The medical therapies for preterm labor range from nonintervention to the use of tocolytic agents to stop preterm contractions. IV hydration and sedation may be ordered when the client initially presents with signs and symptoms of preterm labor. When labor does not progress the client may be admitted to the hospital for a period of observation. Once discharged, she most likely will be placed on bed rest or asked to modify physical activities.

The physician may order antibiotics to treat presumed or confirmed infections that can be causative factors in preterm labor. Corticosteroids may be given to the client to enhance fetal lung maturity. In the case of ongoing preterm labor, the client may receive tocolytic medication given in an attempt to stop uterine contractions.

Nursing Care

Nursing care for the woman experiencing preterm labor includes prompt and thorough assessment of the client on presentation to the hospital, obtaining or assisting in collection of laboratory specimens, administration of prescribed medications and therapies, and client education. Nursing assessment should include taking vital signs, including temperature; assessing the fetal heart rate, evaluating uterine activity, and obtaining a history of the pregnancy and events associated with the onset of the current symptoms. The client should be asked about the presence of vaginal bleeding and rupture of membranes. Common laboratory tests specific for assessment of the client who has preterm labor include urinalysis, urine culture and sensitivity, cervical cultures, and CBC. The nurse must be familiar with the actions, contraindications, and potential side effects of common medications administered in the treatment of preterm labor. The tocolytic agents frequently ordered may have serious side effects (Table 18-1).

The client who is at risk for delivering a preterm infant often is very anxious about the risks to the infant and herself and about the medical therapies ordered. Coincidental concerns often exist about separation from family and loss of income during prolonged hospitalization.

Occupational or recreational therapy often is helpful in providing diversional activities during prolonged hospi-

Table 18-1 Side Effects and Complications of Tocolytic Medications

Medication	Side Effect	Complications
Magnesium sulfate	Flushing, drowsiness, muscle weakness, blurred vision, nausea and vomiting	Pulmonary edema, respiratory depression or arrest, cardiac arrest, profound hypotension Neonate: hypermagnesemia
Beta-adrenergics (ritodrine, terbutaline)	Tachycardia, shortness of breath, chest pain, nausea and vomiting, diarrhea, anxiety	Pulmonary edema, arrhythmias, hyperglycemia, hypokalemia, hypotension, myocardial ischemia
Prostaglandin inhibitors	Epigastric pain, nausea and vomiting	Gastrointestinal bleeding, renal failure Fetus or neonate: premature closure of the ductus arteriosus, necrotizing enterocolitis, intracranial hemorrhage
Calcium channel blockers	Flushing, tachycardia	Profound hypotension, possible decrease in uteroplacental perfusion

PRETERM LABOR

Urinary tract and vaginal infections have been associated with onset of preterm labor.

talization. Social services can be of assistance in financial, housing, and transportation concerns for the client and family.

The nurse should provide information for the client regarding the plan of care for both mother and infant to enable decision-making and reduce anxiety. It may be helpful for the client and family to speak to a health care provider from the nursery about the care planned for the neonate in the event of delivery.

Postterm Pregnancy

Postterm pregnancy is defined as a pregnancy that is greater than 42 postmenstrual weeks' gestation (Resnik & Calder, 1999).

Incidence

Approximately 4% to 14% of pregnancies are postterm and are associated with increased fetal morbidity and mortality (Resnik & Calder 1999). Some risks to the fetus include umbilical cord compression because of decreased amniotic fluid (oligohydramnios), meconium aspiration, large for gestational age fetus (macrosomia), and shoulder dystocia. The frequency of labor induction and cesarean section delivery is increased in this group of postterm clients (Cunningham et al., 1997).

Management

The postterm pregnancy may be managed initially with antepartum fetal testing beginning at 41 to 42 weeks' gestation (Resnik & Calder, 1999). Antepartum fetal surveillance tests include a nonstress test, an oxytocin challenge test, and a biophysical profile and may be scheduled weekly or twice weekly. Clients also are asked to monitor fetal movement and to notify the health care provider if they note a significant decrease in fetal activity. Induction of labor often is ordered when antepartum testing is not reassuring or the pregnancy exceeds 42 weeks' gestation.

Nursing Care

Nursing care specific to the postterm pregnant client usually includes assessing fetal well-being by performance of

fetal surveillance testing as ordered and performing induction of labor as ordered by the provider.

Antepartum surveillance tests should be carried out according to unit protocol or physician's order and the results should be reported to the physician.

Induction of labor should be performed according to unit protocol or physician's order. As with administration of any medication, the nurse must be knowledgeable about the actions, contraindications, and potential side effects of the medications that are ordered.

The postterm client and family often are anxious. Client education is a key aspect of nursing care and can provide some reassurance. The plan of care, including tests, procedures, and ordered medications, should be thoroughly explained to the client and family.

DISORDERS OF AMNIOTIC FLUID VOLUME

Disorders of amniotic fluid volume include polyhydramnios and oligohydramnios. Each condition can be a sign of negative fetal outcomes.

Polyhydramnios

The average amount of amniotic fluid at term is approximately 800 mL. **Polyhydramnios**, also referred to as **hydramnios**, is diagnosed when more than 1,500 to 2,000 mL of amniotic fluid has accumulated (Brace & Resnik, 1999).

Clinical Presentation

Amniotic fluid volume may be affected by a number of factors. During the second trimester of pregnancy the fetus swallows and urinates amniotic fluid. In most cases of severe polyhydramnios a fetal anomaly is present. These anomalies are generally those of the gastrointestinal (GI) system, inhibiting the ability of the fetus to swallow fluid, or the central nervous system (CNS), wherein increased volumes of amniotic fluid can be transferred from the spinal defect into the amniotic cavity (Cunningham et al., 1997). Idiopathic hydramnios is not associated with increased rates of poor outcomes that may be found in fetal anomalies or maternal diabetes mellitus (Panting-Kemp et al., 1999). Yancy and Richards (1994) described the effect of altitude on amniotic fluid volume and found that the average amniotic fluid volume is increased at altitudes of 6,000 feet.

The largely overdistended uterus may put pressure on the surrounding organs. In cases of excessive polyhydramnios the pregnant woman may experience dyspnea secondary to pressure on the lungs and edema of the lower extremities and vulva because of decreased venous return.

The client with polyhydramnios is at increased risk for preterm delivery secondary to contractions occurring with uterine distension.

Management

The client who has mild to moderate polyhydramnios usually does not require treatment. In severe cases of polyhydramnios that causes dyspnea or pain the client may be hospitalized. In these cases an amniocentesis may be performed to relieve these symptoms. In this procedure a catheter is placed through the maternal abdomen into the amniotic cavity and is attached to a IV tubing set, which drains amniotic fluid into a container placed at floor level. The rate of fluid drainage is controlled to avoid rapid decompression (Cunningham et al., 1997). This procedure can provide immediate symptomatic relief for the client.

Nursing Care

Nurse caring for the client with polyhydramnios includes monitoring the client for symptoms of dyspnea, abdominal pain, uterine contractions, and severe edema of the lower extremities and vulva. When a therapeutic amniocentesis is performed, the nurse assists the physician in the procedure by positioning the client and helping with the mechanism of the drainage apparatus. The nurse monitors the rate of fluid drainage, amount and characteristics of the fluid, and response of mother and fetus. The nurse ensures that the client has an opportunity to ask questions and understands the procedure.

Oligohydramnios

Oligohydramnios can occur as a result of premature rupture of membranes or may not have a clear cause. Regardless of the cause, the condition may require a decision regarding whether the fetus should remain in utero.

Clinical Presentation

When the amniotic fluid volume decreases to as little as 500 mL, the condition is termed **oligohydramnios** (Brace & Resnik, 1999). The cause of oligohydramnios is not always apparent. Any condition that prevents the fetus from making urine or that blocks the entry of urine into the amniotic sac can cause oligohydramnios. Leaking of the bag of water or frank rupture of membranes also may cause oligohydramnios. Hypertension in pregnancy, uteroplacental insufficiency, and diabetes also are factors associated with oligohydramnios in late pregnancy (Cunningham et al., 1997). The diagnosis of oligohydramnios is made by ultrasonographic examination because as the client will have no presenting symptoms.

Oligohydramnios more frequently develops late in pregnancy. The volume of fluid normally is diminished

after 35 weeks' gestation. The development of oligohydramnios in early pregnancy may be an ominous sign (Cunningham et al, 1997; Brace & Resnik, 1999).

The risks of oligohydramnios to the fetus can be quite serious. Umbilical cord compression may occur, diminishing perfusion to the fetus. Adhesions can develop between the fetus and the amnion, which can cause serious fetal deformities and possibly amputation of fetal parts. The fetus also may suffer from musculoskeletal deformities as it is compressed in utero (Cunningham et al., 1997). Pulmonary hypoplasia possibly related to mechanical restriction of the fetal chest can occur in the presence of very low amniotic fluid levels (Brace & Resnik, 1999).

Management

The client who has oligohydramnios may be managed outside the hospital setting, with serial ultrasonographic evaluations and fetal surveillance testing. Once delivery is inevitable and the membranes have ruptured, an **amnio-infusion** may be performed to replace fluid in the amniotic cavity (Brace & Resnik, 1999). In this procedure crystalloid fluid is infused through an intrauterine catheter placed through the cervix into the uterine cavity. The infusion is administered in a controlled manner to prevent overdistension of the uterus.

Nursing Care

The client who has oligohydramnios and a viable fetus and is not hospitalized will require periodic evaluation of fetal well-being. Nursing care may include fetal surveillance testing, such as a nonstress test or contraction stress test. In the intrapartum period the nurse observes for fetal intolerance of labor and may assist in the performance of amnioinfusion. When amnioinfusion is ordered the nurse infuses fluid into the client's uterus by way of an intrauterine catheter at a prescribed rate. The return of amniotic fluid onto the bed linen and maternal and fetal tolerance of the procedure should be observed and documented. The nurse should provide an explanation of the plan of care to the client and family.

HIGH-RISK FETAL CONDITIONS

Fetal conditions that increase the risk for negative fetal outcomes include multiple gestation, Rh isoimmunization and ABO incompatibility, and nonimmune hydrops fetalis.

Multiple Gestation

Multiple gestation increases pregnancy risks because of the high risks for preterm labor and delivery and conditions related to prematurity.

Incidence

The incidence of multiple births in the United States is relatively infrequent yet represents a large proportion of poor pregnancy outcomes. Multiple gestation pregnancies are at increased risk for preterm delivery and intrauterine fetal demise. Maternal morbidity is significantly increased in these pregnancies (Malone & D'Alton, 1999).

The incidence of twins, triplets, and higher-order multiples has dramatically increased because of the widespread use of fertility drugs and advanced reproductive techniques (ACOG, 1998b). Twins frequently are the result of two separate ova, called **dizygotic** or “fraternal” twins. The incidence of this type of twinning is highly variable according to maternal age, race, parity, and heredity. Twins resulting from a single fertilized ovum that then divides are called **monozygotic** or “identical” twins; the incidence of identical twins is about 1 in 250 births (Cunningham et al., 1997). The process is the same in higher-order multiples, with quadruplets being the result of either one or four fertilized ova.

Clinical Presentation

In the second trimester a discrepancy between the measured fundal height and gestational age of the fetus often is the first clue that there may be a multifetal pregnancy. The diagnosis of a multiple gestation pregnancy generally is made or confirmed by ultrasonographic examination.

Multiple gestation pregnancies are at increased risk for many complications. Early pregnancy loss is more common in a multifetal pregnancy. Multiple gestations also have a greater incidence of low birth weight secondary to intrauterine growth restriction or preterm delivery (ACOG, 1998b).

Maternal complications in a multiple gestation pregnancy can be significant. The incidence of pregnancy-induced hypertension (PIH), gestational diabetes, postpartum hemorrhage, anemia, urinary tract infections (UTIs), endometritis, and need for cesarean delivery are increased in multifetal pregnancies. Among parous women, multiple gestation is associated with a two-fold increase in risk of death compared with a singleton pregnancy (Conde-Agudelo, Belizan, & Lindmark, 2000; Myatt & Miodovnik, 1999).

The incidence of spontaneous abortion is higher for monozygotic than for dizygotic twins (Cunningham et al., 1997). A further complicating condition referred to as twin-to-twin transfusion describes the process in which blood is shunted from one twin to the other. The twin who is underperfused becomes anemic, and the other, the overperfused twin, becomes polycythemic (Malone & D'Alton, 1999).

Significant weight differences can develop in twins in the second or third trimester of pregnancy, with one twin

being growth restricted. The incidence of fetal death in these discordant twin pregnancies is greatly increased (Cunningham et al., 1997).

Management

The client with a multifetal pregnancy likely will be followed throughout her pregnancy with serial ultrasonographic examinations to assess for fetal growth and development. Fetal surveillance testing often is initiated late in the second trimester. The client who develops signs and symptoms of preterm labor and whose fetus develops complications often will be managed in the hospital setting, which allows for closer and more frequent observation.

The intrapartum period can be a particularly risk-filled time in the multifetal pregnancy. These pregnancies are at increased risk for complications, such as fetal malpresentation, dysfunctional labor, PIH, abruptio placentae, umbilical cord prolapse, cesarean delivery, and endometritis (Conde-Agudelo, Belizan, & Lindmark, 2000; Myatt & Miodovnik, 1999). In the intrapartum period, electronic fetal monitoring is employed to evaluate for fetal tolerance to labor or evidence of cord prolapse. After vaginal delivery of the first twin the client is reassessed to determine if vaginal delivery of the second twin is possible and imminent. Vaginal delivery of the second twin may be minutes to hours after the first delivery. The client may require cesarean section for the second twin if it is in a nonvertex position (Malone & D'Alton, 1999).

Nursing Care

Outpatient nursing care for the client with multifetal pregnancy focuses on assessment of the client at each visit for signs and symptoms of possible complications, such as threatened abortion, PIH, and preterm labor. Once the decision is made to initiate fetal surveillance testing, the nurse performs nonstress tests or contraction stress tests.

Clients who are admitted to the hospital for complications such as PIH or preterm labor receive care as discussed in the applicable sections of this chapter. The client admitted for labor and planned vaginal delivery usually receives continuous electronic fetal monitoring to provide assessment data for both uterine activity and fetal tolerance to labor. Adequate personnel to attend to the mother and to each neonate should be available at the time of delivery. The client and family should be informed of the potential for cesarean delivery and all questions should be answered.

Rh Isoimmunization and ABO Incompatibility

Immunization, or sensitization, occurs when fetal blood enters the maternal circulation causing antibodies to be

formed in the maternal blood. Once formed, these antibodies are able to cross the placenta into the fetal circulation and attack fetal erythrocytes, with resulting hemolysis.

Rh sensitization is the most common and most significant cause of maternal immunization and hemolysis in the fetus or newborn (Bowman, 1999). In this process an Rh-negative mother, or a mother with absent Rh_o(D) antigen, who is carrying an Rh-positive fetus forms anti-D antibodies whenever fetal erythrocytes enter the maternal bloodstream. A very small amount of Rh-positive fetal blood in the maternal bloodstream can result in the formation of antibodies (Duffy, 1999). The amount of hemolysis that results varies, with severe hemolysis causing fetal anemia. The severely affected fetus develops **hydrops fetalis** in which the fetus and placenta have severe edema; the fetus also may develop pleural and cardiac effusions, cardiac enlargement, hepatomegaly, and splenomegaly (Cunningham et al., 1997).

Clinical Presentation

The injection of fetal blood into the maternal circulation occurs most commonly at the time of delivery but may occur during the course of the pregnancy. A significant number of women who become Rh immunized do so at about 28 weeks' gestation or within 3 days after delivery. Approximately 75% of women have some evidence of a transplacental hemorrhage during the pregnancy or in the immediate postpartum period (Bowman, 1999). Sensitization may occur in the antepartum period after abortion; after an invasive procedure, such as amniocentesis; or in the disruption of the placenta with abruption or placenta previa (Cunningham et al., 1997). Once antibodies are formed, subsequent pregnancies are at risk for hemolytic disease of the fetus and newborn.

ABO incompatibility is a less serious form of isoimmunization that may occur when a mother who has type O blood is pregnant with a fetus who has type A or B blood. The mother may form antibodies that can lead to hemolysis in the fetus and neonate. These infants may develop hyperbilirubinemia, requiring phototherapy. The development of hydrops in ABO incompatibility is rare (Bowman, 1999).

Management

Pregnant women undergo routine screening for sensitization at the first prenatal visit when blood is drawn for blood typing, determination of Rh factor, an antibody titer test, or indirect Coombs test (ACOG, 1996b). The presence of anti-Rh_o(D) antibodies on the laboratory test results indicates sensitization has occurred and alerts the clinician to the possibility of an affected fetus. The fetus is monitored throughout the pregnancy, and the mother has repeated titer tests. A titer of 1:8 or higher usually indicates the

need for further testing and evaluation (Cunningham et al., 1997).

The client who has titer values that are increasing will undergo repeated ultrasonography to evaluate fetal growth, amniocentesis, or percutaneous blood sampling to evaluate fetal condition. In an **amniocentesis** fluid is withdrawn from the uterus with a needle to evaluate for the presence and amount of bilirubin, which is evidence of hemolysis. Amniotic fluid with high levels of bilirubin may indicate a fetus who needs immediate treatment to survive.

Percutaneous umbilical blood sampling (PUBS) is a direct sampling of fetal blood from the umbilical cord guided by ultrasonography. The severely affected fetus may undergo intrauterine fetal transfusion. This is accomplished by transfusion of blood into the fetal peritoneal cavity or directly into the umbilical vein (ACOG, 1996b). Intravascular transfusion into the umbilical vessels is associated with good long-term outcomes (Grab et al., 1999).

Preterm delivery may be necessary for the severely affected fetus. The neonate is evaluated at birth for severity of hemolytic disease of the newborn and may require treatment ranging from phototherapy to exchange transfusion.

The client with negative indirect antibody test results on entry into prenatal care usually is retested at 28 weeks' gestation. If the test results remain negative, at that time the mother is given a prophylactic dose of Rh_o(D) immune globulin (RhoGAM) (ACOG, 1999a). Administration of this Rh antibody can prevent an active antibody response by providing passive immunity to the mother (Bowman, 1999).

In the postpartum period, clients who are Rh-negative are considered for postpartum administration of RhoGAM. Mothers of infants who are Rh-positive will receive RhoGAM as prophylaxis within 72 hours after delivery. Women experiencing a first-trimester pregnancy loss or those undergoing invasive procedures, such as amniocentesis or fetal blood sampling, also should receive RhoGAM (ACOG, 1999).

Nursing Care

In the antepartum period the nurse should evaluate routine maternal laboratory tests and alert the primary care provider of the maternal blood type in the Rh_o(D)-negative client. It is very important that RhoGAM be administered as ordered at approximately 28 weeks' gestation. The administration of RhoGAM should be documented in the client's medical records.

Clients who are determined to be sensitized will need thorough explanation of the implications of Rh isoimmunization and the plan of care for the pregnancy. The invasive procedures described previously that may be performed in the severely affected fetus are very anxiety-

provoking for most clients. The nurse should provide support to the mother and family as the mother undergoes these procedures.

In the postpartum period the nurse obtains maternal and neonatal laboratory values, assesses the need for RhoGAM, and administers the prophylactic dose as ordered by the primary care provider.

Nonimmune Hydrops Fetalis

Nonimmune hydrops fetalis (NIHF) is severe edema of the fetus that is not the result of isoimmunization. This syndrome has many different causes, including fetal cardiac anomalies; fetal heart rate abnormalities; chromosomal abnormalities; fetal malformations; twin-to-twin transfusion; and viral infections, such as parvovirus or herpes infection (Wilkins, 1999).

Clinical Presentation

The diagnosis of NIHF initially is made by ultrasonographic examination. Further testing is performed in an attempt to determine the cause of NIHF. Maternal blood tests are performed to assess for maternofetal hemorrhage and infection. PUBS is performed to evaluate the fetus for hematologic, genetic, or infectious causes. Many cases of NIHF ultimately will result in intrauterine fetal demise, with a reported mortality rate of greater than 50% (Wilkins, 1999). As reported by Rodis et al. (1998), NIHF occurring early in pregnancy may spontaneously resolve before term; otherwise treatment largely is based on the cause.

Management

Once a determination of the cause of NIHF is made, treatment is directed toward resolution of the cause if possible. When disturbances of fetal heart rate are determined to be a causative factor, medications (such as digoxin or an anti-dysrhythmic agent) may be administered to the mother to improve fetal cardiac function (Cunningham et al., 1997). Anemia may result from hematologic or infectious causes and is treated much the same as is anemia caused by Rh isoimmunization, which has been discussed previously.

Nursing Care

Once the diagnosis of hydrops is made the nurse may assist in obtaining a detailed medical history from the client in an effort to identify potential causative factors. Nurses caring for the pregnant client whose fetus has NIHF should provide explanations for the disease process and the proposed plan of care and allow the client and family an opportunity to ask questions. The prognosis for the fetus often is poor. The nurse should offer emotional support to the client and family. In the event of fetal or neonatal

death the client should be offered additional support, such as client educational materials, spiritual support, and information on support groups if available.

HYPERTENSION

Over 20 large clinical trials involving more than 50,000 participants have established that antihypertensive treatment in adults with mild to moderate hypertension reduces mortality and morbidity (Murrow et al., 2000). Few randomized trials have been undertaken to examine issues related to pregnancy and hypertension.

Terminology used in describing hypertension in pregnancy has changed over many years of studying this disease process. The National High Blood Pressure Education Program Working Group on High Blood Pressure in Pregnancy (2000) recently published a report that includes classification, pathophysiology, and management of the hypertensive disorders of pregnancy. Hypertension as defined by this group is a blood pressure 140 mm Hg systolic or higher or 90 mm Hg diastolic or higher. The classifications developed by the group are as follows:

- ❖ Chronic hypertension is defined as hypertension that occurs before pregnancy or is diagnosed before 20 weeks' gestation. Hypertension diagnosed for the first time during pregnancy that persists beyond the postpartum period also is classified as chronic hypertension.
- ❖ Preeclampsia-eclampsia is a pregnancy-specific syndrome usually occurring after 20 weeks' gestation. The diagnosis is determined by (1) increased blood pressure, over 140 mm Hg systolic or over 90 mm Hg diastolic in a woman who has had normal blood pressure before 20 weeks' gestation; and (2) proteinuria, which is defined as more than 0.3 g of protein in a 24-hour urine collection. **Eclampsia** is the occurrence of seizures in a pregnant woman who has preeclampsia that cannot be attributed to another cause. The presence of edema has long been included as one of the classic signs of preeclampsia but has been excluded as a marker by this Working Group because it is a common finding in normal pregnancies.
- ❖ Preeclampsia superimposed on chronic hypertension is "highly likely" with the findings of (1) women with hypertension and no proteinuria before 20 weeks' gestation that have new onset of proteinuria; and (2) women who have hypertension and proteinuria before 20 weeks' gestation who develop any of the following: (a) sudden increase in proteinuria, (b) sudden increase in blood pressure, (c) thrombocytopenia, (d) increase in alanine aminotransferase or aspartate aminotransferase.

REFLECTIONS FROM A FAMILY

"I was really excited to find out I was pregnant. My husband and I had planned a family for a long time. Then my wonderful pregnancy turned into a horror show when I developed preeclampsia. The doctor was not able to control my condition at home. I was admitted to the hospital at 32 weeks' gestation, and was told I would need to stay in the hospital on bed rest until my due date. I cannot explain how that changed my life. I went from being happy and excited to being full of dread and fear. Luckily, the nurses on the unit where I was hospitalized were able to teach me what to expect. It reduced my fear tremendously."

- Gestational hypertension is used to describe blood pressure elevation occurring for the first time after midpregnancy and without proteinuria. This diagnosis may change to that of preeclampsia if other symptoms develop. The definitive diagnosis of gestational hypertension can only be made if the hypertension has resolved after 12 weeks postpartum.

Incidence

Hypertension occurs in 6% to 8% of pregnancies and is the second leading cause of maternal mortality in the United States, accounting for 15% to 18% of deaths (ACOG, 1996a; Berg et al., 1996). Complications of PIH are outlined in Table 18-2.

Clinical Presentation

Many theories regarding the cause of PIH have been proposed but none proven. PIH has been shown to occur more commonly in the primipara, in women with pregestational diabetes mellitus, in multiple gestation pregnancies, and in older women who have an increased incidence of chronic hypertension (Myatt & Miodovnik, 1999; Sibai et al., 2000a; Sibai et al., 2000b; Abu-Heija, Jallad, & Abukteish, 2000). The only known "cure" for PIH is delivery of both fetus and placenta.

Preeclampsia is a disease characterized by generalized vasospasm, a significant decrease in circulating blood volume, and an activation of the coagulation system. The end

Table 18-2 Potential Complications of Pregnancy-Induced Hypertension

Organ or System	Potential Complications
Cardiopulmonary	Pulmonary edema, hypertensive crisis, stroke
Renal	Decreased glomerular filtration, increased plasma uric acid and creatinine, necrosis (rarely)
Neurologic	Retinal detachment (rarely), cerebral edema, seizures, cerebral hemorrhage, coma
Hematologic	Thrombocytopenia, hemorrhage, disseminated intravascular coagulation
Hepatic	Hematoma, rupture
Fetus	Intrauterine growth restriction, hypoxia, intrauterine death, prematurity

result of these changes is hypertension, decreased perfusion, and resultant ischemia particularly to the placenta, kidneys, liver, and brain (National High Blood Pressure Working Group, 2000).

The fetus may be significantly impacted by decreased uteroplacental perfusion. In cases of long-standing hypertension the fetus is at increased risk for mortality and morbidity, such as intrauterine growth retardation. The additional complication of superimposed preeclampsia significantly increases the risk to the fetus (National High Blood Pressure Working Group, 2000). Delivery of the fetus may be indicated by worsening maternal or fetal condition, placing the fetus of the client who has preeclampsia at increased risk for low birth weight and prematurity.

Renal blood flow and the glomerular filtration rate are decreased in preeclampsia. Proteinuria is a common finding in preeclampsia but is highly variable from hour to hour, and thus, is not a sensitive marker for severity of the disease process. Oliguria may occur in severe disease. Renal insufficiency is rarely severe enough to cause permanent damage, and the client usually will have complete recovery of renal function after delivery (Cunningham et al., 1997; Roberts, 1999).

The coagulation effects of preeclampsia may include **thrombocytopenia**, a decrease in platelets to less than 100,000, placing the client at increased risk for hemorrhage. This coagulation problem may occur at any time during pregnancy. Symptoms may antecede blood pressure elevation.

