time, can help the survivors as they work through the grief and incorporate the meaning of this loss into their lives.

Nurses working with a family in crisis must be consistent, especially in the use of concepts and terminology. The ability to have common nomenclature and definitions is critical to education, discussion of issues, and understanding concerns related to perinatal loss and bereavement. Refer to the Key Terms section for common nomenclature.

Fetal Death

Even though fetal death through spontaneous abortion Carson (2000) is the most common reproductive loss (occurring in 2 out of every 15 pregnancies), historically our society has not recognized this event as being significant. Over the past 15 years, however, religious leaders and funeral directors have noted the move toward families wanting services and burial or cremation for their losses that have occurred before 20 weeks' gestation, whether or not there is an identifiable fetus. The client may not recognize the depth of the impact of this pregnancy loss because her support system has no outward expression of sympathy. Fetal loss that occurs in the first trimester also may symbolizes a loss of self because at this point in the pregnancy the fetus is not yet perceived as a separate person. Reconciliation of this loss occurs when the client or couple acknowledges that the outcome was not within their control.

Postmiscarriage distress is identified by perceived physical and emotional trauma at delivery and emotional distress related to poor follow-up (Lee & Slade, 1996). Because of the possibility that a follow-up program or support group would lessen the emotional distress, written resources and a telephone number to use when needed should be part of the discharge information.

Therapeutic abortion is the termination of a pregnancy by medical intervention owing to a fatal anomaly or risk to the mother's life. Two procedures are used. Dilatation and curettage (D&C), which is opening of the cervix and scraping of the uterine lining to empty the contents, can be done in the surgical suite of a labor and delivery unit. Dilatation and evacuation (D&E), in which suction is used to remove the products of conception, also is a surgical procedure. Regardless of the circumstance, a feeling of sadness and regret may be experienced. When an abnormality in the fetus is diagnosed, the client or couple are given a choice. If the mother's life is not in jeopardy, the choice is to end the pregnancy now or let nature take its course. The decision must be made quickly in most cases because test results usually are not available until around the time of fetal viability. Once beyond that point, most hospitals in most states will not permit a therapeutic abortion to be performed. Families who undergo elective abortion, for whatever reason, experience loss.

In addition to the termination of a pregnancy owing to a fatal diagnosis, some families who are grappling with the excitement and fears of a multiple pregnancy are faced with the decision of selective reduction to save the remaining fetuses. Whether multiple gestation is due to fertility drugs or naturally occurring, the human body is not structured to maintain multiple gestations. In many cases, the client will have complications, with preterm labor being the most common. In order to do the greatest good, a recommendation may be made to decrease the number

of developing fetuses, to give the remaining babies the nutrition, circulation, and room they need to have better outcomes. When a decision of this magnitude must be made, it is critical to recognize there will be unanswered questions and the need for information. Written materials for the client to take home are beneficial because she may be unable to absorb and retain new information easily.

When a multiple pregnancy is progressing well and one (or more) fetus dies, either before or after birth, the grief response becomes more complex. The parents are attempting to attach to the surviving infants while grieving the loss of the one who has died. Bowlby (1980), who identified the tasks in attachment, said it is humanly impossible to attach to more than one human being at a time. When parents are attempting to attach to several infants and to grieve for the one who has died, their emotions are confusing. As they plan for the burial of the one who has died, the parents will have to work to get to know the surviving infants. The attachment process may be interrupted as the parents grieve. They may rationalize that the sibling died so that the others could live. Because this situation is unique, it calls for a specialized type of grief work. Support programs exist for families who experience a multiple gestation pregnancy in which not all infants survive.

Once fetal movement is felt, parents are filled with hope and expectation. They feel a level of comfort knowing there really is a separate living person in the mother's womb. Antepartum death at this point usually occurs suddenly and without warning. Spontaneous labor usually begins within 2 weeks of the death. When the death is diagnosed before delivery the knowledge that the fetus is dead will result in great emotional difficulty for the mother. She may be given the option of having labor induced. Because she has a sense of helplessness and disbelief, however, the mother may choose to wait until labor begins spontaneously. During labor, she has hope that everyone is wrong, resulting in the conflicting emotions of hope and dread. Her pain is heightened, and the need for pain management is critical. The mother staying alert during the delivery and being able to see her infant allows her to confirm what the infant looks like and to connect the infant with her family. Being able to see and touch the infant facilitates the grief work. Mementos of the infant's life inside the womb become precious. Ultrasonographic pictures may be the only tangible evidence of the infant's existence.

REFLECTIONS FROM A CLIENT

"They told us we had a choice! Therapeutic abortion or delivery of a dead fetus? What kind of a choice is that? We want our baby. At first we were in shock, but when they said we only had 3 days to decide, we had to pull ourselves together and ask some questions. Our questions were mainly about how sure they were and if there was anything that could be done to save our child. We never even asked about the procedure or thought about how we would feel after the procedure. What a terrible position to be in, to have to make this decision. No one else could truly understand the chaos churning inside us."

Loss of the Perfect Baby

Once the pregnancy test result is positive, a woman begins to plan. She knows the possible due date and begins to fantasize about her child's future. This trajectory of hopes and dreams that may extend into the child's adult years can be halted abruptly by the birth of an infant who does not meet parents' expectations or by the death of the

Critical Thinking

Fetal Demise

How do you feel about entering the room of a client whose infant is dying? Will your need to “make it better” cause you to use clichés or try to find a reason for parents? Will you choose to limit your contact with the client because of your discomfort? Or, can you sit down and listen to the family’s story?

infant. Parents will grieve the loss of their expectations: a full-term healthy boy or girl with certain features. They also must grieve the loss of the idealized infant before they will be able to adapt and attach to the real child. Parents of premature infants and infants who have anomalies or deformities will ask themselves how a thing such as this could have happened. As the parents attempt to attach, they also have concerns that the child may not survive. The roller coaster of emotions may be overwhelming. Nurses can be most helpful by listening to parents without making judgments. The degree of their grief reaction may not be equal to the level of severity or critical state of the child. It is the personal meaning of the anomaly or the reaction to the shock of not having the child they imagined that will give form to the grief.

Once a child is born, parents are relieved. Even when the infant is born prematurely, parents believe something can be done to help their infant survive, especially since technology has improved so much in recent years. In many cases, something can be done. It must be remembered, however, that these parents have been thrown into the role of preterm parents without warning. It is frightening to see one’s infant for the first time attached to equipment and wires. Most staff of neonatal intensive care units (NICUs) have a good working knowledge of what it takes to orient parents to the unit and the importance of getting them involved as early as possible as parents. Supporting the new mother to provide breast milk for her infant from the beginning—even though it may be weeks before it can be used—helps foster the parental role. Care of the infant by parents continues to show results in the infant through improved weight gain and response to therapy. If the infant were to die in the NICU, the interdisciplinary care team would continue to work with parents to assist them in making the transition from having the hope of taking their infant home to having the needs involved in the death of a child. The death of an infant will have a life-long effect on the family. The care provided to them in the

Nursing Tip

SPIRITUAL ASSESSMENT

Routinely include the chaplain in the admission process so that a spiritual assessment can be done. Valuable information gained related to the religious and cultural beliefs that surround birth and death will assist the nurse in planning care for families of infants in crisis.

hospital and the follow-up care during the first 18 months after the death will shape their future.

Sudden Infant Death

If the child is healthy at birth or is premature and survives the neonatal period, graduating from the NICU, the family will be given instructions on what to do to decrease the risk of SIDS. **Sudden infant death syndrome**, or **SIDS**, refers to any death of an infant that is unexpected and in which a thorough postmortem examination, medical history, and case study demonstrate adequate care before death (www.sidsalliance.org). Infants are most at risk for SIDS during the first 6 months of life. SIDS usually occurs during sleep, with no evidence of disease.

Relinquishment

Relinquishment refers to a mother’s decision to give up her right to parent her child. Doing so may cause silent grieving that needs recognition. By carrying an infant to term, the feelings of attachment and detachment are simultaneous. A woman who goes through the birth process and then relinquishes her infant will experience a grief process that is prolonged and that may intensify over time

REFLECTIONS FROM A CLIENT

“Why me? All my friends are sexually active. Why was I the one to get pregnant? It’s so unfair to me and my baby. I couldn’t even look at a couple with a new baby without getting angry. I knew adoption was the right thing to do for my baby, but deep down I still did not want to give him up.”

Nursing Tip

KEY ACTIONS FOR WORKING WITH MOTHERS WHO ARE RELINQUISHING

1. Prepare the birth parents for hospitalization and delivery. Explain their rights, discuss their options for contact with the child, and ensure that decisions and information are provided in written form. Include information on the grief process early in all discussions.
2. Validate the importance of the birth parents' roles. Recognize the birth mother's contribution to the child's life through caring for herself during the pregnancy and the work of delivery. Naming the infant is another way to validate the experience and give the birth parents someone for whom to grieve.
3. Encourage the birth parents to see, hold, and spend time in private with the baby. According to Roles (1997), one of the main regrets of parents who give up the right to parent their child is the decision not to see the infant.
4. Reconfirm the commitment to the adoption decision. Doubts that arise must be discussed immediately with the social worker or counselor before consent forms are signed. Parents need to understand the adoption law that rules the waiting period, that they have the opportunity to change their minds, and the irrevocability of the consent once the form is signed.
5. Assist the birth parents in creating memories. Just as it is recommended that mementos be created for parents grieving the death of an infant, the same rationale applies here.
6. Acknowledge the birth mother's role. Give ample opportunity during the postpartum period for the birth mother to discuss the pregnancy, labor, and birth, especially because the opportunity may be limited once she returns home.
7. Treat birth mothers with respect. When mothers are able to care for their infants for a short time after the birth, they may have less guilt in the future. When they choose this option, birth mothers will need the support, reassurance, and teaching provided to all new mothers.
8. Validate the significance of the loss. Be aware of the normal grief response and provide education about it to birth mothers. Offer resources that can be used immediately after discharge.
9. Be creative in ways the birth parents might say good-bye. There are booklets, such as a "Service in Giving a Child in Love," and "Given in Love," by Maureen Connelly from the Centering Corporation, that offer suggestions. Beginning to write in a journal or writing a letter to the adoptive parents and one to the child explaining why this choice was made and including the birth parents' medical histories can be helpful for all involved.
10. Encourage open dialogue and support. Refer the parents for family counseling.
11. Act as a neutral advocate. Facilitate information about issues, such as legal rights and rights to information, while birth mothers are in the hospital.

Adapted from Roles, P. (1997). Birth parents' grief: Relinquishing a baby for adoption. In J. R. Wood & J. L. Esposito (Eds.). *Loss during pregnancy or in the newborn period: Principles of care with clinical cases and analysis*. Pitman, NJ: Jannetti Publications.

(Davis, 1994; Askren & Bloom, 1999). This incomplete loss may contribute to the chronic aspect of the grief. The reasons for the relinquishment and the decision to have an open or closed adoption will be factors in the experience. The nurse caring for the woman at the time of relinquishment can be supportive by acknowledging the loss and the significance of the child to the birth mother. As the client goes through the labor and delivery process, the nurse should give her the opportunity to describe her decision to place the child for adoption. The nurse should work with the client to create mementos that have meaning for the birth mother. The nurse must recognize that the

mother will experience shock as she goes through the confusing feelings of pride and joy when she give birth and the feelings of pain and sadness in the process of letting go.

The client may describe feelings of depression as the shock of relinquishing her infant diminishes. Everything will remind her of the infant that is no longer with her. Fatigue, sleep disturbances, and changes in eating habits are part of the grieving process. As described previously, anger and guilt occur during the searching and yearning stage. When a woman experiences anger while in the hospital, it may indicate a perceived lack of free choice, being

overwhelmed by the legal issues, or the feeling of being rushed. When anger is noted, the social worker or chaplain can be an excellent source of support during this critical time.

Feelings of guilt are manifested by “If only.” The mother may make statements such as, “If only I had made different decisions. . .,” or, “If only I had listened, I would not be in this situation.”

The birth mother recognizes that her choices are limited. She chooses to give her child the best chance possible and wants to be an advocate in the adoption process. Many choices follow the initial decision, including whether to see and hold the infant and receive mementos of the birth. The client needs to let go of the parental role and define what it means to be a birth parent. Despite the pain, she may feel a sense of release when the responsibilities of parenting are transferred to the adoptive parents, especially if she believes they are trustworthy and prepared. Because the grief process often is a lifelong experience, clients’ reactions to relinquishment can differ greatly. In an open adoption, the birth mother is able to spend time with her child subsequent to the adoption and continue to know the decision she made was the best at the time. Thus, the birth mother continues her work to accept and reconcile her loss and incorporate its meaning into her life.

Because many birth mothers do not realize they will experience a normal grief reaction, an opportunity exists for education and preparation. Clients may have been told before delivery about grieving; however, a sense of denial exists that may hinder learning. Clients may experience **anticipatory grieving**, which is an emotional response based on the perception of a potential or expected loss. When clients are hospitalized and faced with the reality of the decision, it is important to have someone there to listen to them and to provide resources so that follow-up and support are available after discharge.

GRIEF RESPONSE

Supporting clients during the grieving process in the hospital is critical because it is a window of opportunity to assist the parents to begin a healthy grief process. The parents will be faced with learning a new role and decision-making at a time when they are in shock and least capable of making informed decisions. Flashbacks to painful moments when the problem was first diagnosed and the events surrounding the birth and death of the infant are very common. Flashbacks are an attempt by the grieving parent to put together more of the puzzle of what happened during the crisis. When assessing a grieving client, understand these are normal reactions. In addition, be aware of the signs and history that would put this client at risk. It is the responsibility of each caregiver throughout

the client’s experience to make observations, document concerns, and access resources. Whether assessing a client in the doctor’s office, the hospital, or as part of a community health visit, it is essential to include an assessment of the grief response. The nurse needs to understand that clients will not do their grief work sequentially but will move through the process, touching on each stage as needed. In the assessment, a discussion of the personal meaning of this pregnancy and the meaning of the loss for the client will help the nurse identify the client’s progress in terms of the grieving process. With 20% of confirmed pregnancies ending in miscarriage and women stating that miscarriage is not perceived by medical staff as important or an emergency (Lee & Slade, 1996), it is little wonder that a woman would question herself. Self-esteem is diminished when no one confirms her reaction as being normal and a part of the grieving process.

DEPRESSION AND GRIEF WORK

The early assessment of women at risk for depression (Janssen, 1997) can be done during hospital admission. Symptoms of depression can be identified and incorporated into the plan of care (Table 37-2). Continued assessment of the risk for depression should be done as measured by the Munich Grief Scale, which assesses anxiety and depression from the time of the initial loss to 3 months after the loss. A post loss assessment also should be considered between 3 and 18 months to identify the progress of the grief work and the reorganization phase. This is the time when grieving parents can sense a level of release and have identified how the child’s life and death can be incorporated into their lives.

Nursing Alert

POSTPARTUM RISK

When you hear something that sounds like a flat affect or hopelessness during a follow-up phone call following a perinatal loss, you need to document and act on the observation. You can say, “I am concerned, and I would like you to talk with someone. Are you willing?” If the concern is severe, do not hang up. Instead, ask to speak with a family member and suggest bringing the client to the emergency room. Contact social services or a nursing psychiatric liaison to support your efforts.

Table 37-2 Normal Grief and Depression Assessment

Normal Grief (Beutel)	Early Assessment of Women at Risk for Depression (Janssen)	Continued Assessment of Depression Risk (loss to 3 mo)	Postloss Assessment of Depression (3–18 mo)
<ul style="list-style-type: none"> • A state that changes with time • Note a process of confronting the loss • Gradual detachment from the person who died • Shock, preoccupation, resolution • Feelings of sadness • Feelings of loneliness • Feeling the world is empty • Positive social support 	<ul style="list-style-type: none"> • Previous prenatal loss • No living children • Previous psychiatric problems • Longer length of gestation before loss • Older maternal age 	<ul style="list-style-type: none"> • Verbalizing feelings of dejection • Irritation • Guilt • Alienation from others • Feelings of emptiness • Gloominess and despair • Sleep disturbances • Altered food intake • Loss and pain that may not be direct focus of attention 	<ul style="list-style-type: none"> • No change in state • Dwelling on loss • Continued feelings of dejection, irritation, and guilt

A prospective study of risk factors predicting grief intensity following pregnancy loss. *Archives of General Psychiatry*, 54, 56–61.

DYSFUNCTIONAL GRIEVING

Dysfunctional grieving can be described as extended, unsuccessful emotional response to a perceived loss. Dysfunctional grieving is difficult to assess early in the grief process owing to the emotional and physical aspects of the normal process of grief. However, follow-up telephone calls, physician's office visits, and support group participation provide opportunities to assess the client for dysfunctional grieving.

Avoidance

Families and professionals alike can be well-meaning in their attempts to lessen the emotional pain of loss and death. The use of clichés in the hope of helping the bereaved feel better actually can cause more pain, upset, and anger. Trying to move the client past the pain by talking about the future and not talking about the experience is a disservice. Doing so gives the message that grief can be bypassed and life can continue as before, or that it is not

appropriate to discuss what has happened and the associated feelings. The only way to get beyond grief is to experience it. If attempts are made to suppress the extreme emotional upset caused by the loss, the results can lead to pathological grief (Box 37-2). Nursing interventions should be supportive. The supportive intervention should be open to discussion, questions, and clarification of factual information. It also will help to focus on the individual client's emotional state. Teaching parents about grief work and what others have found to be helpful can open their eyes to what is ahead and allow for a good foundation from which they can progress.

Prolonged and Exaggerated Grief

Because there is no hard and fast rule for the length of time one should grieve, prolonged grief is difficult to recognize. As stated earlier, it takes at least 18 to 24 months before many clients feel a sense of reorganization. This

Box 37-2 Behaviors in Pathological Grief

- Overactivity without a sense of loss, or activities that bear a resemblance to those of the deceased.
- Symptoms belonging to those of the deceased.
- Initial episodes or exacerbations of diseases known to be associated with stress or psychosomatic conditions, such as ulcerative colitis, rheumatoid arthritis, and asthma.
- Alterations in relationships with friends and relatives owing to feelings of irritability and a marked desire to be left alone, which leads to progressive social isolation.
- Furious hostility against a specific person, particularly professionals, such as physicians and nurses.
- Affectivity and conduct resembling schizophrenic behavior often as a result of attempting to hide hostility.
- Lasting loss of social interaction patterns that also can include lack of decision-making and lack of initiative to participate in social activities without the intervention of a friend.
- Activities detrimental to personal economic and social existence, including spending large sums of money or engaging in activities, such as excessive drinking, leading to job loss.
- Agitated depression, including tension, agitation, insomnia, feelings of worthlessness, bitter self-accusation, and suicidal tendencies.

does not mean they have finished grieving. In fact, they are now able to recognize exaggerated grief, and they have some experience of what they need to do when they feel overwhelmed by the memory of their pregnancy loss or infant death. According to Janssen et al. (1997), the definition of complicated or pathological grief has not been universally established. Only 10% to 15% of mothers have an extreme response and meet the criteria for a psychiatric mood disorder. Within this group, a history of mental health problems was identified. The risk exists for an episode of major depressive disorder within 6 months after a miscarriage or infant death in women who were childless and those with a history of major depressive disorder (Carrera, Diez-Domingo, Montanana, Minguez, and Monleon, 1998). Clients may have an exaggerated response to a loss that is dependent on the definition of a so-called normal response. Keep in mind that culture and tradition play a role in a person's response to a crisis. The assessment for this situation is to recognize previous losses or

depressive reactions in an admission history, be available to listen, and create a plan to involve professionals able to respond to symptoms of depression that go beyond normal perinatal bereavement.

Multiple Losses

A situation that can exacerbate depression and serves as a red flag for the nurse is a history of multiple losses within a given time frame, usually a 12-month period. When thinking back to types of losses as discussed by Peretz, multiple losses can include the loss of other pregnancies or loss from a multiple gestation, or more commonly, the death of another family member or close friend. Multiple losses also can include other types of losses, such as job loss (for either the mother or father) or being involved in a natural disaster, burglary, or assault. When losses multiply or are “stacked” one on another, there is inadequate time and energy to appropriately grieve and work through each event before the next event occurs (Kowalski, 1996). Consequently, the coping mechanisms for subsequent losses are lacking and behaviors can become abnormal or pathological, with depression being a common occurrence. The intense feelings, search for understanding, and search for an answer to the question, “Why me?,” complicate and confuse the perinatal loss situation, thus making the grief work much more difficult. Therefore, it is imperative that the nurse discover multiple losses in the admission assessment database. With this information, appropriate interventions can be developed.

Chronic Grief

The term **chronic grief** has been used to describe the prolonged and recurrent sorrow felt by parents whose child has a serious physical anomaly or mental disability but does not die at birth (Kowalski, 1987). Chronic grief also can occur after an infant's death and is predicted mainly by a lack of social support. According to Kay, Roman, & Schulte (1997), factors associated with the intensity of grief include previous poor adjustment to a death, loss of a planned pregnancy, not seeing the baby, marital problems, presence of a surviving twin, subsequent pregnancy within 5 months of the loss, and multiple losses within a short time.

Isolation

Because the death of a child and the associated hopes and dreams are very deep and personal experiences, it is not unusual for a woman to draw into herself, becoming physically and socially isolated. This isolation usually lasts for a brief period during which the client takes time for herself to try to understand what has happened. When a client

continues to seek isolation and is preoccupied with the memory of the child who has died, there is need for intervention. Unless a caring family member brings the situation to the attention of a trained professional, the person may continue to move further away from contact with others.

SOCIOCULTURAL ISSUES

As parents and families respond to difficult and tragic events, the nurse observes the social network surrounding them that influences the experience. The funeral, a memorial, and prayer services are the sociocultural rites of passages associated with death. These transition rites benefit parents and their relationship to the social group rather than the infant. These rites are personal in their focus but societal in their consequences, and they are influenced by the cultural beliefs of each ethnic group. Through these rites of passage, the body is prepared for disposition and the bereaved are assisted through their process of shock and social reorientation. Such rites of passage make it possible for the entire social network to adjust to the loss of a human being. Through the shared experience, many times bonds are enhanced among members of the social network or family. Bereaved parents are in need of support from members of their social network. They need assurance that their feelings are understood and normal. Congruency in the perception of the loss between the parents and the social network facilitates the bereavement process (Kowalski, 1996). When there is incongruence or lack of common experience or beliefs, the network may be unable to provide support. In perinatal loss, members of the social group sometimes do not recognize the importance of the infant because they did not know the infant. A critical dividing point can arise when the bereaved parents are unable to share the experience with family or close friends. Some religions do not have a standard for recognizing the death of an unborn infant or one who dies before the first birthday, which may cause the parents to feel that their faith is not supporting their needs. Parents can seek a shared perspective of the death in other ways, including participation in bereavement support groups and attending an annual memorial service at which their child's life is recognized. Through a shared experience and common perspective, the healing process can begin. Failure to receive appropriate support may result in pathological avoidance of the intense emotions of acute grief.

Religious Practices and Spirituality

Spirituality is broader than religion. It is an important aspect of wellness and is indispensable in nursing care (Wright, 1998). *Spirituality* can be defined as the ability of

the human person to decide how much he or she will adopt of the various physical, intellectual, social, political, and religious stimuli by which we are influenced, and thereby engage in a continual process of defining meaning. When spirituality is considered along with physical and psychological care, a more stable approach to grief support can be provided.

This perspective of loss and bereavement focuses on shared beliefs or, perhaps, a whole attitude or approach to one's very existence. Spirituality refers to the personal search for meaning and purpose in life, whereas religion refers to beliefs and practices associated with organized groups such as churches or synagogues (Fitchett & Handzo, 1998). Kowalski (1984) found that parents who were in a closely-knit religious congregation perceived the death of an infant in a similar way: "We may not understand why this tragedy occurred. However, God, who is all-knowing, understands. God loves us and will help and support us through this very difficult time; the parents and the baby will be reunited together in the afterlife."

Some Native American beliefs (Warrick, 1993) provide techniques for expressing fear and loss. In one Native American spiritual context, it is believed that everyone has *medicine*, that is, a healing energy that is always available and accessible. Within this spiritual context, a bereavement counselor is viewed as a friend whose function is to remind us that there is goodness in our hearts and the task is to bring forward that goodness.

It is important to include a spiritual assessment in the admission process, especially if a crisis has been identified. The spiritual assessment provides guidance as to the type of spiritual care needed and the ability to work from a recognized framework. Using the client's religious leader or the chaplain of the hospital, an assessment can help guide supportive action, such as relying on prayer for comfort or relaxation. Here are some examples. Muslims may request that the patient's bed face the Holy City of Mecca and that after death the body to be washed three times by a Muslim of the same sex as the one who has died. An Orthodox Jewish family may request the patient's bed sheets be buried with the body if they contain bodily fluids (Paulanka & Purnell, 1998). Again, some faiths do not have a prescribed way of dealing with the infant death.

Creating Memories and Finding Meaning

In perinatal loss, couples need ways to create memories. In harmony with their beliefs, a blessing, baptism, or naming ceremony can be created to recognize the infant-individual for whom they are grieving. If the ceremony is to be performed before the baby is born (or surgical procedure is begun), it can be done on the mother's abdomen. Prayers,

Figure 37-1 A memory kit may help grieving families preserve precious moments of their baby.

chants, and readings can be done by the family in the informal setting of the client's room, chapel, or later in their place of worship. Resources to assist in planning a farewell service are available, such as *Bittersweet, Hello . . . Good-bye*, edited by Sr. Jane Marie Lamb (1988). These types of rituals are important to families who want to celebrate a life and keep the memory of these moments in their hearts forever (Figure 37-1).

EFFECTS OF LOSS ON THE FAMILY

Pregnancy loss is experienced by the woman as a loss of part of her being. In most cases, the father's grief is not the same as that of the mother. Immediately after pregnancy loss or infant death, a couple may feel a closeness created by the crisis. This is a survival mode that begins to fall apart as the differences in expectations surface. A father often will take on the active protector-provider role of planning the funeral, managing the household and returning to work. Being around people while performing all these functions allows him repeated opportunities to talk through the experience. Fathers receive reinforcement for this role of "doing" and for behaving with stoic strength. Yet, fathers often verbalize feelings of being left out when asked by co-workers how the woman is doing. They may feel that no one is asking about their feelings.