HELLP Syndrome is a complication of pre-eclampsia/eclampsia. In 1982, Weinstein first described 29 cases of severe preeclampsia/eclampsia complicated by hemolytic anemia, elevated liver enzymes, and low platelet counts.

This syndrome was given the acronym HELLP to describe its clinical presentation of Hemolysis of red blood cells, Elevated Liver enzymes, and low Platelet count. Since 1982, numerous cases of this syndrome have been reported.

Boston and Sibai (2001) discuss a classification system for HELLP syndrome. Class 1 is the most severe and occurs when the platelet count reaches a low of $<50,000$ per mm^3 . Class 2 occurs when the platelet count reaches a low between 51,000 and 100,000 per mm^3 . Class 3 occurs when the platelet count reaches a low of 101,000 to 150,000 per mm^3 . These classes are used to predict postpartum disease recovery, risk of recurrence of HELLP syndrome, perinatal outcome, and the need for plasmapheresis.

At University of Tennessee in Memphis, where much research has been done related to PIH and its complications, they have developed the following criteria for the diagnosis of HELLP syndrome. The criteria for hemolysis are abnormal peripheral blood smear; a total bilirubin of 1.2 mg.d/L or greater; and LDH (lactic dehydrogenase) of 600 U/L. To meet the criteria for elevated liver enzymes requires serum aspartate aminotransferase of ≥ 70 U/L; and a LDH of >600 U/L (Barton & Sibai, 2001).

The incidence of HELLP syndrome is significantly higher in the Caucasian population and multiparous women as well as among pre-eclampsics who are being managed conservatively (Barton & Sibai, 2001).

Clinical manifestations of HELLP syndrome include remoteness from term with right upper quadrant pain, some have nausea and vomiting, and others have nonspecific flu-like symptoms. Clients with HELLP syndrome usually exhibit significant weight gain and generalized edema. They usually have severe hypertension.

Pathophysiology of HELLP syndrome involves hemolytic anemia, this type of anemia can occur in other conditions besides HELLP syndrome and may confuse the diagnosis. The elevated liver enzymes are a result of liver involvement. The most common liver lesion is liver necrosis. Periportal hemorrhage is associated with fibrin deposition. Steatosis or fat degradations is associated significantly with abnormalities in platelet count (Barton & Sibai, 2001).

Management of HELLP syndrome involves stabilization of the maternal condition, evaluation of fetal well being, and estimation of fetal lung maturity. Management may be aggressive or conservative. Aggressive management includes delivery of the infant by Cesarean Section as quickly as the maternal condition is stabilized.

Conservative management includes use of antihypertensives and MgSO_4 . The predominate reason for terminating the pregnancy is fetal distress or fetal demise. Usually the pregnancy is not terminated due to maternal conditions. Potential risks associated with conservative management are abruption of the placenta, pulmonary edema, acute renal failure, eclampsia, perinatal death, and maternal death (Barton & Sibai, 2001).

Complications of HELLP syndrome may include delayed wound closure, eclampsia, and hematoma or infarction of the liver. If a hepatic hematoma occurs, there is potential for liver rupture. Other severe complications include DIC, acute renal failure, severe ascites, pulmonary edema, pulmonary effusions, cerebral edema, retinal detachment, and laryngeal edema (Barton & Sibai, 2001).

HELLP syndrome can occur in the antepartum or postpartum period. If the woman survives this complicated pregnancy, there is a 19-27% risk of developing recurrent HELLP syndrome in future pregnancies (Barton and Sibai, 2001).

Management

Clients who develop mild elevation of blood pressure in pregnancy may be managed conservatively by the physician and placed on bed rest at home, with increased frequency of office visits and laboratory evaluations (National Heart, Lung and Blood Institute, 2000). Once the client is admitted to the hospital for evaluation and management of preeclampsia, the course of treatment is highly individualized and based on disease severity. A client with mild preeclampsia may be managed on an antepartum unit, with evaluation for signs and symptoms of worsening disease, fetal evaluation, and laboratory testing. In the case of worsening or severe preeclampsia the client often is managed with administration of magnesium sulfate, frequent targeted assessments, laboratory tests, electronic fetal monitoring if indicated by the gestational age, and possibly the induction of labor. Those clients who are more severely affected are likely to be found on the labor and

TARGETED ASSESSMENTS IN CLIENTS WITH PREECLAMPSIA

- Blood pressure measurement
- Urine dipstick evaluation for protein
- Intake and output measurements
- Physical assessments for:
 - presence and location of edema
 - Deep tendon reflexes
 - Presence of headache and visual changes
 - Presence of nausea, vomiting, and epigastric or right upper quadrant pain
- Fetal evaluation appropriate for gestational age and fetal well-being

delivery unit where they can receive more intensive nursing care.

Nursing Care

Skilled nursing assessments are necessary for the pregnant woman with preeclampsia. A thorough physical assessment should be performed at the start of each shift, followed by frequent targeted assessments. Magnesium sulfate, antihypertensive agents, and medications for cervical ripening and induction of labor are administered as ordered. The nurse must be familiar with the actions of, side effects of, and complications that may arise from the use of these medications. Laboratory tests should be obtained as ordered, and abnormal results should be reported to the physician promptly. Significant findings from nursing assessments also should be reported promptly (see the Nursing Alert).

Client and family education should begin as soon as the diagnosis is made. Education should include an explanation of the disease process; signs and symptoms of worsening disease; proposed course of treatment, including physical and laboratory assessments; medications; potential complications for the client and fetus; and the plan for delivery, as indicated. If the infant is to be delivered preterm, it is very important for the client and family to be made aware of the proposed plan of care for the baby.

ENDOCRINE DISORDERS

Endocrine disorders may predate pregnancy or be precipitated by pregnancy. Either way, these disorders can have profound effects on the pregnant woman and her fetus.

Diabetes

Diabetes has serious implications for the mother and fetus even though survival rates for both have improved dramatically over the past few decades.

Incidence

Diabetes results in complications in 2% to 3% of all pregnancies in the United States and is the most common medical complication in pregnancy (ACOG, 1994; Cunningham et al., 1997). Pregnancy outcomes for women with diabetes have improved dramatically since the beginning of the 20th Century, when perinatal survival was approximately 40% and maternal death was common (Cunningham et al., 1997). The use of insulin in the 1920s greatly impacted maternal survival but had little impact on perinatal survival (Inzucchi, 1999). In the late 1940s the development of the Caucasian classification of diabetes, which is based on age of onset, duration, and vascular complications of diabetes, demonstrated fetal risk proportional to severity of the disease. Prediction of pregnancy outcome

and timing of the delivery on an individual basis improved perinatal survival rates to about 85% by the late 1950s (Cunningham et al., 1997). The improvement in survival rates has now reached mortality rates similar to those in normal pregnancy after accounting for fetal malformations, which occur approximately four times more often in women with pregestational diabetes (ACOG, 1994). Although death in the pregnant woman with diabetes is rare, the mortality rate is greatly increased compared with that of the general population. Death often is the result of diabetic ketoacidosis, concomitant hypertension or PIH, and complications associated with pyelonephritis (Cunningham et al., 1997).

Clinical Presentation

Diabetes is classified into three categories: **Type I diabetes mellitus**, or insulin-dependent diabetes; **Type II diabetes mellitus**, or non-insulin-dependent diabetes; and **gestational diabetes**, or diabetes diagnosed during pregnancy. Type I diabetes, is an immune disorder in which the beta cells of the pancreas are destroyed, resulting in a lack of insulin secretion. This type of diabetes is most often diagnosed before the age of 30 years and requires lifelong insulin therapy and dietary management. Type II diabetes, is characterized by abnormal insulin secretion and insulin resistance and most often is found in persons over the age of 40 years and in overweight individuals. This type of diabetes may be managed by diet alone or with oral hypoglycemic agents, although oral hypoglycemic agents are contraindicated during pregnancy. Gestational diabetes is the onset of abnormal carbohydrate metabolism diagnosed during pregnancy. Approximately 90% of clients with diabetes treated during pregnancy have gestational diabetes (Inzucchi, 1999; Kendrick, 1999; ACOG, 1994).

In general, pregnant women with any form of diabetes are at increased risk for additional maternal, fetal, and neonatal complications. Women with pregestational Type I diabetes are at increased risk for the development of preeclampsia and adverse neonatal outcomes, and the rates of these complications increase with disease severity (Sibai, 2000). Hypoglycemia generally occurs with greater frequency and severity in early pregnancy (Inzucchi, 1999). This increase in hypoglycemia may be related to the strict glycemic control attempted in this population but also may be induced by nausea and vomiting associated with pregnancy and an increased sensitivity to insulin in the first trimester (Kendrick, 1999).

The pregnant woman who has diabetes has an increased incidence of UTIs. Screening for asymptomatic bacteruria may reduce the impact of this complication. The incidence of hydramnios also is more common in women who have diabetes (Moore, 1999).

Approximately 1% of diabetic pregnancies are affected by ketoacidosis. This complication is more common in the pregnant woman who has diabetes (Inzucchi, 1999). **Ketoacidosis** is diagnosed when glucose levels are greater than 300 mg/100 mL, positive serum ketones are at a level of 1:4, and metabolic acidosis is present (Moore, 1999). This life-threatening condition may result from poor compliance, hyperemesis gravidarum, infection, or use of beta-sympathomimetic drugs or corticosteroids (Moore, 1999). Diabetic ketoacidosis carries a perinatal mortality rate of approximately 20%, making prompt recognition and treatment critical (Cunningham et al., 1997).

The major causes of fetal death are congenital malformations, RDS, extreme prematurity, and unexplained stillbirth during the antepartum period (Cunningham et al., 1997; Moore, 1999). Perinatal mortality, especially late fetal death, is significantly increased for the fetus of the woman with Type II diabetes (Cundy et al., 2000).

From 15% to 45% of infants of mothers who have diabetes may be at increased risk for *macrosomia*, defined as a fetal weight of 4,000 g or higher, and therefore may be at increased risk of a difficult delivery (Moore, 1999).

Hypoglycemia occurs in approximately 30% to 50% of neonates and may be manifested immediately after delivery and for the next 24 hours of life. The incidence of hypoglycemia is increased significantly in infants of mothers with poor glucose control in the antepartum period and elevated glucose levels during labor (Inzucchi, 1999). Infants of mothers who have diabetes also may develop significant hypocalcemia in the first few days of life, the cause of which has not yet been clearly determined (Moore, 1999). Hyperbilirubinemia is common, occurring in 20% to 25% of infants born to mothers who have diabetes.

Infants of mothers who have diabetes are at increased risk for RDS because of physiologic pulmonary immaturity (Inzucchi, 1999). This risk is taken into account in the determination of planned deliveries and care is taken to avoid delivery of a premature infant.

Management

Screening for gestational diabetes is a routine test in pregnancy that usually is performed at 26 to 28 weeks' gestation. A serum glucose measurement is obtained 1 hour after administration of 50 g of glucola. A serum glucose level of 140 mg/dL is considered abnormal and is followed up with a 3-hour glucose tolerance test with administration of 100 g of glucola (ACOG, 1994) (Box 18-2).

Management of the pregnant woman who has diabetes is focused on tight glycemic control and evaluation of fetal well-being throughout the pregnancy. Prenatal visits are scheduled with greater frequency than in a normal pregnancy. Control of diet is an essential aspect of client management, and nutritional counseling regarding a dia-

Box 18-2 Diagnostic Criteria for the 3-Hour Glucose Tolerance Test

	Fasting	1-Hour	2-Hour	3-Hour
Results (mg/dL)	105	190	165	145

For results to be considered abnormal, two of the values must exceed the normal values listed here.

betic diet is critical in this effort. The goals for glycemic control include fasting blood glucose levels consistently less than 105 mg/dL and 2-hour postprandial levels of less than 120 mg/dL (ACOG, 1994). The woman is asked to monitor her blood glucose levels several times daily and to record her dietary intake. Insulin therapy usually is begun when the prescribed diabetic diet does not result in a consistent fasting glucose level of less than 105 mg/dL or a 2-hour postprandial glucose of less than 120 mg/dL (ACOG, 1994). Women with poorly controlled diabetes or concomitant hypertension usually are hospitalized.

In the antepartum period the pregnant woman who has diabetes typically receives serial ultrasonographic evaluations of fetal growth and additional fetal surveillance testing, such as a nonstress test, an oxytocin challenge test, or a biophysical profile, beginning at about 28 to 34 weeks' gestation (Moore, 1999). Fetal surveillance may be ordered earlier than 26 weeks' gestation for clients with uncontrolled diabetes or those with additional complications (ACOG, 1994).

Delivery timing is individualized and ideally occurs around term. Maintaining maternal glucose levels within the normal range during the intrapartum period is important to avoid stimulation of the fetal pancreas, with resulting fetal or neonatal hypoglycemia. In the client who has Type I diabetes, long-acting insulin is avoided during labor and an infusion of regular insulin along with an IV glucose infusion may be ordered to be administered by way of infusion pump (Moore, 1999). Blood glucose is checked frequently during this period, and adjustments are made to the infusion. Additional boluses of insulin may be ordered as needed.

The increased insulin resistance occurring in the pregnant woman who has diabetes often resolves in a matter of a few hours after delivery. The insulin infusion generally is discontinued at the time of delivery, and many women will not require insulin during the first 24 hours. Because clients with type I diabetes can have sharp decreases in insulin requirements during the first 24 hours after delivery, the insulin dose is titrated to measured blood glucose levels in the immediate postpartum period (Inzucchi, 1999).

Pregnant women who develop gestational diabetes may be counseled about the strong possibility of developing overt diabetes in the next 20 years (Buchanan & Kjos,

1999). It is important that a 1-hour glucose tolerance test be performed 6 to 8 weeks postpartally to ensure return to normoglycemia.

Nursing Care

Antepartum nursing care of the pregnant woman who has diabetes may include reviewing blood glucose values obtained between prenatal visits and obtaining blood glucose values at the time of the visit. All pregnant women should have routine screening of blood glucose levels. Nursing care also often will include performance of fetal surveillance testing, such as a nonstress test or an oxytocin challenge test, as ordered. Nonreassuring test results should be reported to the physician promptly.

In the intrapartum period the frequency of vital sign and fetal assessments is individualized based on the client's condition and the stage of labor. The nurse should be alert for signs of fetal intolerance to labor and report these to the physician promptly. A continuous insulin infusion may be ordered and serum or capillary blood glucose levels are monitored as ordered by the physician during labor. The nurse should assess the client frequently for signs and symptoms of hypoglycemia and institute prompt administration of glucose according to unit protocol or physician's order. Hourly intake and output monitoring usually is initiated during the intrapartum period.

Education of the diabetic gravida and her family members is critical for the successful management of diabetes. The diagnosis of diabetes can be very frightening, and the volume of information needed to be imparted to the woman and family can be overwhelming. The plan of care for antepartum management should be reviewed carefully. Teaching regarding a culturally appropriate diabetic diet is very important and may need to be reinforced periodically. The dietician is a valuable member of the health care team and can assist in tailoring the diet for the client's preferences. Clients and family members also will need thorough instruction on blood glucose testing, goals for blood glucose values, insulin administration, and common signs and symptoms of hypoglycemia and hyperglycemia. In addition to these self-management principles the potential maternal, fetal, and neonatal complications should be addressed.

Hypothyroidism

Hypothyroidism is a condition frequently encountered in women of childbearing age. This condition has been associated with difficulty in conception and other negative outcomes.

Incidence

Thyroid disease occurs more commonly in women than in men (Burrow, 1999). Hypothyroidism occurs in about 1 of

every 1,600 to 2,000 pregnancies (Montoro, 1997). Clients with severe hypothyroidism often have difficulty conceiving, and women with hypothyroidism are at increased risk for pregnancy loss (Burrow, 1999).

Clinical Presentation

Hormonal and metabolic changes that occur in pregnancy may stress thyroid function. Clients who have mild or moderate hypothyroidism generally are able to achieve pregnancy, and the disease does not significantly impact the pregnancy in most cases (Glinioer, 1999).

In general, the client who has hypothyroidism may present with complaints of cold intolerance, coarse hair, and dry skin. Hypothyroidism rarely is first diagnosed during pregnancy. Women who are pregnant and have hypothyroidism may complain of increased fatigue in addition to the above-mentioned complaints. Laboratory assessments may reveal an elevated level of serum thyroid-stimulating hormone (TSH) and a low serum level of free thyroxine, or T₄ (Seely & Burrow, 1999).

Congenital hypothyroidism is difficult to diagnose clinically and is found in about 1 in 4,000 to 7,000 infants (Cunningham et al., 1997). Because of the risk of severe neurologic deficits as a result of a deficiency of thyroid hormone, screening of neonates is strongly recommended (Seely & Burrow, 1999).

In regions where there is dietary deficiency of iodine, fetal brain damage may result. The severe manifestation of this damage is referred to as cretinism, which is characterized by marked developmental retardation, deaf mutism, spasticity, strabismus, and abnormal sexual development (Haddow et al., 1999; Seely & Burrow, 1999).

Management

Replacement thyroxine is given to the pregnant woman, with dosages titrated until thyroid function tests are within the normal range. The dosage usually is increased approximately every 4 weeks until TSH levels are within the normal range (Seely & Burrow, 1999). Clients who have received thyroxine replacement therapy before pregnancy often require higher dosages during pregnancy (Brent, 1999).

Nursing Care

Antepartum nursing care for the client with hypothyroidism includes monitoring for signs and symptoms of worsening disease, such as increased fatigue, dry skin, and coarse hair. The nurse should provide education to the client regarding the disease process and the medical management plan. There are no specific nursing care issues in the intrapartum period. In the postpartum period, clients may not have thyroid hormone replacement therapy until

thyroid function studies can be evaluated several weeks after delivery.

Hyperthyroidism

Hyperthyroidism can cause menstrual irregularities but usually does not affect fertility, and pregnancy does not alter the disease (Major & Nageotte, 1999). The primary maternal concern is uncontrolled disease called thyroid storm, which is a medical emergency. Heart failure also is of concern. Hyperthyroidism has been associated with adverse fetal outcomes.

Incidence

Hyperthyroidism, or **thyrotoxicosis**, is common in the general population, affecting approximately 2% of women and 0.02% of men (Gittoes & Franklyn, 1998). Similar to hypothyroidism the diagnosis of hyperthyroidism rarely is made during pregnancy, and the disease causes complications in about 0.2% of pregnancies (Mestman, 1997).

Clinical Presentation

The classic signs of hyperthyroidism include heat intolerance, diaphoresis, warm skin, fatigue, anxiety, emotional lability, tachycardia, and vomiting, which also are found frequently in a normal pregnancy. A lack of weight gain, unanticipated weight loss, and increased heart rate above the norm for pregnancy may be signs that would help differentiate hyperthyroidism from the symptoms of a normal pregnancy. Laboratory values in the diagnosis of hyperthyroidism indicate an elevated serum level of free thyroxine and a low TSH level (Cunningham et al., 1997; Seely & Burrow, 1999).

Approximately 95% of cases of hyperthyroidism are caused by Graves disease, which is an autoimmune process (Seely & Burrow, 1999). Perinatal outcomes in hyperthyroidism are largely dependent on control of the disease state in pregnancy. Adverse outcomes associated with hyperthyroidism include an increased risk for PIH, preterm labor, congestive heart failure, and intrauterine fetal demise (ACOG, 1993; Burrow, 1999). Rarely, clients will undergo thyroid storm, which is a potentially life-threatening complication resulting in cardiac failure (Cunningham et al., 1997).

Rarely, fetal and neonatal hyperthyroidism may result from transplacental passage of thyroid-stimulating immunoglobulins. Fetal hyperthyroidism may increase the risk for intrauterine growth retardation, nonimmune hydrops, and intrauterine fetal death (Zimmerman, 1999). The neonate born to a client who has hyperthyroidism also may have hyperthyroidism that may require medical treatment. These infants may demonstrate hyperkinesis, irritability, poor feeding, vomiting, diarrhea, poor weight

gain, jaundice, ophthalmopathy, cardiac failure, hypertension, and thrombocytopenia up to 5 to 10 days after delivery (Zimmerman, 1999; Seely & Burrow, 1999). A neonate who has been exposed to antithyroid medication in utero also may develop hypothyroidism, with development of a goiter and exophthalmos.

Management

Hyperthyroidism usually is managed with thionamide drugs, such as propylthiouracil (PTU). The dosage of this medication is titrated until the free thyroxine levels are within the normal range for pregnancy and the clinical symptoms appear to be improved. The drug is administered at the lowest possible dosage to maintain normal serum levels. In many cases, PTU can be discontinued at about 32 to 36 weeks' gestation (Seely & Burrow, 1999). In rare cases during pregnancy, a thyroidectomy may be performed when medical management fails (Cunningham et al., 1997).

Nursing Care

The nursing care of the client with hyperthyroidism includes monitoring for signs and symptoms of worsening disease and client education regarding the disease process and medical plan of management. The nurse also may perform fetal surveillance testing as ordered. The client with thyroid storm or cardiac failure will need intensive nursing care, the discussion of which is beyond the scope of this chapter.

CARDIOVASCULAR DISORDERS

Cardiovascular disease in pregnant women is either congenital or acquired. The consequences of heart diseases for the mother and fetus depend on disease type and severity.

Clinical Presentation

In the recent past, many women with congenital or acquired heart disease were counseled to avoid pregnancy and in some cases did not survive to childbearing age themselves. Advances in health care have allowed for surgical repair of structural defects and have vastly improved outcomes for this group of women. Women with existing heart disease can present a challenge to the health care team because many significant cardiovascular changes occur during pregnancy.

Most pregnant women with significant cardiovascular disease are diagnosed before pregnancy. Some cases of heart disease are first detected during pregnancy when the hemodynamic changes of pregnancy begin to place stress on the heart. Normal symptoms found in pregnancy, such

as palpitations, tachypnea, fatigue, edema, and syncope, are similar to symptoms of cardiovascular disease. A careful evaluation of existing symptoms is needed for the pregnant woman and any new or additional symptoms, or an increase in symptoms with exertion, should be cause for further evaluation. Symptoms that should prompt further evaluation include severe dyspnea, syncope with exertion, hemoptysis, paroxysmal nocturnal tachycardia, and chest pain on exertion (Shabetai, 1999).

Many specific cardiovascular structural defects may be affected by pregnancy. The discussion of these defects is beyond the scope of this chapter because each one would require a discussion of the specific defect and a detailed discussion of the medical management. Cardiovascular conditions that are specific to or common in pregnancy or that need special consideration include peripartum cardiomyopathy, cardiac arrhythmias, and myocardial infarction (MI).

Peripartum cardiomyopathy is a rare form of heart failure occurring during pregnancy or in the first 5 months postpartum (Hibbard, Lindheimer, & Lang, 1999). Approximately 1,000 women in the United States are expected to develop this complication each year (Brown & Bertolet, 1998). The mortality rate for this complication is significant at 25% to 60% (Aziz et al., 1999; Hibbard, Lindheimer, & Lang, 1999). The cause of peripartum cardiomyopathy is unknown; however, viral and autoimmune causes often are associated with this type of heart failure (Heider et al., 1999; Brown & Bertolet, 1998).

The woman with peripartum cardiomyopathy presents in a way similar to clients with other types of congestive heart failure, that is, with edema, fatigue, and dyspnea. Weight gain, jugular vein distension, and an enlarged heart may be present on examination (Shabetai, 1999). The management of cardiomyopathy is primarily supportive (Heider et al., 1999). Approximately 30% of women who develop peripartum cardiomyopathy will recover to their baseline ventricular function within 6 months of delivery (Lampert, Wernwor, Thippert, Korcarz, Lindheimer, & Lang, 1997).

Cardiac arrhythmias appear to increase in frequency during pregnancy, often are benign, and do not require treatment (Wolbrette & Patel, 1999; Shabetai, 1999). Sustained and symptomatic arrhythmias may jeopardize the health of the mother and fetus and may be life-threatening (Shabetai, 1999).

Myocardial infarction is a rare event in pregnancy, occurring in 1 per 10,000 to 30,000 deliveries (Samuels et al., 1998; Webber, Halligan, & Schumacher, 1997). The mortality rate from this complication is high, reportedly from 37% to 50%. Mortality increases in clients experiencing MIs in the third trimester of pregnancy, when delivery occurs within 2 weeks of the event, in clients less than 35 years of age, and in clients who deliver by cesarean section (Webber et al., 1997).

Pregnancy generally is contraindicated in clients who have experienced an MI before becoming pregnant and who have severe left ventricular damage and heart failure (Shabetai, 1999). When pregnancy occurs accidentally, the woman may be asked to consider terminating the pregnancy if her condition is severe.

Management

Each client with cardiovascular complications should have an individualized plan of care determined by a multidisciplinary team and based on her underlying disease process or structural defect. Certain principles in the management of the pregnant women with cardiovascular disease can be applied to most all types of disease. These clients generally should have frequent prenatal visits and consultation with a specialist. They also may need to be placed on bed rest at any point in the pregnancy as they become symptomatic or as cardiac function is impaired (Shabetai, 1999). The physician may choose conservative management of clients who are stable and not hemodynamically compromised, including observation and bed rest.

The pregnant woman with peripartum cardiomyopathy usually is treated similarly to clients with congestive heart failure, with bed rest, digitalization, diuretics, and sodium restriction (Clark et al., 1997). Clients who do not exhibit improved ventricular function may be considered for heart transplantation (Heider et al., 1999; Aziz et al., 1999).

Women who have certain tachyarrhythmias may first be instructed to use vagal maneuvers to alleviate the dysrhythmia (Cunningham et al., 1997). If these maneuvers fail and the client is symptomatic, she is frequently managed with antiarrhythmic drugs. These drugs usually are well tolerated by clients and pose relatively low risk in pregnancy (Cunningham et al., 1997; Joglar & Page, 1999). Beta-blockers frequently are prescribed in the treatment of tachyarrhythmias. These medications may cause neonatal hypoglycemia and bradycardia; however these conditions usually are not serious. Beta-blockers are excreted in the breast milk and may cause bradycardia and hypotension in the neonate (Clark et al., 1997).

A pacemaker may be used to treat certain arrhythmias, and these devices should not impact the pregnancy (Shabetai, 1999). Cardioversion has also been effectively used to treat maternal dysrhythmias and is well tolerated by the client and fetus (Joglar & Page, 1999; Shabetai, 1999).

The woman who has experienced a MI previously is counseled to wait 1 year before becoming pregnant (Shabetai, 1999). Once pregnant, women often will be placed on bed rest during pregnancy. The client whose delivery occurs within 2 weeks of the MI has an increased risk for death, and therefore, adequate rest during this time is very important (Clark et al., 1997; Shabetai, 1999). In the intra-

partum period, efforts are made to minimize hemodynamic changes and optimize perfusion. The client is labored in a lateral position, provided with adequate pain relief, and given oxygen (Clark et al., 1997). Invasive hemodynamic monitoring may be necessary (Clark et al., 1997; Shabetai, 1999).