A woman experiencing a pregnancy loss feels an emptiness she cannot describe; her arms ache, and tears come easily. She may exhibit outward signs of grief, which

Client Education

Neonatal Loss

Because many couples separate or divorce after a perinatal loss, nurses can be instrumental in facilitating coping. It is often helpful to inform families of the following:

- That there are patterns of grieving, such as those described by Davidson.
- That individuals grieve according to their own timetable.
- That the grieving process is not linear and many times a person may have conflicting feelings.
- That the mother and father may be experiencing different feelings at a given time and this sometimes leads to conflict. For example, one person is experiencing anger whereas the other is experiencing guilt.
- That men and women express their grief and feelings in gender-scripted ways. For example, women may be more comfortable expressing sadness and crying than men; conversely, men may be more comfortable expressing anger than women.
- That an understanding of these aspects of the grief process is the basis for the couple to communicate and support each other through the grieving process.
- That if there are other children in the family, their understanding and expression of grief and loss varies with their age.
- That resources are available to help the couple with grief and to help them work with their children.

can be very healthy because they are a safety valve for stress. When the mother is tearful, the father may try to maintain control. The differences are significant, and each wonders if the other will ever understand. They ask themselves questions, such as "Will she ever stop crying," and "Did he love or want this baby as much as I did, since he doesn't show his feelings?" Unless the couple is able to talk about and respect each other's differences, this conflict can escalate into a serious relationship problem.

To avoid this additional stress, the support team at the hospital can prepare the couple by identifying tasks that create a strong bond for their relationship. Reading materi-

als that explain normal grief are helpful to guide expectations. Supporting the parents as they talk about the experience (each from their own perspective, without making the other person's viewpoint seem wrong), is a positive learning experience. It is very helpful to provide a list of resources parents can contact as needed that includes the support contact person at the hospital (nurse, chaplain, social worker, or physician), support group meetings in their area, and the names of professional counselors or therapists. Ideally, support will come from several sources: one's self, one's partner, and the community. Community includes people, activities, meditation, faith, self-help groups, education, and counseling (Simonton & Mathews-Simonton, 1978).

Issues of Intimacy and Communication

Owing to physical and emotional issues, intimacy can be difficult to re-establish after the ending of a pregnancy or death of a child. The woman is recovering from a vaginal delivery or surgical procedure. Many things can inhibit the desire for closeness: feeling tired; experiencing pain, cramping, or mood swings; and having breast tenderness. In some situations, sexual intercourse reminds the client of her infant and of how all this pain began, and deep sadness occurs. There can be a need for intense physical contact to escape the emotional pain temporarily. Because of the wide variations in needs, the focus must be on communicating the desire for intimacy because the partner may not be able to determine what would be fulfilling. In most cases, couples re-establish intimacy by holding each other and talking, actually scheduling quiet time together. Taking 5 minutes, five times a day to hold each other can go a long way toward renewing feelings of security at a time when the pervasive feeling is that of being out of control.

Gender Issues Related to the Grief Response

Although gender differences are not clear-cut, the responses of the man and woman can be influenced by tradition and cultural gender roles. As parents move beyond the initial period of shock and numbness, two types of physical reactions occur. The grieving person can be inwardly or outwardly bereaved. Persons who are *inwardly bereaved* do not find comfort in talking or crying with others. More effort is put into work, sports, and physical labor than ever before. They attempt to stay in control by staying busy and not thinking about the emptiness created by the loss. Clients who are *outwardly bereaved* appreciate speaking about what has happened and why, processing the information out loud. Tears, anger, signs of frustration,

and confusion are common. The outwardly bereaved show emotions and receive support when someone listens, especially if it is another grieving parent. The task at this point is education. Parents will need to identify which type of bereavement style each person exhibits and provide the appropriate support. Nurses also can help the parents understand the difference in grief coping styles and timetables, which will help parents support each other at a time when relationships can be strained.

Communication

When attempting to teach or communicate with grieving parents, nurse assessment of their roles within the family is a key caregiving point. When speaking with the woman as the client, keep in mind that if she is hesitant to share information or make decisions, it is not necessarily because she does not understand or cannot decide. It may be that in her culture, the male head of the family makes all decisions regarding the family, even if the woman does not agree. When speaking with a man, keep in mind that many men find it more comfortable to speak about emotional topics when they are occupied with something else. Talking may come much easier if, for example, the nurse walks with the man to get something to drink rather than sitting face to face and talking. To some men, especially when under stress, eye-to-eye contact is confrontational. In contrast, women generally want to look into your eyes and see the truth and when trying to comprehend the depth of what you are saying. Therefore, the method of delivery may be more important than the message itself. The grieving parents need to be made aware of the different communication styles. They also need to know that they cannot be everything to each other, especially during a crisis. They need to talk things out between themselves; however, they also need to discuss the issues on a different level, or with a different focus, with their friends. Communication problems sometime arise from persons being unaware of their true feelings. Only through talking in different social circles will meaning and understanding begin to surface.

Traditional support groups may not be helpful for the bereaved male. Chethik (2000) recognizes four categories of male bereavement. Doers are the most common who cope by walking, running, and building. Doing things allows for processing and a gradual release of energy. It would be difficult for these men to sit in a circle during a parent meeting and discuss how they feel. It is by doing that they begin to understand their feelings. For many men, self-esteem is reinforced with accomplishment. A father may see the death of his child as his failure. Unable to protect his family and unable to fix things, he may feel a loss of control. The woman may want him to fix things, to make things right. The result is anger. He is angry about

the loss. He believes he is responsible for a solution and blames himself for causing the pain, or he feels guilty because her body must do all the work of the pregnancy and things are not going well. The failure may be in the form of genetic defects, inability to save the infant, inability to stop the birth process, or even inability to move God to work a miracle. He has a need to feel useful. To do so he searches for a solution, which may take the form of questioning. Given this information, the nurse can begin to help the couple understand there are differences and different needs during this crisis. In this way, the parents are educated to avoid the pitfalls of having expectations that cannot be fulfilled by the other.

Grandparents

Many couples express frustration when they speak of the response of their own parents to their loss. Yet, these are the persons from whom the grieving couple most expects to receive support and understanding. This may be problematic, however, because close family members also are grieving. A grandparent is experiencing the death of a grandchild and the pain of not being able to make things better for his or her own adult child. Grandparents are at a loss as they search for the right thing to say or do, and can be perceived as not caring when they do not talk about feelings or bring up the topic of this baby's death or pregnancy loss. Grandparents, other family members, and friends may try to minimize the pain by using clichés such as "You're young; you can have another baby" or "There probably was something wrong with the baby." These statements can cause confusion and anger because they send the message that *this* child is not important. The feelings of the parents may be hurt because they are attempting to make sense out of what has happened.

Parents will be able to receive the type of support from their family that will help them through the grief process if the staff educates the family on the importance of listening, limits of the parents ability to cope during the shock phase, individual nature of grief, and possible intensity of grief over the ensuing 18 to 24 months.

Siblings

Johnson (1989) states, "We fail to recognize that by teaching our children about death, we also teach them about life and joy." Death is part of life. Incorporating the teaching about death into everyday life best prepares children for when it happens to someone who is close to them. When children have the ability to name their emotions, feel included in the event, and feel they have family to talk with and feel secure with, then children will be able to move through the grief process (Table 37-3). When someone is very sick a child's first fear is of abandonment, especially when the focus is on the mother and the unborn baby. It is best to use words that are truthful, basic, and consistent. It is important to use the words *dead* and *died*. When parents try to make things better by saying, "God took our baby" or "The baby is sleeping," fear is instilled in children that they might also be taken. Information must be consistent and questions encouraged. When parents cry, it is important they share their feelings with their children. It can be a frightening feeling for a child to see their parents upset, and sharing the feelings can bring a sense of security to the situation. When parents are emotionally unable to support their surviving children, a plan needs to be made for a trusted relative or family friend to stay with the children during the critical moments at the hospital or, in the case of the infant's death, accompany the children to services acknowledging the death.

A child of any age can be part of saying goodbye. Vin-ing (1982) said it simply in the booklet "Grief": "the visitation is a social release of the body; the funeral is the spiritual release; and the burial is the physical release." With this in mind, staff can support parents in their decision to allow the surviving children to stay with the family during any ceremony. Children can also confirm the tangible part of death at the funeral. If it is an open-casket service, they can see that the body is not working. They can draw a picture, write a letter, or bring a flower to be put in the casket with the baby.

Many families look for ways other than a private burial to celebrate their infant's existence. Suggestions range from attending an annual memorial service to donating a tree in their child's name or naming a star. The celebration can be as creative and personal as parents like, and this is a project with which children can help. According to Bluebond-Langer (1978), adequate information and support allows for integration and synthesis of information,

GRIEF PROCESS

Well-meaning family members can be guided to assist by recognizing the parents' need to experience the pain and tears to begin healthy grief. Part of the grief process includes telling the story of their pregnancy and infant's birth and subsequent death along with the tears. Grieving also includes the process of creating mementos and putting away baby items when the parents are ready, not when everyone else thinks they should be ready.

Table 37-3 Stages of Infant and Child Development Related to Death

Age	Concept of Death	Developmental Factors
Infant (birth to 2 years)	No concept of death.	Birth–6 mo: separation anxiety is not operative. 6 mo–2 ys: strong ties between infant and mother; not okay with substitute. Death is seen as separation. Can sense sorrow and pain in others; will respond with distress.
Toddler	Death is seen as separation. No concept of permanence.	2–3-year-old: not upset with sight of a dead animal. Objects that disappear are not considered gone.
Preschool age	Distressed at separation not death.	May respond with anger. Awareness that death occurs, especially from television. Play includes car crashes and gun play. Believes thoughts can make someone die. Magical thinking—operational stage. 5–6-year-old: can talk about death but not permanence. Believe death is temporary and reversible. Can be frightened when anesthesia is referred to as being “put to sleep.”
School age (5 to 9 years old)	Sees death as permanent but not inevitable and not related to themselves.	5–7-year-old: needs to have repeated opportunities to talk. Will understand more information with each interaction. 7–9-year-old: may be curious about death. 7–11-year-old: identifies concrete causes for death (guns, poison, cancer) but is unable to incorporate into own experience.
9 to 10 years old	Believes it could happen to anyone.	Incorporates the experiences of others.
11 to 15 years old	Adultlike understanding but also into risk-taking.	Can verbalize consequences associated with high-risk activity. Belief in invincibility and that death happens to others.
Adolescent	Recognizes death as a fact of life. Meaning of life and death will vary with the individual.	Intellectual understanding does not mean emotional understanding. Intense concern with body image. Any threat to existence is a threat to identity. Can romanticize the death experience or see it as an escape.

which is the key to understanding. Understanding is not a function of age or intellectual ability.

Asking questions is how children learn, and thus they will ask many questions when a family has an infant who has died. Basic and consistent answers will best serve their long-term needs. When a parent looks to the nurse for suggestions, the nurse should respond that the goal is to stress that the child did not do or think anything that caused the infant's death. The reaction to the death will depend on the child's developmental stage. Preschoolers may believe that a wish made this happen. Allowing them to play is the best way for children to work out some of their feelings. As they play, they will come back to their parents with questions. When the questions are answered the same way each time, the young child will begin to comprehend the information over time and will feel a sense of security. It is comforting for a child to hear that it is uncommon for a baby to die and that death usually comes to those who are

very old and have lived a long life. Children also need reassurance that their parents are healthy. It also is important to explain that the baby died because his or her body was too little or too sick to survive.

School-aged children need to be an integral part of what is happening with the baby to decrease their feelings of abandonment. They are developing a sense of permanence, and they can be angry because of the unfairness of it all. They can display anger toward the baby for being sick and taking so much of their parents' time and energy, or anger toward the parents for not spending time together. When children are involved and supported in the knowledge that their feelings are normal, they will be a great source of comfort to their parents. The school-aged child may benefit from learning how to use a journal or art to express their feelings. Some children are able to write a letter to the baby and in that way release some of their emotions.

The teenaged and adolescent years are full of turmoil. When a crisis occurs during this time of major change, the focus is on finding a safe place where teenagers can work out their feelings and the meaning of what is going on with their family. Their feelings are deep and often confusing. A special time set aside to do something with their parents and a time for them to be with the dying baby or involved in the planning of the ceremony can be helpful. Whether tears, resentment, anger, or silence is exhibited during this time, adolescents need reassurance and comfort.

CARE FOR THE GRIEVING FAMILY

Over the past 25 years both research and anecdotal stories of bereaved families have appeared in the literature. In Kavanaugh's (1997) research, behaviors that are perceived by the parents as supportive include accepting parents' feelings and behaviors, being there, and sharing the experience. Families expect they will receive competent care, accurate information, and special attention (Figure 37-2). The continuum of care in supporting a grieving family begins wherever the crisis is first identified and follows the client through the experience. Having some type of structure available during a time of feeling out of control, can be reassuring for all parties involved. This holds true for families receiving a fatal prenatal diagnosis and those ex-

Figure 37-2 Placing a rose or card on the door of a client who has suffered a neonatal loss is a gentle reminder to staff of the need for sensitive care.

Nursing Tip

CARING FOR A BEREAVED FAMILY

Many of the behaviors that began in the initial crisis period must continue through the continuum of care. The following are tips for nursing care of a bereaved family:

- Recognize the initial confusion and shock.
- Provide ample time for taking-in the information.
- Repeat information as needed. Encourage parents to repeat or summarize what they have heard. Prepare written information.
- Prepare other health care workers and support their work with parents in a caring way whenever they need care in an area of the facility other than the obstetrics.
- Help parents with the logistics of admission to the facility.
- Acknowledge the difficulty in concentrating and understanding.
- Encourage the presence of a support person.
- Identify important cultural and spiritual practices.
- Provide opportunities for the client to tell her story.
- Recognize the unique aspects of the infant that binds the infant to the family, and treat the infant with respect.
- Identify and address fears as defined by the client.
- Be attentive during labor even though the baby cannot be saved.
- Provide comfort measures, such as music, massage, whirlpool baths, and family support.
- Support the client to experience the many emotions that may arise during labor.
- Refrain from comments that attempt to fix or minimize the parents' experience.
- Facilitate holding the baby as the parents desire.
- Create mementos consistent with hospital practices.
- Support sharing the experience with other family members.
- Discuss options regarding funeral or memorial services.

Critical Thinking

Grief Process

Many parents experiencing the death of an infant are in shock emotionally. They initially think it would be easier not to see and hold their baby, have a photograph, name their baby, or have a private burial.

- Do you think these activities can assist the parents in their grief process by identifying the infant?
- How would you assist them to recognize the importance of mementos and rituals in their grief process and still support their needs?

periencing a stillbirth or neonatal death. Woods (1997) states: "Patients have expectations that their physician will supply answers to the following questions: What does this horrific information you have provided mean; how did you arrive at this terrible conclusion; is my own health at risk/(spouse) is my wife at risk; do we know everything we need to know; what are my options; how quickly do I need to make decisions; in what order must these decisions be made; how will I respond to questions from my family; how will I tell my children?" Another question might be "what if you are wrong?"

Bereavement Program

It is important to come together as a community to recognize the children who have died and the hopes and dreams carried by their parents. An annual memorial service or walk to remember that is sponsored by the hospital is an excellent way for families and staff to come together to recognize the life and death that occurred at the hospital. It also allows staff to reconnect with families and see how they are progressing with their grief work after the hospital experience.

The knowledge gained from families' input is invaluable to learning. The follow-up mechanism of a bereavement program, such as support groups where staff are invited to attend, follow-up phone calls, feedback from doctor's offices, and letters from families that are shared routinely with staff, becomes an important learning tool. This feedback can be both oral and written and can be used as the starting point for quality improvement projects. Knowing the parents' pain did not end when they left the hospital and hearing what parents have done to reconcile this death into their lives gives the staff the opportunity to

REFLECTIONS FROM FAMILIES

"I will never forget the nurse who came in and spent time with us. I know she had other patients and it probably would have been easy to say she was busy. I feel she spent quality time with us by listening to us, allowing us to piece together what happened, and even crying with us. She validated that what happened was very significant and that our baby was very precious. No matter what the gestation or diagnosis, he still was our baby."

improve actions taken in the hospital during the crisis. Families do not easily forget the face or name of the nurse who helped them through the beginning of their nightmare, nor do they forget what was helpful and not helpful during that time. Take every chance to learn the client's perception of the experience because it can be very different from how you perceived the hospital stay. Box 37-3 lists the rights of parents, siblings, and the baby when an infant dies. The rights were developed by the Perinatal Bereavement Team at Women's College, Toronto, Canada, and adapted by the SHARE Pregnancy and Infant Loss Support, Inc. They are used worldwide to guide care and set standards (Levine, 1998).

Care for the Caregivers

One of the most difficult things nurses are required to do is to stay focused in the moment with someone who is experiencing intense psychological pain. Seldom is this pain more intense than at the death of a loved one, particularly a child. There is grieving for the loss of a significant human being, the newborn baby. There also is loss of all

REFLECTIONS FROM A NURSE

"The death of a child is a fire in the mind—a fire that burns a long time, for no other loss is so difficult to accept; no other loss feels so utterly un-natural. It is a loss beyond comprehension."

Box 37-3 The Rights of Parents and Baby when an Infant Dies

Rights of Parents when a Baby Dies

- To be given the opportunity to see, hold, and touch their baby at any time before or after death within reason.
- To have photographs taken of their baby and made available or held in security until the parents wish to see them.
- To be given as many mementos as possible, that is, the crib card, baby beads, ultrasound pictures and photographs, a lock of hair, feet prints and handprints, and a record of the baby's weight and length.
- To name their child and bond with their child.
- To observe cultural and religious practices.
- To be cared for by an empathetic staff who respects their feelings, thoughts, beliefs, and individual requests.
- To be with each other as much as possible throughout the hospitalization.
- To be informed of the grieving process.
- To be given time alone with their baby, allowing for individual needs.
- To request an autopsy. In case of miscarriage, to request to have or not have an autopsy or pathology examination performed as determined by applicable law.
- To have information presented in terminology understandable to the parents regarding their baby's status and cause of death, including autopsy and pathology reports and medical records.

- To plan a farewell ritual, burial, or cremation in compliance with local and state regulations and according to their personal beliefs, religious beliefs, or cultural traditions.
- To be provided with information about support resources that assist in the healing process, that is, support groups, counseling, reading materials, and perinatal loss newsletters.

Rights of the Baby

- To be recognized as a person who was born and died.
- To be named.
- To be seen, touched, and held by the family.
- To have the ending of life acknowledged.
- To be put to rest with dignity.

Rights of Children when a Sibling Dies

- To be acknowledged as persons who have feelings that need to be expressed.
- To be given the choice to see and hold the baby before and after the death within reason.
- To have the option of being considered in the choices parents make.
- To be informed about the feelings of grief in our terms, giving us the choice of a support group or counselor.
- To be recognized by our society that we will always love and miss our sibling.

Lammert, C. (1991). Rights of children when a sibling dies. *SHARE Pregnancy and Infant Loss Support, Inc.*, 1, (3).

the hopes and dreams that surrounded the child. There is grieving for the loss of the future because children, in many respects, are our future and our link to immortality.

Nursing Responses

Working with families suffering the intense pain of a death can stimulate memories of nurses' own losses. When the loved one is a newborn infant or a wanted pregnancy, multiple aspects of bereavement occur simultaneously. There are several perspectives from which death and grief in pregnancy reproduction can be considered. Ontology is the science of "being," focusing on "what is," concentrat-

ing on the present moment rather than the past or the future. From an ontological perspective, focusing on the present is time spent without judgment but focused on possibilities. From this point of view, persons always have choice. We choose our responses to any given situation, including the death of a newborn. During a career, a nurse can observe families and persons who spiral into depression partly because of their feelings of helplessness as they attempt to cope with a loss. The professional nurse can educate clients about choices, reality, acceptance, pain and suffering, and forgiveness of self and others in association with the loss of a much desired pregnancy (Kowalski, 1996).

Supporting the Caregivers

Because the nursing staff often internalizes losses suffered by clients and these events bring up past experiences, a feeling of being out of control and unable to help can result. Putting the client in a room at the end of the hall and closing the door to give her privacy is one way the nursing staff attempts to avoid an uncomfortable interaction with a grieving client. In contrast, a nurse may be unable to accept death and thus attempt to prolong life by encouraging heroic interventions. These actions usually only serve to prolong death. According to Karen Soto, “There is an arrogance in Western Medicine that we can cure everything, that we have the cure-all and the quick fix for every illness. But we don’t. Death is a welcome rest and source of comfort for some and we need to be gracious about that invaluable experience we will all have one day” (Soto, 1996).

Companioning as a Support Technique

Traditional bereavement care is based on the medical model in which grief is seen as an illness that demands a cure. In this model, we get a sense nurses are the experts and must fix what is wrong. This type of thinking sets up expectations that clients will recover from grief, let go, and return to normal. The more a nurse experiences death and grief with families, the clearer it becomes that this is not what happens. As educators, nurses are not experts in this family’s grief experience. When it comes to death, nurses cannot direct or guide but can bring knowledge and experience. They can support parents to begin their journey through grief instead of trying to script parents’ experiences. It is a very individual and lonely journey.

Alan Wolfelt (1998) speaks of a growth-oriented model that focuses on “companioning.” As companions, nurses can learn to be present with a person’s pain, respect disorder, listen to their heart, be still, and walk alongside the grieving person. In Wolfelt’s model, growth means change, never returning to the old self. It means encountering pain and experiencing it in doses, yet having a safe place to retreat and acknowledge the pain and growth. A new inner balance is sought that has no end point. It allows us to explore and challenge our assumptions about life while actualizing the loss and fueling the potential within.

This broad approach to grief support allows the nurse the freedom not to have all the answers. As a member of a team, which includes the family, nurses can provide resources; however, but most importantly, they must let go of the dependency of “doing” (the focus of high-tech) and look to the idea of companioning of “being” (high-touch) with families. The opportunity to listen with the heart, one example of being, is almost a lost art as we depend more

and more on machines to tell us what is happening with clients. By listening and empathizing with the crisis that is occurring inside these grieving parents, the nurse has the responsibility to create a safe place where they can touch the pain and not feel as though the nurse needs to eliminate the pain—to fix it. The sense of loss of control, disorder, and confusion in grief work, needs to be acknowledged. From these depths will come a higher functioning person, one that can experience healing. The nurse can use compassionate caring to discover the gift of silence, recognizing there is so much going on within the newly bereaved that often they have no ability or energy to speak. There is no expectation for the nurse to fill the silence. Just being still and paying attention can support parents who may fear being alone during this tragedy and give them the space to express their feelings and their experience without interruption.

Staff Education and Support

Few nursing care situations produce more anxiety than being left alone with a grieving patient or family. The first few times a nurse cares for such a client, an experienced nurse or the bereavement resource person should be present. The nurse needs to feel supported to sort through the feelings and responses stimulated by working with parents in intense psychological pain who are in shock and denial. An overview of the bereavement program also should be included in new staff orientation for nurses and physicians. This overview could include the philosophy and goals of the program; the process used to support families (such as checklists, books, consultants, and mementos); and most importantly, an organized opportunity to discuss concerns and past experiences.

Ongoing education and support for staff, even in tertiary care centers in which death may occur more frequently, is pivotal to the well-being of the staff. An example of supportive education is a discussion that focuses on case studies and ethical issues emphasizing difficult situations. Key points in these discussions might include those found in Box 37-4.

Care Team

Identify key unit and hospital support team members. The ideal goal is to minimize the number of staff who interact with the family. A bereavement resource person can work through the main team members by coaching them or joining them when time does not allow for coaching. Team members can include the bedside nurse and physician, the chaplain or family’s religious representative, the social worker or counterpart, a close friend or family member, the parents, and the dying child or baby. Each member of the team can assist the family at different times with

Box 37-4 Key Discussion Points in an Educational Session after a Stillborn or Newborn Loss

- Never underestimate the supportive power of your peers.
- Offer opportunities to express emotions and gain an understanding of the management of the case.
- Schedule debriefing sessions as close as possible to a major incident.
- Encourage staff to hear all sides of the situation without judgment.
- Work to establish feelings of trust and support.
- Recognize your own response regarding how you can learn and grow from the experience.
- Work to build confidence in the staff in supporting grieving parents.
- Perform an annual review of the program, philosophy, and goals, with input from staff.
- Create a clinical competency that ensures all staff, including the nurse, doctor, social workers and chaplains, have a basic understanding of perinatal grief.

different information. One of the nurse's most important roles is to slow the pace of the events (such as decisions, information, and phone calls) and involve the family to ensure understanding of each aspect of the process they are experiencing. Recognize that what professionals see during the hospital stay is only a glimpse of what has occurred and how families are responding. For the care team to be able to acknowledge the intensity of the crisis, ongoing education of staff and the use of resources are necessary.

Ideally, the members of the team should meet the client before she is in advanced labor or before the surgical procedure occurs. Thus, the work to be done after the delivery or death of the baby will not be complicated by introducing new personnel. In the delivery room, recognize the unique aspect of the birth when a child has died or when lethal anomalies have been discovered. Heavy sedation will compound the psychological needs of the grieving parent and delay the reality. In turn, the grief response will be delayed. Remember that the mother needs to say hello and goodbye at the same time. No limit should be placed on the time the mother spends with her infant. She needs to be included in bathing and dressing the infant. Depending on the mother's customs and beliefs, there may be very specific procedures for this part of the care of the body. Remember that the mother will never

*Nursing Tip***NON-ENGLISH-SPEAKING CLIENTS**

A one-page information sheet in bulleted format that highlights the most important issues a parent might face must be available for your non-English-speaking clients. Examples of content follow: a policy on finding an interpreter; types of questions they can expect to be asked; burial options; policy on photographs; religious and spiritual resources. This document needs to be translated by a certified individual or company (or preprinted booklets can be used). When you use a member of the client's family or staff as the interpreter, always document the person's name and relationship to the client in your notes. Include the chaplain, social worker, and grief support person in the plan of care.

have another opportunity to do these things for her infant. Include a private place where family can join her to help share her grief. Having family members present also will make the transition to home easier because she will know that others saw her baby.

Allowing the mother to go home soon after a D&E or D&C does not provide the best support to the family. They have little to no time to process what has happened, ask questions, and learn about the grief process. At the very least, each family needs to leave the hospital with a phone number for a support program, an appointment for medical follow-up, and instructions written in understandable language. To be consistent, many hospitals have gone to a task checklist or a set of guidelines. For examples of these lists see the following references: Brost & Kenny, 1992; Calhoun, 1994; Hutti, 1988; Lawson, 1990; 1988; Mueller, 1991; Null, 1989; Rosas & Rosas, 1987; Ryan, Corte-Arsenault, & Sugarman, 1991; Weinfield, 1990; Welch, 1991; Wheeler & Limbo, 1990; Woods & Esposito, 1987.

*Nursing Tip***PRENATAL DEATH**

If the pregnancy ended at 10 to 16 weeks' gestation or the infant was stillborn, the infant can be viewed. Care must be taken owing to the delicate nature of the fetal tissue. Many hospital programs have a special cradle or basket to bring the infant to the parents for viewing.

NURSING PROCESS

Implementation of the nursing process is very useful in working with bereaved parents and their family and friends. The nursing process provides a structure to make certain that all steps in caring for a family experiencing loss are addressed. The following is an example of the process to help nurses begin thinking in this way about perinatal loss.