The specific cardiovascular complications and the condition of the client will help determine the method of delivery. In general, the mode of delivery usually is decided based on obstetric indications. The second stage of labor may be shortened by the use of forceps or vacuum extraction to avoid the prolonged Valsalva maneuver in pushing (Cunningham et al., 1997). In some specific cardiac complications, to avoid the strain of labor an elective cesarean section may be performed. The stress of major surgery, the potential for infection, and increased blood loss as compared with vaginal delivery is taken into consideration in planning the method of delivery (Clark et al., 1997).

Clients with cardiovascular complications who will undergo labor and anticipated vaginal delivery often need special considerations. During the intrapartum period attempts are made to minimize changes in blood pressure and pulse, including placing the client in a lateral position, adequate pain management, and the avoidance of hemorrhage. The avoidance of infection is an important consideration because an infection can have a detrimental effect on the client's overall condition. Supplemental oxygen and antibiotics frequently are prescribed (Clark et al., 1997).

Nursing Care

Nursing care of clients who have cardiovascular disease can be very challenging. In some cases, nurses from the obstetric, cardiovascular, or critical care service may need to collaborate in the care. Thorough physical assessments should be performed, and any change in cardiopulmonary status should be reported to the physician promptly. Meticulous care should be given to aseptic technique to avoid an infection because infection could have a serious impact on the client's overall condition. Intake and output should be monitored closely in most clients with cardiovascular disease to avoid volume overload. The nurse should have a thorough understanding of the pathophysiology of the specific cardiovascular disease and be familiar with any vasoactive drugs that may be used.

Clients and families are often very anxious and need thorough explanations regarding the plan of care. Emotional support is an essential piece in the care of these clients, and spiritual needs should be considered.

PULMONARY DISORDERS

Pulmonary disorders that can complicate pregnancy include asthma and tuberculosis (TB). The impact this dis-

ease has on the mother and fetus is related to the severity of the disease process.

Asthma

Asthma is considered to be an obstructive pulmonary disease.

Incidence

Asthma affects about 1% to 4% of pregnancies, which is a lower incidence than in the general population in which the reported incidence is 3% to 5% (Kurinczuk et al., 1999; Weinberger & Weiss, 1999).

Clinical Presentation

Bronchospasm and increased mucous production cause air flow to be limited, especially during expiration. Exacerbation of asthma may be related to specific events or "triggers," such as dust, animal dander, exercise, and respiratory infection; in contrast, there may be no obvious precipitating event. Symptoms of exacerbation of asthma, or an "attack," include coughing, wheezing, and dyspnea. Maternal and perinatal outcomes in clients with asthma depend on disease severity and treatment adequacy throughout pregnancy (Weinberger & Weiss, 1999).

Asthma usually begins in childhood but can occur at any age. The course of asthma in pregnancy is unpredictable; some clients experience worsening of the disease, some improve, and an equal number remain unchanged (Weinberger & Weiss, 1999). Pregnant clients rarely will experience an asthma attack during pregnancy, although the reason for this is not clear (Swiet, 1999).

Management

Treatment for women with asthma who are pregnant compared with that for those who are not pregnant varies little. Treatment is aimed at preventing and relieving bronchospasm. Undertreatment of pregnant women with asthma is common and based on fears about the effects medications used to treat asthma may have on the fetus. A study by Cydulka et al. (1999) found that pregnant women who presented to the emergency room for acute asthma attacks were less likely to receive appropriate treatment with corticosteroids. Most medications used for treatment of asthma in the general population are safe for use in pregnancy (Swiet, 1999). The risks to the patient of leaving severe asthma untreated are greater than are the risks of using medication to control asthma during pregnancy (Schatz, 1999). Poorly controlled asthma in the pregnant client places the fetus at greater risk than do most medical therapies used in the treatment of asthma (Weinberger & Weiss, 1999; Schatz, 1999).

Clients with mild or occasional asthma attacks are generally managed outside the hospital setting with inhaled beta-agonist agents, such as albuterol. Clients experiencing several attacks a week may be placed on scheduled doses of inhaled anti-inflammatory medications as a preventive measure. Inhaled corticosteroids also are used to prevent airway inflammation in clients who have moderate or severe asthma (Swiet, 1999; Cunningham et al., 1997). In very severe cases of asthma, parenteral or oral steroids may become necessary. The treatment is usually converted to inhaled steroids over time (Cunningham et al., 1997).

The Working Group on Asthma and Pregnancy, National Institutes of Health, National Heart, Lung, and Blood Institute, was established in 1993 by the National Asthma Education and Prevention Program to address the problems of asthma management in pregnancy. Key concepts from the recommendations of this Working Group include aggressive asthma management principles integrated with obstetric care. This Working Group suggests that management be as aggressive for the pregnant patient as for the nonpregnant patient and that medications used to treat asthma should include a short-acting beta-agonist and a long-term daily medication to reduce inflammation (Clark, 1993; Luskin, 1999).

In a severe asthma attack the goals are to correct maternal hypoxia, relieve bronchospasm, ensure adequate ventilation, and support uteroplacental perfusion. Intubation and mechanical ventilation may be necessary for clients who are unresponsive to medical therapy (Clark et al., 1997).

Nursing Care

Client education is a key part of nursing care for the pregnant woman who has asthma. The client should be counseled that her asthma might possibly improve, worsen, or remain unchanged during pregnancy. The importance of using inhalers and other prescribed medications as ordered by the primary care provider should be stressed. Many pregnant women are fearful of taking any type of drug during pregnancy and should be reassured about the safety of these medications.

The technique of inhaler use should be evaluated because proper dosing depends on adequate use of the device. Clients who have difficulty with traditional inhalers can be offered the use of a spacer, an additional device that helps deliver accurate doses.

A severe asthma attack is a medical emergency. A pregnant woman who is experiencing a severe asthma attack should be observed closely and receive a thorough physical assessment. The client should be placed in a lateral recumbent position to optimize ventilation and uteroplacental circulation. The client's response or lack of response to medications should be noted and reported to the physician.

The client experiencing an asthma attack will exhibit anxiety and often will be anxious about the fetal condition and her own. Reassurance should be offered to the client and family as should thorough explanations about procedures, medications, and the medical plan of management.

Tuberculosis

Tuberculosis is a worldwide health concern and a major cause of illness and death. The prevalence of TB is increasing worldwide. Many causes have been implicated in the resurgence of TB in recent years in the United States: presence of the human immunodeficiency virus (HIV), development of drug-resistant strains of TB, an increase in the number of immigrants, difficulty accessing medical care in the population with TB, and lack of adequate resources to handle the increasing number of cases (Saade, 1997; Hageman, 1997; Anderson, 1997).

Clinical Presentation

The lung is the major site of involvement. Some clients, however, will have extrapulmonary disease, including endometrial, lymphatic, intestinal, skeletal, renal, meningeal, and genital TB (Jana et al., 1999; Soussis et al., 1998). The diagnosis of TB generally is made by isolation of the organism *Mycobacterium tuberculosis* from involved sites. The organism is cultured from a sputum specimen in the case of pulmonary TB. Infection is caused by inhalation of the *M. tuberculosis* organism. Clients can be asymptomatic at the time of primary infection. TB may lie dormant for long periods of time before reactivating. Clinical manifestations include symptoms of pneumonia, such as fever and a cough that may be nonproductive, pleuritic chest pain, hemoptysis, and weight loss. Outcomes for clients who have TB during pregnancy are related to disease severity and treatment adequacy.

Management

The tuberculin skin test is a routine but important screening test for TB that may be performed in high-risk women during pregnancy (Nolan, Espinosa, & Pastorek, 1997; Riley, 1997). Clients at high risk include those who have HIV, those with close contact with persons known to have TB, persons who recently have immigrated to the United States, and clients who are incarcerated or in long-term care facilities (Cunningham et al., 1997). A chest radiograph may be performed in the client who has a positive result on a skin test and who previously has had a negative test result, or in the client whose medical history or physical examination is suggestive of TB. When a chest radiograph is indicated, it should be delayed until after the first trimester if possible to avoid exposing the rapidly developing fetus to radiation. Shielding also can be used to reduce fetal exposure.

Pregnant women who test positive for TB but do not have clinical evidence of active disease may delay treatment until after delivery (Cunningham et al., 1997). Treatment of pulmonary TB in pregnant women is similar to that in women who are not pregnant (Saade, 1997). Treatment consists of daily doses of isoniazid (INH), rifampin, pyrazinamide, and ethambuton over a 6-month period. These first-line agents appear to have minimal risks for the development of congenital anomalies and may be started as soon as the diagnosis of TB is made (Brost & Newman, 1997). Clients who have HIV and TB are placed on extended regimens. Hepatitis is a major side effect of INH; therefore, clients may require serial liver enzyme testing (Cunningham et al., 1997).

Neonatal infection is uncommon if the mother has received adequate treatment for at least 2 weeks before delivery. The neonate is at greatest risk for the development of TB shortly after birth because the newborn is susceptible to TB infection (Starke, 1997). The newborn is isolated from the mother for up to 2 weeks if she has active disease (Swiet, 1999).

Nursing Care

Clients who are in high-risk groups should be screened for TB in pregnancy. A thorough medical history will include information on potential exposure to TB and any signs and symptoms of the disease. The client will often need education about the disease process, potential complications, and management plan. Compliance to the medication regimen, if prescribed, is key to optimal outcome in the mother and fetus and should be stressed.

The pregnant client who has TB will need emotional support in dealing with the implications of the disease. The client who must be isolated from her newborn may be very distraught. She should be made aware of the rationale for isolation and offered the opportunity to verbalize her concern and grief.

AUTOIMMUNE DISEASE

Autoimmune disease is a condition in which a person demonstrates an immune response to constituents of one's self. It is thought to be caused by a combination of factors, including environment, genetics, and host factors (Branch & Porter, 1999).

Systemic Lupus Erythematosus

Systemic lupus erythematosus is an inflammatory autoimmune disease that affects multiple organ systems. Autoimmune diseases occur most commonly in women of childbearing age and with greater frequency in African

American and Hispanic women than in Caucasian women (Silver & Branch, 1997).

Clinical Presentation

The diagnosis of lupus generally is based on the presence of clinical signs and symptoms. The most common complaints are a low-grade fever that comes and goes, extreme fatigue, muscle and joint pain, and weight loss (Clark et al., 1997; Swiet, 1999). Other symptoms used as criteria for the diagnosis of lupus include malar or discoid rash; photosensitivity; arthritis; and specific renal, neurologic, and hematologic manifestations. The client who has lupus undergoes periods of remission and may improve, worsen, or remain unchanged during pregnancy. Confirmation of the diagnosis is made by the presence of autoantibodies on antinuclear antibody tests (Swiet, 1999).

The development of PIH in the client who has lupus is common and reported to occur in 20% to 30% of pregnancies (Clark et al., 1997). The differentiation between a lupus flare-up and PIH is difficult because of the similarity in clinical presentation, each one having common findings of hypertension and proteinuria. There are no tests that are helpful in distinguishing between the two diseases, and in some cases the client may actually be experiencing a flare-up of lupus (Clark et al., 1997).

The rate of pregnancy loss in women with lupus is increased related primarily to hypertension, renal complications, and premature rupture of membranes (Swiet, 1999; Meng & Lockshin, 1999; Rahman, Gladman, & Urowitz, 1998; Reichlin, 1998). Most pregnancy losses are intrauterine fetal deaths occurring in the second and third trimesters of pregnancy (Clark et al., 1997). Lupus also is associated with an increased risk of intrauterine growth retardation, and premature delivery. Premature delivery may be medically induced because of maternal or fetal complications. Clients who have active disease, who have had established lupus rather than late onset, and who have uncontrolled disease have higher rates of abortion and premature birth. The remission of lupus in the 6 to 12 months before pregnancy most likely decreases the chance for a flare-up during pregnancy and the postpartum period (Silver & Branch, 1997).

Neonatal lupus erythematosus is rare and is characterized by skin lesions; cardiac abnormalities, such as heart block; and hematologic abnormalities, such as thrombocytopenia and anemia (Meng & Lockshin, 1999; Reichlin, 1998; Rabinerson et al., 1997). Skin lesions are the most common finding, appearing in the first few weeks after delivery; they usually resolve at about 6 months of age.

Management

Glucocorticoids, such as prednisone, are used in the treatment of lupus in the general population and are continued

during pregnancy (Silver & Branch, 1997). Patients are monitored closely for an increase in the symptoms of lupus. Mild to moderate exacerbations of lupus symptoms generally are treated with an increased oral dose of prednisone for several days to weeks (Cunningham et al., 1997; Swiet, 1999). Tapering of the drug is initiated after an improvement in symptoms (Cunningham et al., 1997). Severe exacerbations, including renal or CNS involvement, require large doses of IV glucocorticoids over several days. The client is then placed on oral therapy and weaned over approximately 1 month. Clients who have been on continuous administration of glucocorticoids will require a supplemental IV dose, or “stress dose,” during labor or surgical procedures (Clark et al., 1997; Gladman & Urowitz, 1999).

Nursing Care

The client who has lupus can be counseled to postpone pregnancy until she has had a period of 6 to 12 months without a flare-up of the disease. These women will have frequent prenatal visits, and at each visit should be asked about an increase in symptoms or new symptoms of lupus. Clients who are newly diagnosed will require extensive education about the disease process, the implications for pregnancy, and the long-term prognosis. Clients and families should receive emotional support in dealing with the diagnosis of lupus and with the prospects for perinatal complications.

In the intrapartum period clients should be closely monitored for signs of worsening disease, such as the presence of hypertension, CNS involvement, or renal involvement.

HEMATOLOGIC DISORDERS

Hematologic disorders in pregnancy range from iron deficiency anemia to idiopathic thrombocytopenic purpura. Some of these disorders are a mere annoyance, whereas others are life-threatening.

Immunological Idiopathic Thrombocytopenic Purpura

Immunologic thrombocytopenic purpura (ITP), also referred to as idiopathic thrombocytopenic purpura, is a process in which antibodies are directed against platelets and usually is an immune response to drugs or viral infections (Duffy, 1999).

Clinical Presentation

Acute cases of thrombocytopenia often follow a viral infection and usually resolve spontaneously (Cunningham et al., 1997). Chronic cases of ITP are most common in young

women and occur in about 7% to 8% of pregnancies. The initial diagnosis of ITP sometimes is made during pregnancy when a routine CBC reveals a decreased platelet count (ACOG, 1999b). It is unclear what impact pregnancy could have on chronic ITP.

Antibodies are able to cross the placenta and cause thrombocytopenia in the fetus and neonate. Concern exists that the fetus with thrombocytopenia is at risk for intracranial hemorrhage during labor and delivery, prompting direct measurement of fetal platelet count by PUBS or fetal scalp sampling (Cunningham et al., 1997). The actual incidence of moderate to severe neonatal thrombocytopenia and intracranial hemorrhage is low (Payne et al., 1997; Song et al., 1999; Burrows & Kelton, 1993). It is estimated that significant neonatal thrombocytopenia occurs in 10% of babies born to patients with ITP (Bussel, 1997).

Management

Once thrombocytopenia is diagnosed, secondary causative factors are investigated, such as lupus, leukemia, and lymphoma. Clients whose very low platelet counts persist (less than 50,000) are usually treated with steroids. The goal of therapy is to decrease the incidence of hemorrhage. Improvement usually occurs within 2 to 3 weeks. More than 70% of clients will have an increase in platelet count, and the steroid dose is tapered as the platelet count is normalized (Kilpatrick & Laros, 1999). Clients who continue to have persistent severe thrombocytopenia and who are bleeding despite steroid therapy may require a splenectomy; however, this is rarely required in pregnancy (Bussel, 1997; Duffy, 1999). Women who are asymptomatic and have ITP and a platelet count greater than 50,000 usually do not require treatment (Duffy, 1999).

Clinicians have attempted to predict fetal and neonatal thrombocytopenia based on maternal characteristics without much success (Cunningham et al., 1997; Payne et al., 1997). Some clinicians will opt to deliver the baby by cesarean section if the fetus has thrombocytopenia (Duffy, 1999; Cunningham et al., 1997). Laboratory tests used to determine fetal platelet count are expensive, and there is a significant risk to the fetus from the procedures (Burrows & Kelton, 1993; Song et al., 1999; Payne et al., 1997). Studies have been performed that have found that neither the determination of fetal platelet count nor performance of a cesarean section significantly impact neonatal outcomes. Although this remains a controversial issue, many clinicians determine the route of delivery based strictly on obstetric indications. (Payne et al., 1997; Song et al., 1999; Burrows & Kelton, 1993b; Silver, Branch, & Scott, 1995).

Nursing Care

Clients diagnosed with ITP will need thorough explanations of the disease process and of possible maternal and

fetal implications. The medical plan of management, including considerations for the route of delivery, should be discussed with the client and family.

Sickle Cell Disease

Sickle cell disease encompasses several inherited disorders of hemoglobin synthesis, with sickle cell anemia (SS disease), sickle cell–hemoglobin C disease (SC disease), and sickle cell– β -thalassemia (S- β -thalassemia) being the most common forms.

Clinical Presentation

Sickle cell anemia (SS disease) occurs when the gene for S hemoglobin is inherited from both parents. Sickle cell trait, which is the inheritance of one gene for the production of S hemoglobin and one for normal hemoglobin, occurs in 1 of 12 African Americans. SC disease, in which there is a gene for the production of hemoglobin C, occurs in approximately 1 in 2,000 African American women (Cunningham et al., 1997). S- β -thalassemia occurs with the inheritance of an S gene and a β -thalassemia gene. S- β -thalassemia occurs in approximately 1 of every 2,000 women (Cunningham et al., 1997). Pregnancy places a strain on women with sickle hemoglobinopathies and, accordingly, they have significant maternal and perinatal morbidity and mortality.

The diagnosis of hemoglobinopathies is made by hemoglobin electrophoresis, which identifies the type and percentage of abnormal hemoglobin.

Most of the signs and symptoms of SS disease are a result of hemolysis, vaso-occlusive disease, or increased susceptibility to infection (Kilpatrick & Laros, 1999). Patients with SS disease experience sickling of erythrocytes and resulting occlusion of the microvasculature precipitated by hypoxemia. Chronic anemia and episodes of “crises” in which there is vaso-occlusion causing ischemia, acute pain, and possible organ failure are characteristic of the disease. These painful episodes of sickle cell crisis may occur in the long bones, abdomen, chest, or back; these episodes are potentially life-threatening and often increase in frequency during pregnancy (Clark et al., 1997; Kilpatrick & Laros, 1999).

In general, clients who have SS disease are more susceptible to infection. Infections and pulmonary complications are major causes of morbidity and mortality in women who have SS disease and are more common in pregnancy (Cunningham et al., 1997).

During pregnancy women who have SC disease may have an increased incidence of severe bone pain and additional serious complications, even though they often are asymptomatic before pregnancy. Maternal and perinatal mortality rates are higher than in the general population but much lower than in SS disease (Duffy, 1999).

Pregnancy outcomes for clients who have β -thalassemia usually are good. These women may experience mild to moderate anemia during pregnancy (Duffy, 1999).

Management

Hemoglobin electrophoresis may be ordered prenatally as a screening test for African American women. The pregnant woman with a sickle hemoglobinopathy generally will have chronic hemolytic anemia and requires increased folic acid supplementation throughout pregnancy. Disease treatment mainly consists relieving symptoms, with the objective being to end painful crisis and fight infection (Kilpatrick & Laros, 1999).

Transfusions of erythrocytes are used in cases of chronic anemia to prevent acute or chronic complications based on the client's symptoms (Simon et al., 1998).

Clients are monitored throughout pregnancy for asymptomatic bacteruria because women with sickle cell hemoglobin have a greatly increased risk for bacteruria (Pastore, Savitz, & Thorp, 1999). Infections are poorly tolerated and are managed aggressively to avoid precipitation of a crisis.

The management of sickle cell crisis usually involves hospitalization, evaluation for sources of potential infection, rest, hydration, and pain management. IV therapy to correct dehydration is a key aspect of therapy because it can lower the blood viscosity and may help alleviate vaso-occlusion (Kilpatrick & Laros, 1999). Oxygen therapy is reserved for clients who are experiencing hypoxia, those with a pulmonary infection, and those in labor (Clark et al., 1997). The pain of sickle cell crisis can last for up to a week and is managed according to severity; some clients require narcotic analgesia.

Nursing Care

Clients who have sickle hemoglobinopathies require education about the impact of pregnancy on their disease. Avoidance of infection is an important consideration and should be stressed. Pregnant women are more susceptible to UTIs than are women in the general population, and clients should be instructed to alert their health care provider as soon as the first symptoms of UTI appear. In fact, routine screening is likely to be included in prenatal care because of asymptomatic bacteruria.

Clients experiencing crisis will require supportive care: a warm restful environment, adequate pain control, IV hydration, and oxygen therapy as ordered. Intake and output should be recorded; however, catheterization should be avoided because of risk of infection. Crisis is an extremely anxiety-provoking event, with the very real threat of death. Clients require emotional support and reassurance from family and health care providers.

NEUROLOGIC DISORDERS

Neurologic disorders, namely epilepsy, can affect the health of the mother and baby.

Seizure Disorders

Seizure disorders may be acquired as a result of trauma, tumors, or metabolic disorders.

Incidence

Most frequently the seizure activity is idiopathic and is known as epilepsy (ACOG, 1996d). Epilepsy is common in the general population and affects an estimated 1 million women of childbearing age (Chang & McAuely, 1998). Seizure disorders are the most common major neurologic complication seen in pregnancy, affecting approximately 0.5% of all pregnancies (Nulman, Laslo, & Koren, 1999; ACOG, 1996d). This section focuses on epilepsy.

Clinical Presentation

Preconceptual counseling for women of childbearing age who have epilepsy is very important. The outcome of the pregnancy is greatly determined by control of the seizure disorder, achieving therapeutic blood levels of the prescribed anticonvulsant, compliance with the medication regimen, and vitamin supplementation.

During pregnancy psychological, hormonal, and pharmacokinetic changes can cause an increase in seizure activity. As many as half of women with epilepsy will experience an increase in seizure activity during pregnancy (Cunningham et al., 1997). Status epilepticus is a rare condition in which recurrent generalized seizures occur. This condition is an emergency because the mother and fetus are at risk for hypoxia. This complication seems to occur more frequently in the third trimester (Licht & Sankar, 1999; ACOG, 1996d).

Serum levels of anticonvulsant drugs can change dramatically during pregnancy, usually decreasing as the pregnancy progresses. These changes may be related to nausea and vomiting, delayed gastric emptying, increased plasma volume, and altered protein binding. Serum levels fluctuations may cause a nontherapeutic level of the anticonvulsant drug or, in some cases, maternal toxicity (Nulman, Laslo, & Koren, 1999; ACOG, 1996d). Therefore, close monitoring is required during pregnancy.

Most anticonvulsant drugs interfere with metabolism of the essential vitamins folic acid and vitamin K. Folic acid deficiency is associated with an increased incidence of neural tube defects and other major malformations. Interference with vitamin K metabolism places the neonate at increased risk for bleeding because certain clotting factors are dependent on vitamin K (Chang & McAuely, 1998; ACOG, 1996d).

Children born to women without seizure disorders have a 0.5% to 1% risk of developing epilepsy. Children born to a woman with epilepsy are four times more likely to develop epilepsy (ACOG, 1996d). Children exposed to phenytoin in utero are at risk for cleft lip and fetal hydantoin syndrome.

Management

Women of childbearing age who have epilepsy may be started on folic acid supplementation even before conception. Once pregnant, the woman should receive folic acid supplementation throughout the first trimester (Nulman, Laslo, & Koren, 1999; Lewis et al., 1998; Morrell, 1998; Chang & McAuely, 1998; ACOG, 1996d). Some clinicians prescribe vitamin K supplementation during the last month of pregnancy. The infant also receives a vitamin K injection at birth (Nulman, Laslo, & Koren, 1999; ACOG, 1996d).

The woman with epilepsy should be counseled regarding possible teratogenic effects of uncontrolled seizures and the increased risk for major congenital malformations associated with the anticonvulsant medications (Nulman, Laslo, & Koren, 1999; Samren et al., 1999; Holmes et al., 2000). There is about a two to three times increased risk for birth defects in infants with mothers who have epilepsy compared with the general population (ACOG, 1996d). Seizure control is preferably achieved at least 6 months before conception.

Medical therapy during pregnancy is ideally accomplished with the lowest possible effective dose of a single antiseizure medication (Morrell, 1998; Chang & McAuely, 1998; Ellers, Patterson, & Webb, 1997; ACOG, 1996d). Because serum levels of drugs considered therapeutic in patients who are not pregnant are not reliable during pregnancy and because of the fluctuations, drug levels are checked periodically as the pregnancy progresses. Clients should be educated regarding the signs and symptoms of drug toxicity (ACOG, 1996d).

Some clients are reluctant to take the prescribed anticonvulsant medications because of fear of fetal effects (ACOG, 1996d). Patients should be strongly advised to adhere to the medical regimen and report increase in seizure activity. Because lack of sleep and stress may cause an increase in seizure activity, the pregnant client should be encouraged to get adequate rest.

During the early antepartum period clients are offered screening for potential neural tube defects using a maternal serum alpha-fetoprotein determination and ultrasonography. If these tests are inconclusive the woman may be offered an amniocentesis for a definitive diagnosis. Frequently, a comprehensive ultrasonography to assess for congenital malformations is performed at approximately 18 to 22 weeks' gestation. Further antepartum surveillance is not always necessary and is determined based on the individual client's condition (ACOG, 1996d).

In the event of status epilepticus the physician may order IV phenytoin, which must be administered slowly to avoid significant cardiac dysrhythmias. Phenobarbital or diazepam may be ordered alternatively; however, both these drugs may cause respiratory depression. Emergency supplies for endotracheal intubation, oxygen, and suction equipment should be readily available (ACOG, 1996d).

During labor the client may be unable to take prescribed oral medications. Serum drug levels may be evaluated and the client may receive an anticonvulsant parenterally.

In the postpartum period serum levels of anticonvulsants may increase rapidly. When the drug dosage is increased during pregnancy, it frequently needs to be decreased in the postpartum period (Aminoff, 1999). Serum levels are checked frequently to avoid toxic drug levels (ACOG, 1996d). Antiepileptic drugs interact with oral contraceptives, making them less effective. Clients should be counseled on the need for increased dosage or a second method of birth control to avoid an unplanned pregnancy (Chang & McAuley, 1998; ACOG, 1996d).

Infants born to mothers with epilepsy who are receiving barbiturates may experience withdrawal symptoms beginning about 1 week after birth and lasting 1 to 2 weeks. A breast-fed infant may develop withdrawal with abrupt cessation of breast-feeding and may require low-dose phenobarbital with gradual withdrawal (ACOG, 1996d).

Nursing Care

In the antepartum period most clients will need education regarding the effect their pregnancy might have on their

disease, medical therapy prescribed, potential complications for the fetus and neonate, and the medical plan of care. Clients diagnosed with epilepsy and their families may be fearful of the effects their disease can have on their babies and will need accurate information about their disease and emotional support throughout the pregnancy.

NURSING IMPLICATIONS

Few events over the course of a lifetime have such a momentous impact on women and their families as do a pregnancy and the eventual birth of the baby. Pregnancy can be a time of great hope and joy or, when complications arise, a time of great concern and even despair. Major advances in obstetric care have been made in the last half of the 20th Century that have allowed women with serious medical and obstetric complications to achieve positive pregnancy outcomes. The availability of adequate prenatal care, early identification of risk factors, and an interdisciplinary approach to the management of the high-risk pregnancy is critical to optimize outcomes for the family.

The role of the nurse in caring for the high-risk obstetric client will vary depending on the condition and setting. For the client being managed in the community, your role may be one of counseling, teaching, and case management. It is very important that the client and family understand the pathophysiology of the condition and which self-help measures can be taken. It also is important to teach danger signs and the procedure that should be followed in the event of a change in the woman's condition. The intervention depends not only on the condition but the severity of the condition, with home care used for milder cases in which client compliance is not likely to be an issue.

Nurses working with pregnant women and families must be familiar with common complications that can arise during the course of pregnancy. Nurses should be prepared to function as an integral part of the health care team, performing thorough nursing assessments, administering medications and treatments, and providing clients and families with education and support.

Critical Thinking

Significant Findings from Nursing Assessment

Nurses are in a position to detect early signs of obstetric risks. What might be the significance of the following findings from a nursing assessment?

- Oliguria of less than 30 mL/h
- Significant change in vital signs
- Diastolic blood pressure of 110 mmHg or higher
- Nonreassuring fetal status
- Seizure activity
- Vaginal bleeding
- Severe epigastric or upper right quadrant pain
- Altered mental status
- Signs and symptoms of pulmonary edema
- Abnormal laboratory results

Web Activities

- Use a search engine such as PubMed or Ovid to search a specific condition discussed in this chapter.
- Visit the website of the American College of Obstetricians and Gynecologists for clinical guidelines on managing pregnant clients with hypertensive and cardiovascular disorders.

Key Concepts

- Pregnancy is considered a normal process with minimal risks. However, the potential exists for development of risks.
- The best practice is to anticipate and attempt to reduce risks or prevent the occurrence of complications.
- A pregnant woman has the potential for changing from being normal to being high risk very quickly.

Review Questions and Activities

1. Why is it important for you to differentiate the following: complete abortion, threatened abortion, and missed abortion?
2. Which signs and symptoms would alert you to a potential ectopic pregnancy?
3. When providing care for a woman who is in the third trimester of pregnancy and bleeding, what should you include in emergency preparations?
4. When magnesium sulfate is given to the pregnant woman, which complications or adverse effects will you need to monitor?
5. Why is it important to identify the blood type and Rh factor of all pregnant women?
6. Why is gestational diabetes a health problem for the pregnant woman? For the neonate?
7. What are the differences between chronic hypertension, pregnancy-induced hypertension, and superimposed hypertension?
8. What is peripartum cardiomyopathy, and why is this complication significant?
9. What is the HELLP syndrome and how does it affect the pregnant women?

Pregnancy in Special Populations

Working with young, HIV-positive, or older pregnant clients can be a challenging and rewarding nursing experience. Understanding the complex psychosocial factors that lead these women to become pregnant is essential in providing supportive care to them and to their families. You may need to explore your own feelings relative to adolescent sexuality, AIDS, and pregnancy after age 35 to facilitate a therapeutic relationship with these clients. Consider the following:

- ❖ *How do I feel about teens who are sexually active?*
- ❖ *How do I feel about unmarried teens who become pregnant?*
- ❖ *What role do I think unmarried teen fathers should play in their partners' pregnancy and delivery?*
- ❖ *How can I relate to an HIV-positive woman who chooses to complete a pregnancy? Can I offer sensitive care to this client and her newborn?*
- ❖ *Do I know the risks of pregnancy after age 35? What is my opinion of pregnancy resulting from use of fertility drugs?*

Key Terms

Acquired immunodeficiency syndrome (AIDS)	Advanced reproductive age	Elderly primagravida	Seroconversion
Adolescence	Antiretroviral therapy	Embryo transfer (ET)	Sexual maturation
Adolescent pregnancy	Cognitive development	Human immunodeficiency virus (HIV)	Vertical transmission
	Developmental tasks		

Competencies

Upon completion of this chapter, the reader should be able to:

1. Describe the scope and significance of adolescent pregnancy.
2. Analyze the reasons that adolescents become pregnant.
3. Describe the psychosocial and physical risks for pregnant adolescents and their children.
4. Discuss adolescent sexuality and appropriate contraceptive methods.
5. Formulate a nursing care plan for pregnant adolescents.
6. Describe the significance of HIV infection in pregnant adolescents and young adults.
7. Discuss the importance of prevention of vertical and perinatal transmission of HIV infection.
8. Discuss the clinical manifestations and medical management of HIV-infected pregnant women and neonates.
9. Identify the effects of aging on reproductive function.
10. Discuss the medical risks for older women during pregnancy.
11. Discuss the issues concerning artificial conception in postmenopausal women.
12. Provide anticipatory guidance for older first-time pregnant couples.

Pregnancy in special populations refers to those populations that have unique issues related to the physical and psychosocial aspects of pregnancy. The populations discussed in this chapter include the pregnant adolescent; the pregnant HIV-infected woman; and the pregnant middle-aged and postmenopausal woman. Each of these special populations provides a unique challenge to nurses in providing holistic and age-appropriate nursing care during pregnancy and delivery. Advances in medical technology account for the following: (1) effective low-dose hormonal methods of contraception that should significantly decrease the teen birth rate, although statistics remain remarkably high; (2) improved outcomes for pregnant women with HIV infection, using new multi-drug antiretroviral therapy; and (3) innovative methods for fostering conception and full-term births in older women. Along with the advances in technol-

ogy come many controversial ethical and social issues related to pregnancy outcomes, most of which have been highly debated in professional and lay literature and have received widespread media attention. This chapter discusses issues relevant to pregnancy in special populations.

PREGNANCY IN ADOLESCENCE

The period known as **adolescence** spans ages 11 to 19 and is defined as the biologic and psychologic transition from childhood to adulthood. Pregnancy in adolescence is not a new phenomenon but is of increasing concern because childbearing during the teenage years has profound socioeconomic and physical consequences for both the teen mother and her offspring. **Adolescent pregnancy**

(the state of pregnancy in young females ages 11 to 19) is a complex, multifaceted problem with no easy or obvious solutions. The burden of an unintended pregnancy is especially heavy for young teens who are still in high school and are trying to juggle their education, their own identity formation, and the physical and emotional changes occurring with pregnancy (Stevens-Simon, 1997).

Incidence and Significance

Approximately 1,000,000 teen pregnancies occur in the United States annually (Alan Guttmacher Institute, 1997). The majority (about 82%) of teen pregnancies are unplanned (Stevens-Simon, 1997) and most teens (about 79%) who had a baby in 1998 were unmarried (National Center for Health Statistics, 1999).

According to the 1999 data from the National Center for Health Statistics (NCHS), the worldwide rate of adolescent pregnancy is declining, although the adolescent pregnancy rate in the United States remains among the highest in the industrialized world. When compared to other developed countries, such as Canada, France, Sweden, and Great Britain, the United States has higher rates of adolescent pregnancies, births, and elective abortions, despite comparable levels of sexual activity among adolescents. Overall, teen pregnancy rates have declined in the past decade from a peak in 1992 to a low in 1996 (Ventura, Mosher, Curtain, Abma, & Henshaw, 1999) (Figure 19-1). In 1998, the number of births to teenage girls ages 15 to 19 increased slightly but was still less than the record highs in 1990 and 1991 (NCHS, 1999). Reasons for the decline in teen pregnancy rates include decreased sexual activity, increased condom use, and the use of injectable and implant contraceptives (Ventura et al., 1999). While these statistics may initially appear encouraging, the facts suggest that teen birth rates have remained relatively stable over

the past decade (Figure 19-2). Reasons for the stability in birth rates are the decrease in spontaneous abortions (miscarriages) and elective abortions among adolescents.

Because poor, unmarried teens are more likely to become parents than their more affluent peers, some believe that welfare in the form of Aid to Families with Dependent Children (AFDC) contributes to early and out-of-wedlock births. Others argue that poverty, the loosening of social mores, and the decline of the family structure are the driving forces behind adolescent pregnancy; the adolescent's poverty predates her pregnancy. Although unintended pregnancies among Caucasian, unmarried teens have increased, "the African American teenage mother has come to personify the social, economic, and sexual trends that in one way or another have affected almost everyone in America" (Luker, 1996, p. 83). Ethnicity appears to play a part in teen pregnancy. The pregnancy rates for non-Hispanic African American and Hispanic teenagers are about twice that of non-Hispanic Caucasian teens (Ventura et al., 1999).

The cost of adolescent pregnancy is staggering; the estimate is \$25.1 billion for 1992 and up to \$29 billion for 1996 (Maynard, 1996). Cost estimates in 1996 included AFDC, food stamps, Medicaid, loss of productivity, foster care, and the entire web of social problems that confront adolescent parents and lead to poor outcomes for their children. Estimates suggest that a cost savings of \$10 billion could be achieved if adolescents delayed giving birth until after the age of 20 and focused on completing their basic education and initiating employment (Burnhill, 1994). Approximately two-thirds of adolescent mothers are high school dropouts and obtain less work experience, receive lower wages, and earn less over a lifetime than young women who delay childbearing (Greene & Cromer, 1991). Others argue that because poverty is often an antecedent to pregnancy among adolescents, pregnancy only compounds a pre-existing condition in which

Figure 19-1 Pregnancy Rates Per Thousand Women Ages 15–19, 1986–1996. (Note: Data from Highlights of trends in pregnancies and pregnancy rates by outcome: Estimates for the United States, 1976–1996, by Ventura, S., Mosher, W., Curtain, S., Abma, J., & Henshaw, S. Figure 19-2 Birthrates Per Thousand Women Ages 15–19, 1986–1996. (Note: Data from Highlights of trends in pregnancies and pregnancy rates by outcome: Estimates for the United States, 1976–1996, by Ventura, S., Mosher, W., Curtain, S., Abma, J., & Henshaw, S. (1999) *National Vital Statistics Reports* 47, (29), 1–10.)

poverty is the established standard (Luker, 1996). In a synthesis of the literature on adolescent pregnancy over the past decade, investigators concluded that “adolescent childbearing is a means of adapting to urban poverty” (Stevens-Simon & Lowy, 1995, p. 912). Childbearing is viewed as a personal accomplishment and is recognized by others as a transition to adulthood. Many of the studies suggest that adolescent parents often drop out of high school before they become pregnant. Therefore, school attendance and achievement before pregnancy is the best predictor of academic success after pregnancy. The completion of high school is a basic educational achievement, but the lack of a high school diploma prevents young people from entering the military, obtaining a postsecondary degree, and participating in many of the vocational training programs that enhance employment opportunities.

Adolescent Abortion

The number of induced abortions among adolescents has declined for all age groups in the past two decades. However, induced abortions among older adolescent women (ages 18 to 19) remain significantly higher than for younger adolescents (under age 17) (Ventura et al., 1999). Adolescents who elect abortion differ from those who do not in that they are more likely to remain in or complete high school, have higher educational aspirations, and come from families of higher socioeconomic status. Impoverished teens from minority backgrounds who do not seek birth control are more vulnerable to unplanned pregnancies and most often keep their babies after delivery. Approximately 2% to 3% of adolescent mothers put their babies up for adoption (Stevens-Simon & McAnarney, 1992). Making the decision to relinquish a baby is a complex and multifaceted task that requires a degree of maturity lacking in many teen parents. Those mothers who are older and more educated are more likely to offer a child for adoption. More female babies are relinquished than males; some researchers believe that male infants are less likely to be given up for adoption because of the greater interest shown by the baby’s father (Bachrach, Stolley, & London, 1992).

With the legalization of abortion in the 1970s, the rate of abortion among pregnant adolescents initially increased and then leveled off in the mid-1980s. Racial differences in abortion rates explained higher pregnancy rates among African American adolescents; yet proportionately, abortion among ethnic or racial groups is comparable during the teen years (U.S. Bureau of the Census, 1993). However, these statistics may change as state and federal dollars decline for elective abortions among indigent women, and the controversy continues as to whether parents of minors should be informed when their adolescent children

under the age of 18 seek pregnancy termination. Proponents of parental notification or consent for adolescent abortion believe that this legislation would discourage sexual activity. Those opposed to such legislation believe that teens would be more inclined to (1) hide their pregnancy from adults and parents; (2) not obtain prenatal health care, thus increasing perinatal morbidity and mortality rates; (3) delay action beyond the gestational age limits of legal abortion; (4) seek illegal or self-induced abortions; or (5) try to deliver the fetus alone with no medical assistance. Recent cases of criminal charges against adolescents, who delivered and then hid or discarded newborns in trash cans, increase concerns about limiting abortion options for teens (Reuters News Service, 1997).

Adolescent Fathers

Although adolescent mothers have been studied extensively, there is little data on adolescent fathers. However, adolescent mothers are known to fare better in terms of maternal satisfaction when they have the emotional and financial support of their family and the baby’s father. In one study that examined the characteristics of adolescent fathers, the investigators found that those who were teen fathers or those older than 20 who fathered babies born to teen mothers, were severely educationally disadvantaged (Hardy & Duggan, 1988). More than 50% of fathers are over the age of 20, but they have disproportionately more problems with academics, behavior, and substance abuse than their childless peers (Stevens-Simon & McAnarney, 1992). The relationships between teen parenting (by either sex) and inadequate education and low-paying occupations appear well-established, regardless of whether adolescent pregnancy is the cause or the consequence of poverty.

Infant and Child Outcomes

Costs related to adolescent pregnancy can also be measured in terms of negative infant and child outcomes (Table 19-1). Infants born to adolescents are often premature (less than 37 weeks’ gestation) or low-birth-weight (less than 2500 grams), constituting the two most common and serious risks associated with adolescent pregnancy. Infants born to adolescents under the age of 16 are twice as likely to be of low weight at birth, which is largely the result of the adolescent mother’s smaller body and the lack of appropriate nutrition and prenatal care during pregnancy (Stevens-Simon & McAnarney, 1992).

In addition, untreated sexually transmitted diseases (STDs), smoking, and substance abuse are factors that contribute to preterm labor, prematurity, intrauterine growth retardation (IUGR), and low-birth-weight infants. Cigarette smoking among pregnant women of all ages has

been shown to have a significant relationship to delivery of low-birth-weight infants. It is estimated that 25% of low-birth-weight infants are born to teen mothers and that these infants are 50 times more likely to die than normal-weight infants (Tsang, 1993). Premature infants born to teen mothers are more likely to experience infant death and to suffer from serious respiratory complications, cerebral palsy, and chronic cognitive deficits.

In the postneonatal period, the mortality rate of infants born to adolescent mothers, age 17 and younger, is twice as high as that of infants born to more mature women. The lack of knowledge about child development, appropriate discipline, supervision, and adequate health care are thought to contribute to the increased incidence of illness, injury, and mortality among infants and young children of teenage parents (Stevens-Simon & McAnarney, 1991).

Adolescents under age 18 who become pregnant are more likely to engage in other risk-taking behaviors than young women who are not pregnant. Cigarette smoking has increased among teens in recent years; 64% of high school seniors report smoking and 41% report using marijuana (Bragg, 1997). The likelihood of smoking among pregnant teens is high. However, a recent study found that, although drug use is common among pregnant teens, with education, these young women substantially decreased drug use during pregnancy for the benefit of the fetus (Gilchrist, Hussey, Gillmore, Lohr, & Morrison, 1996). The investigators did note that a steady increase in substance abuse occurred during the first 6 months postpartum, suggesting that substance abuse among adolescent mothers is significant and potentially harmful to infants and young children. Maternal drug use may adversely affect parenting capabilities and the safety of the environment in which children are raised.

Table 19-1 Negative Infant/Child Outcomes Indirectly Related to Adolescent Pregnancy

Infant	Child
Prematurity	Neglect and abuse
Low-birth-weight	Chronic cognitive defects
Infant death	Developmental delays
Serious respiratory problems	Chronic behavioral problems
Blindness/deafness	School failure/withdrawal
Cerebral palsy	Chronic runaway
Mental retardation	Foster/alternative placement

Client Education

Teen Pregnancy and Smoking

You may wish to provide and discuss information with expectant teen mothers on the adverse effects of cigarette smoking during pregnancy, including the following points.

- There is a clear association between maternal smoking and perinatal loss.
- Smokers have three and one-half to four times more risk for small-for-gestational-age babies than nonsmokers.
- The average weight of infants born to smokers is 170 to 200 grams less than infants born to nonsmokers.
- Studies have shown increased premature rupture of membranes in smokers.
- Newborns of smokers are smaller at every gestational age.
- Infants who are born to women who have stopped smoking early in their pregnancy are of normal weight at birth.
- There may be an increase in sudden infant death syndrome (SIDS) among infants born to mothers who smoke.

Note: Data from *Smoking and women's health* by American College of Obstetricians and Gynecologists, 1997. *ACOG Educational Bulletin*, No. 240, copyright 1997 by American College of Obstetricians and Gynecologists.

Clearly, the psychosocial consequences for children born to adolescent mothers appear to be less than optimal. Children of adolescent mothers exhibit greater cognitive and behavioral problems and more frequently repeat school grades because of low academic achievement; it is estimated that only 77% earn a high school diploma by adulthood. Such children are also more frequently abused or neglected and are recipients of harsh discipline, which may contribute to chronic runaway behavior and the use of alternative living placements, such as shelters or group homes. Daughters of adolescent mothers are at a significantly higher risk of becoming adolescent parents themselves, and the sons of adolescent mothers are almost three times more likely to become incarcerated (Maynard, 1996). Because the typical profile of the adolescent mother is unmarried and poor, there is a strong association between the effects of poverty, single parenting, and negative child outcomes.

Adolescent Psychosocial Development

The physical and psychosocial consequences for adolescent mothers and their offspring are substantial. To understand the context of adolescent pregnancy, a knowledge of adolescent psychosocial development and acquisition of developmental tasks is necessary. **Developmental tasks** of adolescence include the competencies in psychosexual development related to identity formation, sexual and vocational identity, and independence. Adolescence overlaps with the younger, school-age child in the developmental tasks of early adolescence at one end of the age continuum and with the young adult in the developmental tasks of young adulthood at the other end. Although the adolescent years have been described as a period of turmoil, many adolescents experience a smooth transition into adulthood. In the search for their personal identity, adolescents try on many new roles, until they discover a role that fits and an identity is formed. Having completed identity formation, the adolescent is emancipated from the family and becomes independent. According to Erikson (1968), the major developmental tasks of adolescence are the development of identity and the establishment of autonomy, or the ability to be self-governing. The adolescent achieves autonomy by the use of abstract reasoning, which allows analytical thinking, problem solving, and planning for the future. Other developmental tasks include the formation of a sexual and vocational identity (see Box 19-1).

Cognitive development, or the age-related development of intellectual reasoning and perception, influences every aspect of adolescent psychosocial development. According to Piaget (1969), cognition moves from concrete to abstract thinking during the three phases of adolescent development (i.e., early, middle, and late adolescence). Concrete thinking focuses on the present, with little thought to later consequences; abstract thinking in early adolescence encompasses inductive and deductive reasoning and the ability to connect separate events and to understand later consequences; and abstract thinking, in late adolescence, is increasingly logical and complex. Some older adolescents remain concrete thinkers because of low intellect, lack of education, or chronic substance abuse.

Box 19-1 Adolescent Developmental Tasks

- Formation of identity/self-perception
- Acquisition of education/vocation
- Emancipation from family/independence
- Formation of sexual identity
- Development of social network of peers

Critical Thinking

Counseling and Cognition

You need to consider the adolescent's cognitive capacity when doing any counseling or education. Counseling a group of teens about birth control may be ineffective if the consequences of their behavior are tied to the future, when their thinking focuses only on the present. What other aspects of adolescent's behavior would you need to consider in relation to cognitive capacity?

The acquisition of cognitive abilities and the resolution of developmental tasks occur over time. While age parameters are suggested for the completion of developmental tasks, they are somewhat variable and adolescents may move back and forth on the developmental continuum, depending on their personal circumstances. For example, it is not unusual for teens to regress in their level of independence during the uncertainty of pregnancy, labor, and delivery and to become more reliant on their parents, usually mothers, in this period.

The adolescent is described as being egocentric or self-absorbed. Frustrated parents often describe teenagers as self-centered, lazy, or irresponsible because they spend their time and energy concentrating on themselves. The

Nursing Tip

NEGOTIATING WITH TEENS

Whenever possible, you should negotiate choices with teens and always consider how teens are judged by their peers. Knowledge of specific peer group norms is essential and limits should appear reasonable and acceptable to teens. For example, when educating pregnant teens about the importance of prenatal nutrition, you should be sensitive to food preferences and develop a diet plan that is realistic for teens to follow. Adequate intake of calcium can be obtained by a variety of products, such as yogurt, ice cream, and cheese. Diet planning also should include meals consumed outside the home, such as those at school and teen social events.

Figure 19-3 Interaction with peers is a key factor in adolescent development.

transition from childhood to adulthood is a phase of experimentation during which teens are not yet ready to make a commitment or make ones that are only tentative. The lack of commitment is illustrated by the adolescent's frequent change of interests; this has implications for the young adolescent mother. The reality of raising an infant may conflict with the adolescent's interest in trying on new roles; the role of parent is not so easily abandoned.

The peer group plays an essential role in adolescent identity formation (Figure 19-3). The peer group provides support as adolescents emotionally move away from the family and struggle with their own identity. Teenagers take their cues for appearance, social behavior, and language from the peer group; the peer group validates acceptable

behavior. In a peer group where early sexual activity, pregnancy, and parenting are the norm, it is difficult for the adolescent to break away from the accepted cycle of behavior. Changes in the adolescent's body image, psychosocial development, and peer group acceptance are closely related.

There is a wide developmental age span between early and late adolescence (ages 11 to 21). Each age group has unique reactions to the developmental tasks, which are influenced by the adolescent's cognitive thinking and are tied to the adolescent's sexuality (Table 19-2).

Early Adolescence

Early adolescents (ages 11 to 14) have intense feelings about body image and concerns about whether the changes taking place are normal. Young teens have many questions about normal body functions such as menstruation, spontaneous nocturnal ejaculation, and masturbation. The nurse is in a pivotal role to answer the teen's questions about physical changes and to use correct terminology in discussing sexual functions. Sexual fantasies involving celebrities (like rock and movie stars) and crushes on both sexes are not uncommon. Young teens are less confident with members of the opposite sex and tend to have best friends and form groups of the same sex (Figure 19-4). Sexual experimentation among early adolescents is increasing as the age of sexual maturation declines, but experimentation has not yet reached the intensity of middle adolescence (Stevens-Simon, 1998). Incest and sexual abuse

Figure 19-4 In the early years of adolescence, teens often prefer the company of friends of the same gender.

Nursing Tip

ASSESSMENT AND SEXUAL ABUSE

You should always consider aspects of sexual abuse in any health care encounter as young teens begin to reach physical and sexual maturation. Questions relative to the adolescent's sexuality should be included in the health history. For example, you may begin a discussion of the teen's sexuality by stating: "Many young people your age begin to think about sexual behavior, tell me what you think." Consider what your responsibilities are in asking teens about sexually sensitive information.

Table 19-2 Stages of Cognition and Aspects of Adolescent Sexuality and Pregnancy

	Early Adolescence (ages 11–14) Concrete Thinking	Middle Adolescence (ages 15–17) Early Abstract Thought	Late Adolescence (ages 18–21) Abstract Reasoning
Cognitive Thinking	Limited abstract thought Appreciates the here and now Little sense of later consequences	Use of inductive/deductive reasoning Ability to understand later consequences of actions Ability to connect separate events and to project into the future Introspective/narcissistic	Ability to abstract and conceptualize Ability to analyze and plan for the future Consider another's needs above their own Concern for society as a whole
Issues in Sexuality	Changing body image Sexual fantasy Sexual vocabulary Sexual abuse/incest Masturbation Menstruation Nocturnal emissions Limited sexual experimentation Same sex peers	Sexual experimentation Peer pressure for sex activity Self-esteem issues and sexuality Over-the-counter contraception Sexual abuse/incest Homosexuality/safe sex practices Sexually transmitted diseases Responsible decision-making related to sexual issues Adequate/effective contraception Sexual preference may still be in flux Short-term commitments to partners Peer acceptance at peak	Responsible sexual decision making Correct use of contraceptive Sexual preference set Greater intimacy/long-term commitments Pregnancy/parenting Some continuation of sexual experimentation More realistic expectation of partner's role Peers of less influence
Issues in Pregnancy	Failure to recognize signs of pregnancy Denial of pregnancy if recognized Fear of telling partner/parents/other adults about pregnancy Delay in seeking pregnancy diagnosis Delay in seeking prenatal care Disturbed about body changes Family upset about pregnancy Ambivalence about pregnancy Other coexisting risk-taking behaviors (drugs; etc.) Conflict in maternal role Lacks problem-solving abilities re: pregnancy Fears related to labor and delivery Lack of ability to plan for the future Partner often not involved	Same Same Same Seeks pregnancy diagnosis from over-the-counter-test kits May seek professional diagnosis of pregnancy Ambivalent about body changes Same Same or desires pregnancy May be the same Same Some problem-solving skills present re: pregnancy Able to learn about labor and delivery but still may fear experience May be able to plan for pregnancy and consider future consequences Partner sometimes involved	Recognizes signs of pregnancy Confirms pregnancy Tells partner and/or parents about pregnancy Seeks professional diagnosis of pregnancy Seeks prenatal care early Accepts body changes Family ambivalent or accepts pregnancy Realistic decisions about pregnancy Less risk-taking evident although risk-taking may still occur Accepts maternal role if pregnancy is desired Able to solve problem re: pregnancy Realistic about labor and delivery Able to plan for future Considers options to pregnancy Partner may be involved, especially for older adolescent/young adult

may occur in both sexes as the adolescent approaches sexual maturity and bodily changes become evident.