Assessment

When making an assessment, the nursing history is the first step. The areas that are important can be discovered by asking the following:

- Did the parents have days or even hours of advanced warning that the baby was dead or very ill? Are there medical complications for the mother?
- Was the pregnancy wanted or unwanted? When a pregnancy is unwanted, one or both parents can exhibit a combination of guilt and relief that appears different from the feelings exhibited in a planned pregnancy.
- Were there multiple losses? Parents who have had other pregnancy losses or other significant losses often feel overwhelmed and lack fundamental coping mechanisms.
- How do their religious beliefs or culture support them? Parents who have very strong religious or cultural beliefs often have a structure of support that can be very helpful.
- Are there close friends or family who share the same culture or beliefs, and are they able to help? Seek information from family and friends regarding beliefs and customs.
- What are the size and type of social connections within the network of friends and family that surround the parents? What is the relationship between the infant's mother and father? These relationships can make a huge difference in how parents handle the loss and progress through the bereavement process.
- Do the parents, family, and friends express their feelings regarding the loss? Does evidence exist of anger, tears, guilt, sadness, shock, and numbness?

Nursing Diagnosis

Problems need to be identified on an individual basis because each family unit will cope with loss differently. Examples of some general nursing diagnosis include the following:

- Fear related to the initial diagnosis of infant death as evidenced by increased tension and expression of horror or dread.
- Ineffective coping related to gender differences in coping strategies, uncertainty, inadequate social support, a high degree of threat, or disturbance in the pattern of tension release as evidenced by a lack of goal-directed behavior, poor concentration, destructive behavior toward self or others, or fatigue.
- Spiritual distress related to perinatal loss as evidenced by energy-consuming anxiety, physical or psychological stress, loss of a loved one, or poor relationships.
- Health-seeking behaviors related to effective managing of adaptive tasks by the family as evidenced by the family moving in the direction of a health-promoting and enriching lifestyle that supports maturational processes.

Outcome Identification/Planning

Planning for desired outcomes must be constructed with the participation of the mother and her partner. Planning also could involve friends and family:

- Mother and father will be able to work through the bereavement process, each at their own pace, with understanding and support for one another.
- At 1 or 2 years after the loss, the parents will be able to identify positive growth for themselves from the experience.

Nursing Intervention

The nurse needs to take the following actions with the client and her partner:

- Physical care. After delivery, the mother has the same needs as does a mother whose baby was born alive. Do not forget breast engorgement because there is not an infant to empty the breasts. Sleeping medication is

Web Activities

- Develop a plan of care for a family with a single parent, siblings, and grandparents who are coping with a perinatal loss.
- Visit three of the grief websites listed in this chapter. Compare the information they offer for families and health care provided.

Case Study/Care Plan

CLIENT EXPERIENCING INTRAUTERINE FETAL DEMISE

Bonnie is registered nurse in a labor and delivery ward of a busy county hospital. She has her bachelor's degree and has been working on this particular ward for 2 years. Her morning assignment includes care of a laboring patient, Mrs. Kay, a 29-year-old Caucasian American, gravida 1, para 0, with an intrauterine fetal demise (IUD) at 36 weeks' gestation. Mrs. Kay entered the hospital last night at 3 a.m. with complaints of contractions. She and her husband were not aware there was a problem with the baby because her pregnancy had been without complications. Mrs. Kay was diagnosed with a term IUD shortly after admission. Owing to the rapid progression of her labor, Mrs. Kay has not had much time to grieve. She currently dilated at 6 cm. The report from the night shift reveals that Mrs. Kay received intravenous Demerol, which had been controlling her pain until the last 30 minutes or so when she started becoming restless. No support services were activated because the admission had been in the middle of the night. Mr. and Mrs. Kay are new to the area; all their family and friends live 500 miles away. Although their immediate families have been notified, there are no plans for them to come at this time.

Assessment

Mrs. Kay lay in the labor bed staring out of the window. Her face is stained with tears. Her husband is sitting quietly with his hand on hers, and there is no verbal communication between the two. Her contractions are coming every 3 minutes, and she breathes hard and cries out with each contraction. Between contractions, Mrs. Kay tells Bonnie that she is in terrible pain and that she is frightened about delivering the baby. Mrs. Kay also states that she and her husband would like to see a member of the clergy.

Nursing Diagnosis

Pain as related to contractions associated with active labor as evidenced by crying out and an accelerated respiratory rate.

Expected Outcomes The client-family will be able to manage the pain experience through partner support, breathing techniques, and medications.

Planning Pain management and support are interventions aimed at assisting the client now.

Nursing Interventions

1. Use pain medications that do not alter alertness.

Rationales

1. Although the client may feel distressed at this particular time, mind altering medications will only prolong the grieving process. The woman also may grieve the inability to remember her baby.

Evaluation As is the healing process, evaluation is ongoing. Management of pain in the intrapartum period while soothing fears and anxiety may be monitored by the labor nurse. Effective management of the client may be evidenced by the client stating she has little pain or is pain-free while also monitoring mental alertness.

(continued)

not usually helpful because it dulls the feelings and delays coping until after the client has left the hospital, when she cannot receive help as easily.

- Psychological and emotional care. Keep parents and families informed and together. Support seeing and holding the infant and create memories, including

photographs and mementos. Support decision-making regarding paperwork and disposition of the infant's body. Encourage choices and an increased sense of control. Listen.

- Educational care. Provide educational pamphlets and booklists. Discuss the bereavement process.

Nursing Diagnosis

Fear related to delivering a dead infant, as evidenced by the client's apprehension and increased tension.

Expected Outcomes The couple supports each other through the labor process, with help of the nurse, clergy, physician, and other support members.

Planning The nurse must plan interventions aimed at assisting the client and family with immediate and future needs.

Nursing Interventions

1. Use coaching techniques for labor and encourage use. Speak softly and respectfully.

Rationales

1. The client's response during labor usually is focused on what is happening from moment to moment. By providing support, encouragement, and direction, the nurse may help ease the client's anxiety and fear.

Evaluation Levels of anxiety and fear may be monitored by verbal and nonverbal cues from the client and family.

Nursing Diagnosis

Spiritual distress related to perinatal loss as evidenced by energy-consuming anxiety, psychological stress, and loss of a loved one.

Expected Outcomes Work through the grieving process at their own pace with understanding and support for each other.

Identify positive growth for themselves from the experience.

Planning Consultations with the clergy and grief counselor may assist the client and family in the near future.

Nursing Interventions

1. Follow institution guidelines to create momentos: footprints, photographs, and certificates.

Rationales

1. Momentos are helpful in assisting the family move through the grieving process. Parents may desire to look at these reminders of their baby for years to come.

Evaluation The family is meeting with a grief counselor and or clergy; this is just the first step in a long journey.

Encourage questions. Address issues, such as burial arrangements, funeral, or memorial service; and telling the other children, family, friends and strangers who know the mother was pregnant. Identify the available resources, such as support groups, reading materials, and websites.

- Follow-up. With much briefer hospital stays today than in the past, follow-up is even more important. It is critical to have a physician follow-up visit scheduled.

There may be community follow-up available with a public health nurse. Some facilities have a perinatal loss clinic in which clients receive special attention.

Evaluation

Ongoing evaluation of the bereavement process is important. Encourage couples to seek help and support. Facilities that have a significant volume of deliveries need a

nurse or social worker who is responsible for follow-up phone calls to see how the couple is managing. Issues, such as subsequent pregnancy, need extensive discussion as to when, where, and how it fits into the bereavement

process. It is evident from the previous example that working with families experiencing loss is not easy. Doing so requires thoughtfulness and strong communication and listening skills.

Key Concepts

- Nursing care and support for parents and families when a pregnancy ends or a baby dies, constitutes a difficult nursing intervention in an environment that is supposed to be happy, exciting, and focused on new life.
- Understanding the theories of loss and attachment and how they relate to reproductive loss can assist the nurse in planning care for the grieving family.
- The concepts of gender differences and cultural variations have major impacts on reaction to the loss.
- When caring for clients at any point during a reproductive loss, it is the individualization of the plan that

will give the family the best opportunity to successfully grieve the loss.

- Using resources that include hospital policies and staff, support programs, written materials, and websites will best prepare the caregiver when the opportunity arises to care for a grieving client.
- Reproductive loss can be meaningful, growth-producing and may have positive aspects when the nursing staff can look at this death and loss and create the best possible experience for this family, given the intensely painful situation.

Review Questions and Activities

1. There are some identifiable phases in the bereavement process that always occur in the same order, one step at a time. True or False?

The correct response is false.

2. Saying, "I know how you feel," will help the family to know that you care and will ease the expression of their grief. True or False?

The correct response is false.

3. Mementos and pictures are important for grieving parents. True or False?

The correct response is true.

4. Parents should be encouraged to join an infant loss support group. True or False?

The correct response is true.

5. List three feelings that parents may display in response to their loss.

6. List five ways that caregivers can be sensitive to the emotions and needs of parents.

7. List the four phases of the grief process as described in this chapter.

8. Which of the following would not express a feeling parents may have regarding their loss?

- a. Anger
- b. Guilt
- c. Easy decision making
- d. Loss of control

The correct response is c.

9. Construct an active listening exercise to stress the importance of listening to rather than talking with bereaved parents. For example, practice in dyads what it feels like to dominate the conversation, not listen to the other person, and interrupt. Then practice empathetic listening.

10. Build a case example (preferably one that has happened to the instructor or someone in the class) and then conduct a debriefing, educational meeting, or discussion of staff response to the example using the guidelines in Box 37-4.

Community and Home Health Care Nursing for the High-Risk Infant

Current health care practices have forced nurses to focus on creating new ways to provide high-quality care while keeping down costs. Health care delivered during home visits can significantly benefit high-risk infants and their families. These benefits are evidenced by improvements in maternal health, mother-infant interaction, infant health and development, and overall family function. Home health care nurses need to take the lead in delivering health care in the home to promote continuity of care for high-risk infants. This type of intervention is important in the health care surveillance and maintenance of high-risk infants and their families.

Barrier to service utilization

Follow-up services

Home care

Home care nursing

Competencies

Upon completion of this chapter, the reader should be able to:

1. Discuss the significance of home care in the present health care delivery system.
2. Describe the nurse's role in home care to promote and maintain the health of infants and families.
3. Discuss a nursing model with application to the home care of infants and their caregivers.
4. Explore significant factors in the environment that influence the health of infants.
5. Apply the nursing process to home care.
6. Discuss the standards of care for home visiting of high-risk infants.

One of the most heartening indicators of the improvement in health in the United States during the 20th century has been the steady decrease in the infant mortality rate. Between 1950 and 1987, the U.S. infant mortality rate decreased from 29.2 per 1,000 live births to 10.1; the rate in 1998 was 7.2. The U.S. international ranking is 26, which indicates that the infant mortality rate is higher in the United States than in many other countries worldwide. The continuing disparities between minority and majority populations represent a major health challenge. In 1987, the mortality rate for African American infants was still more than twice that of Caucasian infants. The infant mortality rate in 1998 was 6 for Caucasians and 14.3 for African Americans. Neonatal deaths were 4.8 overall, 4.0 for Caucasians and 9.5 for African Americans based on a denominator of 1,000 live births.

Infant mortality rates provide a summary measure of the effect of major health threats to the developing fetus and newborn baby. For every 10 babies who die, however, 990 live. Some of those who live have been harmed, often permanently, by unhealthy beginnings. In the United States, complications of prematurity account for more than 70% of fetal & neonatal deaths annually in infants without anomalies (Colombo & Ians, 2000). The quality, not just the quantity, of their lives is a function of health during the prenatal and infant periods. Although overall infant mortality rates have declined, there has been no improvement in preterm birth rates (American College of Obstetricians and Gynecologists [ACOG] 1995). The incidence of preterm births also has increased from 9.4% in 1981 to 11.9% in 1997 (a 20% increase) (Ventura, Martin, Curtin, Mathews, & Park 1998).

Technology has contributed significantly to the improved prospects for infant survival over the past several decades. Neonatal intensive care, new surgical techniques, and other medical interventions save lives and overcome conditions that formerly guaranteed lifelong disability. Opportunities for primary prevention offer new frontiers for improving infant health in the coming years. Some opportunities will result from breakthroughs in understanding the genetic origins of human diseases; most will be in areas of personal lifestyle and use of existing health interventions.

ECONOMICS AND HOME HEALTH CARE

The 1990s marked the transition from hospital-based care to home care for chronic conditions (Stutts, 1994). In neonatal medicine, this move to home care was directed by motivation for health. The goals of health care providers are to assist families in identifying health needs and in developing problem-skills using the family's own resources. To meet these goals the nurse needs to identify the family's perception of healthy or unhealthy practices, which greatly influences participation in health-promoting activities. Age, gender, educational level, cultural orientation, financial status, and occupation influence health perception. If parents believe the infant is more susceptible to a health problem they will become more motivated to adopt the behavior (Pennacchia, 1994).

The family as the unit of care has long been the focus of home care nurses. In **home care nursing**, nurses de-

liver care in the home environment. Many clients who receive home health care would not be able to remain in their homes if it were not for family members who devote themselves to their care (Bradley & Alpers, 1996). Therefore, the basic and most important approach when addressing health promotion and disease prevention issues with a client is through their family. According to McCarthy (1994) it is in families that children and adults are nurtured, provided for, and taught about health values by word and example. It is in families that an individual is socialized and first learns to make choices that promote personal physical and emotional health.

The nurse's role is to help the parents recognize the infant's susceptibility and the potential consequences when good-quality health practices are not used. The nurse must work within the family's health perception framework to become acquainted with the characteristics that strongly influence the infant's health. Unless caregivers meet their own needs, they will be less able to meet their infant's physical and mental needs (Janosik & Green, 1992). The nurse supports the parents, building up their parental confidence and self-esteem, providing information in meeting the infant's needs, and reinforcing their health perception and management patterns (Pennacchia, 1994).

The nursing process guides and supports the family and nurse during the development of a plan that will enhance wellness or solve problems or potential problems. This process and encounter can occur in multiple settings. Home care services have become a rapidly expanding and popular area of health care in the past 5 years. The home is a natural environment for all families. Members of different age groups—infants, children, and older persons—are apt to be more readily available in the home. The home health care nurse also can observe firsthand the physical environment during the home visit. The nurse can see the whole family as a unit, observing mealtime rituals, roles of family members, and interpersonal interactions. Including each member of the family in the visit will provide the nurse with a broader perspective than will observing and interviewing an isolated member. During the home visit the nursing process is carried out *with* the family and not *for* the family; the family becomes a partner with the nurse in all phases of the process (McCarthy, 1994).

Using a systems perspective when working with a family to enhance health promotion and disease prevention, the nurse's role includes the following tasks (McCarthy, 1994):

- ✿ To become aware of family attitudes and behaviors toward health promotion and disease prevention
- ✿ To serve as a role model for the family
- ✿ To collaborate with family members in assessing, improving, enhancing, and evaluating their current health practices

- ✿ To assist the family in growth and development behaviors
- ✿ To assist the family in identifying risk-taking behaviors
- ✿ To assist the family in decision-making regarding lifestyle choices
- ✿ To provide reinforcement for positive health behaviors
- ✿ To assist the family in learning behaviors that promote health and prevent disease
- ✿ To serve as a liaison for referral or collaboration between community resources and the family

The home care nurse should enter the relationship with an open approach to assess the norms and expectations of family members, communication patterns, decision-making patterns (collectively or individually), and how family members address each other's needs. Employing the nursing process and a systems perspective when working with families during home care helps the nurse and family strive for optimal levels of health promotion and disease prevention (McCarthy, 1994).

MULTICULTURAL DIVERSITY IN HOME HEALTH CARE

The issue of cultural influence is relevant when working with clients and families, even with families of the same cultural background as the home nurse. Persons in a nurse-client relationship should respect each other and appreciate each other's diversity. Cultural influences can directly affect the health care practices clients turn to for healing. For example, a person may turn to an alternative health care practitioner because of a language barrier, lack of trust, and lack of satisfaction with the treatment plan provided by the Western medical or nurse practitioner. Therefore, culturally competent nursing care promotes the well-being of the infant and family and should be a major component of providing family-centered home care services (Ahmann, 1996). Cultural traditions provide a sense of security that families refer to for guidance, comfort, and dealing with stressful situations, that is, the health-illness of their infant.

A **barrier to service utilization** is any real or perceived deterrent that prevents or delays use of available health care. These barriers may have underpinnings of social or cultural influences. According to Spector (1994) innumerable barriers of a social nature, including poverty, language, and transportation, restrict infants and their families from using health care services in ordinary and expected ways. The major factor is poverty because it restricts a person's access to these services. Other barriers

Critical Thinking

Foster Care Practices

EM is a Caucasian male born at 26 weeks' gestational age to a mother who uses cocaine. His urine drug screening test was positive for cocaine. Child protective services placed EM in foster care after hospital discharge. EM was released to an African American foster mother at 7 months of age. The foster mother could not participate in his care during the hospital stay. EM's medical history includes having a gastric tube in place for feeding and apnea of prematurity for which he remains on an apnea monitor and medication.

- What are some of the cultural issues related to an African American foster parent raising a Caucasian infant or vice versa?
- What are some American cultural values reflected in the process of placing this infant in a foster home?

may include lack of childcare, inconvenience, provider characteristics, immigration status, and failure to work within a person's belief system.

Nurses must be aware of and sensitive to cultural factors that influence the client and family in seeking health care services. Moreover, the nurse should be aware of these influences when assessing a community, family, and client. A cultural assessment provides a database from which the home care nurse can obtain an idea of the client's attitudes, values, and beliefs about the world. If culture provides standards for behavior, then home health nurses should assess their own culture of health care both from the viewpoint of the culture of origin (what they were taught to believe when growing up) and from that of the system into which they have been socialized. Home health care nurses need to explore values because they form the basis for behavior (Ahmann, 1996).

HISTORY OF HOME CARE

During the early 1900s demographic changes in the United States influenced the development of the visiting nurse. Many new child and family services were developed and implemented to address the issues associated with urbanization, immigration, poverty, contagious diseases, unhealthy living conditions, and high infant mortality rates. During this time period, it was felt that environmental conditions were major contributors to personal problems and

illness. Consequently, strong efforts were directed at changing poor social conditions, particularly those contributing to illness, accidents, and infant mortality. The role of the visiting nurse continued to develop and expand, and two additional roles for service were developed: visiting teachers and social workers (Wasik, Bryant, & Lyons, 1990).

Visiting nurses also addressed preventive care in their efforts to provide home health care. By 1910, most large urban visiting nurse associations had developed and implemented preventive programs for infants, children, mothers, and patients with tuberculosis (Buhler-Wilkerson, 1985). Voluntary and publicly funded institutions, however, dominated public health and prevention efforts and voiced that these issues were in their domain. Moreover, these institutions objected to visiting nurses' involvement in prevention. Buhler-Wilkerson (1985) reported that this assertion and possession of health care preventive efforts outraged nursing leaders. Visiting nurses, they insisted, had taken the lead to teach prevention and hygiene and had, in fact, "blazed the trail" for all health department preventive program. Although debate over the roles of visiting and public health nurses in the community continued to evolve, in practice, both groups of nurses were actively involved in home care throughout the 20th century. Today, home visiting and public health nurses continue to have a strong presence in the community health arena.

The Family Preservation and Support Act of 1993 was the first major change in Title IV-B of the Social Security Act since the enactment of the Adoption Assistance and Child Welfare Act of 1980. The Family Preservation and Support Act of 1993 provides federal funding through the states for services to strengthen and support families to enable them to provide a safe and nurturing environment for their children. Services are aimed at prevention to reduce the risks of out-of-home placement and family disintegration. Through the Home Visiting for At-Risk Families (HVAF) state health planning initiative, the Maternal and Child Health Bureau (on behalf of the Health Resources and Services Administration) and the Children's Bureau (on behalf of the Administration for Children and Families) have come together to stimulate and support coordinated planning for family preservation and to support the development of systems of care that will focus on prevention and address the range of health, social, and related concerns facing families (National Center for Education in Maternal and Child Health, 1995).

RESEARCH ON HOME VISITING PROGRAMS

Olds and Kitzman (1990; 1993) provided a comprehensive review of home visitation programs. In 1993, the *Future of Children: Home Visiting* analyzed 31 randomized trials of

Research Highlight

Home Visitation and Parenting Skills

Purpose

To examine the outcomes of home visits by nurses to teach parenting skills.

Methods

Sixty-one low income, first-time adolescent and nonadolescent mothers were enrolled. Mothers were single, with a mean age of 18.5 years, predominantly Caucasian, having a low educational level, unemployed, and were living with at least one parent or sibling or with their husband. Each participant was enrolled in the Parent Education/Home Visitation Program that consisted of weekly in-home education sessions over a 6-month period. A trained female “parent educator” conducted the sessions targeted at enhancing the development of the parent and child and fostering the parent-child relationship. Outcomes were based on six variables, that is, parenting developmental expectations, parenting skill knowledge of empathy, role reversal, corporal punishment, safety of the home, and community agency involvement, in four areas:

1. Parent’s knowledge level of appropriate developmental expectations.
2. Parent’s knowledge of appropriate parenting skills.
3. Safety of the home.
4. Use of community resources.

Findings

The results indicated that the mothers had significant improvement in five of the six outcomes (all but corporal punishment). After 6 months it also was noted that adolescent mothers, compared with nonadolescent mothers, improved their scores (adolescents had lower scores than did nonadolescents at the beginning of the study) for empathy and child-parent roles.

Nursing Implications

Nursing research has shown that home health care visits to mother-infant dyads are effective in promoting support for the physiologic, behavioral-psychosocial, and family aspects of parenting. The most successful of these programs include use of nurses, structured teaching of maternal skills for infant care, long-term follow-up, additional comprehensive services and resources, flexibility and variety in outreach methods, and maternal focused support and recognition. Although not consistently supported in research, infant outcomes have purported to promote development and intelligence; improve responsiveness and interaction with mothers; yield fewer emergency room visits and fewer days of hospitalization; and result in fewer problems with temperament and behavior. Clients were also more likely to have safer homes and increased child use of health care. Research and clinical experience uphold the belief that women, and their children, at highest risk (those of low income with poor self-esteem who are young, unmarried, poorly educated, unemployed, and involved in domestic violence or abuse) show the greatest need and have the best outcomes.

Culp, A. M., Culp, R. E., Blankemeyer, M., Passmark, L. (1998). Parent Education/Home Visitation Program: Adolescent and non-adolescent mother comparison after six months of intervention. *Infant Mental Health Journal*, 19, (2), 111–123.

home visiting programs. The review was divided into five major sections: prenatal programs, programs to improve the health and development of low-birth-weight or preterm infants and their parents, programs for children from families at social or economic risk, programs designed for children with developmental disabilities or chronic illnesses, and programs that evaluated program costs and savings. Some of the noteworthy conclusions follow:

- Home visiting can promote the development of preterm and low-birth-weight infants for those families who remain enrolled in these programs.
- Teenagers who are members of families with low income and unmarried teenagers are responsive to home visiting programs.
- Programs that had professionals (nurses) or highly trained staff should produce positive effects on children's intellectual functioning.
- Professionals (nurses) and comprehensive service models produced a greater chance of influencing the quality of parental caregiving.
- The positive effects of home visiting were greatest for those at highest psychosocial risk.
- Mothers valued the nurses as home visitors because nurses addressed concerns mothers' about child health.
- Flexible programs (that allowed the frequency of contact to be adjusted to the family's specific needs) proved more successful than did programs that were inflexible.

The implications of this review by Olds and Kitzman are that not only is further research necessary but, with the increase in vulnerable families, systematic understanding of which preventative strategies are most effective is more important to uncover.

BARNARD'S NURSING MODEL

The Barnard Parent-Child Interaction Theory can be used as a foundation when working with high-risk infants and their mothers. The theory was developed from earlier work by Barnard on the Nursing Child Assessment Project, a longitudinal study that examined the developmental outcomes of children prenatally and postnatally at 1 month, 8 months, 1 year, 2 years, and 7 years (Barnard and Kelly, 1990). The three concepts of Barnard's theory are the mother, child, and environment. The mother is required to adapt to the infant's needs and demands and to use positive and negative feedback with her verbal and nonverbal cues. The infant, in turn, is required to respond to the mother through changing its behavior. The environment includes animate (other peo-

ple and animals), inanimate (toys, sounds, and objects), and the surrounding milieu. This important interaction between the three components asserts a major influence on the infant (Barnard & Eyres, 1979).

Barnard describes this mother-infant interaction as a dialogue or a mutually adaptive "waltz" between partners (Barnard, 1976). If the cues (verbal and nonverbal behavior) given by the infant are not clear or the mother is unable to recognize the cues, the health of the infant is affected, resulting in poor development and developmental delays. For example, research that investigates parent interaction links synchronous mother-infant interaction with positive developmental outcomes (Barnard, 1997).

This middle range theory deals with the mother-infant-environment relationship and suggests that the relationship between the mother and the infant will directly affect the health of the infant. The Barnard model is based on various disciplines, including medicine, child development, psychology, and sociology. The theory is testable, and several tools have been derived from the model, for example, the Nursing Child Assessment Feeding Scale and Nursing Child Assessment Teaching Scale.

Barnard also developed a program called Keys to Caregiving to present up-to-date information about infant behavior, describe the impact of caregiving, and aid nurses in translating this information to parents. For example, one of the earliest forms of infant communication occurs during feeding. It is during this interaction that Barnard focuses her attention on promoting positive caregiving behaviors. Her research has demonstrated that the absence of these skills by either partner (mother or infant) has a major impact on the nature of the caregiver-infant interaction pattern and later development (Barnard, 1980). This example illustrates how theory and research provide the foundation for nursing practice.

MULTIDISCIPLINARY TEAM APPROACH TO HOME HEALTH CARE

Collaboration in the assessment process, as an in-service provision, has two areas: collaboration between the family and the nurse or other professionals (parent-professional collaboration) and collaboration between the many disciplines that may be involved in the care of the infant and family (multidisciplinary collaboration).

To best meet the needs of the infant-child and family, care must be planned that reflects the family's values, goals, and priorities. To accomplish this plan of care, a central aspect of the assessment process is for family members to identify their needs or problems and strengths or resources. Involving families in the assessment process may be new to many nurses; however, active participation of the family

members in developing the plan of care ensures a plan that meets their needs (Ahmann & Floyd, 1996).

The nurse brings special experience and expertise to the collaborative effort. This expertise can be shared with the family in a way that can foster collaboration. The nurse can share observations, comments, and knowledge with the family in a neutral manner, that is, without value judgment and without subverting the family's central decision-making role (Bond, Phillips, & Rollins, 1994). An essential part of the assessment process is assisting the family in determining whether the infant-child or family may need additional services and disciplines not originally prescribed as part of the plan of care. Such services might include those of a social worker; a physical, occupational, or speech therapist; or a registered dietitian. Each home care agency should have preestablished criteria that can guide the nurse in deciding when such referrals are appropriate for more in-depth assessment or intervention.