The early adolescent is very egocentric and preoccupied with appearances. A great deal of time is spent looking in the mirror and selecting clothing that is desired and sanctioned by the peer group. Self-conscious behavior is thought to be the result of the physical and emotional transition to middle adolescence. The early adolescent is losing the familiar role of the child but does not yet feel comfortable with the role of the adult. Concrete thinking limits the young adolescent to the here and now, and ambivalence towards the future is not uncommon. When early adolescents become pregnant and give birth, they may be ambivalent about caring for the baby and may see child care responsibilities as their parent's concern rather than their own. Caring for the baby and planning for even basic needs, such as child and medical care, may prove challenging for the young adolescent mother who is most preoccupied with herself.

Middle Adolescence

Middle adolescence (ages 15 to 17) is described by parents as the most frustrating period of adolescent development because teens become even more introspective and narcissistic. Conformity to peer group norms becomes even more important, and conflicts between teenagers and parents often escalate (Figure 19-5). The testing of limits and outright rebellion may occur in relation to just about anything; activities related to sex, drugs, alcohol, and violence may have negative outcomes that can last a lifetime. Parental expectations become clear when discipline and structure are consistent. Parental involvement actually makes adolescents feel more secure; decision making can be shared between parent and teen. However, parents must be aware that middle-stage adolescents are impul-

Figure 19-5 Making adjustments in family power configurations is necessary to provide opportunities for teenagers to develop their own identities.

sive, impatient, and egocentric. Because of their egocentrism, adolescents see themselves as invulnerable; negative consequences (such as HIV infection) “can’t happen to me.” Concern by parents may be viewed by teens as interference and may be met with resistance and resentment.

Feelings about self-image and social relationships with the opposite sex are intense. Dating in couples occurs and sexual experimentation becomes common. Sexual activity, peer pressure, and self-esteem issues are frequently linked, and adolescents with the poorest self-esteem are most vulnerable to engaging in risky behaviors. Relationships are generally short-term and sexual activity is often unplanned, with little regard to later consequences. Over-the-counter contraception may be used: condoms have become more popular because the public has become more educated about HIV and AIDS. Long-term methods of contraception have proven less effective among teens, because relationships are short-term and contraceptive practices are inconsistent (Stevens-Simon, 1998).

Nurses may help by providing accurate information to assist adolescents in making appropriate choices related to sexuality and by encouraging parents to maintain open communication and guide teenagers in sexual decision making (Figure 19-6). Parental guidance regarding sexual behavior is not an easy task during middle adolescence, when privacy is of extreme importance and communication tends to decrease with parents and increase with peers. Guided peer-group discussion has been shown to

Figure 19-6 Wellness promotion for the adolescent may include in-school seminars by school nurses, such as this one on AIDS prevention.

be beneficial in providing information on sexually related issues and allowing teens to express their feelings about their own sexuality. As adolescents move from concrete to abstract reasoning, the consequences of their sexual decisions become more real to them.

Late Adolescence

Late adolescence (age 18 to 19) is characterized by abstract thinking, verbal conceptualization, and anticipation of the consequences of actions. Teens in late adolescence tend to be idealistic about love, social issues, ethics, and lifestyles, until their experiences modify their beliefs. Conformity becomes less important as teens become more confident of their personal identity. Parent-teen relationships may become more respectful, unless values clash, and relationships with both family and friends become important. Intimate relationships become more mutual, and expectations of partners become more realistic. Although some degree of sexual experimentation may continue, older adolescents typically have a greater capacity for long-term commitment.

Emancipation is a major issue. Teens in late adolescence prepare themselves to meet this challenge by education or vocational training. Older adolescents and young adults are generally better suited to parenthood by virtue of their greater education, greater earning power, and more sustained relationships than younger teens. However, emancipation may become difficult if the adolescent is single, unmarried, and impoverished. Dependence on welfare payments and the existing family is often the end result, and the developmental tasks of adolescence may never be fully achieved.

Issues Related to Adolescent Sexuality, Pregnancy, and Parenting

Adolescence is a period of transition: Pregnancy at any stage of adolescent development, but particularly in early and middle adolescence, poses an additional transition that makes identity formation more difficult. Sadler and Catrone (1983) describe adolescent pregnancy as a “dual developmental crisis” and describe major areas of potential conflict (Table 19-3).

The change in body image is particularly distressing to young adolescents who may find labor, delivery, and lactation not only frightening but unpleasant and undesirable. The father-to-be may also find his partner’s body changes unattractive, throwing the young expectant mother into despair over her rapidly changing appearance. Because relationships are relatively short during early and middle adolescence, partners may terminate the relationship before the baby’s birth (Figure 19-7). Approximately two-thirds of teen relationships in which pregnancy occurs end

Table 19-3 Dual Developmental Tasks of Adolescent Mothers	
Adolescence Versus Parenthood	
<ul style="list-style-type: none"> • Narcissistic and egocentrist/introspective, self-absorbed; focus on own needs • Ambivalent attachment to child • Identity formation through role experimentation; no firm commitment to a specific role • Sexual identity formation/body image development • Emancipation from family • Cognitive development: transition from concrete to abstract thinking 	<ul style="list-style-type: none"> • Empathy with the child; place child's needs before own • Mutuality between mother and child; mother's needs met through parenting • Maternal role identification and definition • Body image changes of pregnancy, delivery, and postpartum • Family role reassignments: from child to mother • Problem solving and decision making skills necessary for raising child

Figure 19-7 Teen pregnancy: now you see him, now you don't.

before delivery. A recent study showed that fathers who attend prenatal care sessions, visit the infant in the hospital after birth, and have an established relationship with the young mother's family are more likely to still be involved when their children are 24 months old (Cox & Bithoney, 1995). Programs that acknowledge and promote a more active participation by young fathers are needed to encourage the formulation of paternal roles and responsibilities.

Adolescents who give birth may actually have little understanding of their own body functions or their own sexuality. Nurses are in an excellent position, in both the prenatal and postpartum periods, to explore these areas with teen mothers. Pregnancy and subsequent parenthood limit the teen's time, mobility, and ability to experiment with new roles because the responsibilities of child care must be assumed. Conflicts may arise regarding whose needs are being met as the adolescent mother attempts to differentiate her needs from her infant's needs during the normal adolescent transition period. Emancipation issues may become an area of conflict for the teen mother and her family. Developmentally, the teen mother needs to move away from the family and become autonomous, but realistically, she may be dependent on the family for financial and child care assistance.

Who's in charge and how the infant is raised is a likely area for disagreement. It is not uncommon to see the young adolescent mother step aside as her own mother takes over decisions related to the child's health and welfare. Finally, all aspects of parenting are influenced by the mother's cognitive development. Adolescent parents who lack the cognitive skills to understand their child's behavior and development may have unrealistically high expectations for their infants and young children and may be harsh disciplinarians who use physical punishment frequently. A young mother who does not realize that a toddler has a limited memory may become easily frustrated and angry when the child fails to follow her commands. The mother's ability to understand the principles of child development and to project and plan for the future has a definitive effect on the child's well-being (see Table 19-2).

Adolescent Sexual Activity

The scenario in the "Reflections" box is not uncommon among teen mothers, and yet, after over 30 years of effective and available birth control measures, adults often ask, why. The path to teen pregnancy is influenced by many factors. Experimentation with sexual relationships, the need to love and be loved, peer pressure, promotion of self-esteem, partner pressure, and the need to feel grown up are reasons cited by teens as motivation for early sexual activity (Moore, 1996). Furthermore, teens state that loneliness, lack of understanding child care responsibilities, poor self-respect, lack of knowledge about their bod-

REFLECTIONS FROM A TEEN MOTHER

"I never expected to get pregnant," says 15-year-old Alyce, "It just sort of happened. Now I'm struggling with school, and I have to get up a lot earlier just so I can get the baby ready, take him to day-care, and make it to class. It's getting harder to stay in school as he gets older; he wants my attention all the time. I wish my mother would just take care of him so I could get on with my life."

ies and birth control, drinking and drug use, and a general dissatisfaction with their lives contribute to an early, unplanned pregnancy (Chassler, 1997).

On a national level, the use of drugs and alcohol among adolescents has risen steadily, the family structure and social mores that discouraged unwed motherhood have diminished, and religious affiliations have declined. Responsible sexual behavior and the consequences of sexual risk-taking are not taught consistently. Some adolescents view having a child as their only real accomplishment, when even a high school diploma doesn't guarantee a job. One young man, who had fathered several children by different women, described his children as "something I can leave to the world, sort of like art work." The fact that he was unemployed and did not support any of his children appeared to be of little concern to him.

The age at which adolescents initiate sexual activity has declined as the age of **sexual maturation** (the establishment of menstruation and ovulation in females and the development of spermatogenesis in males) has declined. Unfortunately, emotional maturity develops later than physical maturity, and many adolescents who engage in sexual relations to meet their biologic needs do not think of future consequences. Young people are confronted with sexual feelings and opportunities for sexual activity for which they may be cognitively and emotionally unprepared. This lack of preparation undoubtedly predisposes American teenagers to the negative consequences of sexual experimentation, among which are unintended pregnancy and STDs. Approximately 50% of all adolescent pregnancies occur within the first 6 months of initiating sexual intercourse, but only about 40% of teens seek contraceptive services within the first year of initiating sexual activity; two-thirds do not use birth control routinely (The Contraception Report, 1995). Contraceptive practices are

often influenced by the adolescent's limited cognitive ability or lack of ability to think abstractly.

Taking an accurate sexual history from adolescents during routine health care visits is an opportunity to discuss the adolescent's sexuality and to assist her or him in selecting a method of contraception or help prepare for the initiation of sexual intercourse (Figure 19-8). Adolescents respond best to direct, open questions that are stated clearly and in terms they understand. It is necessary to be sincere and to demonstrate empathy, support, and understanding when questioning the adolescent about such sensitive issues (Box 19-2).

The average age of first-time sexual experience in girls is age 17 and in boys, age 15 to 16 (Centers for Disease Control and Prevention [CDC], 1994b). Approximately 24% of American youth report first intercourse before age 15 (Haffner, 1995). Variation in the age of first-time sexual intercourse is often culturally driven. African American adolescents are shown to engage in sexual intercourse earlier than Caucasian and Hispanic adolescents, African American males are the youngest to initiate sexual activity (CDC, 1996). According to the 1995 Youth Risk Behavior Surveillance System (YRBSS), which surveyed over 10,000 high school students nationally in grades 9 through 12,

Figure 19-8 A straightforward, friendly approach when taking a health history from a teen facilitates a discussion about sexuality and birth control.

African American males were significantly more likely to initiate sexual intercourse before age 13, have sexual intercourse with multiple partners, use alcohol or drugs at the time of sexual intercourse, and to impregnate a partner. On a more positive note, African American males were

Box 19-2 Taking the Adolescent Sexual History

- Many young people your age begin to have sexual thoughts and feeling. Tell me about yours.
- What age did you start menstruation/ejaculation? Tell me how you are feeling about this development.
- You do have a choice about whether or not you want to have sex. Do you feel that you have a choice? Tell me something about what choices you have made.
- Are you having sex now? *(If yes)* With females/males/both? Oral or anal sex? With the same partner or different partners? At what age did you have your first sexual experience? Is having sex pleasurable for you? Tell me about the last time you had sex. Are you or your partner using anything to prevent pregnancy or sexually transmitted diseases STDs? What methods do you use?
- Have you ever been pregnant? Tell me about it.
- Have you ever had a sexually transmitted disease? How was this treated? Was your partner(s) treated also? What do you understand about this disease?
- What would you do if you (or your partner) became pregnant?
- Would you like to know about methods to prevent pregnancy?
- Tell me what you know about HIV/AIDS. Do you know what it means to have "safe sex"? Have you ever used (or practiced using) a condom? What would you like to know about condoms?
(If no to sex now) Have you had sex in the past? Tell me how you felt about it.
- Are your friends having sex? having babies?
- Before having sex, would you talk to your parent(s) about making that decision? Perhaps to a friend or another adult? How do you feel about using condoms? Have you considered what method of birth control you would use? How do you feel about becoming pregnant now?
- Have you ever been sexually assaulted? Sexually abused? Touched in a private way that you did not want? *(If yes)* Tell me about what happened to you. How did you feel about this? Who supported you after this happened? Did you have any counseling? *(If yes)* Describe how you felt about the counseling. *(If no)* Would you consider counseling now?

CONFIDENTIALITY AND REFERRAL

You should know the laws of confidentiality in your state for providing care to adolescents and have resources available for all adolescents, including minors, who are pregnant or are engaging in high-risk sexual behaviors.

significantly more likely to have used a condom at last intercourse and to have discussed HIV infection and AIDS with a parent or another adult.

Adolescent Attitudes Toward Contraception

While it is commonly believed that adolescents do not use contraception because sexual relations are impulsive and unplanned, there are other factors that also contribute to lack of contraceptive use. Many unplanned and untimely pregnancies are suspected to really be planned and wanted. For some teens, a pregnancy, which was neither planned or unplanned, is an occurrence that validates their level of maturity through fertility. In some cultural groups, the state of pregnancy confers adult status. In a recent study, investigators examined the reasons for lack of contraceptive use among indigent adolescent women, ages 13 to 18 (Stevens-Simon, Kelly, Singer, & Cox, 1996). The findings of this study suggest that indigent adolescent females have positive or ambivalent feelings about becoming pregnant that interfere with consistent, effective contraceptive use. Young people may view parenting as a means to escape a current living situation, maintain a tenuous relationship, or please an older sexual partner. Still other reasons for lack of contraceptive use include: lack of knowledge about and access to birth control, defiance of parental authority, fear of being discovered as sexually active by parents, denial of participating in sexual activity that requires birth control, fear of contraceptives or a pelvic examination, contraceptive failure, and feelings of invulnerability, i.e., “it can’t happen to me” (Stevens-Simon, 1997). Clearly nurses, especially those in schools or adolescent specialty clinics, are in a key position to educate young people about risk-taking behaviors related to sexual activity.

Adolescent Contraceptive Methods

“Just say no,” or abstinence-only, programs aimed at sexually mature teens have proven to be unrealistic and largely ineffective in significantly delaying the initiation or slow-

ing the frequency of sexual activity (Stout & Kirby, 1993). Abstinence-focused pregnancy prevention programs given in combination with reproductive and contraceptive information are more effective in reducing early sexual involvement but their efficacy in preventing adolescent pregnancy is questionable. Programs that stress knowledge content, values clarification, decision-making, and communication skills between partners and parents are thought to improve decision-making skills of teens with regard to sexual behavior. However, a review of these intervention programs demonstrated little effect on sexual or contraceptive behavior past the immediate period after the programs (Stout & Kirby, 1993).

Because of the high rate of pregnancy and STDs among all adolescents, nurses and other health care providers should not shy away from suggesting abstinence as a means of contraception. Teens need to consider abstinence as an option and to know that they have a choice about becoming sexually active. Abstinence not only prevents pregnancy but offers the greatest protection against STDs. Some adolescents, in the face of peer pressure, may need continued support to maintain abstinence. Whatever contraceptive method is chosen, the most effective contraceptives for teens are those that are acceptable to teens and match their needs; obviously, contraceptives that are not used will not be effective. Chapter 14 discusses contraceptives in greater detail.

Choosing an appropriate contraceptive is a decision that should ideally be made by couples. Nurses working with adolescents should emphasize that contraception is a shared responsibility (Figure 19-9). Studies suggest that teens agree that contraception should be a shared responsibility (Sheehan, Ostwald, and Rothenberger, 1988), but clinical evidence suggests that often nobody takes responsibility. A contraceptive method that is not acceptable to both partners is likely to be unused. Factors that should be

Figure 19-9 Learning about contraceptive choices as a couple helps teens learn that birth control is a shared responsibility.

considered in selecting contraceptive methods are described in Table 19-4.

Adolescents use withdrawal, condoms, and oral contraceptive pills (OCs) as the most frequent methods of contraception (Stevens-Simon, 1997). Most adolescents rarely maintain consistent compliance, and failure rates are much higher than those described for adults. Cost and easy accessibility are two of the most important factors in selecting contraceptive methods. For these reasons, condoms and withdrawal are methods likely to be selected first by sexually active teens. Methods such as diaphragms or injections, which are expensive or require contact with health care services, are less likely to be used. School-based clinics and free or sliding scale primary care clinics marketed for teens increase the availability of all methods of contraception.

The withdrawal method of contraception is the removal of the penis from the vagina before ejaculation. Withdrawal is relatively ineffective (18% failure rate) and requires a great deal of control. Seminal fluid is often deposited into the vagina before ejaculation, and pregnancy can and does occur. However, withdrawal does not cost money and may be the only option when sexual intercourse is spontaneous and unplanned.

Condoms are becoming more popular as awareness of AIDS has increased among adolescents. According to the 1995 YRBSS study, 54% of high school males and 48.6% of high school females reported condom use at last intercourse (CDC, 1996). Condoms are available at a relatively low cost but are only moderately effective (9% to

12% failure, rate if used consistently and properly). Condoms made out of latex provide the best protection from pregnancy and disease. Latex helps prevent the passage of HIV, herpes virus, and hepatitis virus, although no condom is 100% effective. Adolescents should be encouraged to read labels and select condoms that are made in the United States. The U.S. Food and Drug Administration (FDA) has strict requirements regarding permeability, strength, and shelf life (expiration date). Lubricated condoms that contain the spermicide nonoxynol-9 are the most effective against disease and pregnancy. In addition to killing sperm, nonoxynol-9 is known to be somewhat effective as an antibacterial and antiviral agent.

Adolescent couples need explicit instruction on condom use and should be able to demonstrate how to safely put on and remove a condom (Figure 19-10). Teens should be encouraged to use condoms along with spermicides containing nonoxynol-9, such as contraceptive foam, cream, or suppositories, for greater protection. When used consistently and correctly, the efficacy of condoms plus spermicides approaches that of oral contraceptives. Of the spermicides on the market, contraceptive foam is most preferred by adolescents because it provides additional lubrication, yet leaves little residue after intercourse. Spermicidal jelly, KY Jelly, or other water-based products can be used for additional lubrication. A lack of sufficient lubrication in adolescent females can account for condoms slipping when being used by teen couples. Products containing oil, such as petroleum jelly or baby lotion, can cause latex to deteriorate and make condoms ineffective. Misuse

Table 19-4 Factors to Consider in the Selection of Adolescent Contraception

- | | |
|---|---|
| • Cognitive development (concrete vs abstract thinking) | • Problem solving abilities (appeal to logic and feelings of power over body) |
| • Clarification of attitudes and values | • Communication with parents or other adults |
| • Sexual maturity rating (SMR) | • Physical/mental health |
| • Communication with partner | • Motivation of both partners |
| • Use of more than one Method | • Concrete, graphic instruction on all methods |
| • Frequency of intercourse | • Number and gender of partners |
| • Appropriate Information (3 messages per visit) | • Encouragement that abstinence is OK |
| • Knowledge of back-up methods | • Availability of resources |

Figure 19-10 The condom should be unrolled on an erect penis, all the way to the base, having about a half-inch of space at the end for a semen reservoir.

Nursing Alert

LATEX ALLERGY

Warn teens of the possibility of latex allergy. Symptoms range from eczematous contact dermatitis to anaphylactic shock.

of condoms accounts for the higher failure rate of condoms among teens. Other barrier methods, such as diaphragms, are relatively unpopular or ineffective. Adolescent females must be comfortable with their bodies and highly motivated to use the cervical cap or diaphragm (Figure 19-11), and the use of spermicidal alone has a high failure rate (21%) (Hatcher et al., 1998).

The most effective method of birth control for adolescent females is OCPs, if used correctly. According to Hatcher et al. (1998) combination OCPs (those containing estrogen and progestin) have a failure rate of 0.1%. The actual failure rate for teens using OCPs for the first time is 5%. Teens are doubly vulnerable to birth control failures in that they have intercourse frequently and are often less experienced and less motivated to use a method consistently. OCPs are stopped when relationships end and not necessarily restarted appropriately with a new sexual partner. Combined OCPs work by suppressing ovulation, increasing the thickness of the cervical mucosa (preventing penetration by sperm), and decreasing the thickness of the uterine lining (preventing implantation of the egg). Side effects of combined OCPs include weight gain, breast tenderness, headaches, and breakthrough bleeding. Teens experienc-

ing OCP side effects should not discontinue pills but contact their health care provider. Side effects are generally from the amount of estrogen and progestin contained in the pill. With numerous OCPs on the market, changing pills can usually minimize undesirable side effects. In addition to preventing pregnancy, OCPs are known to confer protection against ovarian and endometrial cancers, pelvic inflammatory disease, ectopic pregnancy, and toxic shock syndrome (Stevens-Simon, 1997).

Relatively new to the U.S. market are injectable medroxyprogesterone, Depo-Provera, and a subdermal progestin, Norplant. Neither of these methods of birth control contains estrogen, which makes them particularly suitable for women with cardiovascular conditions or who are lactating. The progestin-only methods work in a similar manner to combined OCPs but have the added advantage of long-acting contraception not tied to sexual activity. Depo-Provera is an injection that is received every 3 months and is effective for approximately 16 weeks. Norplant, a set of capsules containing progestin that is placed under the skin in the hip or upper arm, is visible if inserted correctly. The visibility of the Norplant may be an issue with teens who desire the utmost privacy about their sexual activity. The set of capsules releases a continuous dose of progestin for 5 years.

The injectable and implantable devices are highly effective methods of birth control, but can cause side effects that include amenorrhea, irregular periods, heavy bleeding, and weight gain. Headaches, hair loss, and depression are less common side effects but warrant consideration. The long-term methods of birth control are appealing to young women who do not plan pregnancy any time in the near future. However, problems with the frequency of progestin-related side effects and the visibility and necessity for removal of the capsules in the Norplant system have made use of long-acting progestin methods of contraception controversial (Mashburn, 1994).

In 1997, the FDA gave approval for the use of certain oral contraceptives to be used as a postcoital, or “morning-after,” method of birth control. Although these have been used for years in the U.S. and other countries, drug companies were not allowed to advertise combined pills as a postcoital method of contraception because such use had not yet been approved by the FDA. The use of the OCPs as a postcoital method of contraception is commonly recommended after rape, and the method has also become popular among college students. Controversy has surrounded the use of morning-after pills as an abortifacient; the method of action prevents fertilization of an egg or stops a fertilized egg from implanting in the uterus.

Two combined oral contraceptive pills containing 200 µg of ethinyl estradiol and 2 mg of levonorgestrel are taken within 72 hours of intercourse (preferably within 12 to 24 hours); then two more pills are taken 12 hours later.

Figure 19-11 Demonstration with an anatomical model helps this teen understand correct diaphragm use.

CONTRACEPTIVE METHODS

Whatever method of contraception is used by teens, it should *a/ways* be accompanied by condom use to decrease the likelihood of transmission of STDs.

The morning-after method is known to be effective, with few side effects other than nausea and cramping. The pills are most often given with an antiemetic to minimize nausea and vomiting. Bleeding generally occurs between 14 to 21 days after taking the pills and lowers the risk of pregnancy to less than 8%. It is essential to determine if the teenager is already pregnant; if pregnancy is confirmed, the morning-after pills should not be given. If used correctly, postcoital contraception is highly effective in preventing an unwanted pregnancy but should not serve as a substitute for a consistent, effective method of birth control.

Adolescents should be encouraged to discuss their sexuality, sexual behavior, contraception, and pregnancy with their parents or another trusted adult whenever possible, but nurses must guarantee the confidentiality of such communication. The nurse's professional role is to assist adolescents in making knowledgeable and responsible decisions regarding their sexual behavior (Figure 19-12). Primary prevention must emphasize assisting adolescents to develop coping strategies to meet their needs in ways other than through sexual behavior. Life skills training programs, organized sports, and church activities can help point the adolescent's time and energy in a positive direction. On a national level, social welfare policies should promote educational and vocational experiences that are meaningful and accessible to adolescents as a means of encouraging future planning and discouraging early parenting.

Adolescents can be educated to consider the negative outcomes of risky sexual behavior and weigh the consequences of their actions. In a school-based or primary care clinic, the nurse's role may be one of "gatekeeper" or case manager in facilitating access to intervention programs and

Figure 19-12 Adolescents may wish to look up information on sexual behaviors as they make decisions about their own sexuality. Nurses can also counsel teens and offer information and devices designed specifically for the adolescent population.

Critical Thinking

The Nurse and Sexuality

Nurses who are open, honest, and comfortable with their own sexuality are the most likely to gain the adolescent's trust and confidence, and to interact with adolescents in a confidential atmosphere. How comfortable are you with your own sexuality and discussing sexual issues with teens? How do you feel about maintaining confidentiality with information that you think an involved parent might want to know?

other community resources. Dealing with the unwanted consequences of adolescent pregnancy can be complicated and collaboration with other health care providers is essential in meeting the needs of sexually active youth.

Repeat Adolescent Pregnancy

Without effective contraception and intensive postpartum support and follow-up to maintain contraception, repeat adolescent pregnancy is common. The repeat pregnancy rate is estimated to be 30% in the first year after delivery and 25% to 50% during the second postpartum year. Young women at highest risk for a second pregnancy are those who (1) are under 16 years of age at conception of the first pregnancy, (2) have a boyfriend older than age 20, (3) are high school drop-outs, (4) are below appropriate grade level for age, (5) are dependent on welfare compensation after the first birth, (6) had complications with the first pregnancy (such as prematurity), and (7) had no established method of birth control after hospital discharge (Stevens-Simon & McAnarney, 1992). Multigravidity, which has its roots in adolescence, is consistently linked to educational disadvantage and poverty. The risk of a preterm delivery increases with each successive adolescent pregnancy and positive neonatal outcomes decline.

Nursing Implications

Early diagnosis of an adolescent pregnancy is important for counseling purposes and for early entry into prenatal care. Many adolescents delay diagnosis and have no prenatal care in the first trimester of pregnancy. Early and consistent prenatal care is known to decrease the negative outcomes to the fetus, especially those born to women under the age of 16 (Stevens-Simon & White, 1991). Pregnant adolescents may initially present for confirmation

or diagnosis of pregnancy with a variety of complaints. Some present with typical signs and symptoms of pregnancy, others present with vague complaints that may or may not be helpful in establishing a diagnosis of pregnancy. Teens who are in denial may be vague with respect to their last menses and complain of fatigue, headache, or abdominal pain. Because adolescents often do not know when they became pregnant, pelvic ultrasound is helpful in estimating gestational age. Approximately one-third of adolescents have vaginal bleeding during the first trimester and may mistake this for regular menses, denying the possibility of a pregnancy. The adolescent's sense of invulnerability may be in full operation and denial is common. "I thought I was too young to get pregnant" and "I had sex a lot and I didn't get pregnant so I thought I couldn't" are frequent comments when pregnancy is confirmed.

The use of a good sexual history is essential in obtaining information that leads to the confirmation of pregnancy. Once the pregnancy is confirmed, the adolescent should be counseled regarding her options and appropriate referrals should be made. Pregnant adolescents may have difficulty in solving problems and making decisions related to the pregnancy. Because adolescents need a great deal of support they should be strongly encouraged to share their pregnancy with their parents or another adult who can help them solve problems. Young women should also be encouraged to share confirmation of their pregnancy with the father of the baby. Teens who have short-lived relationships are often reluctant to share pregnancy information with the father of their child. Roles for the adolescent father can include taking responsibility for the pregnancy, participating in the decision-making process related to the pregnancy, and offering financial and emotional support if possible (Figure 19-13).

Figure 19-13 Expectant fathers who participate in prenatal visits gain a better understanding of pregnancy and the imminent responsibilities of parenthood.

Prenatal Care, Labor and Delivery, and Postpartum Care

If the adolescent decides to continue the pregnancy, she should be referred to a comprehensive adolescent maternity program. Such programs are best at providing age-appropriate care and for offering prenatal education that is developmentally appropriate. Young teens who are concrete thinkers are best taught by simple, graphic instruction and demonstration. Videotapes, role modeling, interacting with other teen mothers, parenting exercises, and a hands-on approach to prenatal care are methods of instruction that are more effective than just providing verbal and written materials to pregnant teens. Being in a similar peer group assists the pregnant adolescent in adjusting to the pregnancy and becoming engaged in the activities necessary for a successful outcome. School-based clinics and programs, such as Communities in Schools (CIS), that provide prenatal education for pregnant couples are effective in preparing young teens for pregnancy, labor, delivery, and parenting. Prenatal education should include anatomy and physiology of the mother's body, the developing fetus, and the physiologic aspects of labor and delivery. Young women are particularly interested in seeing pictures of the developing fetus and graphic illustration (such as videotapes) of labor and delivery. Graphic illustrations provide the adolescent with a visual experience and help to decrease the misconceptions about body changes and what to expect during labor and delivery.

Other aspects of prenatal care should include the importance and frequency of:

- Prenatal visits
- Prenatal diet and exercises
- Treatment of STDs
- Immunizations
- Use of medications and abstinence from cigarettes, alcohol and other drugs
- Preparation for labor and delivery
- Recognition of signs of labor, who to call, and where to go
- Discharge planning and postpartum follow-up

Prenatal education involving the infant would include:

- Information on breast feeding, formulas, and infant nutrition
- Identification and acquisition of the necessary clothing and equipment for the newborn
- The need for and identification of appropriate resources for well child care
- Basic skills, such as bathing, diapering, and feeding newborns
- How to take a temperature

- Recognition of urgent and emergent conditions in newborns
- Identification of emergency resources
- Automobile and child safety
- Infant and child development with particular emphasis on age-appropriate discipline

Ideally, comprehensive maternity programs include the baby's father and offer classes with other young expectant couples over a series of weeks or months in preparation for the baby's birth. Adolescents should be strongly encouraged to remain in school during the pregnancy, and school-based maternity programs are particularly supportive to that outcome. Community- or school-based programs designed especially for teens also emphasize issues in the transition to parenting and offer guidance for couples in maintaining relationships and dealing with conflicts related to their change in lifestyle. Negotiating an intimate relationship is often difficult enough for teen couples; the additional stress of finances and childrearing can be devastating given the tenuous nature of many adolescent relationships. More children of teen mothers grow up in a single-parent household than any other group in the U.S. (Maynard, 1996).

Pregnant teens under the age of 16 years are at greatest risk for obstetric complications. These complications are thought to be less causally related to physiologic factors but strongly linked to factors associated with teen pregnancy, such as poverty, poor nutritional habits, and inadequate and late prenatal care. Pregnant teens are at greater risk for iron-deficiency anemia that is secondary to poor nutritional intake. Teens need help in selecting iron-rich foods that are palatable and acceptable; most maternity services refer to a nutritionist to assist teens in developing diet plans that are nutritionally sound but include "fast foods" that are popular with teens. For low-income families with a pregnant adolescent, federal- and community-supported food resources are generally available. Body changes may be disturbing, and pregnant teens may restrict their caloric intake to maintain a pre-pregnant figure. Information on the increased nutritional needs of the body and the developing fetus is important. Assurances that diet and exercise after birth will return the teen to her pre-pregnant weight are encouraging.

Pregnancy-induced hypertension appears to be related to parity and weight gain. In multiparous adolescents, blood pressure and weight gain should be monitored frequently after baseline data have been established (Figure 19-14). Cephalopelvic disproportion (CPD) is common only in very young adolescents (ages 11 to 13) who have not established complete pelvic growth and is more causally related to body type than to maternal age. STDs and substance abuse are known to be common co-existing factors in adolescents who exhibit other high-risk behav-

Figure 19-14 The adolescent's blood pressure should be carefully monitored throughout a pregnancy.

Client Education

Home Visit Guidelines for Adolescent Parents

- Assess the social support system (parents, relatives, friends, neighbors, community agencies) for the adolescent parents
- Encourage ongoing contact with the health care system for parents and infant, including community agencies such as the Visiting Nurse Service (VNS)
- Review the parents's knowledge of child development and expectations for their child
- Identify school- and community-based services that would encourage continuing education for the parents and enhance infant development
- Provide support to adolescent couples who may experience stress in the parenting role
- Include the baby's father in all aspects of infant care, when possible
- Identify referral sources for social, educational, and vocational needs
- Provide information on reproductive physiology and family planning
- Provide support for future plans, if adolescent parents choose to stay together

iors. Therefore, STDs and substance abuse must be considered in any adolescent pregnancy. Adolescents with a history of multiple partners and drug abuse should be counseled and tested for HIV infection. Specific and consistent follow-up is extremely important in decreasing the **vertical transmission** of HIV from the mother to the fetus during pregnancy or delivery and to the neonate during breastfeeding. STDs should be treated appropriately for both partners. Pregnant teens should also receive education regarding the effects of smoking, alcohol, and drugs on themselves and the developing fetus. Teens with a casual drug habit are more inclined to discontinue or decrease drug use during pregnancy. Teens who are addicted are more likely to remain addicted during pregnancy; crack cocaine is frequently the drug of choice. Referral to substance abuse treatment may be a viable option.

Although the postpartum period most often focuses on maternal identity and infant care, ongoing primary care for the mother and the baby should be identified early and become well-established. Adolescent mothers often seek care for their baby but lack care for themselves. Clinics that offer health care for both the mother and child are more successful in delivering services that support child health and consistent contraceptive practices, thus decreasing repeat pregnancy and encouraging education and vocation (Figure 19-15). Young couples with multiple social problems are best referred to comprehensive

Figure 19-15 Postpartum and infant health check-ups are especially important for new teenage mothers who are learning to care for themselves and their new babies.

Case Study/Care Plan

ADOLESCENT PREGNANCY

Shannon, a 10th grader, is an average student, yet outgoing and popular. It seems that she always has a new boyfriend and is hopelessly romantic. She talks on the phone to her friends for hours about boys and dreams that someday she will become an actress. Shannon is 15 years old and presents to the school-based clinic complaining of nausea and a headache. Shannon's symptoms are vague, but she says that she has had nausea and some vomiting in the morning off and on for the past couple of months. After doing a complete health history and a brief physical examination, the nurse asks Shannon if she thinks she might be pregnant. Shannon denies being pregnant and tells the nurse that she can't possibly be pregnant because she broke up with her boyfriend over 6 weeks ago and she is having regular periods. On further questioning, Shannon admits the couple only used condoms "sometimes." She further adds that her periods are a little different, and she hasn't had as much bleeding as she usually does. She's also noticed that her breasts are tender and somewhat enlarged. After a positive result on a urine pregnancy test and a pelvic examination, she is estimated to be approximately 10 to 12 weeks pregnant. Shannon begins to cry and says, "What am I going to do? My parents will kill me! They were so glad when I broke up with my boyfriend and now this! Please, don't tell my mother," she sobs.

Assessment

- Single, pregnant adolescent
- High school student
- Lives with parents
- Unplanned pregnancy
- Unknown date of conception
- Concrete thinker
- Emotionally upset at confirmation of pregnancy
- Inadequate support at present

Nursing Diagnosis

Ineffective individual coping related to confirmation of unplanned pregnancy and parental notification.

Expected Outcome Shannon will receive support and assistance from the health care staff and her family in problem solving, planning, and decision making regarding the current pregnancy.

Planning Encourage Shannon and help her to outline the steps she feels are necessary to come to terms with this pregnancy.

Nursing Interventions

Rationales

- | | |
|---|---|
| 1. Encourage Shannon to verbalize her fears related to the pregnancy and notification of her parents and the baby's father. | 1. Decreases anxiety level and encourages beginning to solve problems. |
| 2. Encourage Shannon to tell her parents immediately about the pregnancy and also encourage her to tell the baby's father. | 2. Adolescent mothers need family support and also support from the baby's father, if possible. If the baby's father cannot support Shannon, he should be encouraged to assume some responsibilities related to the pregnancy. |
| 3. Offer to assist Shannon in parental notification of the pregnancy but assure her of confidentiality if she refuses. | 3. In developing a therapeutic relationship with adolescents, confidentiality is of utmost importance. Some teens welcome assistance in notifying their parents of an unplanned pregnancy and others prefer to tell them on their own. Nurses and other health care staff can assist adolescents with decisions about notification and provide support in this process. |

(continued)

Nursing Interventions**Rationales**

4. Have Shannon identify who will be her immediate support person regarding the pregnancy today.

4. An immediate support person can decrease Shannon's anxiety about the pregnancy confirmation and parent and partner notification and assist her in immediate decision making.

Evaluation Shannon identified her best friend as an immediate support person and, with her assistance, notified her parents of her pregnancy. She chose not to notify the baby's father at this time. Shannon's anxiety decreased and she is considering her options regarding the pregnancy.

Nursing Diagnosis

Knowledge deficit related to lack of experience with the normal signs and symptoms of pregnancy.

Expected Outcome Shannon will demonstrate a basic understanding of the signs and symptoms of pregnancy.

Planning Gather materials for Shannon that outline the normal indicators of pregnancy.

Nursing Interventions**Rationales**

1. Discuss the signs and symptoms of pregnancy in the first trimester.
2. Encourage Shannon to ask any questions related to the pregnancy and provide anticipatory guidance. Provide written information for Shannon about the signs and symptoms of pregnancy during the first trimester.

1. Providing information related to the normal physiologic and emotional changes of pregnancy allows Shannon to adjust to the pregnancy and decrease her anxiety about what is normal. Simple graphic instruction, in terms Shannon understands, will not overwhelm her in this time of crisis.
2. Adequate knowledge about the pregnancy will assist Shannon to set immediate expectations and decrease her anxiety about the pregnancy.

Evaluation After discussion with the nurse, Shannon understood how she got pregnant, approximately when, and why she still had minimal monthly bleeding and other signs of pregnancy.

Nursing Diagnosis

Knowledge deficit regarding decisions about pregnancy alternatives.

Expected Outcome Shannon will make an informed decision about the alternatives regarding her pregnancy.

Planning Gather materials and information appropriate to her level of understanding to share with Shannon the different pregnancy options.

Nursing Interventions**Rationales**

1. Discuss all the possible alternatives relative to the pregnancy: termination, adoption, and keeping the baby.

1. Although many adolescents know of alternatives to pregnancy, they are often unaware of the timing of pregnancy termination, available resources, how to access resources, and costs. Health care providers can assist the adolescent and their support persons through this decision-making process in a nonjudgmental manner.

(continued)

Nursing Interventions

2. Encourage Shannon to discuss her feelings, values, and needs related to each alternative presented.
3. Encourage Shannon to discuss her decision regarding pregnancy alternatives with her parents.

Rationales

2. It is important to allow Shannon to discuss the consequences of all possible outcomes of the pregnancy and to support her in the decision she makes.
3. Shannon needs support from her parents in whatever decision she makes. Cultural mores and family and religious values often play a part in the decision to terminate or retain a pregnancy.

Evaluation After an ultrasound examination which established an estimate 10-week pregnancy, Shannon elected to undergo pregnancy termination. Shannon's ex-boyfriend was not consulted about this decision, and Shannon has continued with school. She is currently unattached and is not sexually active, but she says that she will seek a birth control method before becoming sexually active in the future. Shannon's parents have remained supportive and have encouraged Shannon to concentrate on school and set realistic expectations for the future.

adolescent parenting classes that are designed to meet their social, psychological, and health care needs. Such programs are generally available through state and federal maternal-child health services at low cost or free to the participants. More comprehensive information on normal pregnancy, prenatal care, labor and delivery, and postpartum care is covered in Chapters 15, 16, 23, and 29.

PREGNANCY IN HIV-INFECTED WOMEN

AIDS is a debilitating and life-threatening condition caused by HIV, a retrovirus. HIV is transmitted by exposure to an infected person's body secretions, including blood, vaginal fluid, semen, breast milk, and saliva.

Incidence and Significance

Women of reproductive age are increasingly affected by HIV infection; many women become HIV-infected during the adolescent years and manifest the symptoms of AIDS as young adults. One in five of all reported cases of AIDS occurs in the persons ages 20 to 29, and adolescent minority females are more proportionately represented than adolescent males (King, 1996). Given that the mean time from viral infection to the development of AIDS is approximately 10 years, many of those in the 20 to 29 age category were infected with HIV as adolescents.

The statistics on women with HIV infection and AIDS are alarming. HIV infection is a major cause of morbidity and mortality among women and children in the U.S. In 1995, women accounted for approximately 19% of all reported AIDS cases compared with 12.8% in 1991. Infection

by HIV and the subsequent development of AIDS is reported as the third leading cause of death for all women ages 25 to 44 and is the leading cause of death among African American women in this age group (CDC, 1996). The racial distribution of AIDS has changed dramatically over the past decade. During the first part of the AIDS epidemic, Caucasians were overwhelmingly affected. By 1991, however, 46% of all men with AIDS and 75% of all women with AIDS were African American or Hispanic; transmission in these populations was largely the result of heterosexual contact or infection by contaminated needles (CDC, 1993a).

Over 90% of the reported cases of pediatric AIDS in the U.S. are acquired by transmission from an HIV-infected mother. An estimated 7000 infants are born annually to HIV-infected women and approximately 15% to 30% of these infants would become HIV-infected if no treatment with **antiretroviral therapy** (medications used to suppress HIV replication and reduce viral load) were instituted (CDC, 1996). Approximately 25% to 50% of children with perinatally acquired HIV infection manifest AIDS in the first year of life, and about 80% have clinical symptoms of the disease within 3 to 5 years (Mauskopf, Paul, Wichman, White, & Tilson, 1996). Recognizing the devastating effects of HIV infection on children and their caregivers, it is clear that, from an economic and a humanitarian perspective, prevention of vertical and perinatal transmission is essential.

The most effective way to reduce vertical and perinatal transmission of HIV infection is through prevention of infection of women during their reproductive years. However, despite adequate screening, detection, and educational efforts, the HIV-infection rate among heterosexual women of reproductive age continues to rise. In 1996, the

overall incidence of AIDS-related opportunistic infections declined for the first time since 1985, except among African American and Hispanic males and African American females who had heterosexual risk or exposures (CDC, 1997c). The number of deaths attributed to AIDS also declined among all ethnic groups and men but increased 3% among women. With grave implications for perinatal transmission, the infection rate by heterosexual contact among young females between ages 13 and 24 is significantly higher in comparison to adolescent males, through 1996 (Figure 19-16).

The young heterosexual female population accounts for an increase in new HIV **seroconversions** (i.e., conversion of the blood serum from negative to positive for HIV infection), primarily from transmission by HIV-infected intravenous drug users to their heterosexual partners (CDC, 1997a). For many young women, the only identifiable risk factor is their male sexual partner. During the 1980s, the proportion of adolescents who reported being sexually active increased significantly, yet many young women remain naive about their partner's history of sexual activity or of intravenous drug use (IVDU). Because

Figure 19-16 AIDS cases in male and female adolescents and young adults by heterosexual contact through 1996, United States. (Note: Adapted from *AIDS Surveillance in Adolescents. L265 Slide Series*, by Centers for Disease Control and Prevention (1997). http://www.edc.gov/nchstph/hiv_aids/graphics/adolescent.htm)

adolescents and young adults have proportionately higher rates of STDs, they are more vulnerable to HIV infection. HIV transmission during sexual contact may be facilitated by STDs that cause open genital lesions, such as herpes, syphilis, and chancroid. A break in the skin and mucous membranes of the perianal and genital areas is thought to increase the risk of transmission of HIV during intercourse, and male-to-female transmission is significantly greater than female-to-male (Padian, Shiboski, & Jewell, 1991).

REFLECTIONS FROM A NEW MOTHER

"I always wanted to have children," states 22-year-old Janice. "I never dreamed that it would end up being like this. Our baby developed pneumonia in the newborn nursery and didn't respond well to treatment, so they tested him for HIV. We thought this was just routine and we were shocked when he was HIV-positive. How could that be? Where could he get HIV? My doctor looked at me and said, 'He got it from you, and both you and your husband need to be tested as soon as possible.' We were stunned. I had sex with different partners in high school and college and my biggest fear was getting pregnant, not getting HIV. I didn't think that anyone I knew could be HIV-positive. I admit I wasn't always as careful as I should have been. I just didn't think this could happen to me. Now my baby is sick, my husband is in shock, and I am so afraid. What will happen to us?"

Screening, Testing, and Diagnosis

Although the cure for AIDS is yet undetermined, the statistics on longevity among women and their children appear promising, if antiretroviral therapy is initiated in a timely manner. Until an effective vaccine is developed, early detection and treatment, behavioral risk reduction, and other preventative strategies targeted toward high-risk populations remain the most effective methods of reducing the spread of HIV to noninfected persons and delaying the onset of full-blown AIDS in those who are infected. However, many HIV-infected women are not tested for the virus until symptoms of AIDS are apparent or they deliver a child who has an AIDS-related condition.

Controversy continues about who should be screened for HIV. Because of the availability and efficacy of early antiretroviral treatment and the problems associated with selecting who should be screened, many authorities advocate voluntary prenatal testing of all pregnant women, regardless of their actual or perceived risk of infection. Young women, especially teenagers, often believe AIDS to be a disease that occurs only among homosexual men or IVDUs, and therefore feel invulnerable to the disease. Because many women do not receive any prenatal care or receive prenatal care only in the last trimester of pregnancy, counseling and testing are recommended for all adoles-

Research Highlight

Economic Impact of Zidovudine Treatment for HIV-Infected Pregnant Women and Newborns

Purpose

The purpose of this study was to examine the number of pediatric HIV cases and the costs of screening and prophylactic ZDV treatment in pregnant women compared with the long-term costs of treatment of HIV infection in pediatric clients.

1. To estimate the economic impact of treating pregnant women who are HIV-positive with ZDV during pregnancy.
2. To estimate the economic impact of voluntary screening programs for pregnant women and of offering antiretroviral treatment with ZDV for those women who are HIV-positive.

Methods

Cost estimates were based on a study of 100 HIV-positive women who were treated with ZDV compared with 100 HIV-positive women who received no antiretroviral treatment during pregnancy. Cost estimates were then projected for treatment and care of offspring of the infected women, based on a number of reported parameters. Cost and health effects were also estimated for voluntary screening of a hypothetical 1000 pregnant women, whose HIV status was unknown, and for treatment of those who were found to be infected. A cost-threshold analysis was performed relative to HIV infection prevalence rates and the impact of ZDV on disease transmission.

Findings

Using ZDV according to the ACTG 076 Protocol, treatment costs of \$104,502 for 100 HIV-positive pregnant women and their offspring were offset by a reduction in costs of \$1,701,333 because of the lower number of cases of pediatric HIV infection in the treated group, which resulted in a net savings of \$1,596,831.

Nursing Implications

Providing ZDV treatment to HIV-positive pregnant women has the potential to decrease the number of pediatric HIV infections by vertical transmission and to significantly reduce health care costs. Voluntary screening programs for pregnant women further reduce perinatal transmission of HIV because HIV-positive women are identified early in pregnancy and treatment is offered in a timely manner.

Note: From Economic impact of treatment of HIV-positive pregnant women and their newborns with zidovudine, by Mauskopf J, Paul J, Wichman D, White A and Tilson H, (1996), *JAMA*. 132–138;276:(2).

cents and young adults who use drugs or engage in unprotected sexual intercourse, especially those with multiple partners and those diagnosed with STDs. Broadening the scope of screening and testing may identify those who are infected with HIV before pregnancy or early in an existing pregnancy (CDC, 1999). The economic impact of a significant cost-saving through screening, early intervention, and the prevention of vertical transmission to neonates is considerable (see Research Highlight box). Additionally, any persons who consider themselves at risk and

request testing should be offered that option. Box 19-3 identifies women who are considered to be at risk for HIV infection and for whom screening and testing services should be made available. Mandatory pre- and post-test counseling should always be available in a confidential setting.

HIV infection (seroconversion) is identified by the use of the enzyme-linked immunosorbent assay (ELISA), which detects serum antibodies to HIV and is confirmed by the Western blot test. Results of these diagnostic tests are

highly reliable; false-positives and false-negatives rarely occur. Seroconversion among adolescents and adults generally occurs from 6 to 12 weeks after transmission of the virus. The diagnosis of HIV infection in infants born to HIV-positive mothers is confounded by the presence of maternal immunoglobulin G (IgG) antibodies to HIV. Detection of HIV DNA and RNA by polymerase chain reaction (PCR), detection of the serum p24 antigen, and viral cultures for the virus are the tests used to confirm HIV in the neonate (Barrett & Sleasman, 1997). A presumptive diagnosis of HIV infection is confirmed by two positive results on PCR tests or viral cultures. Because some HIV-infected neonates have undetectable virus levels, diagnostic tests should be repeated at 1 and 4 months. The HIV ELISA should be used to test for HIV in these infants from 6 months to 18 months of age. In uninfected neonates, the maternal antibodies disappear by approximately 18 months of age, and the child remains asymptomatic.

After HIV is confirmed by screening tests, the level of immunocompetence is measured by counting the CD4+ T-lymphocyte cells and, in research settings, by measuring plasma RNA levels of HIV. Progressive depletion of CD4+ T-lymphocytes and rising plasma levels of HIV RNA are associated with an increased likelihood of clinical disease and opportunistic infections (CDC, 1997b; Carpenter et al., 1997). The average CD4+ T-lymphocyte cell count in healthy individuals is approximately 1000 cells/ μ L. HIV-infected persons lose approximately 200 to 300 CD4+ T-lymphocyte cells per microliter of blood in the first year of infection, followed by a subsequent decline of 50 to 80 CD4+ T-lymphocyte cells per microliter yearly thereafter (Stein, Korvick, & Vermund, 1992). Opportunistic infec-

Box 19-3 Characteristics of Women at Risk for HIV Infection

- Current or past history of drug use, especially intravenous drug use
- History of prostitution
- Frequent sexual intercourse with multiple partners
- Sexual intercourse under the influence of drugs
- Sexual intercourse with men who also have sex with men
- Residence in an area of the country with high prevalence of HIV infection, particularly in the northeast and southeast areas of the United States
- Received a blood transfusion or blood products before 1985, when HIV screening became available for blood donors
- Current or past history of sexual intercourse with any persons with any of these characteristics

Client Education

Pre-Test Counseling for HIV Infection

- Explain that testing is confidential
- Assess the client's understanding of HIV risk
- Obtain a careful sexual history
- Explain the modes of HIV transmission
- Explain the relationship between infection and transmission
- Discuss the prevention of transmission to others, including methods of safe sex
- Provide age-appropriate reading materials on HIV transmission, detection, and treatment
- Describe and explain the serologic tests used to confirm HIV infection
- Discuss what test results mean, including false-negative and false-positive results
- Make a plan for the client to receive test results and post-test counseling

Note: Adapted from *HIV Counseling, Testing, and Referral Standards and Guidelines*, Centers for Disease and Control, 1994a. Washington, DC: U.S. Department of Health & Human Services.

tions and clinical symptoms of AIDS generally occur when the CD4+ T-lymphocyte cell count declines to 200/ μ L or less. While many factors influence the progression of HIV disease, time remains the most significant prognostic indicator of mortality in clients with HIV infection. In 1993, the CDC expanded the AIDS surveillance case definition to include persons with CD4+ T-lymphocyte cell counts of less than 200 cells/ μ L along with HIV-related wasting syndrome, HIV-related dementia, disseminated tuberculosis (TB); or one of the following conditions: pulmonary TB, recurrent bacterial pneumonia within 12 months, or invasive cervical carcinoma (CDC, 1993b).

Clinical Manifestations of HIV Infection in Pregnant Women

While there is no conclusive data that nongynecologic opportunistic infections of HIV differ in men and women, it has been suggested that women present with higher rates of candidal esophagitis as an AIDS-defining condition (Carpenter et al., 1997). HIV-infected women may initially present with complicated gynecologic conditions rather than the traditional AIDS-defining diagnoses. The most frequent manifestation of HIV infection in females is recur-

Client Education

Post-Test Counseling and Education for HIV Infection

HIV-Negative Results

- Inform client of negative results and the need for future testing related to exposure
- Review pre-testing educational materials, the need to screen partners, and avoidance of other risk behaviors
- Offer contraception information
- Offer counseling and education to partners
- Review safe sex practices
- Identify community resources for health care and substance abuse if necessary
- Advise client not to donate blood, plasma, or organs until HIV status is firmly established

HIV-Positive Results

- Offer immediate psychological support
- Help the client understand what the test result means
- Review methods of transmission and assess the client's risk of transmitting HIV to others
- Explain that treatment is available
- Identify immediate health care resources
- Identify immediate psychiatric services, as appropriate
- Assist the client in developing a plan to notify all sexual partners of exposure
- Help the client develop a plan to notify all others who may need to know about their HIV status
- Offer counseling and education to partners
- Offer contraception information
- Review safe sex practices and other risk reduction strategies
- Advise client not to donate blood, plasma, or organs

Note: Adapted from *HIV Counseling, Testing, and Referral Standards and Guidelines*, Centers for Disease and Control, 1994a. Washington, DC: U.S. Department of Health & Human Services.

disease (PID), which may lead to abscess formation and resistant to antibiotic therapy; (3) genital herpes infections, which are frequent, persistent, and progress to severe ulcerating disease; (4) human papillomavirus (HPV) infection, with an accelerated progression to cervical neoplasia; (5) rapidly progressing cervical neoplasia; and (6) co-infection with syphilis, which has an aggressive progression to neurosyphilis (Eldred and Chaisson, 1996). Women rarely exhibit Kaposi's sarcoma, but do present with *Pneumocystis carinii* pneumonia (PCP), wasting syndrome, and HIV-related dementia (McDonnell & Kessenich, 2000).