As the team extends beyond the nurse and family, multidisciplinary collaboration becomes crucial. Jointly defining initial goals for the client followed by providing consistent communication among disciplines will benefit the family and staff in many ways. Close collaboration will result in more rapid attainment of goals and a higher level of desired client outcomes. Joint visits and team conferencing are two ways multidisciplinary collaboration can be facilitated (Ahmann & Floyd, 1996). Home visits by multidisciplinary teams significantly benefit the infant and family by providing education, emotional support, preventive care, and information on community resources.

Home visits for infants and families that are in high-risk environments provide not only continuity of care after hospital discharge but also play a major role in the successful development of these infants and families (Kang et al., 1995; Olds et al., 1995; Starn, 1992).

Nursing Guidelines and Recommendations for Home Health Care

The Association of Women's Health, Obstetric, and Neonatal Nurses (AWHONN) has set forth standards and guidelines for the home care of women and newborns. These guidelines state that care in the home provides an opportunity for clients to receive technical and psychological support for their particular need or problem in a familiar, noninstitutional setting. Care in the home is designed to help the client achieve an optimal level of health. The importance of considering the mother or newborn as a whole person is underscored in the home care environment. Care often is provided by a multidisciplinary team, with the nurse coordinating the components (AWHONN, 1998). This association defines **home care** as the provi-

sion of technical, psychological, and other therapeutic support in the client's home environment rather than in an institution. The scope of nursing care delivered within the home setting is necessarily limited to practices deemed safe and appropriate to be carried out in an environment that is physically separated from a health care institution and its resources.

The guidelines for providing home care to mothers and their newborns include the following:

- Women and newborns are given the same level of nursing care and expertise in the home as would be expected in an inpatient setting.
- The plan of care for the client is developed collaboratively with the nurse, health care provider, and family members, taking into consideration the various aspects of the home life.
- Nursing practice in a home care setting is consistent with federal and state regulations or Canadian provincial regulations that direct home care practice. The nurse demonstrates practice competence through formalized orientation and ongoing clinical education and performance evaluation in the respective home care agency. Standards for practice from key specialty organizations (such as AWHONN, the American College of Obstetricians and Gynecologists [ACOG], American Academy of Pediatrics [AAP], and Intravenous Nurse Society [INS]) provide the basis for clinical protocols and pathways and organizational programs in home care practice. The joint Commission on Accreditation of Healthcare Organizations (JCAHO) provides criteria for home care operations.
- The client's physiologic needs are the focus for planning. In addition, the client's social, spiritual, and psychological needs and the needs of the family are assessed and included in the plan of care. Many factors beyond those of hospital care are considered. The nurse's responsibilities may include the following:
 - Planning for comprehensive home health services, 24 hours a day, 7 days a week, with clients and families.
 - Supervising rehabilitation specialists who provide client services.
 - Acting as a coordinator in communicating a plan of care between clients and primary care providers.
 - Recording and communicating clients' responses to the plan of care and family support of the care.
 - Acting as a liaison with ancillary health care providers.
 - Developing and supervising a written plan of care for the homemaker or home health aide.

—Acting as an advocate for clients by promoting informed decision-making regarding care and orienting, supervising, and evaluating persons on the home health team as appropriate.

Home health care for mothers, infants, and families may require creative use of resources and adaptation of the more traditional methods of teaching and learning, especially in light of the limited technologic resources in the home (AWHONN, 1998).

The Council on Child and Adolescent Health, representing the AAP, published a policy statement in 1998 on *The Role of Home Visitation Programs in Improving Health Outcomes for Children and Families* (AAP, 1998). In this publication, cited and endorsed were a clear recognition of the postnatal effects of home visiting (improved maternal-child interaction, maternal satisfaction, and higher developmental quotients in infants visited), the long-term benefits (fewer maternal behavioral impairments attributable to alcohol and drug abuse), and elements of what constitutes a successful home visiting program. The recommendations of the Council included full support of home visiting programs, support for the use of home visitors as integral and active members of the health care team, and encouragement of early referral of known high-risk parents.

NURSING ROLE IN THE HOME HEALTH CARE OF THE HIGH-RISK INFANT

Home health visits are made by nurses from different disciplines. The purpose of home visits is to provide nursing care to clients and families in the home. The specific objectives and services provided by nurses vary depending on the type of agency providing services and the population served (Lyon, Bolla, & Nies, 1997). Historically, home visits were provided by community health nurses who were employed by public health departments, visiting nurse associations, and home health care agencies. These home visits focused on the investigation of chronic and communicable diseases. More recently, home visiting programs have expanded so that the major focus is on the health outcomes of the mother, infant, and family.

Home care nursing is in its early developmental stage and is getting stronger. Home care nurses practice under the direction of standards set by the American Nurses Association (ANA). Home health care nurses also can become certified in home care as nursing generalists. Many nurses are joining the home health care arena, and more research is being conducted to guide their practice (Humphrey, 1996).

The number of home health care agencies certified by Medicare increases annually. Downsizing continues in

many hospitals. Nurses leave acute care settings seeking employment in home health care. Nurses are attracted to home care by flexible schedules and competitive salaries. The challenge to the home health care management staff is to recruit and orient nurses with varied levels of educational preparation to assume the responsibilities as home health care nurses in today's environment of rapid change (Ark & Nies, 1996). Home health care nurses need to be more knowledgeable and experienced in dealing with various factors specific to home health care, for example, family structure, folk medicine, and cultural differences. Moreover, home health care nurses develop their interventions based on the community resources available.

The focus of all home visits is on the infant for whom the referral is received. The home health care nurse makes an assessment of the interaction between the infant and family then provides education and intervention. The nurse then evaluates how the infant and family interact as part of an aggregate group in the community. The need for referrals for community services is identified by the home health care nurse and made as necessary (Lyon, Bolla, & Nies, 1997).

HOME VISIT PREPARATION

Once the high-risk infant is discharged from the hospital, special care needs do not stop. Many of these infants have needs that exceed routine well-child care. Special attention must be given to their growth and nutrition, immunizations, vision and hearing, and sequelae of illnesses experienced during the neonatal period. Premature infants have an increased likelihood of long-term sequelae and continuing medical problems compared with term infants; however, many of the issues discussed specifically about prematurity also apply to term infants (Bernbaum, 1994).

Critical Thinking

Organizing Home Health Care for the Infant

When you begin home visits to a family, the following questions should be addressed:

- What is the extent of the medical and nursing care needed?
- In what time frame is the care needed (e.g., the entire day or night, or only during the waking hours)?
- What are the physical, social, and emotional needs of the parents and family?
- What are the teaching needs of the family?

Nursing Tip

SAFETY FOR HOME HEALTH CARE VISITS

Here are some safety tips for the home health care nurse (Humphrey and Milone-Nuzzo, 1996):

- Know where you are going and how to get there.
- Avoid walking down alleys or on private property to and from a client's residence.
- Avoid carrying a purse or pocketbook.
- Park as close as possible to the client's home.
- Dress appropriately.
- If you have fears about your safety while in the home (e.g., if you feel threatened by someone who is intoxicated or if weapons are evident) leave the home.
- If pets are bothersome during the home visit, insist that they be put in another room.
- Know the telephone numbers of your agency, the local police, and the fire department.
- Keep your nursing bag within your sight.
- Do not attempt to break up a domestic argument.
- Never walk into a home uninvited.

The first home visit is important for several reasons. First, it is the beginning of the relationship between the home health care nurse and the family. In all likelihood, the first visit will set the tone of the relationship and thus influence subsequent visits. Second, in most agencies, the first home visit requires the most documentation (e.g., permission forms, insurance information, and medical history). Third, the first home visit must include an immediate assessment of the infant's status and safety at home. Fourth, nursing interventions, including teaching and direct care, may be required on the first home visit (Ahman & Floyd, 1996).

TRANSITION FROM HOSPITAL TO HOME HEALTH CARE

The transition of care from the hospital to home for high-risk infants has been advanced by the increased availability of new technologies for use in the home (such as ventilators, infusion pumps, and apnea monitors) and supported by the need for health care cost containment and an increase in patient knowledge and participation in

self-care. Home care of the high-risk infant has many advantages compared with hospitalization. Such as parnatal education, social support, and linkage with community services. Home care allows for a normal environment-patient interaction and minimizes family disruption (Kerner & Bagwell, 1998).

High-risk infants have many conditions with the potential for long-term sequelae, accounting for the morbidity in this population. Having an infant who might remain dependent on technology for survival impacts the entire family unit. The normal progression and emotional preparation for parenting has been interrupted by the infant's illness. Moreover, the family also has the fears that accompany having a family member who is seriously ill or at high risk for future illnesses. Parents may exhibit feelings of helplessness, anger, grief, and depression. These feelings along with the financial burden of care may exhaust the family's financial, emotional, and physical resources. Consequently, the parent-infant interaction may be altered. Home health care helps identify issues surrounding the parent-infant relationship, helps parents deal with the illness, and supports parents caring for high-risk infants (Fleming et al., 1994).

Discharge and Home Health Care Planning

Admission of an infant to the neonatal intensive care unit (NICU) places the infant and family at risk. Because this high-risk situation will trigger others, careful discharge planning is important. Continuity of care that is directed by discharge planning can minimize fragmentation, help avoid repetition and delay, and ensure information about essential community resources is provided. By using a comprehensive discharge plan the nurse will help ensure that the family is adequately prepared to care for the infant at home. This plan should include organized **follow-up services** (health care services provided after discharge from the hospital) for the infant and family. Many high-risk infants have needs that are far from routine, in addition to requiring well-care. Attention should be given to the infant's growth and nutrition, immunizations, vision and hearing, and illnesses that may occur during the neonatal period (Bernbaum, 1994).

An accurate and detailed assessment is the basis for optimal care. The consistency of care from hospital to home provided by a primary care team enables these assessments to be comprehensive and highly individualized. Beginning with admission, the team identifies problems or needs that require special planning, intervention, teaching, or follow-up. Before hospital discharge, the needs of the infant, family, and environment once again are assessed (Cox, 1996). The results of the assessment should be clearly communicated to the nurse who will provide the home

Client Education

Information to Help Parents Understand their Infant's Behaviors

- **Infant temperament:** Infants have different temperaments that are expressed immediately after birth. These are stable characteristics and are a part of the infant's personality. Parents can benefit from a discussion regarding temperament.
- **Crying:** Infants express their needs and emotions through crying. Infants expend large amounts of energy while crying. Parents can benefit from learning to distinguish different cries and methods of calming the infant.
- **Poor feeding habits:** High-risk infants may have difficulty feeding after they go home. Nurses may need to help the family employ special feeding techniques.

health care. Ideally, the home visit should be part of a team effort. The following is a discharge planning checklist:

- ✿ The infant's medical issues are well defined.
- ✿ Medications are labeled clearly and verified before being sent home with the family.
- ✿ The home visiting nurse and family members have been given clear instructions on the use of required monitoring devices.
- ✿ Special formulas and diet have been explained to the nurse and family members.
- ✿ Instructions and demonstrations on specialized needs (e.g., shunts, gastrostomy, and home oxygen) have been given to the nurse and family.

The following should be performed before the infant is discharged:

- ✿ Metabolic screening
- ✿ Hearing evaluation
- ✿ Ophthalmologic examination
- ✿ Developmental assessment
- ✿ Blood tests for hematocrit level, reticulocyte count, and levels of theophylline and anticonvulsants
- ✿ Continuing evaluation of or serial physical examinations for medical conditions such as chronic lung disease and birth asphyxia

Every family has the right to discharge planning. Some infants will require relatively simple preparation for dis-

charge, with a focus on well-infant care and routine medical follow-up. A more complex level of planning, however, may be required for infants who have special needs. The family should be an integral part of the planning team. Including the family will improve the appropriateness of the assessment and the likelihood that the plan is realistic and can be implemented effectively (Cox & Ahmann, 1996).

Follow-up Care for the High-Risk Infant

Follow-up programs should be an integral extension of every NICU. Specialized care must be available for problems of growth, development, and chronic disease and is best provided within the setting of a neonatal follow-up program. The follow-up care initially should be provided by the neonatologist, pediatrician, nurse practitioner, developmental specialist, and community health nurse. This initial continuity of care is important to reassure the family that the same persons responsible for the life-saving decisions are continuing to assume responsibility during the child's adaptation to home life. Furthermore, even if the neonatal staff members do not continue the follow-up for a long period, they will benefit greatly by maintaining contact with the infants leaving the nursery and recognizing the sequelae of early neonatal interventions. Growth (height, weight, and head circumference), neurologic development, psychomotor development, vision, and hearing should be sequentially assessed (Hack et al., 1994).

Follow-up care after hospital discharge provides the opportunity for assessment of the infant and identification of actual or potential problems (Box 38-1). Follow-up care allows the experienced neonatal registered nurse to teach,

Box 38-1 Successful Follow-up Outcomes

- Decrease in the number of rehospitalizations during the first year of life.
- Decrease in the number of emergency room visits during the first year of life.
- Decrease in the number of acute care visits and calls to the primary care provider.
- Positive growth patterns.
- Positive integration of the neonate into the family unit.
- Client and caregiver satisfaction.
- Client and caregiver competence and confidence.
- Absence of child abuse and neglect.
- Neurobehavioral and motor stability, with positive progress toward developmental milestones.

Nursing Tip

INTERVENTIONS TO ENHANCE PARENT-INFANT INTERACTION DURING HOME HEALTH CARE VISIT

You should do the following:

- Encourage eye-to eye contact during feeding and playing with the infant.
- Discuss the importance of stimulation during “social time.”
- Identify the infant’s attributes and unique qualities.
- Demonstrate appropriate feeding positions.

provide a role model, and assess parent-infant interactions. Follow-up care promotes the transition from hospital to home. Parent satisfaction with health care is increased when individualized follow-up care is planned and coordinated before discharge. Since 1986, Brooten’s team of researchers has advocated long-term follow-up for these neonates and families (extending up to 18 months after discharge) by registered nurses with a master’s degree. In today’s health care structure of health maintenance organization and health alliances, such long-term visitation may not be feasible or necessary (Brooten et al., 1996). However, an experienced neonatal home care nurse should perform home visits. Ideally, a home visit should be made before the neonate is discharged from the hospital.

Infants at the highest risk for later neurodevelopmental problems include those who have had severe asphyxia, severe intraventricular or other intracranial hemorrhage, meningitis, seizures, respiratory failure resulting from pneumonia, persistent fetal circulation, severe respiratory distress syndrome, multisystem congenital malformations, and those born with very low birth weight (less than 1500 g) (Hack, Klein, & Taylor, 1995).

THE HOME HEALTH CARE VISIT

The first home health care visit in the postdischarge period should occur within 24 to 48 hours. This visit should include physical, developmental, nutritional, and social-environmental assessments; obtaining blood for laboratory tests; specific teaching; and referrals.

Physical Assessment

Assessment by systems should follow this sequence (Humphrey & Milone-Nuzzo, 1996):

Nursing Alert

RED FLAGS DURING HOME HEALTH CARE VISITS

During the home visit you should be alert for any red flags specific to the overall health of the infant. *Red flags* refer to the physical, emotional, or social aspect of infant behavior or appearance that requires attention or further investigation. Red flags provide clues to possible problems: social, emotional, growth and development problems; inadequate nutrition; parenting difficulties; environmental (safety) concerns; illness; and abuse and neglect. Some general red flags regarding health might include the following:

- Vomiting
- Diarrhea
- Slow development
- Noted change in any behavior (e.g., sleep and appetite)
- Constant crying
- Weight change
- Feeding difficulties
- Color changes
- Less responsiveness
- Stiff or limp (muscle tone)

1. Weight
2. Length
3. Head circumference
4. Thermal stability
5. Fontanel: size and shape
6. Vital signs, peripheral pulses, and auscultation of heart and lung sounds
7. Color: dusky, pale, cyanotic, or jaundiced (validated with pulse oximetry when indicated)
8. Sleep-wake cycles

Developmental Assessment

A development assessment or screening should always be included in follow-up care of the infant. We recommend the use of the Bayley Infant Neurodevelopmental Screen (BINS) initiated at 3 to 4 months corrected age. The Bayley Screen needs to be administered and interpreted by trained personnel. In order to evaluate the development of parent-child interaction as it unfolds, Barnard suggests the use of Nursing Child Assessment Satellite Training (NCAS

Nursing Tip

NURSING ASSESSMENT

The following questions are helpful in conducting a nutritional assessment:

- Is thrush present?
- Does the caregiver prop a bottle in the crib?
- How are utensils, bottles, and equipment sterilized or cleaned?
- Is a pacifier used? If so, how is it cleaned?

scales), particularly feeding and teaching, to support parent-child interaction. Both the BINS and NCAST scales are reliable and valid measures for positive infant growth and development and positive parenting. These scales provide outcomes data for the problems and development of interventions, and a method for outcomes to be evaluated.

Nutritional Assessment

A nutritional assessment will include the following:

- ✦ Assessment of breast-feeding, bottle-feeding, or alternative method of feeding
- ✦ Assessment of formula preparation
- ✦ Assessment of breast-feeding technique, breast care, pumping, and storage of breast milk
- ✦ With any feeding method (enteral, parenteral, or both), the following must be assessed: the volume being delivered; success of the feeding; frequency of feedings; urinary and stooling patterns; indications of intolerance; and most importantly, weight gain.

Social and Environmental Assessment

Social and environmental assessment helps identify potential health risks and barriers that may pose problems for the infant or family. Areas to assess include the following:

- ✦ Parent or caregiver interaction with the infant, ideally through the use of the NCAST scale, otherwise by observing the caregiver's handling of the neonate and sensitivity to stability and stress cues
- ✦ Parent or caregiver coping skills
- ✦ Availability of support such as community, financial, extended family, home care professionals, equipment companies, and employers

Client Teaching

The High-Risk Infant

Parents of high-risk infants often have the need to learn about parenting and general infant care as well as infant medical needs and procedures. The following are some teaching ideas for families of high-risk infants:

- General infant care: bathing; cord care; circumcision care; feeding techniques; nutritional needs; how to dress the infant for weather changes; sleep-wake patterns; a supportive environment; infant stability and stress cues; growth spurts, that is, what to do and when to expect them
 - General safety issues, including crib safety
 - Recommended sleeping positions and association with the prevention of sudden infant death syndrome (SIDS)
 - Signs and symptoms of dehydration, fever, hypothermia, infection, or other illnesses
 - Urination and stooling patterns, including the differences between bottle-fed and breast-fed infants
 - When and whom to call for health care needs
 - Care procedures needed for the neonate, for example, medication or special feeding administration
 - Use and troubleshooting of home durable medical equipment and supplies
 - Available community resources
 - Possible sources for referrals
 - Need for primary care follow-up, which includes routine physical examinations, immunization schedules, eye and hearing examinations, and appropriate specialty care
 - Information about help available on a 24-hour basis
 - Use of a car seat and current recommendations
 - Sibling issues
-
- ✦ Home safety, including the availability of utility priorities: electricity, running water, sanitation, heat, and telephone services
 - ✦ Parent or caregiver knowledge of infant care, safety, and specialized needs

- Parents' or caregivers' plans for infant care in their absence

Laboratory Tests

Laboratory tests will include tests as ordered by the primary care provider (the neonatologist, pediatrician, or nurse practitioner). These tests may include blood samples for serum bilirubin levels, serum levels to monitor drug therapy, neonatal screening tests, and others as indicated.

Referrals

The home health care visit often highlights the family's need for referrals to and information about resources and other agencies. Some of these referrals might include the following for infants with special needs:

- Social service agencies can help with financial or psychological adaptation.
- Occupational therapists and nutritionists provide support for infants with feeding problems.
- Nurses or occupational therapists with special education can help with the infant's developmental care.
- Lactation consultants can work with mothers of preterm and high-risk infants regarding breast-feeding.
- Breast-feeding support groups, such as La Leche League, can help parents.
- Support groups, such as the March of Dimes, can provide a listing of support groups for parents.
- Paraprofessional help, such as homemakers and providers of respite care, can be contacted through social service agencies.
- Equipment companies for technical support can be accessed through the hospital or nurse home visiting agency.
- Early intervention programs may be helpful for long-term education of the child.
- Professional therapists, such as occupational, physical, and speech therapists, often are a part of interdisciplinary teams working with high-risk infants.
- Family and grief counselors may be found through social service agencies.

Recording the Visit

The home visit record documents the maternal medical history, the physical and developmental assessments, client needs, services provided, and follow-up recommendations and appointments. Home care records often are forms in triplicate, with one copy going to the client, one kept on file at the home health care agency, and one for the nurse's records. Complete and accurate documentation is necessary because these records are a part of the client's permanent medical record. Figure 38-1 shows an example of a home visit record.

PROGRAMS FOR THE INFANT AND FAMILY WITH SPECIAL NEEDS

Selected special needs situations and potential programs are discussed.

Home Health Care for the Infant Exposed to Drugs

It is difficult to determine the actual number of women who use alcohol or drugs before and during pregnancy and, thus, the number of infants exposed to alcohol or drugs in utero. Currently, identification of alcohol and drug use by pregnant women is primarily based self-reporting and sporadic testing at the time of delivery. Self-reporting is an unreliable method, and drug screening of pregnant women is not done routinely (Sackoff et al., 1992; Donaldson & Ahmann, 1996). According to Dungy-Poythress (1995), toxicology testing for most drugs can detect substances only for a short time after use. Thus, frequency, dosage, and gestational timing of drug use often are not addressed reliably. Confounding variables also often exist and include polysubstance abuse, absence of or poor prenatal care, poor general health, and nutritional

DEVELOPING A TEACHING PLAN

Before the home health care nurse can develop a teaching plan, the following assessments should be made:

- Level of knowledge of material to be taught
- Ability to address the cultural, social, and religious factors regarding the client
- Knowledge of the socioeconomic status of the client
- Awareness that the learning needs of the client are important
- Ability or level of the home nurse's skill in teaching
- Importance of evaluating client understanding before completing teaching tasks

deficiencies. All these factors contribute to the difficulty of studying the effects on infants of alcohol and drug use during pregnancy; however, national and regional studies conducted over the past few years continue to document an increasing number of women of childbearing age who regularly use substances, such as cocaine, alcohol, and marijuana, and continue to do so during pregnancy (Chasnoff, Landress, & Barrett, 1990; Mathias, 1995).

The health care problems associated with alcohol or drug abuse during pregnancy include spontaneous abortion, low birth weight, premature birth, small for gestational age growth parameters, central nervous system damage, teratogenic effects, withdrawal effects, and an increased incidence of SIDS (Davis, 1993; Kelley, 1992; Famularo, Kinscherff, & Fenton, 1992).

Ideally, the process of identification, intervention, referral, and treatment of a mother's substance abuse problem begins prenatally, with a focus on the current pregnancy. Unfortunately, substance abuse usually is identified after delivery of the infant by a positive result on urine drug screening or by maternal self-reporting. At this point, child protective services usually are called and several options are evaluated and discussed. The infant can be discharged in the care of the parents or a close relative, or can be placed in a foster home. The history and type of drug use, family support, and the mother's willingness to seek drug treatment generally are the determining factors in placement of the infant (Donaldson & Ahmann, 1996).

The infant may be discharged to a relative, frequently the maternal grandmother, which may create a problem if the mother lives in the same household. An unhealthy environment for the infant and mother may continue. According to Donaldson & Ahmann (1996), recognizing unsafe and undesirable living conditions owing to a current alcohol or drug problem in the home is an important nursing intervention. Signs causing concern may include the following:

- An unkempt house
- Little or no food in the refrigerator
- Signs of illicit drug paraphernalia, alcohol use, and tobacco use
- Signs of personal hygiene neglect
- Signs of maternal depression such as a flat affect, excessive sleeping, and crying
- Mother's harsh or derogatory language when talking to or about the infant
- Lack of attention to the infant's needs
- Poor maternal-infant interaction

Donaldson & Ahmann (1996) suggest that the approach to working with mothers who abuse substances should be a three-pronged one:

1. Support the mother and assist in referring her for treatment.
2. Identify the special needs of the infant.
3. Provide special training and support to caregivers as needed.

Programs that provide a comprehensive approach to families of infants and young children of mothers who abuse substances are described next.

CRADLES Integrated Children's Project

Infants exposed to drugs in utero are the primary beneficiaries of an innovative project by the Houston Council on Alcoholism and Drug Abuse (HCADA) called CRADLES. CRADLES works in a collaborative effort with the Harris County Hospital District and its own coalition comprised of other community institutions and agencies in Harris County dedicated to the well-being of children. CRADLES is a four-pronged project that provides intensive case management through regular in-home visits to assist specific clients, that is, infants exposed to substances, and their caregivers and families. Clients are assigned from the Harris County Hospital District (Ben Taub General Hospital and Lyndon B. Johnson General Hospital) after an assessment by an alcohol and drug abuse counselor from HCADA who is licensed by the state.

The mission of CRADLES is to enhance the overall development of infants through strengthening the family unity with the intent to impact the transgenerational nature of drug abuse (Box 38-2). The foundation of the project is the regular in-home visits with the family using an intensive case management model designed to provide information about access to needed resources. These resources include access to medical, psychiatric, and emotional care; treatment for substance abuse and dependence; relapse prevention; education; various types of therapy; and job training. Also included are the necessities of daily living such as housing, food, and transportation. To ensure that the needs of the clients are met, case managers and parents-caregivers work together to create and maintain a plan of action known as the Individual Family Service Plan (IFSP). The plan, a viable working document, is revised over time as goals are met and as needs change. Clients who, for a variety of reasons, do not meet the criteria for inclusion in the intensive regular home visit but whose mothers are using or abusing substances are followed by the hospital counselor on a supportive basis.

During the home visit the nurse should gather information to develop a plan for the mother-infant dyad by asking the mother questions and by observation. The role

Box 38-2 Proposed Goals for C.R.A.D.L.E.S.

- To develop a network of communication and collaboration between service providers for these special families.
- To eliminate gaps in services for women who use alcohol and illegal substances during pregnancy and their exposed children.
- To identify and develop supportive services to meet the needs of families, including those significant others and caregivers who contribute to or are affected by substance and alcohol use.
- To promote community awareness and support for mothers exposed to substances and their infants and children.
- To provide education and promote understanding among other health professionals regarding the needs and resources available to these special families and their care providers.

of the nurse working in collaboration with CRADLES case managers is to:

- ✿ Monitor and advise on the overall health status of the infant.
- ✿ Assess, record, and monitor growth and development.
- ✿ Offer anticipatory guidance on all aspects of the infant's health.
- ✿ Evaluate and recommend basic infant nutritional needs.
- ✿ Document health interventions and their outcomes.
- ✿ Advise parents-caregivers on issues relevant to optimal infant care practices and provide opportunities for parents to raise issues pertaining to health issues.
- ✿ Offer a written evaluation and suggestions to case managers for each home visit.
- ✿ Act as a liaison between health care professionals and case managers.
- ✿ Provide a means of continuity of health care.