There is no conclusive evidence that maternal HIV infection has an adverse effect on the fetal outcome in pregnancy. Studies conducted in the U.S. that have been controlled for substance abuse factors have not shown significant obstetrical or perinatal complications. Limited studies identified low birth weight, preterm deliveries, and fetal deaths as complications to HIV-related pregnancy (Koonin et al., 1989; Temmerman et al., 1994). However, poverty, lack of prenatal care, drug abuse, and HIV infection are often concomitant, and the combination is costly in terms of obstetrical and perinatal complications and adverse neonatal outcomes.

Clinical Manifestations of HIV in Neonates

Although studies are inconclusive, it appears that HIV can be transferred from mother to the baby during pregnancy or birth and while breastfeeding and that most perinatal transmission occurs at the time of labor and delivery (Riley and Green, 1999). Many attempts have been made at identifying predictors of HIV transmission, but the results are inconclusive. In a study of twins born to HIV-infected mothers, it was found that the first twin to pass through the birth canal had a significantly greater chance of becoming HIV-infected (Goedert, Duliege, Amos, Felton, & Biggar, 1991). It was speculated that the first twin experiences more trauma during birth and may be exposed longer to potentially infectious blood, mucus, and vaginal secretions. However, cesarean delivery alone has not significantly reduced transmission of the virus. It has also been hypothesized that HIV viral load, severity of illness at delivery, and fetal membranes ruptured more than 4 hours before delivery have some predictive value related to fetal and neonatal transmission (Mofenson, 1998).

Clinical signs of HIV infection in the neonatal period are difficult to identify. In approximately 20% of vertically infected infants, high levels of plasma viral load in the first year of life appear to predict rapid progression of disease (Barrett and Sleasman, 1997). These infants are likely to manifest signs of opportunistic infections such as PCP, in-

rent vaginal candidiasis in otherwise healthy women. As the number of CD4+ T-lymphocyte cells decline, women exhibit: (1) candidal vaginitis; (2) pelvic inflammatory

terstitial lymphocytic pneumonia (ILP), candidal diaper rash, thrush, diarrhea, and other recurrent bacterial infections. Growth failure, neurologic problems, and developmental delays are also common.

Nursing Implications

Pregnant women who are HIV-positive or who have clinical AIDS should be identified as soon as possible during pregnancy for early intervention (Figure 19-17). Early identification of either pregnancy or HIV status assumes contact with the health care system. However, poor minority women, who are either IVDUs or have unprotected sex with infected persons, are more vulnerable to HIV infection and are less likely to seek health care early. In a recent study of inner-city pregnant women, investigators found that drug users were less likely than non-drug users to initiate early prenatal care, more likely to abort if HIV-positive, and uninformed about HIV transmission and

Figure 19-17 Pregnant woman at risk for AIDS or other sexually-transmitted diseases should be tested immediately, and information on health promotion and treatment options should be provided.

Box 19-4 ACTG-076 Protocol for Administration of Zidovudine During Pregnancy

Client Eligibility Criteria

- Confirmed pregnancy of 14–34 weeks' gestation
- No antiretroviral drug treatment during current pregnancy
- No clinical indication for antiretroviral drug therapy during the antenatal period
- CD4+ T-lymphocyte count $\geq 200 \mu\text{L}$ at initial assessment

Zidovudine Regimen for Mother and Baby

- Zidovudine (ZDV), 100 mg orally, 5 times daily, begun at 14–34 weeks' gestation and continued throughout pregnancy
- During labor, an intravenous loading dose of ZDV of 2 mg/kg over 1 hour, followed by continuous infusion of 1 mg/kg/hr until delivery
- For the neonate, ZDV syrup orally 2 mg/kg, every 6 hours for 6 weeks, beginning 8–12 hours after delivery

Note: Adapted from, Zidovudine for the prevention of HIV transmission from mother to infant. Centers for Disease Control and Prevention, (1994c). Morbidity and Mortality Weekly Report, 43, (16), 286.

treatment for HIV during pregnancy. Over half the sample thought HIV transmission to the fetus occurred most of the time or always, and only 20% had heard of a drug to treat HIV during pregnancy but 95% would take such therapy if it was offered (Silverman, Rohner, & Turner, 1997).

In 1994, the AIDS Clinical Trials Group Protocol #076 (ACTG 076) demonstrated that zidovudine (ZDV), given to HIV-infected women during pregnancy and labor and delivery plus 6 weeks of oral ZDV therapy for the neonate decreased vertical transmission from 25.5% to 8.3% (Connor, Sperling, & Gelber, 1994). The ACTG 076 protocol showed such promising results that the clinical trials using a placebo group were terminated prematurely once the effectiveness of ZDV was demonstrated and all participants were offered the drug. The efficacy of ZDV in decreasing vertical transmission of HIV was a major breakthrough in treatment. Box 19-4 describes the ACTG 076 protocol for administration of ZDV in pregnancy. Table 19-5 identifies various clinical situations of women during pregnancy and ZDV therapy currently recommended to prevent vertical transmission. In all drug treatment regimens offered to pregnant women with HIV infection, the known and unknown risks and benefits to mother and fetus should be

Table 19-5 Recommended Zidovudine Therapy for Prevention of Vertical HIV Transmission

Clinical Status	Recommendations
HIV-infected pregnant women, no previous antiretroviral therapy	Clinical, immunologic, viral evaluation. Risk/benefits of therapy discussed. Three-part ZDV chemoprophylaxis (ACTG Protocol) initiated at 10–12 weeks' gestation.*
HIV-infected pregnant women receiving antiretroviral therapy during pregnancy	Continue antiretroviral therapy if identified after first trimester. If identified during first trimester, risks/benefits of therapy should be discussed and continuation of therapy should be considered. If drug therapy is discontinued during first trimester, drugs should be simultaneously reintroduced to avoid development of drug resistance. If current drug regimen does not contain ZDV, it should be added after 14 weeks' gestation. ZDV is recommended for the pregnant woman during the intrapartum period and for the newborn according to the ACTG Protocol.
HIV-infected pregnant women in labor with no previous antiretroviral therapy	ACTG Protocol 076 for intrapartum and postpartum period along with the 6-week regimen for the newborn. Woman should be evaluated to determine if antiretroviral therapy should be recommended.
Infants born to HIV-infected women who received no antiretroviral therapy during pregnancy or delivery	The ACTG Protocol for neonates should be discussed with the mother and offered for the newborn. ZDV should be initiated as soon as possible after delivery—preferably within 12–24 hours after birth. Woman should be evaluated to determine if antiretroviral therapy should be recommended.

*Dosing of ZDV has changed from the original ACTG Protocol, which recommended 100 mg five times daily, to 200 mg three times daily, or 300 mg twice daily.

Note: Adapted from Public Health Service task force recommendations for the use of antiretroviral drugs in pregnant women infected with HIV-1 for maternal health and for reducing perinatal HIV-1 transmission in the United States. Centers for Disease Control. (1998). *Morbidity and Mortality Weekly Report*. 47, (No. RR-2), 1–31.

considered and discussed before drug treatment is instituted during pregnancy or at delivery.

In 1996, the final results of the ACTG 076 protocol reported mother-to-baby transmission rates of less than 8% (CDC, 1998). Research continues on the use of ZDV in the treatment of pregnant women, with the emphasis on decreasing the frequency of dosing to increase drug compliance among clients and the use of combination therapy (i.e., ZDV and other antiretroviral agents). In 1998, the U.S. Public Health Service Task Force on antiretroviral medications during pregnancy recommended the use of combination therapy for HIV-positive pregnant women. The long-term effects of the ACTG 076 protocol ZDV regimen on women and children is currently unknown, although there appears to be no immediate adverse consequences to the mother or infant or to child development during the first 2 years after therapy (CDC, 1998).

The most promising strategy for reducing perinatal transmission is the combination of elective cesarean section and ZDV therapy. The combined approach reduces

the transmission rate to 2% (Read, 1999). However, elective cesarean section is not financially possible for all women, and women undergoing a cesarean section have more complications than those delivering vaginally (Mofenson, 1998).

Pregnant women who are HIV-infected and already on antiretroviral therapy should immediately inform their health care provider of their pregnancy and continue medications as directed. Treatment of HIV-infected pregnant women should be considered in the context of optimal health care for the mother and pregnancy termination may be considered as an option. Because ZDV is the only drug that has been shown to significantly reduce vertical HIV transmission, ZDV should be included in any regimen of antiretroviral therapy during pregnancy whenever possible. Currently, if pregnant women are taking combinations of antiretroviral drugs that have reduced their plasma levels of HIV to undetectable levels, these women should be encouraged to continue the drug regimen, especially if treatment with ZDV alone has failed (Carpenter et al.,

1997). More research is needed on combination antiretroviral therapy in pregnancy before recommendations can be made relative to efficacy (CDC, 1998).

Multidrug regimens include the use of three types of antiretroviral agents, as described in Table 19-6. Combination therapy, or the “triple-drug cocktail,” has been successful in suppressing HIV to undetectable levels when measured by standard tests and improving the health, length, and quality of life for individuals with HIV. However, the eradication of HIV has remained elusive, and individuals with HIV should continue the expensive (\$15,000/year) triple-drug cocktails indefinitely. While combined therapy is promising, approximately one-third of HIV-infected clients are unresponsive to the drugs, particularly if they have been on previous ZDV therapy. Side effects can include intense nausea, diarrhea, oral ulcers, anemia, peripheral neuropathy, and pancreatitis, and clients must be sufficiently motivated to take more than 20 pills a day at specific times. Failure to follow specific regimens can lead to viral mutations that are resistant to the drug’s effects.

In addition to antiretroviral therapy, pregnant women with HIV infection may also be taking prescribed drugs for treatment or prophylaxis for opportunistic infections or clinical symptoms of AIDS. The management of pregnancy in HIV-infected women can be complex and referral to special health care providers is usually indicated. There is little data available on HIV-infected women who use multidrug therapy during pregnancy, and safety data on the drug effects on the developing fetus are currently unknown. Therefore, it is essential that initiation or continuation of multidrug treatment regimens for HIV-infected pregnant women occur only after a full discussion of the risk/benefit ratio of combined antiretroviral therapy. Carpenter and colleagues (1997) state that “because

ASSESSMENT OF THE HIV-POSITIVE CLIENT

- Client history
 - Age
 - Parity
 - Complete health history
 - Risk level for HIV infection
 - Drug history (particularly injected-drug use)
 - Sexual exposure
 - Environmental or occupational exposure
 - Subjective symptoms of HIV infection
 - Perceptions of HIV status and anxiety level
 - Social support system
- Physical examination
 - Review results of complete physical examination, especially any physical findings related to HIV infection
- Diagnostic studies
 - Enzyme-linked immunosorbent assay (ELISA) and confirmatory Western blot test
 - CD4+ T-lymphocyte cell count, if the client HIV-positive

of the dearth of information on use of antiretroviral drugs other than ZDV during pregnancy, all women who choose to take antiretroviral drugs during pregnancy should be encouraged to enroll in the Antiretroviral Pregnancy Registry managed by several pharmaceutical companies in conjunction with the CDC and the National Institute of Health.” (p. 1967 and see “Resources” at end of chapter).

Contraception for HIV-infected pregnant women should always be addressed in the antepartum period. All methods of contraception should be discussed and selection should focus on methods that are highly effective and fit into the client’s lifestyle. Effective contraception, including the concepts of potential sterilization and abstinence, is of great importance, because women who are HIV-infected are often at high risk for unplanned pregnancies. In addition to contraception, HIV-infected women should use latex condoms with every episode of sexual intercourse to prevent transmission of the virus to others. Nurses are in an excellent position to counsel women regarding effective contraception and safe sexual practices. Additional information on HIV infection, AIDS, and contraception is addressed in Chapters 9, 10, and 14.

Protease inhibitors	<ul style="list-style-type: none"> • Saquinavir • Indinivir • Ritonavir • Nelfinavir

Case Study/Care Plan

HIV TESTING AND COUNSELING

Because Janice and her husband have recently learned that their newborn has HIV-related pneumonia, they are referred for testing, for HIV and counseling before and after testing. Refer back to “Reflections from a New Mother.”

Nursing Diagnosis

Anxiety related to unknown HIV status and fear of a positive result.

Expected Outcome Client will identify support systems and experience a reduction in anxiety.

Planning With clients, make a list of potential support persons with whom they can share their news.

Nursing Interventions	Rationales
1. Assure Janice that test results and any information she shares is confidential.	1. Clients are more likely to share sensitive information if confidentiality is assured.
2. Encourage Janice to vent her feelings related to a possible HIV-positive test result.	2. Allowing Janice to express her fears will assist her in coping with the testing process.
3. Provide Janice with information about the HIV testing process and what the laboratory test results mean.	3. Providing Janice with factual information will allow her to set her expectations relative to the testing procedure and assist her in understanding what a positive result means for herself and her family.
4. Assist the client in appropriate disclosure of HIV status with others who need to know.	4. Disclosing HIV status is a difficult and sensitive matter. Discrimination against HIV-positive individuals does exist. However, disclosure is important in obtaining appropriate medical and psychosocial support.
5. Encourage Janice to identify immediate support systems within her family and community.	5. Social support increases coping and assists the client in initial problem solving.

Evaluation After discussing her feelings of fear with the nurse, Janice identified her parents, her family physician, and the pastor at her church as a support system for herself and her family. The nurse encouraged Janice to role-play to help decide how and what she would disclose about her HIV status with others, and Janice felt more prepared to share her uncertainty at this difficult time. Factual knowledge of the testing procedure assisted Janice in making an appointment for learning the test results and identifying a support person when obtaining the test results. Although still fearful of a positive result, Janice has identified an initial plan for coping with the test results.

Nursing Diagnosis

Knowledge deficit related to HIV disease process.

Expected Outcome Client will increase understanding of disease process and treatment.

Planning Gather materials, resources, and referrals to ensure that the couple can react to the news from a base of knowledge.

(continued)

Nursing Interventions

1. Assess the client's understanding of HIV risk.
2. Provide information on HIV transmission and effective measures to decrease transmission.
3. Encourage the client to avoid breastfeeding.
4. Discuss sexual abstinence and the use of latex condoms if the client sexually active.
5. Encourage the client to refrain from the use of drugs and alcohol.
6. Advise client not to donate blood, plasma, or organs.
7. Assure client that if test results are positive, treatment and counseling are available.

Rationales

1. Before the nurse can begin client education about HIV, it is important to identify what is known.
2. If the client understands the basis for transmission of HIV, appropriate precautions can be taken to prevent the spread of the disease.
3. Current literature suggests that HIV can be transmitted in breast milk. If the infant is HIV-positive, repeated exposure to the virus can increase viral load.
4. Female-to-male transmission is less common than male-to-female transmission. Latex condoms help to decrease viral transmission to either HIV-positive or HIV-negative partners. Repeated exposure to the HIV virus can increase viral load.
5. Because of a compromised immune system in HIV-positive individuals, drugs and alcohol should be used in limited quantities or not at all.
6. Blood, blood products, and body organs may contain HIV and thus be transmitted to others.
7. Although there is currently no cure for HIV infection, effective treatment can decrease viral load to undetectable levels in the blood. If viral load remains low, opportunistic infections are less likely to occur. Because a diagnosis of HIV can be psychologically devastating, counseling should be made available for the family.

Evaluation Janice has expressed understanding of the disease process and is encouraged that effective treatment is available. She denies other risky behaviors, such as drug and alcohol use and recent exposure to partners other than her husband. If she is HIV-infected, she will seek the nurse's assistance in identifying a plan to notify partners before her marriage. Janice is open to referral to an HIV specialist if her test result is positive.

PREGNANCY IN WOMEN OVER AGE 35

In the past decade, the number of American women over the age of 35 who are giving birth has increased dramatically.

Incidence and Significance

According to the National Center for Health Statistics, in 1993, the number of births among women ages 35 to 39 was higher than in any year since 1960, and the number of

births for women over age 40 was the highest since 1968 (Ventura, Martin, Taftel, Mathews, & Clarke, 1995). From 1976 to 1986, the number of first-time births doubled among women age 40 or older. This trend continues as the disproportionately large number of women in today's childbearing age group (the result of the "baby boom" between 1946 and 1964) reach the end of reproductive maturity. There are numerous explanations for the shift in childbearing among older women, including a longer life expectancy; effective, available contraception; enhanced roles for women; increased female participation in the work force; delayed first marriage; frequency of divorce and remarriage; advanced technology in the treatment of

infertility; and other various lifestyle decisions related to career and educational opportunities. Women who delay childbearing are known to have greater educational and economic status (Aldous & Edmonson, 1993).

The Effects of Age on Reproduction

Fertility decreases proportionately as women age, with the maximum potential for conception at ages 20 to 25, declining to very low levels after age 40. A 95% decrease in fertility occurs in women ages 40 to 45 (Maroulis, 1993). Several factors contribute to the decline in fertility among older women:

- ✦ The reproductive system's decreased efficiency
- ✦ The increased frequency of infectious diseases, diabetes, hypertension, and obesity that may occur with aging
- ✦ The number of pack-years that have accumulated among women who smoke
- ✦ Years of delaying childbearing, during which couples postpone pregnancy until reproductive capability is markedly decreased (Maroulis).

Spermatogenesis declines in males as they age and oocyte depletion in females is an ongoing process from

birth to menopause. Oocyte aging is thought to be the most frequent cause of chromosomal abnormalities, decreased fertility, and increased spontaneous abortions in older pregnant women (Aldous & Edmonson, 1993; Maroulis, 1993; Sauer, Paulson, & Lobo, 1995). Fertilized ova in older women do not implant as well as in younger women, which may be caused by aging of the uterus. The blood supply to the uterus may be compromised by calcification of the uterine vessels. In fertility studies, it has been demonstrated that fertilized ova from young donors implant more often than in women under the age of 35. However, adequate implantation with donor ova has occurred in older women who have been receiving progesterone supplementation after **embryo transfer** (ET), which is the transfer of an externally fertilized egg in embryonic stages by transcervical or other methods. Despite the effects of aging, successful pregnancy and delivery of viable neonates has occurred with ET and exogenous hormone supplementation, even in women who are postmenopausal (Sauer et al, 1995.)

As women age, the endocervix changes with varying levels of estrogen and progesterone. Because of declining estrogen in older women, the cervical mucus becomes dense, making penetration by sperm very difficult. Ovum transport through the fallopian tubes is influenced by normal hormonal functioning. Tubal motility is affected by age and a subsequent decline in estrogen and progesterone levels. Motility of the egg through the fallopian tube decreases, making fertilization less likely. The frequency of ectopic pregnancy increases with age, but the exact causal mechanism is unknown. The changes in transport with the decreased motility of the fallopian tubes may affect the location of ovum fertilization.

REFLECTIONS FROM A MOTHER

"This is a second marriage for us both," says 42-year-old Claire. "We both wanted a large family, even though we realized that we were starting late. We tried for 5 years and I miscarried once during that time. I tried fertility drugs but I felt bloated and irritable, so I didn't stick with them for very long. I also worried about getting pregnant with multiple babies. I kept thinking that I would get pregnant the natural way, but when nothing happened, we saw a fertility specialist who put me on a low-potency fertility drug that didn't make me sick. We were nearly ready to give up when I missed a period. Later, I had an amniocentesis done, and we were told we had a healthy baby girl. I think that was the happiest day of my life."

Medical Risks for Older Pregnant Women and Their Neonates

Although there is no precise age at which women become more susceptible to the complications related to childbearing, age 35 most commonly serves as a reference point, especially when referring to women who are pregnant for the first time. The term **elderly primagravida** was first adopted by the International Federation of Obstetricians and Gynecologists to describe women who were pregnant for the first time and were over age 35. The incidence of maternal complications, including trisomy 21 or Down syndrome, in women over age 35 compared with women in the "ideal" childbearing age range of 20 to 25 received increased attention (Cunningham & Leveno, 1995). Medical evidence suggests that the risk of Down syndrome increases steadily with age, although approximately 70% to 80% of children with Down syndrome are born to women under age 35 (Pauker & Pauker, 1994).

For the past 20 years, amniocentesis and, more recently, chorionic villus sampling (CVS) have been routinely recommended for pregnant women over age 35 to screen for Down syndrome and other chromosomal abnormalities. In the 1980s, it was found that serum levels of alpha fetoprotein were lower in the presence of Down syndrome and two additional serum markers, human chorionic gonadotropin (hCG) and unconjugated estriol, were elevated (Haddow, Palomaki, Knight, Cunningham, Lustig, & Boyd, 1994). Amniocentesis cannot be performed until 14 to 16 weeks' gestation, although CVS may be done at 8 to 10 weeks and the results are available in the first trimester of pregnancy. Prenatal screening is very useful in detecting chromosomal defects and for providing information to assist couples in decision making relative to pregnancy termination. Nurses are in an excellent position to refer couples for genetic counseling and to support couples who may experience difficult decisions related to pregnancy and abortion (see Chapters 13 and 37).

Medical conditions, such as infections, diabetes, hypertension, and obesity, are more common and thus present a challenge in management of pregnant women over age 35. The incidence of type II (insulin-dependent) diabetes mellitus increases with age, and gestational diabetes is more common in older pregnant women, who are also at substantially greater risk for pregnancy-induced hypertension (PIH) or pre-eclampsia than their younger counterparts. Diabetes and PIH account for numerous complications during pregnancy and adverse fetal outcomes. Pregnancies complicated by hypertension are associated with lower gestational age and lower weight at birth and an increased risk of placental abruption and fetal death. Premature separation of the placenta (placenta previa) is thought to be related to aging uterine vessels and chronic hypertensive conditions. Fibroid tumors (leiomyomas) are also more common among older women as a result of the increased secretion of estrogen during pregnancy and may contribute to miscarriage. Large fibroid tumors may contribute to postpartum bleeding because of an inability for adequate contraction after delivery. Because of the potentially serious bleeding complications characteristic of placenta previa, placental abruption, and fibroid tumors, cesarean sections are more common in women over age 35.

The results of the most recent studies related to fetal and maternal mortality vary, although most studies support advanced maternal age as a significant risk factor. In 1995, Fretts and colleagues demonstrated that, even when controlling for coexisting medical conditions, women of age 35 or older had a risk of fetal death twice as high as younger women, a finding that is supported by earlier studies. The relationship between advanced maternal age and fetal death twice as high as younger women, a finding that is supported by earlier studies. The relationship between advanced maternal age and fetal death remains unexplained.

Figure 19-18 The older expectant couple before delivery.

In addition to maternal complications, neonates born to older women have increased perinatal morbidity and mortality. Spontaneous abortions, preterm delivery, low birth weight, fetal anomalies, and antepartum stillbirths occur more commonly in older women (Aldous & Edmonson, 1993; Cunningham & Leveno, 1995). However, because the rate of pregnancy among older women is increasing, studies directed to this population have found that older pregnant women tend to be more likely to be economically secure, carry health insurance, seek early and continuous prenatal care, and be motivated to achieve the best pregnancy outcome. Many of the chronic disorders that go along with aging can be treated and are well controlled during pregnancy. With advanced technology, good counseling, and good medical and nursing care, the outlook for older pregnant women remains optimistic and obstetric and perinatal outcomes appear good (Figure 19-18).

Achieving Pregnancy in Postmenopausal Women

Oocyte donation and embryo transfer (ET) has been used for over 10 years to establish pregnancy in women who were unable to become pregnant as a result of ovarian failure or other structural and functional problems. However, the extension of these services to women of **advanced reproductive age**, who are ages 45 to 50 and are perimenopausal or postmenopausal, remains controversial.

While studies on postmenopausal pregnancies are scarce, preliminary data are positive, and oocyte donation, in vitro fertilization (IVF), and ET for women of advanced reproductive age are gaining in worldwide popularity.

To assist older women in achieving pregnancy, hormone replacement, in the form of sequential estrogen and progesterone, is given to stimulate the secretory response of the endometrium, followed by endometrial biopsy during several cycles to determine if the endometrium is adequate for implantation. Oocyte donors are generally anonymous, although in some cases, relatives act as donors. Sperm is sometimes obtained from husbands or from anonymous donors. The use of semen from men over age 55 is discouraged because of the increased risk of genetic disorders (Sauer, Paulson, & Lobo, 1995). In most procedures, five embryos are transferred transcervically, potentially leading to multiple gestations. Once the pregnancy is confirmed by measurement of serum β -human chorionic gonadotropin (β -hCG) levels and pelvic ultrasonography, a selective reduction is performed on excess embryos. The selective reduction process also remains controversial, particularly when multiple gestations receive popular media attention. From a medical perspective, selective reduction is performed to give a single or twin gestation the best environment in which to develop. Multiple gestations often result in adverse fetal outcomes and fetal death.

Women seeking pregnancy at an advanced reproductive age are generally screened extensively for physical and psychological problems before ET. However, in a 1995 study of the largest series of delivered pregnancies in women over age 50, the incidence of multiple gestations, gestational hypertension, gestational diabetes, preterm labor, and pre-eclampsia were significant (Sauer, Paulson, & Lobo, 1995). The investigators concluded that pregnancy, especially with multiple gestations, precipitated underlying medical problems, yet the perinatal and maternal outcomes in this study were excellent.

Despite the many personal reasons for desiring pregnancy beyond the normal reproductive age, controversy exists in the public domain regarding artificial conception in postmenopausal women. Concerns about treating women beyond reproductive capability focus on the well-being of the child, the potential complications for the mother, and the longevity of the parents in providing for their children.

Nursing Implications

Nursing care for pregnant women over age 35 is much the same as that for other pregnant women. However, several issues are germane to older pregnant women, and older first-time mothers may experience unique stressors in their role transition. Older women becoming pregnant for the first time may have concerns about their ability to carry a

pregnancy to term and their ability to manage labor and delivery. Peer groups of like individuals are helpful in supporting the expectant mother through the pregnancy and delivery process and in the immediate postpartum period. The nurse may assist the older pregnant woman to identify such support groups or help her contact other women in similar circumstances. Because preterm labor is common among older primiparas, bedrest may become necessary at some point during the pregnancy. The nurse could serve as a facilitator for a bedrest support group or inform the pregnant woman of support groups that are available either independently or in association with fetal monitoring equipment companies.