A second important part of the project is the weekly curriculum-based parenting classes conducted simultaneously with play therapy and childcare. Two parenting groups are offered simultaneously with a social hour to encourage interaction with parents-caregivers who also are caring for infants exposed to drugs in utero while maintaining their own sobriety. Childcare is offered during the parenting classes with the purpose of enhancing age-appropriate social development and behavior: Art-play therapy is organized and implemented aimed at helping

younger siblings (who also may have been exposed to substances in utero) attain and maintain age-appropriate social development and behavior.

Curriculum-based parenting classes include the following:

- ✿ One weekly closed parenting class in English during the day
- ✿ One weekly parenting class in Spanish during the day that is open to the community
- ✿ One weekly parenting class in English in the evening that is open to the community

During the parenting classes and while older siblings are in play therapy, another important aspect of the overall project takes place with the infant's younger siblings, that is, purposeful childcare. Purposeful childcare is planned to aid social development for toddlers (aged 1 to 3 years) and infants (from birth to 1 year of age). Moreover, a part of this purposeful childcare includes a counselor in training and invited retirees from various churches and organizations who serve as grandparents and role models.

Massage is demonstrated and taught to parents-caregivers as a method to enhance interaction between parents-caregivers and infants. Massage also serves as a way to calm the baby and, incidentally and simultaneously, the parent-caregiver. Three consultants also are involved with the project: a licensed massage therapist who works with these infants and families, an art-play therapist in charge of the art-play therapy aspect of the project, and a clinical developmental specialist with experience in the area of program development and evaluation who is responsible for the quality control of outcomes measured data.

Healthy Families Alexandria

Healthy Families Alexandria (HFA) adapted the Hawaii Healthy Start model, which also served as the primary model for the Healthy Families America approach to comprehensive and intensive home visit services. The National Committee to Prevent Child Abuse (NCPA) actively promotes the Healthy Families America approach.

The Alexandria program provides outreach and supportive services to prenatal women and serves a significant number of teenage mothers as well as a highly diverse, multicultural population. Prenatal women and first-time mothers with infants no older than 2 months of age are referred and screened for voluntary enrollment until the child is 3 years old. The HFA model provides systematic and proactive early identification of at-risk families and home-based visiting and case management services delivered by trained, largely paraprofessional, family support workers.

Building on its successful adaptation of Hawaii's model in adjacent Fairfax County, Northern Virginia Family

Service designed HFA to address the needs of some of Alexandria's at-risk population. The HFA model incorporates 12 critical elements that reflect over 20 years of research on the structure, organization, staff, and activities of effective home visit programs (as summarized by NCPCA):

1. Initiate services prenatally or at birth.
2. Use a standardized assessment process and tool to identify families in need of services.
3. Offer services voluntarily and in a positive manner to build family trust.
4. Offer services intensely (at least once a week) with well-defined criteria for changing intensity of services and over the long term (3 to 5 years).
5. Offer culturally competent services with staff and materials that reflect the cultural, linguistic, geographic, racial, and ethnic diversity of the population served.
6. Focus on supporting the parent as well as parent-child interaction and child development.
7. Link all families with a medical provider to ensure optimal health and development and to other services, depending on family needs.
8. Limit staff case loads so that home visitors have adequate time with each family.
9. Select staff who have the appropriate personal characteristics (who are nonjudgmental, compassionate, and have the ability to establish a trusting relationship), willingness to work with culturally diverse communities, and the skills to do the job.
10. Select staff whose education or experience enables them to handle the experiences they will encounter in working with at-risk families and have them receive basic training.
11. Have staff receive intensive training specific to their role to understand the essential components of family assessment and home visitation.
12. Ensure that staff receive ongoing and effective supervision so they can develop realistic and effective plans to empower families to meet their objectives, work effectively with families who may not be making progress, and discuss their concerns to solve problems and avoid stress-related burnout.

Healthy Families Alexandria has four primary goals:

1. Ensure adequate prenatal care as prescribed by the mother's medical provider or the ACOG.
2. Ensure preventive well-care as prescribed by the child's medical provider or the AAP and advanced optimal child development (e.g., well-care visits, immunizations, and developmental assessments).

3. Improve new mothers' knowledge of their child's needs and behaviors and enhance parent-child interaction, bonding, and parenting skills.
4. Prevent child abuse and neglect among enrollees.

PUBLIC HEALTH PROGRAMS FOR INFANTS AND CHILDREN

Programs focused on young children and women with children are covered.

Early Childhood Intervention (Birth to 3 Years)

Parents want their children to grow, learn, and reach their potential. Some children with disabilities or developmental delays face unique challenges and need extra help. This extra help is called early childhood intervention. Early childhood intervention (ECI) programs work with more than 20,000 families a year whose children need help growing and learning. ECI staff and families become partners during these important first 3 years of the child's life (Early Childhood Intervention, 1997).

Early Childhood Intervention, which will celebrate 20 years of service in 2002, teaches families how to help their children reach their potential through education and therapy services. There are 71 local ECI programs that serve more than 23,000 children a year. In fiscal year 1997, ECI received \$42 million in state and federal funds. Anyone can refer a family with a child under the age of 3 years who has a disability or suspected developmental delays. The child should be referred as soon as you or the family has a concern about the child's development. A diagnosis is not needed for referral. Federal law requires that professionals refer children for services within 2 working days. ECI provides needed support to families who are beginning to learn about their child's disability or delays. Early identification of children with problems helps minimize and prevent future problems. Local programs conduct free developmental screenings, assess children for developmental delays, and determine eligibility. Once a child is enrolled, a family plan will begin. If the child is not eligible for ECI, staff will refer the family to other resources.

The services of ECI may include the following:

- Assistive technology
- Occupational therapy
- Physical therapy
- Psychological therapy
- Service coordination

- Social work
- Special instruction
- Speech and language therapy
- Transportation
- Vision
- Nursing
- Nutrition
- Audiology
- Early identification, screening and assessment
- Family counseling
- Family education
- Home visits
- Medical (only diagnostic or evaluation services)

Services are provided individually or with other children, depending on how the child would benefit most. Services are delivered in the home; in community-based areas; and in settings with children who do not have delays in their development, such as the child's day-care program. All services are free. To allow more children to be served, ECI will bill Medicaid or ask for permission to bill the health care insurance provider for covered services.

Women, Infants, and Children (WIC) Nutritional Program

The Special Supplemental Nutrition Program for Women, Infants, and Children (WIC) receives funding from the federal Maternal Child Health Block Grant, which is administered by the Public Health Department. The WIC program is a prevention-orientation program that provides nutritional assessment, counseling, and supplemental food to clients in the following categories: pregnant women, non-breast-feeding women, breast-feeding women, infants, and children up to 5 years of age. For families to be eligible for WIC they must meet income guidelines, be considered a nutritional risk (e.g., iron deficiency, low birth weight, and inadequate weight gain), have a medical referral form completed by a health care provider outlining the infant's medical history, and participate in reevaluation and recertification in the program every 6 months. The WIC program has higher income guidelines than does any other federal program, and families should be encouraged to apply.

Zahr and Montijo (1993) evaluated the effectiveness of home visiting in a total of 40 very low-birth-weight infants. All infants in this study required further nursing care after being discharged from NICU. Nursing care was provided for 8 to 24 hours daily initially and was reduced as the infant became more stable or the parents become more competent to provide care. Most of the infants were dis-

charged from the NICU on apnea monitors; pulse oximeters; oxygen therapy; total parenteral nutrition; and a variety of medications such as antibiotics, cardiac drugs, and theophylline. The findings of this study suggest that home care of sick, premature infants by trained nursing personnel can reduce the frequency of medical resource use. The mean number of emergency room visits for this sample of very low-birth-weight infants was lower than the average of emergency room visits reported for infants in earlier studies. All minor illnesses were taken care of by the nurses who provided home care, and there were no reported visits to physicians' offices for such illnesses.

NURSING IMPLICATIONS

While an assessment is essential at the onset of providing home care services, in reality, assessment is an ongoing process, extending over the entire period of working with a family (Ahmann, 1996). Care must be flexible enough to respond to the infant's or child's changing health and developmental needs, multidisciplinary input, and the family's changing priorities (Ahmann & Floyd, 1996).

In some cases, nurses may not be the exclusive providers of care during a home visit program. The plan of care is used as a guide to the provider of care, whether the provider is the nurse, client, or family members. The implementation phase also includes recording the client care on the appropriate documents (Humphrey & Milone-Nuzzo, 1996). The nurse should have a plan for each home visit that addresses one or more aspects of the overall plan of care. Throughout each home visit, the information elicited from parents and other caregivers, with the nurse's skilled observations and assessments, will provide the basis on which the nurse, other disciplines, and family update the plan of care (Ahmann & Floyd, 1996).

Regular evaluation and refinement of the care plan are essential from one visit to the next. Periodically, a more

Web Activities

- The continuum Pediatric Homecare Team is a resource center for home care nurses. Visit the website at www.continuum-nursing.com to determine which resources are offered regarding developing a home visit program.
- Visit Building Blocks Pediatric Home Health Services at www.care4kids.com for useful information and links for nurses and families.

formal review of the entire plan of care, including re-assessment of the goals, is advised. This process should include the nurse, family, and other key providers (Ahmann & Floyd, 1996).

The nurse can encourage the client and family to actively participate in all phases of care. Continuity of care is

ensured through a systematic process of delivering care to clients and an organized and complete home visit record. Accurate communication justifies coverage to third-party payers and also allows the nurse and agency to document care that stands up legally and against standards and regulations.

Key Concepts

- Health promotion is one of the key components of home care.
- Home care is a cost-effective method of meeting health care needs.
- The nurse brings unique skills to the provision of home care.
- Client care is so complex that even home care requires a multidisciplinary team of providers.
- The Barnard nursing model of infant care is applicable to home care.
- Preparing for the home visit and following the steps of the nursing process are appropriate for home care.
- Nurses should be familiar with professional standards for home care.

Review Questions and Activities

1. The health care system is changing, and nurses must take the lead to adapt their health care delivery in the following way:
 - a. Provide high-cost health care
 - b. Provide health care directly to the community
 - c. Provide generic health care to all clients
 - d. Provide high-technology health care to high-risk infants

The correct answer is b.

2. Health care promotion strategies for the high-risk infant in the community include the following except:
 - a. Growth and development
 - b. Sleep-wake patterns
 - c. Religious preference
 - d. Safety and nutrition

The correct answer is c.

3. Barriers to health care use when working with a family from the same cultural background as the home visiting nurse might include the following:
 - a. Poverty, social nature, values, and belief systems
 - b. Family structure, high school attended, and number of children in the family
 - c. Age, food preference, and nutritional status
 - d. Coping skills, music preference, and a history of mental health illness

The correct answer is a.

4. A nursing model for working with high-risk infants and their mothers helps the home visiting nurse to:

- a. Better organize time during the home visit
- b. Provide a foundation for the home visit
- c. Enhance the multipurpose approach
- d. Support safety during the home visit

The correct answer is b.

5. Follow-up care of the high-risk infant in the community helps the home visiting nurse:
 - a. Decrease long-term sequelae owing to medical conditions
 - b. Increase job opportunities for home visiting nurses
 - c. Promote medical consequences in the high-risk infant
 - d. Help doctors in the delivery of health care

The correct answer is a.

6. Priority assessment and screening should always be included in a home visit because they evaluate the following except:
 - a. Feeding practices and techniques
 - b. Parent-infant interactions
 - c. Financial status
 - d. General infant care practices

The correct answer is c.

7. An important issue the nurse must address during a home visit is to:
 - a. Ensure the family has gas money
 - b. Provide a ride for the mother and infant to the clinic

- c. Promote extended family interaction
- d. Recommend referrals to community resources

The correct answer is d.

- 8.** A successful home visiting program for the high-risk infant results in the following outcomes except:
- a. Positive growth patterns

- b. Decrease in the number of emergency room visits during the first year of life
- c. Parent-caregiver satisfaction
- d. Increase reporting to child protective services

The correct answer is d.

APPENDIX A

STANDARDS OF HOLISTIC NURSING PRACTICE

The American Holistic Nurses Association (AHNA) Standards of Holistic Nursing Practice:

- are used in conjunction with the American Nurses Association Standards of Practice and the specific specialty standards where holistic nurses practice.
- contain five core values that are followed by a description and standards of practice action statements. Depending on the setting or area of practice, holistic nurses may or may not use all of these action statements.
- draw on modalities derived from a number of explanatory models, of which biomedicine is only one model.
- reflect the diverse nursing activities in which holistic nurses are engaged.
- serve holistic nurses in personal life, clinical and private practice, education, research, and community service.

CORE VALUE 1: HOLISTIC PHILOSOPHY AND EDUCATION

Holistic Philosophy

Holistic nurses develop and expand their conceptual framework and overall philosophy in the art and science of holistic nursing to model, practice, teach, and conduct research in the most effective manner possible.

© 2000 American Holistic Nurses' Association. Permission is given to duplicate this document for teaching purposes by an educational institution. Written consent is required for duplication by an author or publisher. AHNA, 2733 E. Lakin Dr., Suite 2, Flagstaff, AZ 86004; phone (800) 278-2462, fax (520) 526-2752; <http://www.ahna.org>.

Standards of Practice

Holistic nurses:

- recognize the person's capacity for self-healing and the importance of supporting the natural development and unfolding of that capacity.
- support, share, and recognize expertise and competency in holistic nursing practice that is used in many diverse clinical and community settings.
- participate in person-centered care by being a partner, coach, and mentor who actively listens and supports others in reaching personal goals.
- focus on strategies to bring harmony, unity, and healing to the nursing profession.
- communicate with traditional health care practitioners about appropriate referrals to other holistic practitioners when needed.
- interact with professional organizations in a leadership or membership capacity at local, state, national, and international levels to further expand the knowledge and practice of holistic nursing and awareness of holistic health issues.

Holistic Education

Holistic nurses acquire and maintain current knowledge and competency in holistic nursing practice.

Standards of Practice

Holistic nurses:

- participate in activities of continuing education and related fields that have relevance to holistic nursing practice.
- identify areas of knowledge from nursing and various fields such as biomedical, epidemiology, behavioral medicine, cultural and social theories.
- continually develop and standardize holistic nursing guidelines, protocols, and practice to promote

competency in holistic nursing practice and assure quality of care to individuals.

- use the results of quality care activities to initiate change in holistic nursing practice.
- may seek certification in holistic nursing as one means of advancing the philosophy and practice of holistic nursing.

CORE VALUE 2: HOLISTIC ETHICS, THEORIES, AND RESEARCH

Holistic Ethics

Holistic nurses hold to a professional ethic of caring and healing that seeks to preserve wholeness and dignity of self, students, colleagues, and the person who is receiving care in all practice settings, be it in health promotion, birthing centers, acute or chronic care facilities, end-of-life care centers, and in homes.

Standards of Practice

Holistic nurses:

- identify the ethics of caring and its contribution to unity of self, others, nature, and God/Life Force/Absolute/Transcendent as central to holistic nursing practice.
- integrate the standards of holistic nursing practice with applicable state laws and regulations governing nursing practice.
- engage in activities that respect, nurture, and enhance the integral relationship with the earth, and advocate for the well-being of the global community's economy, education, and social justice.
- advocate for the rights of patients to have educated choices regarding their plan of care.
- participate in peer evaluation to ensure knowledge and competency in holistic nursing practice.
- protect the personal privacy and confidentiality of individuals, especially with health care agencies and managed care organizations.

Holistic Theories

Holistic nurses recognize that holistic nursing theories provide the framework for all aspects of holistic nursing practice and transformational leadership.

Standards of Practice

Holistic nurses:

- strive to use nursing theories to develop holistic nursing practice and transformational leadership.
- interpret, use, and document information relevant to a person's care according to a theoretical framework.

Holistic Research

Holistic nurses provide care and guidance to persons through nursing interventions and holistic therapies consistent with research findings and other sound evidence.

Standards of Practice

Holistic nurses:

- use available research and evidence from different explanatory models to mutually create a plan of care with a person.
- use expert clinical judgment to select appropriate interventions.
- discuss holistic application to clinical situations where rigorous research has not been done.
- create an environment conducive to systematic inquiry into healing and health issues by engaging in research or supporting and utilizing the research of others.
- disseminate research findings at meetings and through publications to further develop the foundation and practice of holistic nursing.
- provide consultation services on holistic nursing interventions to persons and communities based on research.

CORE VALUE 3: HOLISTIC NURSE SELF-CARE

Holistic Nurse Self-Care

Holistic nurses engage in self-care and further develop their own personal awareness as being an instrument of healing to better serve self and others.

Standards of Practice

Holistic nurses:

- recognize that a person's body-mind-spirit has healing capacities that can be enhanced and supported through self-care practices.

- ✿ identify and integrate self-care strategies to enhance their physical, psychological, sociological, and spiritual well-being.
- ✿ recognize and address at-risk health patterns and begin the process of change.
- ✿ consciously cultivate awareness and understanding about the deeper meaning, purpose, inner strengths, and connections with self, others, nature, and God/Life Force/Absolute/Transcendent.
- ✿ use clear intention to care for self and to seek a sense of balance, harmony, and joy in daily life.
- ✿ participate in the evolutionary holistic process with the understanding that crisis creates opportunity in any setting.

CORE VALUE 4: HOLISTIC COMMUNICATION, THERAPEUTIC ENVIRONMENT, AND CULTURAL DIVERSITY

Holistic Communication

Holistic nurses engage in holistic communication to ensure that each person experiences the presence of the nurse as authentic and sincere; there is an atmosphere of shared humanness that includes a sense of connectedness and attention reflecting the individual's uniqueness.

Standards of Practice

Holistic nurses:

- ✿ develop an awareness of the most frequently encountered challenges to holistic communication.
- ✿ increase therapeutic and cultural competence skills to enhance their effectiveness through listening to themselves and others.
- ✿ explore with each person those strategies that can assist her/him, as desired, to understand the deeper meaning, purpose, inner strengths, and connections with self, others, nature, and God/Life Force/Absolute/Transcendent.
- ✿ recognize that holistic communication and awareness of individuals is a continuously evolving multi-level exchange that offers itself through dreams, images, symbols, sensations, meditations, and prayers.
- ✿ respect the person's health trajectory which may be incongruent with conventional wisdom.

Therapeutic Environment

Holistic nurses recognize that each person's environment includes everything that surrounds the individual, both the external and the internal (physical, mental, emotional, and spiritual) as well as patterns not yet understood.

Standards of Practice

Holistic nurses:

- ✿ promote environments conducive to experiencing healing, wholeness, and harmony, and care for the person in as healthy an environment as possible.
- ✿ work toward creating organizations that value sacred space and environments that enhance healing.
- ✿ integrate holistic principles, standards, policies, and procedures in relation to environmental safety and emergency preparedness.
- ✿ recognize that the well-being of the ecosystem of the planet is a prior determining condition for the well-being of the human.
- ✿ promote social networks and social environments where healing can take place.

Cultural Diversity

Holistic nurses recognize each person as whole, being of body-mind-spirit, and mutually create a plan of care consistent with cultural backgrounds, health beliefs, sexual orientation, values, and preferences.

Standards of Practice

Holistic nurses:

- ✿ assess and incorporate the person's cultural practices, values, beliefs, meanings of health, illness, and risk behaviors in care and health education.
- ✿ use appropriate community resources and experts to extend their understanding of different cultures.
- ✿ assess for discriminatory practices and change as necessary.
- ✿ identify discriminatory health care practices as they impact the person and engage in effective nondiscriminatory practices.

CORE VALUE 5: HOLISTIC CARING PROCESS

Assessment

Each person is assessed holistically, using appropriate traditional and holistic methods while the uniqueness of the person is honored.

Standards of Practice

Holistic nurses:

- use an assessment process, including appropriate traditional and holistic methods, to systematically gather information.
- value all types of knowing, including intuition, when gathering data from a person and validate this intuitive knowledge with the person when appropriate.

Patterns/Problems/Needs

Each person's actual and potential patterns/problems/needs/life processes related to health, wellness, disease, or illness, which may or may not facilitate well-being, are identified and prioritized.

Standards of Practice

Holistic nurses:

- assist the person to access inner wisdom that can provide opportunities to enhance and support growth, development, and movement towards health and well-being.
- collect data and collaborate with the person and health care team members as appropriate to identify and record a list of actual and potential patterns/problems/needs.
- use collected data to formulate an etiology of the person's identified actual or potential patterns/problems/needs.
- make referrals to other holistic practitioners or traditional therapists when appropriate.

Outcomes

Each person's actual or potential patterns/problems/needs have appropriate outcomes specified.

Standards of Practice

Holistic nurses:

- honor the person in all phases of her/his healing process regardless of expectations or outcomes.
- identify and partner with the person to specify measurable outcomes and realistic goals.

Therapeutic Care Plan

Each person engages with the holistic nurse to mutually create an appropriate plan of care that focuses on health promotion, recovery, restoration, or peaceful dying so that the person is as independent as possible.

Standards of Practice

Holistic nurses:

- partner with the person in a mutual decision process to create a health care plan for each pattern/problem/need/opportunity to enhance health and well-being.
- help a person identify areas for education to make decisions about life choices in a conscious, informed manner that empowers the person to maintain her/his uniqueness and independence.
- offer self-assessment tools, word associations, storytelling, dreams, and journals as appropriate.
- use skills of cultural competence and communicate acceptance of the person's values, beliefs, culture, religion, and socioeconomic background.
- assist the person in recognizing at-risk patterns/problems/needs for potential or existing health situations (e.g., personal habits, personal and family health history, age-related risk factors), and also assist in recognizing opportunities to enhance well-being.
- engage the person in problem-solving dialogue in relation to living with changes secondary to illness and treatment.

Implementation

Each person's plan of holistic care is prioritized and holistic nursing interventions are implemented accordingly.

Standards of Practice

Holistic nurses:

- implement the mutually created plan of care within the context of assisting the person towards the higher potential of health and well-being.

- support and promote the person's capacity for the highest level of participation and problem-solving in the plan of care and collaborate with other health team members when appropriate.
- use holistic nursing skills in implementing care, including cultural competency and all ways of knowing.
- advocate that the person's plan, choices, and unique healing journey be honored.
- provide care that is clear about and respectful of the economic parameters of practice, balancing justice with compassion.

Evaluation

Each person's responses to holistic care are regularly and systematically evaluated and the continuing holistic nature of the healing process is recognized and honored.

Standards of Practice

Holistic nurses:

- collaborate with the person and with other health care team members when appropriate in evaluating holistic outcomes.
- explore with the person her/his understanding of the cause of any significant deviation between the responses and the expected outcomes.
- mutually create with the person and other team members a revised plan, if needed.

APPENDIX B

ABBREVIATIONS, ACRONYMS, AND SYMBOLS

AA	Alcoholics Anonymous	ARBD	Alcohol Related Birth Defects
AA	arachidonic acid	AROM	artificial rupture of membranes
AANA	American Association of Nurse Anesthetists	ART	assistive reproduction technology
AAP	American Academy of Pediatrics	AUB	abnormal uterine bleeding
ABC	airway breathing circulation	AWHONN	Association of Women's Health, Obstetric, and Neonatal Nurses
ABG	arterial blood gas	AZT	zidovudine
ACE	angiotensin-converting enzyme	β-hCG	β-human chorionic gonadotropin
ACOG	American College of Obstetricians and Gynecologists	BBT	basal body temperature
ACS	American Cancer Society	BINS	Bayley Infant Neurodevelopmental Screen
ACTG	AIDS Clinical Trial Group	BMC	bone mineral content
ADH	antidiuretic hormone	BMD	bone mineral density
ADOPE	age, diabetes, obesity, postterm, excessive	BMR	basal metabolic rate
AFDC	Aid to Families with Dependent Children	BNE	Board of Nursing Examiners
AFP	alpha-fetoprotein	BP	blood pressure
AFV	amniotic fluid volume	bpm	beats per minute
AGA	appropriate for gestational age	BPP	biophysical profile
AHCPR	Agency for Health Care Policy and Research	BRP	bed rest bathroom privileges
AHNA	American Holistic Nurses Association	BSE	breast self-examination
AHPA	American Herbal Products Association	BUBBLE-HE	breasts, uterus, bladder, bowel, lochia, episiotomy, Homan's Sign, emotional status
AHRQ	Agency for Healthcare Research and Quality	BUN	blood urea nitrogen
AI	adequate intake	Ca	calcium
AICR	American Institute for Cancer Research	CAM	complementary and alternative medicine
AIDS	acquired immunodeficiency syndrome	CBC	complete blood count

ANDMCN	American Nursing Division of Maternal Child Nursing	CF	cystic fibrosis
ANRED	Anorexia Nervosa and Related Eating Disorders	C-H	crown-heel
ANS	autonomic nervous system	CHARGE	coloboma, heart disease, choanal atresia, retardation (physical and mental), genital hypoplasia, ear anomalies
AOA	Administration on Aging	CHD	congenital heart defect
APIB	Assessment of Premature Infant Behavior	CHD	coronary heart disease
APN	advanced practice nurse	CHF	congestive heart failure
APS	Adult Protective Services	CHO	carbohydrate

CIMS	Coalition for Improved Maternity Services	EDD	expected date of delivery
CIS	Communities in Schools	EDNP	energy-dense, nutrient-poor
cm	centimeter	EEG	electroencephalogram
CMV	cytomegalovirus	EFM	electronic fetal monitoring
CNM	Certified Nurse Midwife	EFNEP	Expanded Food and Nutrition Education Program
CNS	central nervous system	EIP	early intervention program
CO ₂	carbon dioxide	ELISA	enzyme-linked immunosorbent assay
COC	combined oral contraceptive	EMLA	eutectic mixture of local anesthetics
COPD	chronic obstructive pulmonary disease	ER	estrogen receptors
CPAP	continuous positive airway pressure	ERT	estrogen replacement therapy
CPD	cephalopelvic disproportion	ESPGN	European Society of Pediatric Gastroenterology and Nutrition
CPR	cardiopulmonary resuscitation	ET	embryo transfer
CPS	Canadian Paediatric Society	FAE	fetal alcohol effects
C-R	crown-rump	FAS	fetal acoustic stimulation
CRNA	Certified Registered Nurse Anesthetist	FAS	Fetal Alcohol Syndrome
CRS	congenital rubella syndrome	FCMC	family-centered maternity care
CSF	cerebrospinal fluid	FDA	Food and Drug Administration
CST	contraction stress test	FFN	fetal fibronectin
CT	complementary therapy	FH	familial hypercholesterolemia
CT	computerized tomography	FHR	fetal heart rate
CVD	cardiovascular disease	FHT	fetal heart tone
CVS	chorionic villus sampling	FMC	fetal movement counting
D & C	dilation and curettage	FOBT	fecal occult blood test
D & E	dilation and evacuation	FOC	frontal-occipital-circumference
DDH	developmental dysplasia of the hip	FPAL	full-term deliveries/preterm deliveries/abortions/living children
DDT	dichlorodiphenyltrichloroethane	FSE	fetal scalp electrode
DES	diethylstilbestrol	FSH	follicle-stimulating hormone
DFE	dietary folate equivalent	ftc	footcandle
DHA	docosahexaenoic acid	g	gram
DHHS	Department of Health and Human Services	G6PD	glucose-6-phosphate dehydrogenase
DIC	disseminated intravascular coagulation	GAO	General Accounting Office
dL	deciliter	GBS	group B <i>Streptococcus</i>
DMD	Duchenne muscular dystrophy	GCT	genetic counseling team
DMPA	depot medroxyprogesterone acetate	GFR	glomerular filtration rate
DMPA	Depo-Provera	GI	gastrointestinal
DNA	deoxyribonucleic acid	GIFT	gamete intra-fallopian transfer
DO	Doctor of Osteopathy	gm	gram
DRI	Dietary Reference Intake	GNP	gross national product
DRV	daily reference value	GnRH	gonadotropin releasing hormone
DSHEA	Dietary Supplement Health and Education Act	H & H	hematocrit and hemoglobin
DTR	deep tendon reflex	HbeAg	hepatitis B e antigen
DUB	dysfunctional uterine bleeding	HBIG	hepatitis B immune globulin
DV	daily value	HBsAg	hepatitis B surface antigen
EA	esophageal atresia	HC/AC	head-abdomen circumference
ECG	electrocardiogram	HCADA	Houston Council on Alcoholism and Drug Abuse
ECI	Early Childhood Intervention	hCG	human chorionic gonadotropin
ECMO	extracorporeal membrane oxygenation	Hct	hematocrit
EDB	expected date of birth		
EDC	expected date of confinement		

HDL	high-density lipoprotein	IUD	intrauterine device
HDN	hemolytic disease of the newborn	IUFD	intrauterine fetal demise
HEENT	head, ears, eyes, nose, and throat	IUGR	intrauterine growth restriction
HELLP	hemolysis, elevated liver enzymes, low platelets	IUPC	intrauterine pressure catheter
HexA	hexosaminidase	IV	intravenous
HFA	Healthy Families Alexandria	IVF	in vitro fertilization

GLOSSARY

A

ABO incompatibility Condition that occurs when the blood types of the mother and the fetus do not match.

Abortion Expulsion of the products of conception (termination of pregnancy) before fetal viability.

Abruptio placentae Premature placental separation from the uterine wall; separation may be partial or complete, involve small or large areas, and be hidden.

Acceleration An increase in fetal heart rate above the baseline level, with a return to baseline within 10 minutes.

Accretion Growth in size, especially by addition or accumulation.

Acme Peak or time of greatest intensity of a uterine contraction.

Acquaintance rape Sexual assault that occurs when a perpetrator with whom the victim has had a previous relationship uses deceit and coercion to obtain sex.

Acquired disorder Condition resulting from environmental factors rather than genetic circumstances.

Acquired immunodeficiency syndrome/human immunodeficiency syndrome (AIDS/HIV) Retrovirus that causes progressive and severe impairment of the body's natural immunologic function (HIV), resulting in serious opportunistic infections, various cancers, and eventual death (AIDS).

Acrocyanosis The transient bluish skin color of an infant's feet or hands after delivery.

Active phase The second phase of the first stage of labor during which the cervix dilates from 4 to 7 cm.

Acupressure Application of pressure along certain meridians of the skin.

Acupuncture Insertion of needles into the skin along certain meridians.

Adolescence Period of life beginning with the appearance of secondary sex characteristics and ending with the cessation of growth, approximately 11 to 18 years of age; passage from childhood to maturity.

Adolescent pregnancy Pregnancy in girls ages 11 to 19.

Adult maltreatment syndrome ICD-9 diagnostic code category for the adult who is abused.

Advanced reproductive age Women between ages 45 and 50 who are perimenopausal or postmenopausal.

Afterpains Abdominal cramping caused by the uterus contracting or involuting.

Agonists Drugs that block or reduce the action of a substance in the human body.

Air-block syndrome Term used to encompass pneumomediastinum and pulmonary interstitial emphysema in ventilated infants.

Allantois Small diverticulum of the yolk sac.

Allele Alternative expression of a gene at a given locus.

Allopathy Traditional or established medical or surgical procedures, both invasive and noninvasive, used in the diagnosis and treatment of mental or physical illness.

Alpha-fetoprotein (AFP) Protein produced by the developing fetus that can be used as a marker for neural tube defects (increased AFP) and Down syndrome (decreased AFP).

Alternative therapies Therapies used instead of conventional biomedicine.

Alveoli Secretory units of the mammary gland in which milk production takes place.

Amenorrhea Absence of menstruation for 3 or more months in women who have established menstrual cycles.

Amnihook A plastic instrument with a blunt hook at the distal end used for amniotomy.

Amniocentesis Prenatal diagnostic procedure that consists of withdrawal of a small sample of amniotic fluid for genetic analysis of embryonic cells.

Amnioinfusion An instillation of an isotonic, glucose-free solution into the uterus to cushion the umbilical cord or thin out meconium.

Amnion Inner membrane of the two fetal membranes; it forms the sac in which the fetus and the amniotic fluid are contained.

Amniotic fluid Fluid surrounding the developing fetus during pregnancy; formed from maternal serum and fetal urine.

Amniotic fluid embolism Life-threatening condition in which amniotic fluid and particulate matter such as lanugo, vernix caseosa, meconium, or other fetal cells enter the maternal circulation and obstruct the pulmonary circulation, resulting in classic embolic symptoms.

Amniotomy Artificial rupture of the fetal membranes (AROM) using a plastic amnihook or sometimes a fetal scalp electrode.

Amylophagia Ingestion of nonfood substances, such as laundry starch or cornstarch.

Analgesia Relief of pain.

Anal wink reflex Drawing together of the buttocks in response to a stroking motion. The buttocks come together at the exact anatomic position of the anal opening.

Anencephaly Complete or partial absence of the cerebral hemispheres and the skull overlying the brain.

Anesthesia Absence of sensation.

Anesthesiologist Physician who has completed a postgraduate residency in anesthesia.

Aneuploidy Abnormal chromosome pattern in which the total number of chromosomes is not a multiple of the haploid number ($n=23$).

Anorexia nervosa Condition of self-starvation motivated by excessive concern with weight and an irrational fear of becoming fat.

Anovulatory Lack of ovulation.

Anovulatory cycle Menstrual cycle in which no ovum is discharged.

Anterior fontanel The diamond-shaped open space formed by the anterior and posterior sagittal and frontal sutures on an infant's skull.

Anticipatory grieving Emotional responses based on the perception of potential or expected loss.

Antioxidant A substance that slows down the oxidation of hydrocarbons, oils, and so on, and thus helps to check deterioration.

Antiretroviral therapy Course of medications used to suppress HIV replication and viral load.

Apgar score A scoring system used to evaluate newborns at 1 minute, 5 minutes, and 10 minutes after delivery. The total score is achieved by assessing heart rate, respiratory effort, muscle tone, reflex irritability, and skin color, and assigning a score of 0 to 2 in each of the five categories. The highest possible score is 10.

Apnea Cessation of respirations for more than 20 seconds.

Areola Pigmented ring of tissue surrounding the nipple.

Asphyxia Interference with gas exchange resulting in decreased oxygen delivery (hypoxemia), accumulation of carbon dioxide (hypercapnia), development of respiratory and metabolic acidosis, and inadequate perfusion of the tissues and major organs (ischemia).

Assault Intentional act of inflicting physical injury on another person.

Asymmetric intrauterine growth restriction (IUGR) Fetal growth in which the length and head circumference are at higher percentiles than the measurement for weight based on standardized graphs.

Atony Lack of uterine muscle tone.

Attachment Process of connecting with another human being over time.

Auditory brain evoked response (ABER) A hearing screen designed for newborns that records electrical potentials arising from the auditory nervous system.

Augmentation of labor Stimulation of uterine contractions after labor has already started.

Autonomy An individual's right to hold a particular view, make choices, and undertake actions based on values and beliefs.

Autosome The 22 pairs of chromosomes that do not greatly influence sex determination at conception; excludes the sex chromosomes, X and Y.

Ayurvedic medicine Traditional medicine of India meaning knowledge of life or science of longevity.

B

Ballottement Rebounding of the floating fetus against the examiner's fingers.

Barrier to service utilization Any deterrent, either real or perceived, that prevents or delays use of available health care.

Basal metabolism Energy used to support body functions while the body is at rest.

Baseline fetal heart rate The fetal heart rate between contractions and accelerations.

Beat-to-beat variability Short-term variability in the fetal heart rate from one beat to the next.

Behavioral medicine Branch of medicine that focuses on behavior and cognitive, emotional, motivational, and biobehavioral interactions.

Behavioral state Continuum of levels of consciousness, encompassing quiet sleep, drowsiness, wakeful attentiveness, and hyperalert, agitated, or crying states.

Beneficence The practice of doing good, which may include prevention of harm, removal of evil, or promotion of good.

Biischial diameter Distance between the two ischial tuberosities.

Bilirubin Product of red cell destruction, which may be by natural or hemolytic process.

Binge eating An eating disorder of periodic binge eating (several thousand calories) not normally followed by vomiting, use of laxatives, or excessive exercise.

Bioavailability Rate at which a nutrient enters the bloodstream and is circulated to specific organs or tissues.

Biomedicine The scientific-based professional medicine taught in medical schools and generally practiced in the United States and Canada.

Biophysical profile (BPP) Noninvasive dynamic assessment of the fetus and the fetal environment.

Birth rate Number of births per 1,000 population.

Blastocyst Mammalian conceptus in the postmorula stage; consists of the trophoblast and an inner cell mass and develops into the embryo.

Blended family Family formed through remarriage.

Bloody show Release or expulsion of the thick, tenacious mucous plug that is inside the cervical canal 24–48 hours before the onset of labor.

Body mass index (BMI) Ratio that defines the relationship between height and weight. BMI is calculated by the formula: $BMI = \text{weight (kg)} / \text{height (m}^2\text{)}$ or $\text{weight (lb)} \times 700 / \text{height (in}^2\text{)}$.

Boggy Term used to describe a fundus that is soft, atonic, and nonpalpable; bogginess is a warning sign of uterine atony and possible postpartum hemorrhage.

Botanicals All parts of plants that have medicinal value: roots, rhizomes, leaves, stems, and flowers.

Brachial palsy Paralysis of the muscles involving the upper extremity; occurs as a result of a prolonged and difficult labor followed by a traumatic delivery.

Braxton Hicks contractions Intermittent painless contractions of the uterus observed throughout pregnancy; also known as false labor.

Breech presentation Fetal descent in which the fetal buttocks, legs, feet, or combination of these parts is found first in the maternal pelvis.

Bronchopulmonary dysplasia (BPD) Chronic lung disease in the neonate defined as an oxygen or ventilator requirement at 36 weeks' corrected gestational age.

Brow presentation Fetal descent in which the area between the anterior fontanel and the fetal eyes descend into the maternal pelvis first.

Bulimia nervosa Condition characterized by binge eating, or excessive consumption of calories over a short period of time; purging by self-induced vomiting; use of laxatives or diuretics, or both; excessive exercise; or periods of severe caloric restriction.

C

Calorie Amount of energy needed to raise the temperature of 1 kilogram of water (about 4 cups) from 1°C.

Calorimetry Measurement of the quantity of heat; used for measuring the energy produced by food when oxidized in the body.

Capacitation Process by which the spermatozoon (sperm) is capable of penetrating the ovum.

Caput succedaneum Soft tissue edema or swelling from birth trauma that crosses suture lines; localized between the skin and the periosteum.

Carcinoma in situ Cancer that involves only the cells of the organ in which it began and has not spread to any other tissue.

Carotenoids Pigments in fruits and vegetables, which include alpha carotene, beta carotene, lycopene, lutein, and many other compounds.

Case management, care coordination Process of coordinating care and services to ensure that clients receive appropriate care and services in a timely manner.

Categorical imperative Supreme rule that governs actions.

Cephalhematoma Subperiosteal hemorrhage from birth trauma that causes a swelling that does not cross suture lines.

Cephalopelvic disproportion Abnormal relationship in which the maternal pelvis will not permit the descent of the fetal head for delivery.

Cerclage Suturing to manage an incompetent cervix.

Certified registered nurse anesthetist (CRNA) Advanced practice nurse who has graduated from an accredited program of nurse anesthesia education and has passed the National Certification Examination.

Cervical cancer Neoplasm of the uterine cervix.

Cervical cap Barrier contraceptive device that is held in place by suction over the cervix.

Cervical dilation Widening of the cervical opening that occurs from myometrial contractions in labor, which allow the cervix to accommodate passage of the fetal head through the birth canal.

Cervical infection Inflammation of the cervix caused by a microorganism or foreign body.

Cesarean section Birth of the fetus through a surgical incision in the mother's abdomen.

Chadwick's sign Dark blue or purple coloration in the mucous membranes of the cervix, vagina, and vulva during pregnancy.

Chi Concept in Oriental medicine that refers to the subtle material or energy that influences physiologic function and maintains the health and vitality of the individual.

Chi gong The oriental practice of "working the chi," or exercises to maintain health and vitality.

Child abuse Physical or mental injury, sexual abuse, exploitation, negligent treatment, or maltreatment of a child.

Childbirth education Originally, specific techniques for breathing, relaxation, and positioning to prepare women for labor that reduce the need for medication and unnecessary medical interventions.

Chloasma Brownish pigmentation of the face commonly called "the mask of pregnancy."

Choanal atresia A bony or membranous separation between the nose and the pharynx.

Chorioamnionitis An infection of the amniotic fluid that can be transferred to the infant before delivery, which places the infant at risk for a life-threatening condition.

Chorion Outermost portion of the fetal membrane composed of trophoblast and mesoderm lining; develops villi and becomes vascularized; forms the fetal portion of the placenta.

Chorionic villi Vascular protrusions along the chorion.

Chorionic villus sampling (CVS) Procedure that obtains fetal cells in the first trimester of the developing pregnancy.

Chorioretinitis Inflammation of the membrane of the retina of the eye.

Chromosome Filament-like nuclear structure consisting of chromatin that stores genetic information as base sequences in DNA and whose chromosome number is constant in each species.

Chronic grief Prolonged and recurrent sorrow felt by parents whose child has a serious physical anomaly or mental disability but does not die at birth.

Chronic hypertension Hypertension that occurs before the 20th week of gestation, or continues beyond the 42nd postpartum day.

Civil law Protects individuals by punishing wrongs against the individual.

Clastogen Agent capable of producing chromosome breakage.

Cleansing breath Initial breath taken at the beginning of uterine contraction activity or other conscious breathing technique; helps replenish the oxygen deficit.

Cleft lip Congenital fissure or elongated opening of the lip.

Cleft palate Congenital fissure in the palate.

Clubfoot (talipes equinovarus) Congenital deformity in which portions of the foot and ankle are twisted out of normal position.

Coarctation of the aorta A congenital condition characterized by the narrowing of the arterial walls of the aorta. This condition may be diagnosed in infancy by diminished femoral pulses as compared to radial pulses, a systolic blood pressure >90 mm Hg, and a difference of 10 mm Hg or more lowered systolic blood pressure between the infant's arm and thigh.

Code Definition of professional obligations and responsibilities expected of practitioners by society.

Cognitive development Age-related development of intellectual reasoning and perception.

Cohabitation Couple living together without entering into marriage.

Coitus interruptus Contraceptive method involving removal of the penis from the vagina before ejaculation.

Colostrum A yellowish, protein-rich fluid secreted from the breast during pregnancy and for 3 to 4 days following delivery.

Communal family Group of individuals, couples, or families living together and jointly carrying out family functions.

Complementary therapies Therapies used in addition to or as an adjunct to biomedicine for the promotion of health and well-being.

Congenital disorder Anomaly present at birth; results from genetic or prenatal environmental factors, or both.

Congenital heart defect A structural abnormality or defect of the heart that is present at birth.

Containment Developmental technique using the caregiver's hands or cloth boundaries to support an infant's arms and legs close to the body.

Contraception Prevention of pregnancy.

Contracted maternal pelvis Abnormalities in pelvic measures or shapes that fall short of the measures or shapes required for an average delivery.

Contraction Tightening and shortening of the uterine muscles during labor causing effacement and dilatation of the cervix.

Contraction stress test (CST) Evaluation of uterine contractions for the purpose of assessing fetal response.

Corona radiata Layer of cells surrounding the zona pellucida of the ovum.

Corpus luteum Yellow glandular mass in the ovary formed by an ovarian follicle that has matured and discharged its ovum.

Cost-benefit analysis Process of measuring and comparing the cost of doing something against the outcome in monetary terms.

Cost containment Reduction of expenses by working more efficiently.

Cost-effectiveness analysis Process of comparing the cost of doing something and measuring the outcomes in nonmonetary terms.

Cotyledons Subdivisions along the uterine surface of the placenta.

Couvade Physical symptoms experienced by an expectant father during pregnancy; also the ritualistic behaviors he performs during labor and birth.

Criminal law Addresses public concerns and punishes the wrongs that threaten a group or society.

Crisis Situation in which the balance in an individual or family life is disrupted and new coping strategies must be developed.

Critical thinking Formal and structured type of reasoning used in nursing as the foundation for sound clinical judgment.

Crowning The point at which the fetal head is visible at the vulvar opening.

Cultural competence continuum Progressive description of the ability of an individual or institution to respond to the individual culturally specific needs of the people.

Cultural competency Process of integrating cultural awareness in the delivery of culturally appropriate clinical care.

Culture An individual's way of looking at life, encompassing the person's feelings, beliefs, attitudes, and practices in dealing with family, community, and society.

Cyanosis The bluing of the skin or mucous membranes that results from the inability of the circulatory system to properly oxygenate the tissues. Cyanosis in infancy may be noted centrally on the chest and face or peripherally in the fingers and toes.

Cytogenetics The study of chromosomes, with special focus on chromosome abnormalities.

Cytotrophoblast Inner layer of the trophoblast; also referred to as Langhan's layer.

D

Daily Reference Values (DRVs) Standards for daily intake of total fat, saturated fat, cholesterol, total carbohydrate, dietary fiber, and protein.

Date rape Assault between a dating couple without the consent of one of the participants.

Deceleration Slowing of the fetal heart rate in response to parasympathetic activity.

Decidua Term applied to the endometrium during pregnancy.

Decidua basalis Portion on which the implanted ovum rests.

Decidua capsularis Portion directly overlaying the implanted ovum.

Decidua parietalis Decidua exclusive of the area occupied by the implanted ovum.

Deletion Loss of chromosomal material.

Deontology Form of ethical reasoning that focuses on duty; right actions are those that fulfill duty.

Dermatome Area of the body innervated by a specific spinal nerve.

Descent Progression of the fetal head into the pelvis.

Desire phase First phase of human sexual response in which an individual develops a motivation or intention to be sexual.

Developmental care Infant care protocol designed to promote optimal physical, cognitive, and emotional development in the first weeks or months of life.

Developmental crisis Adjustment of an individual to new stages of development.

Developmental dysplasia of the hip (DDH) Malformation of the hip involving varying degrees of deformity, ranging from subluxation to complete dislocation.

Developmental tasks Competencies in psychosocial development related to identity formation, sexual identity, vocational identity, and autonomy and independence.

Diaphragm Barrier contraceptive device that fits over the cervix.

Diaphragmatic hernia Condition in which the diaphragm fails to close during the seventh or eighth week, allowing the abdominal organs to be displaced into the left chest.

Diastasis recti Muscle separation midline in the abdomen due to pregnancy.

Dietary Guidelines for Americans Guidance on diet and health for the general population with practical recommendations that meet nutritional requirements, promote health, support an active lifestyle, and reduce the risk of chronic disease.

Dilation The widening of the external os of the uterine cervix from closed to a maximum of 10 cm, at which time the cervix is said to be fully dilated.

Dilemma Choice between two equally unsatisfactory alternatives.

Diploid Cell that contains two copies of each chromosome; the diploid number (2n) in humans is 46.

Disease prevention Activities taken to prevent the onset of a disease or disorder.

Disseminated intravascular coagulation (DIC) Hemorrhagic disorder that occurs following the uncontrolled activation of clotting factors and fibrinolytic enzymes throughout small blood vessels, resulting in tissue necrosis and bleeding.

Dizygotic Derived from two separate zygotes (e.g., fraternal twins).

Doctrine of the golden mean Virtues at the midpoint between extremes of less desirable characteristics.

Dominant Allele that is phenotypically expressed in single copy (heterozygote) as well as double copy (homozygote).

Doppler blood studies Measurement of blood flow velocity and direction in major fetal and uterine structures; also known as umbilical vessel velocimetry.

Dosha Term used in Ayurvedic medicine to refer to metabolic types of people.

Doula A woman who is employed by the pregnant woman to assist her through labor by helping her cope with the pain.

Ductus arteriosus Fetal shunt that connects the pulmonary artery to the descending aorta.

Ductus venosus Fetal shunt passing through the liver that connects the umbilical vein to the inferior vena cava.

Due care Legal and ethical standard of performance by which nursing professionals are expected to abide.

Duration Period from the beginning of one contraction to the end of the same contraction.

Dyad Group of two people.

Dysfunctional grieving Extended, unsuccessful use of intellectual and emotional responses by which individuals, families, or communities attempt to work through the process of modifying self-concept based on the perception of loss.

Dysfunctional uterine bleeding (DUB) Any significant deviation from the usual menstrual pattern; also known as abnormal uterine bleeding (AUB).

Dysmenorrhea Painful menses or cramping associated with menstruation.

Dysmotility Low rate of gastrointestinal peristalsis.

Dyspareunia Painful sexual intercourse.

Dystocia Failure of labor to progress.

E

Early onset deceleration Slowing of the fetal heart rate corresponding to the onset of a uterine contraction and a slow return to the baseline soon after the contraction ends, like a mirror image; caused by fetal head compression.

Eclampsia Seizures in a pregnant woman.

ECMO (extracorporeal membrane oxygenation) A type of cardiopulmonary bypass therapy.

Ecologic environment Combined societal context in which a family resides.

Ectopic pregnancy Implantation of a fertilized ovum in a location other than the endometrial lining of the uterus.

EDB Expected date of birth.

EDC Expected date of confinement or “due date.”

EDD Expected date of delivery.

Effacement Shortening and thinning of the cervix that occurs during the labor process.

Elderly primigravida Woman over age 35 who is pregnant for the first time.

Elective abortion Voluntary termination of pregnancy before fetal viability at the request of the client.

Embryo Period of human development from the second week until the eighth week after fertilization; period characterized by cell differentiation and hyperplastic growth.

Embryo transfer (ET) Transfer of an externally fertilized egg in embryonic stage by transcervical or other methods.

Emergency childbirth Childbirth that occurs too rapidly for the mother to get to the hospital.

Emergency contraception Postcoital prevention of pregnancy.

Empowering A therapeutic approach that encourages the family to actively participate in the solution to their problems and acknowledge that capacity.

Empowerment Process of assisting clients to care for themselves.

Enablement Process of assisting clients in locating needed services and resources.

Enabling The approach to interventions that allows competencies to develop in the client.

Encephalocele Herniation of the brain and meninges through a skull defect.

Endometrial cancer Malignant neoplasm of the uterine lining.

Endometriosis Chronic disorder caused by implantation of endometrial tissue outside the uterus.

Endometritis Infection of the uterine lining.

Endometrium Cellular lining of the uterus that is shed monthly at the time of menses.

Enface positioning Face-to-face positioning between parent and newborn.

Engorgement Process of swelling of the breast tissue due to vascular congestion following delivery and preceding lactation.

Engrossment Process characterized by intense paternal interest in the newborn.

Enhancement Process of building on a client's existing strengths to increase capacity for problem solving and self-care.

Epidural Technique used to produce analgesia or anesthesia of the lower body by placing opioid and/or local anesthetic within the epidural space, which then diffuses into the nerve roots as they exit the dura.

Episiotomy Surgical incision made to enlarge the vaginal opening for delivery of the baby's head.

Epispadias Condition in which the urethral meatus is located on the dorsal surface of the penis.

Erythema toxicum A transient, red, irregular rash appearing shortly after birth first on the infant's face and then spreading to the chest and extremities. The cause of the rash is unknown and no special treatment is required.

Erythroblastosis fetalis Vast destruction of fetal red blood cells by maternal antibodies, resulting in fetal anemia.

Esophageal atresia Condition in which the esophagus ends in a blind pouch or narrows into a thin cord and is not connected to the stomach.

Estrogen Female sex hormone produced primarily by the ovary and stored in fat cells.

Estrogen deficiency vulvovaginitis Vulvovaginal burning related to estrogen decline.

Ethic of care Perspective that recognizes the personal concerns and vulnerabilities of clients in health and illness.

Ethics Branch of philosophy that provides rules and principles that can be used for resolving ethical dilemmas.

Ethnic group Community of people who share the same cultural and social beliefs, which have been passed from one generation to another.

Euploid Cell (and, by extension, an individual) whose chromosome number is a multiple of 23.

Evidence-based practice Systematic approach to finding, appraising, and judiciously using research results as a basis for clinical decisions.

Excitement phase Phase of the human sexual response in which physical and emotional changes take place in the person to increase interest in intercourse.

Exstrophy of the bladder Anomaly in which the anterior wall of the bladder and lower portion of the abdominal wall are absent, causing the bladder to lie open and exposed on the lower abdomen.

Extended family Family that includes generations beyond the parents and their children such as grandparents or aunts and uncles; two or more nuclear families together.

External cephalic version Procedure by which the physician manipulates the fetus externally through the maternal abdomen to turn the fetus from an abnormal presentation (usually breech) to a cephalic presentation.

Extrauterine life Life outside of the uterus following birth.

Extremely low birth weight (ELBW) Weight of 1,000 grams or less at birth.

F

Face presentation Fetal descent in which hyperextension of the fetal head and neck allows the fetal face to descend into the maternal pelvis, as opposed to flexion, which results in fetal vertex presentation.

Facial palsy Paralysis of one side of the face.

Facilitated tucking Gentle handling of an infant by providing boundary support.

False discharge Fluid appearing on the nipple or areolar surface that is not secreted by the breast tissue.

Family Group of adults and children linked by biological, kinship, or social bonds.

Family boundaries The demarcations between individuals within a family and between the family and the rest of society.

Family dynamics Concept from psychology that refers to patterns in the interrelationships within the family.

Family planning Cognitive decisions and behavioral practices that enable individuals to conceive a wanted pregnancy and avoid an unwanted or badly timed pregnancy.

Family structure Configuration of the family unit, including who is in the family and their relationship to each other.

Femicide Homicide of women.

Fern test Procedure done to determine presence of amniotic fluid.

Fertility rate Number of births per 1,000 women ages 15 to 44.

Fertilization Process by which the male's sperm unites with the female's ovum.

Fetal alcohol effects Detectable effects of maternal alcohol consumption.

Fetal alcohol syndrome A collection of deformities and disabilities seen in offspring of women who use alcohol heavily in pregnancy.

Fetal attitude Relationship of fetal body parts to one another.

Fetal circulation The pathway of blood circulation in the fetus.

Fetal distress Nonreassuring fetal heart rate responses to the intrauterine environment. Distress reflects hypoxia and respiratory or metabolic acidosis.

Fetal fibronectin (fFN) testing Screening procedure for the prediction of preterm labor.

Fetal heart rate (FHR) The number of times the fetal heart beats per minute.

Fetal lie Relationship of the fetal long axis to that of the maternal long axis or spinal cord.

Fetal movement counting (FMC) Daily maternal assessment of fetal activity by counting the number of fetal movements within a specified time period.

Fetal position Relationship of the fetal presenting part to the left or right side of the maternal pelvis.

Fetal presentation Anatomic part of the fetus that is either in, or closest to, the birth canal.

Fetal tissue sampling Direct biopsy of fetal tissue.

Fibroadenoma Painless solid breast mass or tumor.

Fibrocystic changes Hormonal age-related changes most commonly involving cyst formation and thickening of breast tissue.

Fibroid tumor Benign tumor arising in the myometrium that can protrude into the uterine cavity, bulge through the outer uterine layer, and grow within the myometrium.

Fidelity Quality of being faithful.

Fimbriae Fine, hair-like structures.

First stage of labor Begins with regular contractions and ends when the cervix is completely dilated. The first stage of labor is divided into three phases: latent, active, and transition.

Flexion Occurs when the fetal head meets resistance from the pelvic floor and wall at the cervix, causing the fetal head to flex the chin against the fetal chest.

Focal point Internal or external point of reference that serves as a centering factor. This is used to focus cognitive attention away from the discomforts of labor.

Follicle-stimulating hormone (FSH) Hormone produced by the anterior pituitary whose function is to stimulate the ovary to prepare a mature ovum for release.

Follicular phase Phase of the ovarian cycle in which a follicle becomes mature and prepared for ovulation.

Follow-up services Health care services provided following hospital discharge.

Fontanel Point of intersection where the skull bones are united by membranes that allows the head to mold during the birthing process.

Food Guide Pyramid Translation of the *Dietary Guidelines for Americans* into practical eating portions and, if foods are chosen carefully, they also meet the recommended daily allowances (RDA) and Dietary Reference Intakes (DRI).

Foramen ovale An opening in the septum between the right and the left atria of the fetal heart.

Forceps Metal instruments used on the fetal head to assist in delivery.

Foremilk Thin, watery breastmilk secreted at the beginning of a feeding.

Fourth stage of labor First 4 hours after delivery of the placenta.

FPAL Acronym for the 4 digits of parity: *full-term* deliveries (37–40 weeks gestation); *premature* or *preterm* deliveries (between 20 and 36 weeks gestation); *abortions*, spontaneous or induced (termination of pregnancy before 20 weeks gestation); and *living children* born to the client who are alive at time of data collection.

Frequency Period of time from the beginning of one contraction to the beginning of the next contraction.

Fundus Top portion of the uterus; massaged with the hands after delivery to ascertain and maintain firmness.

G

Galactopoiesis Maintenance of established lactation.

Galactorrhea White discharge from the nipples.

Gamete Mature reproductive cell; spermatozoon or ovum.

Gametogenesis Series of mitotic and meiotic divisions that occurs in the gonads that leads to the production of gametes; in males, *spermatogenesis*, and in females, *oogenesis*.

Gastroesophageal reflux (GER) Spontaneous passage of acidic gastric contents from the stomach into the esophagus.

Gastroschisis Abdominal wall defect to the right of the umbilicus through which the abdominal organs have herniated.

Gavage feeding Feedings given through a tube which is passed through the nose or the mouth into the stomach.

Gene Segment of nucleic acid that contains genetic information necessary to control a certain function, such as the synthesis of a polypeptide (structural gene); also referred to as a site, or locus, on a chromosome.

General anesthesia Loss of sensation from the entire body secondary to loss of consciousness produced by intravenous and/or inhalation anesthetic agents.

Genetic counseling Process by which genetic information is given to clients and their families.

Genetic disorder Inherited defect transmitted from generation to generation.

Genotype Genetic constitution of an individual at any given locus.

Geophagia Ingestion of nonfood substances such as dirt or clay.

Gestational diabetes Diabetes diagnosed in pregnancy.

Goals Broad statements of a desired outcome.

Gonadal Pertaining to the ovaries in the female and the testes in the male.

Gonadotropin releasing hormone (Gn-RH) Neurohormone released by the hypothalamus that acts on the pituitary to stimulate the release of follicle-stimulating hormone, luteinizing hormone, thyroid stimulating hormone, and prolactin.

Goodell's sign Marked softening of the cervix in early pregnancy.

Graafian follicle Fully mature ovum and surrounding elements just before ovulation.

Gravida Number of pregnancies, regardless of duration or outcome.

Gravidity Number of times a woman has been pregnant.

Grief Intense and personal experience in response to a loss.

Grief work Work that includes acceptance of painful emotions, active review of the experience and events, and testing new patterns of interaction and integration of the loss into daily living.

H

Habituation A newborn's ability to alter response to a repeated stimulus by decreasing and finally eliminating the response after repetitions of the stimulus.

Haploid Cell that contains one copy of each chromosome; the haploid number (n) in humans is 23.

Harm Interference with the mental or physical well-being of others.

Healing Restoring to health.

Health care informatics Integration of computer science, information science, and various health care professionals involved in collecting, processing, and managing data.

Health maintenance Preventing, or detecting early, particular health deviations through routine periodic exams and screenings.

Health promotion Process, action, program, or endeavor to obtain the goal of complete physical, mental, and social well-being.

Heavy metal A chemical substance, such as lead or mercury, that may be a by-product of industry.

Hegar's sign Softening of the isthmus of the uterus in pregnancy.

HELLP syndrome A severe manifestation of PIH with hemolysis, elevated liver enzymes, and low platelets.

Heme iron Iron from animal sources, which constitutes about half of the iron available from animal sources.

Hemizygous Condition in which an allele is present in a single copy.

Hemochromatosis Rare genetic defect in iron metabolism in which excess iron is deposited in tissues, causing skin pigmentation, hepatic cirrhosis, and decreased carbohydrate tolerance, which eventually ends in multiple organ failure.

Hemolytic disease of the newborn Destruction of the neonate's red blood cells due to isoimmunization (RH or ABO incompatibility) or inadequate vitamin K, which leads to the inability to produce clotting factors and consequent risk of hemorrhage.

Hemosiderosis Iron storage disorder resulting in iron toxicity.

Herbicide Chemical designed to kill unwanted plant life such as weeds.

Herbs Leafy plants that do not have woody stems.

Heterozygote Individual who has two different alleles at a given locus on a pair of homologous chromosomes.

Hindmilk Thicker, high-fat breastmilk secreted at the end of a feeding.

Holism Philosophy of integration of body, mind, and spirit within a dynamic environment.

Home care Provision of technical, psychological, and other therapeutic support in the client's home environment rather than in an institution.

Home care nursing Delivery of nursing care in the home environment.

Home visit Visit occurring in the family's place of residence or in any such facility where a family may be housed, such as a homeless shelter, group home, church, or halfway house.

Homologous Refers to chromosomes with matching genes.

Homozygote Individual who has a pair of identical alleles at a given locus.

Human chorionic gonadotropin (hCG) Hormone secreted by the corpus luteum of the ovary after conception.

Human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) Retrovirus that causes progressive and severe impairment of the body's natural immunologic function (HIV), resulting in serious opportunistic infections, various cancers, and eventual death (AIDS).

Human placental lactogen (HPL) Hormone produced by the syncytiotrophoblast cell as early as 3 weeks after ovulation and is detectable in the maternal serum at 4 weeks after fertilization.

Hyaline membrane disease Surfactant deficiency characterized by collapsed alveoli and low lung volume.

Hydramnios Excess of amniotic fluid.

Hydrocele Collection of serous fluid in the scrotum.

Hydrocephaly Condition that results from an excess accumulation of cerebrospinal fluid (CSF) in the ventricles of the brain, caused by an imbalance between CSF production and absorption.

Hydrops fetalis Severe form of fetal hemolytic disease; severe anemia results in hypoxia, cardiac decompensation, and hepatosplenomegaly.

Hyperbilirubinemia Elevated level of bilirubin in the blood.

Hyperemesis gravidarum Severe vomiting during pregnancy.

Hyperglycemia Blood glucose level greater than 125 mg/dL in the term infant and greater than 150 mg/dL in the preterm infant.

Hyperkalemia Infant's serum potassium greater than 7 mg/dL.

Hypernatremia Infant's serum sodium greater than 155 mg/dL.

Hyperthermia Dangerous elevation in body temperature due to fever or external heat sources.

Hypertonic contractions Elevated uterine resting tone or contractions that are either too strong in intensity or more frequent than 5 in 10 minutes.

Hypertonic labor Uterine activity characterized by uterine irritability, poor resting tone, and contractions occurring at a frequency of closer than every 2 minutes.

Hyperventilation A change in the oxygen-carbon dioxide exchange; a consequence of breathing too rapidly and too deeply.

Hypocalcemia Low level of calcium in the blood (less than 7 mg/dL).

Hypochromic anemia Anemia characterized by red blood cells lacking in color.

Hypoglycemia A less than normal amount of glucose in the blood; in the newborn, a plasma glucose level of less than 40 mg/dL.

Hyponatremia Infant's serum sodium less than 125 mg/dL.

Hypophyseal-pituitary-ovarian axis Transport mechanism of gonadotropin releasing hormone from the hypothalamus that stimulates the release of gonadotropins from the anterior pituitary that, in turn, causes stimulation of the ovaries to release estrogen and progesterone.

Hypospadias Congenital anomaly in which the urethral meatus is located on the ventral surface of the glans penis instead of at the end.

Hypothalamic-pituitary-gonadal axis Triad of the hypothalamus, pituitary, and ovaries that must function in synchrony in order for conception to occur.

Hypothalamic-pituitary-ovarian axis Transport mechanism of gonadotropin releasing hormone (Gn-RH) from the hypothalamus that stimulates the release of gonadotropins from the anterior pituitary, which then causes stimulation of the ovaries to release estrogen and progesterone.

Hypothermia Rectal or axillary temperature below 97°F.

Hypotonic labor Abnormal labor pattern in which uterine contractions are inadequate in terms of frequency, intensity, or duration.

Hypovolemia Decreased circulating blood volume.

I

Imperforate anus A group of anomalies of the rectum and anus.

Implantable contraception Contraceptive surgically implanted into the client.

Implantation Embedding of the fertilized ovum into the endometrium.

Impotence Inability of the male to achieve or maintain an erection.

Incest Sexual relations between blood relatives or surrogate family members.

Incompetent cervix Used to describe painless dilation of the cervix, which causes the pregnancy to be lost.

Induced abortion Termination of pregnancy brought on intentionally by medical or surgical intervention. Induced abortions may be classified as therapeutic, performed for physical or mental health reasons, or as elective, performed at the request of the patient.

Infant of a diabetic mother (IDM) Infant born to a mother who has diabetes mellitus.

Infertility Diminished or absent ability to produce an offspring despite regular unprotected intercourse for 1 year.

Informed consent Information regarding treatment procedures given to clients, and their consent is secured.

Injectable contraception Contraceptive administered by intramuscular injection.

Insensible water loss Evaporation of water through the skin and mucous membranes.

Insoluble fiber Fiber that resists absorption into the body.

Integrated medicine Provision of health care services combining both biomedical and complementary medicine.

Intensity Strength of the contraction at its peak.

Interdisciplinary team Health care delivered by individuals from various disciplines who share responsibility, authority, and decision-making.

Interspinous diameter Transverse diameter between the two ischial spines of the pelvis.

Intracranial hemorrhage Collection of blood within the cranium.

Intrathecal Technique used to produce analgesia of the lower body by placing a small amount of opioid drug into the cerebral spinal fluid.

Intrauterine growth restriction (IUGR) Term to describe an infant whose birth weight, length, and head circumference are less than the 10th percentile based on standardized graphs.

Intrauterine pressure catheter A fetal monitoring device that accurately monitors internal uterine pressure during labor.

Intraventricular hemorrhage (IVH) Hemorrhage into the ventricles of the brain; common in preterm infants.

Invasive breast cancer Cancer that has extended beyond the local epithelium and has the potential to spread from the breast to other parts of the body.

Invasive cancer Cancer that has spread or infiltrated beyond the original site or organ.

Inversion of the uterus Turning of the uterus inside out, resulting in serious hemorrhage and shock.

Involution Reduction in size of the uterus following childbirth.

Ionizing radiation Energy in wave or particle form (such as x-ray) that is capable of releasing ions from irradiated tissue.

J

Jaundice Accumulation of bilirubin that produces a yellow discoloration of the newborn's skin, mucous membranes, and sclera.

Justice Division of benefits and burdens in society.

K

Kangaroo care Skin-to-skin contact between mother and infant.

Karyotype Chromosome constitution of an individual represented by a laboratory-made display, in which chromosomes are arranged by size and centromere position.

Kernicterus Excess accumulation of unbound, unconjugated bilirubin deposited in brain tissues, especially the basal ganglia.

Ketoacidosis Acidosis with the accumulation of ketone bodies in the body's tissues and fluids.

Kleihauer-Betke test A test used to note evidence of fetal cells in maternal circulation, which is of special significance for Rh-negative pregnant women.

L

Labor Physiologic process by which the fetus, placenta, and membranes are expelled through the uterus; also known as parturition.

Labor augmentation Process of stimulating more effective uterine activity through the use of oxytocin.

Labor induction Stimulation of uterine contractions before the onset of labor for the purpose of accomplishing delivery.

Laceration A tear in the perineum, vagina, or cervix caused by childbirth.

Lactation consultant Specially trained health care provider whose primary focus is providing assistance to help new mothers establish breast-feeding.

Lactation discharge Any secretory breast discharge occurring as a physiologic response to the normal hormonal stimulation of pregnancy, postpartum, or after weaning.

Lactogenesis The process of milk production 2–5 days postpartum.

La Leche League International organization that promotes breast-feeding.

Langhan's layer Inner layer of the trophoblast; also referred to as the cytotrophoblast.

Lanugo Downy hair that is present on the fetus between the 13th week and birth.

Large for gestational age (LGA) Term to describe an infant whose birth weight is 2 standard deviations above the mean weight for gestational age or above the 90th percentile.

Latching-on Proper attachment of the infant to the breast for feeding.

Latent phase First phase of the first stage of labor, from 0–4 centimeters of cervical dilatation.

Late onset deceleration Slowing of the fetal heart rate that commences after the onset of the contraction. The fetal heart rate returns to baseline after the contraction has ended. This ominous pattern is caused by uteroplacental insufficiency and occurs in conjunction with diminished or absent variability.

Laws Rules governing human behavior that represent the minimum standard of mortality.

Leopold's maneuvers Method of abdominal palpation to determine the presentation and position of the fetus.

Let-down reflex Milk ejection from the breast triggered by nipple stimulation or emotional response to the infant.

Letting-go phase Final phase of maternal adjustment characterized by role attainment and relationship adjustment.

Leydig cells Interstitial tissue cells of the testes that produce testosterone.

Liability Accountability for professional conduct according to standards that have been set.

Libido Conscious or unconscious sexual desire.

Life expectancy Average number of years for which a group of individuals of the same age are expected to live.

Lightening Movement of the presenting part of the fetus into the true pelvis.

Linea nigra Dark line of pigmentation that extends from the symphysis pubis to the umbilicus, in the midline of the abdomen, during pregnancy.

LMP Last menstrual period.

Local anesthetic Class of drugs that produces reversible blockade of electrical impulses along nerve fibers.

Local infiltration anesthesia Loss of sensation in a small area owing to blockade of neural impulses as a result of infiltration of tissue with an anesthetic drug such as lidocaine.

Localized breast cancer Cancer that has not metastasized, is usually less than 2 cm in size, is considered noninvasive beyond the breast, and has the best outcome.

Lochia Normal uterine discharge of blood, mucus, and tissue following childbirth.

Long-term variability (LTV) Type of fetal heart rate variability measured in minute intervals from the baseline and rated as decreased, 0–5 bpm; average, 6–25 bpm; or marked, >25 bpm (on a 3-point scale).

Low birth weight (LBW) Weight of 2,500 grams or less at birth.

Low-lying placenta A condition in which the exact relationship of the placenta to the cervical os is not determined, or when apparent placenta previa occurs before the third trimester of pregnancy.

Luteal phase Phase of the ovarian cycle after ovulation when the corpus luteum secretes hormones to prepare the uterine endometrium for implantation until the placenta matures and assumes the function of providing nutrients for the embryo.

Luteinizing hormone (LH) Anterior pituitary hormone whose surge occurs immediately before ovulation and is responsible for release of the ovum.

M

Macrocephaly A head circumference that measures more than 38 cm at delivery and remains 38 cm or larger at 48 hours of life.

Macro-environment Elements that define the caregiving milieu, that is, conditions that define the surrounding space in which caregiving occurs.

Macronutrients Any of the chemical elements, such as carbon, required in relatively large quantities for growth.

Macrosomia Infant with a birth weight above the 90th percentile for gestational age or birth weight greater than 4 kg (8 lb, 12.8 oz).

Magnetic resonance imaging (MRI) Noninvasive diagnostic tool that provides high-resolution cross-sectional images of fluid-filled soft tissues.

Malposition Fetal position other than occiput anterior, including occiput transverse, occiput posterior, and oblique, or acynclitic, positions.

Malpractice Negligence involving the actions of professionals.

Malpresentation Fetal presentation other than vertex, including breech, transverse, compound, shoulder, face, and brow.

Mammogenesis Mammary growth.

Managed care Health care plan with a selected list of providers and institutions from which the recipient is entitled to receive health care that is reimbursed by the insurer.

Marginal placenta previa The placenta lies within 2–3 centimeters of the cervical os.

Mastectomy Excision (removal) of the breast.

Mastitis Infection in the breast, usually confined to a milk duct, characterized by influenza-like symptoms and redness and tenderness in the infected breast.

Material principles of justice Guidelines that can be used to justify the distribution of benefits.

Maternal-infant bonding Formation of an emotional attachment between mother and newborn.

Maternal role attainment Process by which a woman acquires knowledge of maternal behavior that aids in transforming her maternal identity.

Maternal sensitization Process by which the maternal immunologic system forms antibodies against fetal blood cells.

Maternal serum-alpha-fetoprotein (MS-AFP) testing Screening of maternal blood (MS) for the presence and volume of alpha-fetoprotein (AFP).

Mature milk Breast milk that contains 10% solids for energy and growth.

Meconium Initial stool developed in the fetus; it is viscid, sticky, dark in color, sterile, and odorless.

Meconium staining Staining of the newborn's skin and nails; results from fetal passage of stool in utero.

Medicalization of childbirth Treatment of childbirth as a medical event rather than a natural process.

Medical model Biomedical approach to health care oriented to treating specific diagnoses and focused on physical problems.

Meiosis Process by which germ cells divide and decrease their chromosomal number by half.

Menarche Initiation of the first menses.

Meningocele Spinal cord defect in which an external sac protrudes through the defect and contains meninges and cerebrospinal fluid.

Menopause Natural or surgically imposed cessation of menses.

Menses Monthly bleeding from the lining of the uterus.

Menstrual phase Phase of the menstrual cycle when a woman experiences vaginal bleeding.

Meridian In Oriental medicine, the channels or pathways in the body through which Chi travels.

Mesenchyme Meshwork of embryonic connective tissue that forms the connective tissue of the body, blood vessels, and lymph vessels.

Metastatic breast cancer Breast cancer that is found in parts of the body in addition to the breasts.

Microcephaly Condition in which there is a normal-sized head that contains a small brain.

Microcytic anemia Anemia characterized by red blood cells of small size.

Micro-environment Elements that are specifically related to the individual infant's environment or care experiences.

Micronutrients Any of the chemical elements, such as iron, required in minute quantities for growth.

Midpelvis Second of three pelvic planes.

Milia Small, white pimples that appear on the infant's face and chin after delivery.

Mitosis Process in which body cells duplicate themselves and then separate into two new daughter cells.

Mittelschmerz Abdominal pain occurring at the time of ovulation.

Modified-paced breathing Controlled pacing of the increased respiratory rate needed for adequate oxygenation as labor progresses.

Molding Overlapping of the fetal skull bones that helps the fetal head adapt to the size and shape of the maternal pelvis.

Mongolian spots The dark purple-blue or blue-green diffuse skin color noted on the buttocks of an infant.

Monosomy Aneuploid condition of having a chromosome represented by a single copy in a somatic cell; that is, the absence of a chromosome from a given pair.

Monozygotic Derived from one zygote (e.g., identical twins).

Montevideo units A numerical method of calculating adequacy of contraction strength.

Morbidity rate Ratio of the number of cases of a disease or a condition to a given population.

Mortality rate Ratio of the number of deaths in various categories to a given population.

Morula Solid mass of cells formed by cleavage of a fertilized ovum.

Mosaicism Condition that results in an individual (mosaic) with two or more genetically different cell populations.

Mottling A transient skin condition in infancy noted by a lacy framework of blue or red blood vessels surrounding whitened areas of skin in a "cobblestone" appearance; also called *cutis marmorata*.

Moxibustion In Oriental medicine, the burning of herbs near the skin in order to affect movement of Chi.

Multifactorial Resulting from interactions between genetic and environmental factors.

Multipara Woman who has given birth following two or more pregnancies of at least 20 weeks' gestation each.

Multiple gestation Carrying more than one fetus during the same pregnancy.

Mutation Abrupt genetic alteration in an individual, which is transmitted to the offspring.

Myelomeningocele Spinal cord defect in which part of the spinal cord is herniated into an external sac, which contains meninges, neural tissue, and cerebrospinal fluid.

N

Nägele's rule Method for calculating the “due date” from date of last menstrual period.

Necrotizing enterocolitis (NEC) An acquired disease process characterized by necrosis of the mucosal and submucosal layers of the gastrointestinal tract.

Neglect Withholding of essential components of daily living such as food, clothing, medications, and shelter.

Negligence Unintentional wrong caused by failure to act as a reasonable person would under similar circumstances.

Neonatal abstinence syndrome A collection of symptoms that may include sneezing, vomiting, diarrhea, irritability, and seizures seen in newborns withdrawing from prenatal exposure to narcotics.

Neonatal death A live-born infant who dies before completing 28 days of life, regardless of gestational age.

Nephrocalcinosis Renal calcifications of unknown etiology; may be associated with premature infants who require furosemide therapy, fluid retention, and calcium supplementation.

Nesting (energy spurt) Burst of energy experienced by many women 24–48 hours before the onset of labor.

Neurohormonal Pertaining to hormones formed by neurosecretory cells and liberated by nerve impulses.

Neutral thermal environment A set of environmental conditions created to maintain normal body temperature and minimize oxygen consumption and caloric expenditure.

Neutropenia Decreased number of neutrophils.

Nipple discharge Fluid produced by and accumulating within a secretory unit of the breast exiting through the nipple.

Nitrazine test A test for the presence of amniotic fluid. Nitrazine paper is sensitive to pH and turns blue when in contact with the alkaline amniotic fluid.

Nondisjunction Failure of homologous chromosomes, or chromatids, to separate properly during anaphase meiosis I and II, or mitosis, resulting in daughter cells with unequal chromosome numbers; meiotic nondisjunction may result in gametes with abnormal chromosome number, which on fertilization may produce aneuploidy; mitotic nondisjunction that occurs in a developing embryo may result in mosaicism.

Nonheme iron Dietary iron from foods other than meats, in which the iron is not bound in the hemoglobin molecule; comprises half of the iron found in animal sources and all of the iron found in plant sources, including grains and cereals.

Nonimmune hydrops fetalis (NIHF) Severe edema of the fetus that is not the result of isoimmunization.

Nonmaleficence Acting to prevent harm to others.

Nonperiodic fetal heart rate changes Transient changes in fetal heart rate not associated with contractions, although they can occur during a contraction.

Nonstress test (NST) Evaluation of fetal heart rate in response to an increase in either spontaneous or stimulated fetal activity.

Nuchal cord Umbilical cord encircling the fetal neck.

Nuclear family Unit composed of two generations, parents and their children.

Nutrition Facts food label Labeling on processed packaged foods that lists credible health and nutrient content claims, standardized serving sizes, and percent daily values (DV's) based on a 2000-calorie diet.

O

Obesity Body weight of 20% or more over ideal body weight.

Objectives Specific short-term achievements expected to result in the accomplishment of a goal. These are generally written in specific measurable outcomes.

Obstetrical conjugate Anterior-posterior diameter of the pelvic inlet plane; indirect measurement estimated from sacral promontory to back of symphysis pubis.

Oligohydramnios Condition in which the amount of amniotic fluid is significantly less than the amount expected for the third trimester of pregnancy (less than 500 mL) or less than 5 cm total of a four-quadrant sonographic assessment.

Omphalocele Defect covered by a peritoneal sac at the base of the umbilicus, into which portions of the abdominal organs herniate.

Opioid Type of drug that binds to opioid receptors and produces a degree of analgesia; also known as a narcotic.

Opsonization Action of opsonins (substances that coat foreign antigens) to facilitate phagocytosis.

Organogenesis Development of organs.

Orgasmic phase Phase of the human sexual response after the plateau phase in which immense sexual tension is released.

Osteopenia Bone mass below normal levels.

Osteoporosis Progressive bone loss, increased bone fragility, and increased risk for bone fractures, which occurs in postmenopausal women.

Ovarian cancer Malignant neoplasm of the ovary.

Overshoot A rebound increase in fetal heart rate following a variable deceleration.

Ovulation Release of a mature ovum in preparation for conception.

Ovulation prediction Contraceptive method involving female prediction of fertile period through the use of basal body temperature charts and/or cervical mucus changes.

Oxytocin Hormone produced by the posterior pituitary that stimulates uterine contractions and the release of milk from the mammary glands.

P

Paced breathing Deep breathing that is consciously paced to no less than half the woman's normal respiratory rate; used during pregnancy and during the early phase of labor to promote relaxation.

Pagophagia Ingestion of nonfood substances such as ice and ice frost.

Para Number of births after 20 weeks gestation, whether live or stillbirth.

Parenteral Administration of drug via intramuscular or intravenous routes.

Parity Number of past pregnancies that have reached a gestation of viability regardless of whether the infant or infants were alive or stillborn.

Parturient Woman giving birth.

Parturition Physiologic process by which the fetus, placenta, and membranes are expelled through the uterus; also called labor.

Patent ductus arteriosus (PDA) Continued patency of the ductus arteriosus (blood vessel connecting the pulmonary artery with the aorta) after the first 24 hours of life.

Paternalism Interference in the liberty of a person, in which the interference is justified by promoting the well-being of that individual.

Pathologic discharge Results from pathologic conditions affecting the hypothalamic-pituitary axis, prolactin levels, or breast diseases that affect both breasts.

Pathologic grief Distortion of the normal bereavement process, including stoic responses to a death.

Pathologic jaundice Jaundice of the newborn caused by the excessive breakdown of red blood cells as a result of hematologic incompatibility.

Patterned-paced breathing Similar to modified-paced breathing but with the addition of a rhythmic pattern.

PCBs and PBBs Polychlorinated biphenyls and polybromated biphenyls, respectively, chemicals now banned but once produced in industry, that are highly stable and thus last for extended periods of time in the environment and human body. Exposure is hazardous in pregnancy, causing spontaneous abortion, growth deficits, and other problems in fetuses.

Pedigree (genogram) Diagram that describes family relationships and gender, disease status, or other relevant information about a family.

Pelvic inflammatory disease (PID) Inflammation of the uterus, fallopian tubes, or ovaries caused by ascent of vaginal flora or bacteria.

Pelvic inlet First of three pelvic planes encountered by the fetal head during the delivery process; often termed the brim of the true pelvis.

Pelvic outlet Third of the pelvic planes defined by the ischial tuberosities and the tip of the coccyx.

Pelvic relaxation The loss of muscle support of the pelvic organs.

Percutaneous umbilical blood sampling (PUB) Evaluation technique that provides direct access to the fetal circulation and involves direct aspiration of fetal blood.

Perimenopause Time period before the cessation of menses.

Perinatal asphyxia profound Metabolic acidosis at birth associated with Apgar scores of 3 or less that persist after 5 minutes and is associated with multisystem organ dysfunction and neurologic manifestations.

Perinatal education Education offered during the childbearing years to expectant families that provides insight and information about pregnancy, preparation for childbearing, family adaptation, and newborn care and development.

Periodic fetal heart rate changes Changes in the fetal heart rate associated with uterine contraction.

Periventricular leukomalacia (PVL) Symmetric, nonhemorrhagic lesion within the periventricular white matter of the brain.

Perpetrator Person accused of a criminal offense.

Persistent pulmonary hypertension in the newborn (PPHN) A condition caused by a sustained elevation in pulmonary vascular resistance after birth, preventing transition to the normal extrauterine circulatory pattern.

Pesticide Chemical designed to kill insects, rodents, or other unwanted small life forms harmful to crops or human habitation.

Phenotype Any observable or measurable expression of gene function.

Phototherapy Special ultraviolet light used in the treatment of jaundice in the newborn.

Physiologic anemia of pregnancy Disproportionate increase of the plasma volume compared with the red blood cell volume, resulting in a lower-than-normal hemoglobin and hematocrit level during pregnancy.

Physiologic discharge Result of physiologic conditions affecting all breast tissue equally, involving secretory tissue in each breast and resulting in milky white or multicolored fluid.

Physiologic jaundice Benign form of jaundice that usually occurs after the third day of life and is caused by the normal breakdown of superfluous red blood cells.

Phytochemicals Plant-based chemicals.

Phytotherapy The therapeutic use of plants, often referring to herbal remedies.

Pica Psychobehavioral disorder that manifests as persistent ingestion of substances having little or no nutritional value or the craving of unnatural articles as food during pregnancy.

Placenta percreta Abnormal placental attachment that completely penetrates the uterine myometrium.

Placenta previa Implantation of the placenta in the uterus that ranges from completely covering the cervical os (complete previa) to lying next to the os (marginal previa).

Placental stage The third stage of labor that begins as soon as the fetus is delivered and lasts until the placenta is delivered.

Plateau phase Phase of human sexual response occurring just before orgasm.

Plethora Deep rosy red color of the skin often seen with polycythemia, hyperoxia, or overheating.

Plumbism Ingestion of nonfood substances such as lead paint flakes.

Pneumatosis intestinalis Intraluminal gas in the bowel wall commonly seen with necrotizing enterocolitis (NEC).

Polycystic ovary syndrome Endocrine disorder characterized by long-term anovulation and an excess of androgens circulating in the blood; characterized by formation of cysts in the ovaries, a process related to the failure of the ovary to release an ovum.

Polycythemia Increased number of red blood cells.

Polydactyly Presence of more than five fingers or five toes on an infant's hand or foot. The extra digits may or may not include bone and are characteristics of family members.

Polygenic Referring to a trait whose phenotypic expression results from the cooperation of various genes.

Polyhydramnios Condition in which the amount of amniotic fluid in the uterus is increased to 2 or more liters within the third trimester.

Position statement Formalized statement by a professional organization to express the opinion of its membership.

Postconception age An infant's age from conception described in weeks.

Posterior fontanel The triangular-shaped open space between the sagittal suture and the lambdoidal suture.

Postnatal circulation The normal extrauterine circulatory pattern of blood flow through the heart, lungs, and body.

Postterm infant An infant determined to be greater than 42 weeks' gestational age by exam.

Postterm pregnancy A pregnancy that is greater than 42 postmenstrual weeks.

Prana Term used in Ayurvedic medicine referring to vital energy.

Precipitate labor Labor that progresses rapidly and ends with the delivery occurring less than 3 hours after the onset of uterine activity.

Precipitous delivery Unduly rapid progression of labor or occurrence of a delivery in which no physician is in attendance.

Precocious Developing maturity very early or rapidly.

Preconception care Consultation with health care professionals by a client before pregnancy to facilitate optimal pregnancy outcomes.

Preeclampsia Toxemia of pregnancy characterized by hypertension, edema, and proteinuria.

Pregnancy-induced hypertension (PIH) One of the three signs of preeclampsia (proteinuria, edema, and hypertension).

Premature ovarian failure Failure of ovarian estrogen production and ovulation after menarche and before age 40, in which the woman experiences the symptoms of menopause.

Premature rupture of membranes (PROM) Spontaneous rupture of the amniotic membranes before the onset of labor.

Prematurity Delivery at 37 weeks' or less gestation.

Premenstrual syndrome Cyclic cluster of behavioral, emotional, and physical symptoms that occurs during the luteal phase of the menstrual cycle and are of sufficient severity to interrupt normal activity.

Presenting part The part of the fetus that lies closest to the internal os of the cervix.

Preterm An infant born at less than 38 weeks' gestation.

Preterm birth Birth occurring before 37 weeks of gestation.

Preterm infant An infant determined to be younger than 37 weeks' gestational age by exam.

Preterm labor Labor that ensues before 37 completed weeks of gestation.

Preterm premature rupture of membranes (PPROM) Spontaneous rupture of the amniotic membranes before the onset of labor (PROM), which occurs before 37 completed weeks of gestation.

Prima facie A conditional duty that can be overridden by a more stringent duty.

Primary amenorrhea Absence of menarche until age 16 or absence of the development of secondary sex characteristics and menarche until age 14.

Primary apnea A self-limited condition characterized by absence of respiration; occurs in the early stage of asphyxia.

Primary dysmenorrhea Painful menses from uterine causes but without pelvic pathology; usually occurs within three years of the onset of menstrual cycling.

Primary powers Involuntary uterine contractions.

Primipara Term for a woman who has given birth from her first pregnancy of at least 20' weeks gestation.

Proactive Development of capacity to deal with stressors before a crisis.

Proband Clinically identified person who displays the characteristics or features of the disease; also referred to as *index case*, or *propositus* (fem: *proposita*).

Progesterone Antiestrogenic hormone produced by the corpus luteum of the ovary that assists in maintenance of pregnancy through implantation.

Prolactin Hormone from the pituitary gland that triggers milk production in response to tactile stimulation of the breast.

Proliferative phase Phase of the menstrual cycle in which the endometrium becomes prepared for implantation.

Prostaglandins Class of hormones found in many tissues that affects vasodilatation, constriction, and uterine smooth muscle.

Pseudomenstruation Pinkish-white mucoid vaginal discharge noted shortly after birth owing to the maternal transfer of estrogen.

Puberty Period in which the secondary sex characteristics begin to develop and the capability of sexual reproduction is attained; onset of the process of physical maturity.

Pudendal block Technique using local anesthesia to block transmission through the pudendal nerves.

Puerpera Term assigned to the woman during the puerperium.

Puerperal sepsis Postpartum infection.

Puerperium Postpartum period; the period of time lasting from delivery of the placenta to approximately 6 weeks after delivery; also known as the fourth trimester.

Pulmonary vascular resistance Resistance in the pulmonary vascular bed against which the right ventricle must eject blood.

Pushing stage Second stage of labor that begins when the cervix is completely dilated and effaced and ends when the fetus is expelled.

Pustular melanosis A skin condition that develops *in utero* with blister formation that resolves after delivery with the peeling of the outer layer of skin, leaving behind a scale of darker, pigmented skin.

Q

Quickening First fetal movement felt by the mother; usually noticed at about 18 to 20 weeks' gestation.

R

Race Group of people defined by similar physical features, such as skin color, facial features, and texture of body hair.

Rape Nonconsensual sexual penetration of another by force or threat of force.

Reactive nonstress test Presence of at least two spontaneous fetal heart rate accelerations of at least 15 beats per minute and at least 15 seconds duration each within a 10-minute window.

Recessive Allele whose phenotypic expression occurs in homozygous or hemizygous conditions.

Recommended Dietary Allowances (RDAs) Average daily nutrient intake levels recommended for healthy Americans.

Reconstituted family Family formed through remarriage.

Recovery stage Fourth stage of labor defined as the first 4 hours after delivery of the placenta.

Reducing agent Any substance that reduces another substance, or brings about reduction, and is itself oxidized in the process.

Reference Daily Intakes (RDIs) Standards that address the vitamin and mineral content of foods.

Refractory period Period of time after orgasm when the human is incapable of further sexual activity.

Regional anesthesia Loss of sensation from a large area of the body owing to a blockade of neural impulses.

Relactation Reinstitution of lactation after it has been discontinued.

Relinquishment The pregnant woman's decision to "give up" or relinquish her rights to parent her child.

Renal solute load The sum of solutes that must be excreted by the kidneys.

Reproductive loss Any loss related to reproductive function that may result in the process of grieving, including monthly menstruation for the infertile couple, miscarriage, preterm birth, birth of a child with an anomaly, death of one or more of a multiple gestation, intrauterine fetal death, neonatal death, relinquishment, and sudden infant death syndrome.

Residual urine Urine remaining in the bladder after elimination.

Resolution phase Phase of human sexual response when the physiologic changes in the body that occur as a result of sexual activity return to normal.

Respiratory distress syndrome (RDS) A membrane disease, also known as hyaline membrane disease, causing breathing difficulty in infants.

Resuscitation Basic emergency procedure used for life support consisting of airway management, positive pressure ventilation, chest compressions, medication, and thermal support.

Retinopathy of prematurity (ROP) Proliferation of abnormal blood vessels in the newborn retina.

Rh incompatibility (isoimmunization) Hemolytic disease caused by the incompatibility of Rh factors in maternal and fetal blood.

Risk assessment Process of examining the risk factors that may place an individual at risk for disease.

Risk-benefit analysis Determination of the risk of a given procedure versus its potential benefits.

Role attainment Completing the developmental tasks of a new social role.

Role mastery Successful attainment of developmental tasks.

Role transition Process of adopting new behaviors to accomplish change and developmental tasks.

Rooting reflex Normal response of the newborn to move toward whatever touches the area around the mouth.

S

Saltatory pattern Marked long-term variability; a baseline that is chaotic and jumps up and down multiple times each minute.

Screening A test or examination to detect the most characteristic signs of a disorder or disease that may require further investigation.

Secondary amenorrhea Absence of menses for at least 6 months or for three cycles after previously experiencing menstrual cycles.

Secondary apnea An abnormal condition that occurs in the late stages of asphyxia in which respiration is absent and does not resume spontaneously without resuscitation.

Secondary dysmenorrhea Painful menses accompanied by a pathologic process.

Secondary powers A woman's intentional effort to push out the fetus.

Second stage of labor Begins when the cervix is completely dilated and effaced and ends when the fetus is expelled.

Secretory phase Phase of the menstrual cycle that occurs after ovulation and before menstruation.

Seminiferous tubules Tubules that carry semen from the testes.

Sepsis Systemic bacterial, viral, or parasitic infection that invades the bloodstream.

Serial monogamy Practice of having one sexual partner at a time but several partners during a lifetime.

Seroconversion Conversion of blood serum from negative to positive for any infecting agent.

Sexual dysfunction Related to a disorder of one of the phases of human sexual response.

Sexual maturation Establishment of menstruation and ovulation in females and the development of spermatogenesis in males.

Short bowel syndrome Occurs with extensive resection of the gastrointestinal tract. This loss of absorptive surface results in diarrhea, dehydration, and poor growth.

Short-term variability (STV) Type of fetal heart rate variability measured in beat-to-beat changes in the baseline as either present or absent. It is only measurable with internal mode of fetal monitoring.

Shoulder An acceleratory phase preceding or following a variable deceleration.

Shoulder dystocia Condition in which fetal shoulder width prevents the fetal shoulders from being freely delivered beneath the maternal symphysis pubis; related to large fetal size and/or small size of maternal pelvis.

Shoulder presentation Fetal descent in which the shoulder precedes the fetal head in the maternal pelvis alone or along with the fetal arm and hand.

Situational crisis Event or situation that occurs in a personal or a family life that requires the adaptation or acquisition of new coping mechanisms.

Sleep-wake cycle Stages of newborn sleep pattern.

Small for gestational age (SGA) Term to describe an infant whose birth weight is smaller than expected for the gestational age.

Social assets Assets or benefits to one's health that are related to one's social position and socioeconomic status.

Soluble fiber Fiber that binds bile acids and coats the intestines, thus inhibiting absorption.

Solvent Organic compound widely used in industry to clean and manufacture mechanical or electronic components, which is hazardous to fetal well-being.

Somite One of the paired segments along the neural tube of the embryo.

Spermatogenesis Entire process of development and maturation of sperm cells.

Spermatozoon Male gamete or sex cell; spermatozoa (plural).

Sperm capacitation Process by which the tail is removed from the sperm, enabling it to penetrate and fertilize an egg.

Spermicide Chemical method of contraception.

Spina bifida Congenital defect in which the spinal canal does not close and protrudes from the back.

Spinnbarkeit Stringy, elastic character of cervical mucus at the time of ovulation.

Spontaneous abortion Expulsion of products of conception that occurs naturally; commonly referred to as miscarriage.

Stalking Course of conduct directed at a specific person that involves repeated visual or physical proximity; nonconsensual communication; violence toward property; verbal, written, or implied threats; or a combination thereof.

Standards of care Documents developed by members of a profession to establish a mutually adopted level of practice.

Station Relationship between the ischial spines and the presenting part of the fetus in the birth canal.

Sterilization Surgical procedure resulting in permanent loss of reproductive capability.

Stranger rape Nonconsensual sexual experience between a victim and assailant who are strangers.

Stress incontinence Involuntary discharge of urine with a cough, sneeze, or laughter owing to the loss of muscular support at the neck of the urethra.

Stressor Illness or change in family structure or circumstances that may result in change.

Striae gravidarum Pinkish or darkened streaks resulting from stretching of the skin during pregnancy that occurs predominantly on the breasts and abdomen.

Subarachnoid hemorrhage Collection of blood in the subarachnoid space of the brain.

Subdural hemorrhage Collection of blood in the subdural space of the brain.

Subinvolution Failure of the uterus to return to a nonpregnant state; occurs when the process of involution is prolonged or stopped owing to hemorrhage, infection, or retained placental parts.

Sudden infant death syndrome (SIDS) An unexpected baby death in which a thorough postmortem examination, medical history, and case study demonstrate adequate care before death.

Supine hypotension Condition of reduced blood flow to the right atrium when the pregnant woman lies in a supine position.

Surfactant Complete lipoprotein that reduces the surface tension of pulmonary fluids, allowing the exchange of gases in the alveoli of the lungs.

Symmetric IUGR Term to describe fetal growth in which weight, length, and head circumference are all less than the 10th percentile based on standardized graphs.

Sympathomimetic A drug that stimulates the sympathetic nervous system.

Syncytiotrophoblast Outer layer of the trophoblast.

Syndactyly Condition in which fingers or toes are joined together by skin or bone; often called "webbing."

Systemic vascular resistance Resistance against which the left ventricle must eject its stroke volume with each heartbeat.

T

Tachycardia A rapid heart rate. In a neonate, especially one that is above 160 beats/minute.

Tachypnea A rapid respiratory rate. In a neonate, especially one that is equal to or above 70 respirations/minute.

Taking-hold phase Second phase of maternal adjustment characterized by an increased readiness to be involved with the newborn.

Taking-in phase Initial, early period of maternal adjustment characterized by basic maternal needs for food, care, and comfort.

Tanner stages Five stages of female and male physiologic development.

Teratogen Environmental substance that can cause physical defects in the developing embryo and fetus.

Term infant An infant who is determined to be between 37 and 42 weeks' gestational age by exam.

Testosterone The most potent naturally occurring androgen (male) hormone that is made in the testes, ovary, and adrenal cortex.

Thelarche Beginning of the development of the breasts at puberty, with prominence of glandular tissue behind the nipples; the first sign of puberty.

Therapeutic abortion Pregnancy is terminated because of health risks to the mother in continuation of the pregnancy or for fetal disease.

Thermoregulation The control of heat production and heat loss, specifically the maintenance of body temperature through physiologic mechanisms activated by the hypothalamus.

Third stage of labor Begins when the fetus is delivered and lasts until the placenta is delivered.

Thrombocytopenia Decreased platelet count ($<100,000/\mu\text{L}$).

Thyrototoxicosis A disorder of the thyroid gland; hyperthyroidism.

TORCH syndrome A syndrome of infections that includes toxoplasmosis, other infections including hepatitis, rubella, cytomegalovirus, and herpes, of which all have been linked to fetal or neonatal harm.

Tort Civil wrong that may be caused either intentionally or unintentionally.

Total parenteral nutrition (TPN) Intravenous fluid that provides daily requirements of carbohydrates, protein, electrolytes, vitamins, and minerals.

Tracheoesophageal fistula Condition in which the trachea and esophagus are abnormally connected.

Transient tachypnea of the newborn Mild, self-limited, respiratory disorder characterized by increased respiratory rate and mild cyanosis; thought to be related to delayed resorption of fetal lung fluid.

Transition The third phase of the first stage of labor during which the cervix dilates from 8 to 10 cm.

Transitional milk Milk produced at the end of colostrum production and immediately before mature milk comes in the breast.

Translocation Misplacement of genetic material from one chromosome to another.

Transverse lie Involves the fetus assuming a more horizontal position in the uterus.

Trisomy Aneuploid condition caused by the presence of an extra chromosome, which is added to a given chromosome pair and results in a total number of 47 chromosomes per cell; Down syndrome is the most common human autosomal trisomy.

Trophoblast cells Peripheral cells of the blastocyst that attach the fertilized ovum to the uterine wall and develop into the placenta and membranes.

True labor Rhythmic contraction and relaxation of the uterus with progressive effacement and dilatation of the cervix.

Tubal ligation Surgical method of permanent female sterilization in which the fallopian tubes are severed and tied.

Turtle sign Deviation or interruption in fetal descent in which the fetal head pulls back instead of completing the external rotation process and progressing forward to the maternal perineum.

Type 1 diabetes mellitus Insulin-dependent diabetes.

Type 2 diabetes mellitus Non-insulin-dependent diabetes.

U

Ultrasonography Use of high-frequency ($>20,000\text{ Hz}$) sound waves to detect differences in tissue density and to visualize outlines of structures within the body.

Umbilical cord compression Pressure from a fetal body part or the uterine wall applied directly to the umbilical cord in utero, resulting in decreased circulation and oxygenation of the fetus for a period of time.

Umbilical cord prolapse Condition in which a length of umbilical cord precedes the presenting part through the cervix and birth canal.

Undulating variability A fetal heart rate variability waveform pattern that is repetitive and uniform in appearance.

Universalizability Rule used to guide actions that could be followed in all other similar situations.

Upper intake level (UL) Maximum level of daily nutrient intake.

Urge incontinence Occurs when the urge to void is present but the bladder is unable to empty normally.

Uterine atony Inability of the uterus to contract.

Uterine rupture Separation of the uterine wall that may allow protrusion of fetal parts into the abdomen.

Uteroplacental insufficiency Decline in placental function leading to fetal hypoxia and acidosis; evidenced by late onset fetal heart rate decelerations.

Utilitarianism Type of ethical thinking focusing on the consequences of actions; actions are right if they bring about the best possible outcomes and the least bad effects for the greatest number of persons.

V

Vaginal infection Inflammation of the vagina caused by a microorganism or foreign body.

Vaginal ring Contraceptive device that delivers steroids through the vaginal mucosa.

Vaginismus Painful spasms of the muscles of the introitus that prevent penetration.

Variability Fluctuations in the fetal heart rate.

Variable deceleration Slowing of the fetal heart rate not necessarily associated with uterine contractions. Caused by umbilical cord compression.

Varicocele Varicose veins in the spermatic cord.

Vasa previa Involves the cord vessels crossing the cervical os and results in significant compression and possible rupture from the pressure of the fetal head during descent.

Vasectomy Surgical method of permanent male sterilization in which the vas deferens are severed and tied.

Vegan Vegetarian who consumes no animal products.

Velamentous insertion of the cord Condition in which the umbilical cord joins the placenta at the edge.

Ventricular peritoneal shunt A tunneled, external ventricular drain for excess spinal fluid that empties into the peritoneal cavity, where the excess spinal fluid is reabsorbed.

Veracity Truthfulness.

Vertex Crown of the fetal head.

Vertical transmission Transmission of HIV by the mother to the fetus or neonate during pregnancy, delivery, and postnatally, during breast-feeding.

Very low birth weight (VLBW) Weight of 1,500 grams or less at birth.

Virtue Character trait that is valued.

Virtue ethics The way in which personal characteristics of the moral agent or person guide moral action.

Vitalism Term used in 19th century Europe and America referring to a type of vital energy or life force.

W

Weaning Process of discontinuing breast-feeding and accustoming an infant to another feeding method.

Wet nurse Woman employed to breastfeed infants who are not her own.

Wharton's jelly Soft, jelly-like substance of the umbilical cord.

Wife rape Forced sexual experience with a common law or legally married spouse.

Z

Zona pellucida Transparent, noncellular layer surrounding the ovum.

Zygote Cell resulting from the union of the ovum and spermatozoon.

System Requirements for:

Delmar's Gameshell Practice Software

Basic system requirements are:

- Microsoft® Windows 95® or better
- 486 Mhz CPU (Pentium recommended)
- 16 MB or more of RAM
- CD-ROM drive
- 10 MB or more free hard drive space
- 256 color display or better

Set-Up Instructions for:

Delmar's Gameshell Practice Software

1. Insert disk into CD ROM player.
2. From the Start Menu, choose *RUN*.
3. In the *Open* text box, enter *d: setup.exe* then click the *OK* button. (Substitute the letter of your CD ROM drive for *d:*)
4. Follow the installation prompts from there.

License Agreement for Delmar Thomson Learning Educational Software/Data

You the customer, and Delmar Thomson Learning incur certain benefits, rights, and obligations to each other when you open this package and use the software/data it contains. BE SURE YOU READ THE LICENSE AGREEMENT CAREFULLY, SINCE BY USING THE SOFTWARE/DATA YOU INDICATE YOU HAVE READ, UNDERSTOOD, AND ACCEPTED THE TERMS OF THIS AGREEMENT.

Your rights:

1. You enjoy a non-exclusive license to use the software/data on a single microcomputer in consideration for payment of the required license fee, (which may be included in the purchase price of an accompanying print component), or receipt of this software/data, and your acceptance of the terms and conditions of this agreement.
2. You acknowledge that you do not own the aforesaid software/data. You also acknowledge that the software/data is furnished "as is," and contains copyrighted and/or proprietary and confidential information of Delmar Thomson Learning or its licensors.

There are limitations on your rights:

1. You may not copy or print the software/data for any reason whatsoever, except to install it on a hard drive on a single microcomputer and to make one archival copy, unless copying or printing is expressly permitted in writing or statements recorded on the diskette(s).
2. You may not revise, translate, convert, disassemble, or otherwise reverse engineer the software/data except that you may add to or rearrange any data recorded on the media as part of the normal use of the software/data.
3. You may not sell, license, lease, rent, loan, or otherwise distribute or network the software/data except that you may give the software/data to a student or an instructor for use at school or, temporarily at home.

Should you fail to abide by the Copyright Law of the United States as it applies to this software/data your license to use it will become invalid. You agree to erase or otherwise destroy the software/data immediately after receiving note of Delmar Thomson Learning termination of this agreement for violation of its provisions.

Delmar Thomson Learning gives you a LIMITED WARRANTY covering the enclosed software/data. The LIMITED WARRANTY follows this License.

This license is the entire agreement between you and Delmar Thomson Learning interpreted and enforced under New York law.

This warranty does not extend to the software or information recorded on the media. The software and information are pro-

vided "as is." Any statements made about the utility of the software or information are not to be considered as express or implied warranties. Delmar Thomson Learning will not be liable for incidental or consequential damages of any kind incurred by you, the consumer, or any other user.

Some states do not allow the exclusion or limitation of incidental or consequential damages, or limitations on the duration of implied warranties, so the above limitation or exclusion may not apply to you. This warranty gives you specific legal rights, and you may also have other rights which vary from state to state. Address all correspondence to: Delmar Thomson Learning, Box 15015, Albany, NY 12212 Attention: Technology Department.

LIMITED WARRANTY

Delmar Thomson Learning warrants to the original licensee/purchaser of this copy of microcomputer software/data and the media on which it is recorded that the media will be free from defect in material and workmanship for ninety (90) days from the date of original purchase. All implied warranties are limited in duration to this ninety (90) day period. THEREAFTER, ANY IMPLIED WARRANTIES, INCLUDING IMPLIED WARRANTIES OF MERCHANTABILITY AND FITNESS FOR A PARTICULAR PURPOSE, ARE EXCLUDED. THIS WARRANTY IS IN LIEU OF ALL OTHER WARRANTIES, WHETHER ORAL OR WRITTEN, EXPRESS OR IMPLIED.

If you believe the media is defective please return it during the ninety day period to the address shown below. Defective media will be replaced without charge provided that it has not been subjected to misuse or damage.

This warranty does not extend to the software or information recorded on the media. The software and information are provided "as is." Any statements made about the utility of the software or information are not to be considered as express or implied warranties.

Limitation of liability: Our liability to you for any losses shall be limited to direct damages, and shall not exceed the amount you paid for the software. In no event will we be liable to you for any indirect, special, incidental, or consequential damages (including loss of profits) even if we have been advised of the possibility of such damages.

Some states do not allow the exclusion or limitation of incidental or consequential damages, or limitations on the duration of implied warranties, so the above limitation or exclusion may not apply to you. This warranty gives you specific legal rights, and you may also have other rights which vary from state to state. Address all correspondence to: Delmar Thomson Learning, Box 15015, Albany, NY 12212 Attention: Technology Department.