Women over age 35 receive genetic counseling and learning about the increased incidence of medical complications and genetic abnormalities may be stressful for both parents. If genetic screening is performed, waiting for the results is a difficult time for most older expectant couples. If abortion is an option for the couple, the decision may still be stressful: couples need a great deal of support during this period. Nurses working with this population may function in a supportive capacity to individuals or groups or may refer couples to support groups that deal with these issues.

Couples who delay childbearing are generally well-educated. The woman, while having made a conscious decision to have a child, may still be uncomfortable with the role transition from career woman to mother and have doubts about her ability to “keep up” with an active small child. The support of those in the immediate work setting is often perceived as a loss when the new mother is no longer working and has less contact with professional colleagues. Some older mothers may find themselves interacting primarily with new mothers many years younger than themselves. While their concerns for their children may be similar, their life experiences may differ significantly. The need for social interaction with similar individuals is considerable. Also, older women often have higher expectations for themselves as mothers because they have already

Critical Thinking

Counseling and Postmenopausal Conception

Nurses need to consider their own values and feelings when counseling individuals about sensitive or controversial issues. How do your own values about parenting influence your beliefs about postmenopausal conception by oocyte donation and embryo transfer? What are the issues that come to mind?

Figure 19-19 The elderly primipara after delivery.

achieved a measure of success in their careers. Because of their high expectations and the lack of role models, older mothers may experience lower levels of satisfaction with parenting, especially in the first several months postpartum (Reece, 1993). On a positive note, older mothers may feel more financially secure, be devoted to childrearing, and bring a level of maturity to parenting (Figure 19-19).

Early identification of older primiparas with special needs would allow for appropriate nursing interventions, which can begin in the first trimester. Such interventions might include guidance and counseling services related to the pregnancy and delivery, providing parenting classes to address the older couple's special needs, and the development of or referral to parent support groups appropriate for older couples.

Web Activities

- Visit the websites listed above. What types of information do they provide? Is the material targeted to the client or the health care provider?
- What other Internet resources can you find for pregnant teens (i.e., chat rooms, adoption services)?
- Visit nursing and government websites to find their guidelines on optimum ages for pregnancy.
- What does the CDC's site say about pregnancy HIV infection, and AIDS?

Key Concepts

- Adolescent pregnancy is of increasing concern because childbearing during the teenage years has profound socioeconomic and health consequences for teen mothers and their children. The burden of an unintended pregnancy is especially heavy for young teens who are still in high school and are trying to manage their education, develop their own identity, and adapt to the physical and emotional changes occurring with pregnancy.
- The factors contributing to adolescent pregnancy are multifaceted and complex; they are influenced by the adolescent's cognitive and psychosocial development as well as cultural mores and socioeconomic status.
- The psychosocial and physical risks of pregnancy in adolescence are closely related to the adolescent's health and psychosocial well-being and the achievement of normal adolescent developmental tasks. Age, degree of substance abuse, level of nutrition, use of prenatal care, level of family support, and socioeconomic factors greatly influence maternal and neonatal outcomes.
- Adolescence is a period of sexual experimentation for many teens. Appropriate contraceptive methods

for them are ones that are effective, acceptable, and will be consistently used by adolescents. Ideal contraception for adolescents are those methods that are highly effective in prevention of pregnancy and transmission of STDs.

- HIV infection has a significant physical and emotional impact on pregnant adolescents and young adults. Early detection and treatment of HIV infection is essential. With current antiretroviral therapy, vertical and perinatal transmission of HIV can be dramatically reduced and the outlook for greater longevity for mothers and children is promising.
- Childbearing among women over age 35 is becoming increasingly common. With advanced medical technology and appropriate prenatal care, maternal and fetal outcomes are good.
- Older first-time expectant couples experience unique stressors in their transition to parenthood. Anticipatory guidance includes counseling related to prenatal genetic testing, such as amniocentesis and chorionic villus sampling, identification of appropriate social support, and adaptation to parenting.

Review Questions and Activities

- Which of the following socioeconomic factors contributes to the high incidence of adolescent pregnancy in the United States?
 - The lack of adequate birth control
 - Poverty
 - The lack of information on safe sex
 - The availability of public assistance for unmarried mothers

The correct answer is b.

- Which of the following is the most effective contraceptive method for adolescents?
 - Condoms and contraceptive foam
 - Norplant implants
 - OCPs and condoms
 - DMPA injection

The correct answer is c.

- Which of the developmental tasks listed is most affected by an unplanned pregnancy in early to middle adolescence?
 - Identity formation
 - Sexual identity
 - Vocational identity
 - Emancipation

The correct answer is a.

- When is HIV passed from mother to infant?
 - Prenatal period
 - Intrapartum period
 - Postpartum period via breast feeding
 - All of the above

The correct answer is d.

- Which of the following is the drug used to decrease the vertical transmission of HIV from mother to baby?
 - Saquinavir
 - Ritonavir
 - Zidovudine
 - Stavudine

The correct answer is c.

- Which of the following groups in the United States is experiencing an increase in the rate of HIV infection?
 - Homosexual men
 - Heterosexual men
 - Intravenous drug users
 - Heterosexual female adolescents and young adults

The correct answer is d.

- What age defines the elderly primigravida?
 - Over age 30
 - Over age 35
 - Over age 40
 - Ages 45 to 50

The correct answer is b.

- Which genetic screening test for chromosomal abnormalities provides an older expectant couple with information within the first trimester?
 - Chorionic-villus sampling (CVS)
 - Amniocentesis
 - Genetic karyotyping
 - Ultrasonography

The correct answer is a.

Assessment of Fetal Well-Being

Fetal Development

*H*ave you ever considered what a baby looks like at various stages of fetal development? Organs and systems are almost totally complete at the end of the first trimester of pregnancy. Other systems, such as the nervous system, are not fully developed. What implications does fetal development have for your nursing practice?

Competencies

Upon completion of this chapter, the reader should be able to:

1. Describe the process of fertilization, implantation, and cell differentiation.
2. Delineate the structure and function of the placenta, amniotic fluid, and umbilical cord.
3. Identify the major stages of fetal development.
4. Identify the critical developmental stages of organogenesis that may be affected by environmental hazards.
5. Apply the knowledge of fetal growth and development to create high-quality nursing care and teaching plans for the expectant mother and her developing fetus.

There is no process as amazing as the development of a human being from two single cells. In about 40 weeks, a fertilized egg grows from a single cell to a fully developed fetus able to survive the birthing process. Fetal development is an incredible and multifaceted event. This chapter gives an overview of the developmental stages, starting with early cell division, and then reviews fetal development. The organizing framework for this chapter is chronological development of the fetus. Throughout the chapter, concepts that relate to the educational needs and concerns of clients are highlighted.

CELL DIVISION

This chapter presents an overview of fertilization through embryonic and fetal development. A fertilized egg grows from a single cell carrying all the required genetic material, to a fully developed fetus, eventually growing into an adult.

Human development occurs through two cell division processes: mitosis and meiosis. **Mitosis** refers to the process in which body cells duplicate themselves and then separate into two new daughter cells. This is how the human body grows and increases in size. Mitosis is a con-

tinuous process whereby the cell material duplicates and divides and enables the growth of the fetus. The distinct stages of mitosis are illustrated in Figure 20-1. **Meiosis** is the process by which the ovum and sperm divide and mature. In contrast to mitosis, meiosis results in a reduction in the number of human chromosomes. All human cells normally have 46 chromosomes, except the sex cells (ovum and sperm). These chromosomes are paired, thus each cell contains 22 pairs of autosomes and one pair of sex chromosomes. The ovum and sperm undergo the process of meiosis (reduction in total number of chromosomes). In the meiotic process (Figure 20-1) each gamete receives only one chromosome from each pair. Thus each mature ovum and spermatozoon has 23 chromosomes.

IMPLANTATION AND FERTILIZATION

Human development begins before **implantation**, which is the embedding of the fertilized ovum into the endometrium. During ovulation in the female, the ovum is expelled from the **graafian follicle** in the ovary and swept up into the fallopian tube (Figure 20-2). The ovum is surrounded by a layer of cells (**zona pellucida**) and a

Cell Division

Figure 20-1 Cell division. A, mitosis; B, meiosis.

band of cells, known as the **corona radiata**. These layers of cells facilitate the migration of the ovum along the fallopian tube to the uterus. The ovum is propelled through the fallopian tube by waves of fine hair-like structures (**fimbriae**), that line the fallopian tubes. **Fertilization** (Figure 20-3) of the ovum occurs within the first 24 to 48 hours after the release of the ovum into the fallopian tube. If the ovum is not fertilized within this time, the ovum wastes away and becomes nonfunctional. Since the life of

spermatozoa is approximately 48 to 72 hours, the total time span during which fertilization may occur depends on ovulation occurring during the life of the deposited sperm.

At ejaculation during coitus, 200 to 600 million spermatozoa are deposited in the vagina. The spermatozoa propel themselves into the uterus and eventually into the fallopian tube. Only a few sperm survive to reach the ovum. The surviving sperm cluster around the ovum. To penetrate the

Figure 20-2 Ovulation, fertilization, and implantation.

ovum, the head of the sperm must undergo **capacitation**. This process consists of changes in the plasma membrane of the sperm head. The sperm releases hyaluronidase (a proteolytic enzyme) that dissolves the layer of cells protecting the ovum. When a single sperm penetrates the zona pellucida of the ovum, a chemical reaction occurs that prevents other sperm from entering the ovum. Immediately upon entering the ovum, the chromosomal material of the ovum and spermatozoa fuse, resulting in a **zygote**. The fertilized ovum not only forms the fetus but also the accessory structures (placenta and yolk sac) that the fetus will need to support itself during intrauterine life.

Once fertilization is complete, the zygote travels along the fallopian tube toward the uterus. This journey takes approximately 3 to 4 days. During this time, mitotic cell division, or cleavage, occurs. The first cleavage is complete at about 24 hours after fertilization, and this process continues once every 22 to 23 hours. By the time the zygote reaches the uterus, it should consist of 16 to 64 cells. This mass of cells is referred to as a **morula** because of its resemblance to a mulberry. The morula continues to multiply for about 4 more days. During this time, large cells (**trophoblast cells**) cluster on the perimeter of the morula, resulting in a fluid-filled space surrounding the inner cluster of cells, called a **blastocyst**. The outer layer of cells (trophoblast) is part of the structure that forms the placenta, while the inner cluster of cells (blastocyst) develops into the embryo.

On the seventh day after fertilization, the corona and zona pellucida dissolve and disappear. This permits the trophoblast to deeply embed into the endometrium of the uterine wall. The trophoblastic cells produce an enzyme that dissolves the endometrial tissue, permitting the blastocyst to tunnel into the endometrium. As the invasion continues, the cell mass establishes a communication network with the circulatory system of the endometrium.

Implantation generally occurs high in the uterus. If the implantation occurs lower in the uterus, the growing placenta may obstruct the cervix (a situation referred to as placenta previa). Probably one-third of fertilized eggs never implant because there is a major defect in the zygote or the endometrium is not receptive to the invading blastocyst. Of those zygotes that do implant, fewer than one-third progress to establish a productive pregnancy (Moore & Persaud, 1998).

The corpus luteum in the ovary continues to function producing estrogen and progesterone, because of the influence of **human chorionic gonadotropin** (hCG), produced by the trophoblast cells. This allows the endometrium to continue to grow and sustain the pregnancy. At this stage, the endometrium is called the **decidua**. The decidua has three regions: (1) the part resting directly between the embryo and the uterine wall under the **embryo (decidua basalis)**, (2) the portion of the endometrium that surrounds the surface of the trophoblast (**decidua capsularis**), and (3) the remaining

Figure 20-3 Fertilization.

portion of the uterine lining (**decidua parietalis**) (Figure 20-4) (Larsen, 1997).

Once implantation occurs, the trophoblastic layer of cells begins to mature. By the 12th day, **chorionic villi** form and begin to expand into the uterine endometrium. The chorionic villi have a central core of connective tissue that contains fetal capillaries and is covered by two layers of trophoblast cells. The **syncytiotrophoblast** is the outer layer, which facilitates the production of several placental hormones (hCG, human placental lactogen HPL, estrogen, and progesterone). The inner layer (**cytotrophoblast**, or **Langhan's layer**) is present as early as 12 days after fertilization but it disappears between the 20th and 24th weeks of gestation (Larsen, 1997). This layer of cells protects the growing embryo from certain infectious organisms, such as syphilis; however, it does not provide protection against many other viral agents.

PLACENTA

After implantation, the placenta begins to develop. The placenta develops from the trophoblast cells at the site

Figure 20-4 Decidua.

where the developing embryo attaches to the uterine wall. The placenta eventually serves as the lungs, kidneys, endocrine system, and gastrointestinal tract for the fetus. Placental development and circulation begins around the third week of embryonic development. The placenta continues to grow in size until the 20th week of gestation, at which time it covers nearly one-half of the uterine wall. After the 20th week, the placenta becomes thicker but not larger in diameter. At term, the placenta is about 6 to 8 inches (15 to 20 cm) in diameter, with walls 1 to 1.5 inches (2.5 to 3.0 cm) in thickness, and weighs approximately 14 to 21 ounces (400 to 600 g).

The placenta has two parts: the maternal portion and the fetal portion. The maternal portion consists of the decidua basalis and its circulation. Its surface is red, rough, and segmented into irregular convex areas, referred to as **cotyledons**. The fetal portion consists of the chorionic villi and the surface is covered by the amnion, which gives it a shiny, gray appearance.

Functions of the Placenta

The placenta begins to function shortly after implantation and is involved in the metabolic, endocrine, and transport activities necessary for fetal development (Carlson, 1999).

Metabolic

The placenta produces glycogen, cholesterol, and fatty acids for fetal use and hormone production and numerous enzymes required for fetoplacental transfer. It also stores glycogen and iron.

Transport

The placenta controls the exchange of several substances by five mechanisms: simple diffusion, facilitated transport, active transport, pinocytosis, and hydrostatic and osmotic pressure.

1. Simple diffusion occurs when substances from an area of higher concentration pass to an area of lower concentration. Substances that move by simple diffusion are water, oxygen, carbon dioxide, electrolytes, anesthetic gases, and certain drugs.
2. Facilitated transport involves the movement of molecules from an area of greater concentration to an area of lower concentration. Molecules such as glucose, galactose, and some oxygen are transported by this method. The glucose level in the fetal blood is approximately 20% to 30% lower than the glucose level in the maternal blood because the fetus metabolizes glucose rapidly.
3. Active transport can work against a concentration gradient, allowing molecules to move from areas of lower concentration to areas of higher concentration. Amino acids, calcium, iron, iodine, water-soluble vitamins, and glucose are transferred in this manner.
4. Pinocytosis is the process of cellular ingestion by engulfing the cell. Pinocytosis is important for transferring large molecules, such as albumin and gamma globulin. Amoeba-like cells, forming plasma droplets, engulf materials.
5. Hydrostatic and osmotic pressure allow the bulk flow of water and some solutes to the fetus.

Other mechanisms of transfer also exist, for example, fetal red blood cells may pass into the maternal circulation through breaks in the placental membrane. Maternal leukocytes and certain microorganisms can cross the placental membrane under their own power. There is no mixing of maternal blood with fetal blood. As the maternal blood picks up waste products and carbon dioxide from the fetus, it drains back into the maternal circulation. The transfer of substances, the ratio of blood on either side of the placenta, and the binding abilities of certain molecules in the blood affect changes in blood flow between the fetus and the maternal intervillous spaces.

Endocrine

The placenta produces hormones that are vital to the survival of the fetus. These include hCG, human placental lactogen (hPL), and two steroid hormones, estrogen and progesterone.

The hormone hCG prevents the normal involution of the corpus luteum at the end of the menstrual cycle. If the corpus luteum stops functioning before the 11th week of

pregnancy, spontaneous abortion occurs. The hCG stimulates the corpus luteum to secrete increased amounts of estrogen and progesterone. hCG reaches its maximum level around the 60th day and then decreases, as placental hormone production increases. hCG and hPL play a role in preventing the rejection of the placenta and embryo by the mother's body.

After the 11th week, the placenta produces enough progesterone and estrogen to maintain pregnancy. In the male fetus, hCG also exerts a cell-stimulating effect on the fetal testes that results in the production of testosterone. The secretion of testosterone during embryonic development stimulates the growth of the male sex organs.

Progesterone is essential for the maintenance of the pregnancy because it increases the secretions of the fallopian tubes and uterus. These secretions provide appropriate nutritive elements for the developing morula and blastocyst. Progesterone also assists in the transport of the ovum through the fallopian tube. Progesterone causes decidual cells to develop in the uterine endometrium, and it must be present in high levels for implantation to be successful. Progesterone also decreases the contractility of the uterus, thus preventing uterine contractions, which may result in spontaneous abortion. The production of progesterone by the corpus luteum peaks between the seventh and 10th day after ovulation, and implantation occurs at this time. After the 10th week, the placenta takes over the production of progesterone.

By the seventh week, the placenta produces more than 50% of the estrogen in the maternal circulation. Estrogen has a generating function on the uterus, the breasts, and the breast glandular tissue.

Placental Circulation

After the blastocyst implants, the cells differentiate into fetal cells and trophoblastic cells. The trophoblast invades the decidua basalis of the endometrium, resulting in the opening of the uterine capillaries and eventually the larger uterine vessels (Figure 20-5). At the same time, the chorionic villi continue to grow and eventually form the fetal vessels. On about the 12th day, maternal blood pools in the intervillous spaces surrounding the chorionic villi. By the end of the 21st day, oxygen, glucose, and other nutrients diffuse from the maternal blood to the chorionic villi and are transported to the developing embryo.

By the 12th week of gestation, the placenta develops into a discrete organ. The cotyledons on the maternal surface contain branches of the placental villi, allowing for some compartmentalization of the uteroplacental circulation. Each cotyledon contains branching vessels that are distributed throughout the lobules.

The capillaries of the villi are lined with thin endothelium and are surrounded by a layer of connective tissue

Figure 20-5 Placental circulation.

(mesenchyme). In the fully developed umbilical cord, fetal blood flows through two umbilical arteries to the capillaries of the villi and oxygen-enriched blood flows back through the umbilical vein to the fetus.

Maternal blood, rich in oxygen and nutrients, spurts from the uterine arteries into the intervillous spaces. The blood is directed toward the chorionic plate and, as the pressure decreases, it spreads out. Fresh maternal blood enters and exerts pressure on the intervillous spaces, thus pushing blood toward the basal plate. Blood is then drained through the uterine and pelvic veins.

Circulation within the intervillous spaces depends on maternal blood pressure. The lumen of the uterine artery is narrow when it pierces the chorionic plate and enters the intervillous space, resulting in an increase in blood pressure locally. The pressure in the arteries forces the blood into the intervillous space and bathes the villi in oxygenated blood. As the pressure decreases, the blood flows back from the chorionic plate toward the decidua,

where it enters the endometrial veins. Placental exchange functions occur only in fetal vessels that are in intimate contact with the covering syncytial membrane. The syncytium villi have borders containing many microvilli, which greatly increase the exchange rate between maternal and fetal circulation.

Fetal Circulation

The blood circulation after birth is much different from that of the fetus. During fetal development, the lungs are collapsed and do not function. The placenta performs the role of supplying oxygen to the blood and removing carbon dioxide. This requires that there be unique structures (i.e., foramen ovale, ductus venosus, and ductus arteriosus) that play major roles in fetal circulation and disappear after birth.

The blood from the placenta flows through the umbilical vein, which penetrates the abdominal wall of the fetus

A.

Figure 20-6 A. Fetal circulation.

at the site of the umbilicus (Figure 20-6A). It divides into two branches, one of which circulates a small amount of blood through the fetal liver and empties into the inferior vena cava through the hepatic vein. The second and larger branch, called the ductus venosus, empties directly into the fetal vena cava. This blood then enters the right atrium, passes through the foramen ovale into the left atrium, and pours into the left ventricle, which pumps it into the aorta. Some blood returning from the head and upper extremi-

ties by way of the superior vena cava is emptied into the right atrium and passes through the tricuspid valve into the right ventricle. This blood is pumped into the pulmonary artery, and a small amount passes to the lungs and provides nourishment only. The larger portion of blood passes from the pulmonary artery through the ductus arteriosus and into the descending aorta, bypassing the lungs. Finally, blood returns to the placenta through the two umbilical arteries, and the process is repeated.

B.

Figure 20-6 (continued) B. Newborn circulation.

The fetus receives oxygen via diffusion from the maternal circulation. Fetal hemoglobin facilitates obtaining oxygen, since it carries as much as 20% to 30% more oxygen than adult hemoglobin. Fetal circulation delivers the highest available oxygen concentrations to the head, neck, brain, and heart and a lesser amount of oxygenated blood to the abdominal organs and the lower body. This circulatory pattern leads to cephalocaudal (head-to-tail) development of the fetus.

Newborn Circulation

Fetal circulatory shunts are not necessary after birth because the baby is able to oxygenate the blood through the lungs rather than the placenta (Figure 20-6B). As the newborn breathes, the foramen ovale closes as a result of the increased blood flow to the lungs and the decreased pressure in the right side of the heart. The ductus venosus closes when the blood from the umbilical cord stops. The

ductus venosus and the foramen ovale are permanently closed as tissue develops in these structures.

UMBILICAL CORD

While the placenta is developing, the umbilical cord is also being formed. The body stalk, which attaches the embryo to the yolk sac, contains blood vessels that extend into the chorionic villi. As the chorionic villi initiate circulatory communication with the maternal circulatory system, the villi begin to fuse into large vessels. As the body stalk elongates, the vessels in the cord contract into one large vein and two smaller arteries. The larger vein brings the oxygenated blood from the placenta to the fetal circulatory system. The two small arteries carry deoxygenated blood and waste products back to the placenta. About 1% of umbilical cords have only two vessels: one vein and one artery. This may be seen in conjunction with congenital malformations. A specialized connective tissue (**Wharton's jelly**), which is an extension of the amnion, surrounds the blood vessels in the umbilical cord. This tissue, plus the high volume of blood in the vessels, prevents compression of the umbilical cord. The major function of the cord is to transport oxygen and nutrients to the fetus and to return waste products from the fetus to the placenta. At term, the cord is almost 1 inch (2 cm) across and about 22 inches (55 cm) long. The cord can attach itself to the placenta at various sites. Central insertion into the placenta is considered the norm. Umbilical cords can look twisted or spiraled; this is most likely caused by fetal movement. A true knot in the umbilical cord is rare, because of the high pressure and rapid blood flow in the cord. More common are so-called false knots, caused by the folding of the cord vessels. A **nuchal umbilical cord** is one that encircles the fetal neck.

MEMBRANES AND AMNIOTIC FLUID

The fetal membranes include the **amnion** and the chorion; both surround the fetus, along with the yolk sac and the **allantois**. The yolk sac develops in the second week and serves several functions for the embryo in its early stage of development. The yolk sac transfers nutrients to the embryo while the placental circulation is being developed. The yolk sac is important in blood development in the first few weeks of the embryo's life. Blood forms on its walls until the fetal liver takes over the function of blood formation. During the fourth week, the yolk sac becomes incorporated into the embryo and serves as the foundation for the primitive gut. The remaining portion of the yolk sac decreases in size and eventually becomes detached from the embryo. The allantois appears in the third week. It is a small diverticu-

lum of the yolk sac and eventually develops into the urinary bladder.

The amnion is the inner of the two fetal membranes (the outer is the **chorion**). The amnion begins to appear in the second week of gestation. It envelops the embryo and, as the pregnancy progresses, it adheres to the chorion. The sac formed by the amnion and chorion contains an opaque fluid (**amniotic fluid**). The fluid surrounds the embryo and, as the pregnancy progresses, the amount of fluid increases. Amniotic fluid consists of 98% water and 2% organic and inorganic materials. The composition of the fluid changes as pregnancy advances. In the early stages of pregnancy, the amniotic fluid has a composition similar to maternal plasma; later in pregnancy, the amniotic fluid becomes hypotonic as a result of the presence of fetal urine. The volume of amniotic fluid increases as the pregnancy progresses. The volume increases at a rate of about 25 ml per week until the 15th week, and then it increases 50 ml per week until the 28th week. Amniotic fluid volume reaches a peak of approximately 1 L at 38 weeks and then stabilizes or decreases slightly until delivery.

Amniotic fluid's main function is to provide an optimal environment for the fetus. The fetus begins to swallow the fluid in the fourth month and thus it may be important to fetal metabolism. Amniotic fluid helps to dispose of secretions from the kidneys and the respiratory tract, allows the fetus to move with ease in the uterus, equalizes the pressure from sudden external forces, and keeps the fetus at a uniform temperature.

EMBRYONIC AND FETAL DEVELOPMENT

The first days of human development, starting on the day the ovum is fertilized, are referred to as the pre-embryonic stage. This period is characterized by rapid cellular multiplication, cell differentiation, and establishment of the embryonic membranes and primary germ layers. Specific embryonic and fetal assessments to determine the status of the embryo or fetus are described here. The pattern of development is cephalocaudal, proximal to distal, and general to specific.

Embryonic Stage

The stage of the embryo begins about the 14th day and continues until approximately the eighth week of development. The embryonic stage is a period of tissue differentiation, forming of essential organs, and development of external features. During this period, the embryo is vulnerable to **teratogens** (Table 20-1). Teratogens are environmental substances that may cause adverse effects on

Table 20-1 Stages of Fetal Development

	Stage	Fetal Development
	Embryonic or Germinal Stage	
	Weeks 1 and 2	Rapid cell division and differentiation. Germinal layers form.
	Embryonic Stage	
	Week 3*	Primitive nervous system, eyes, ears, and RBCs present. Heart begins to beat on day 21.
 <p>4 weeks</p>	Week 4*	Half the size of a pea.
	Wt 0.4 g L 4–6 mm (crown–rump, C–R)	Brain differentiates. GI tract begins to form. Limb buds appear.
	Week 5*	Cranial nerves present. Muscles innervated.
	L 6–8 mm (C–R)	
	Week 6*	Fetal circulation established. Liver produces RBCs. Central autonomic nervous system forms. Primitive kidneys form. Lung buds present. Cartilage forms. Primitive skeleton forms. Muscles differentiate.
	L 10–14 mm (C–R)	
	Week 7*	Eyelids form. Palate and tongue form. Stomach formed. Diaphragm formed. Arms and legs move.
	L 22–28 mm (C–R)	
 <p>8 weeks</p>	Week 8*	Resembles human being. Eyes moved to face front. Heart development complete. Hands and feet well formed. Bone cells begin replacing cartilage.
	Wt 2 g L 3 cm (1.5 in) (C–R)	All body organs have begun forming.
	Fetal Stage	
	Week 9	Finger and toenails form. Eyelids fuse shut.
	Week 10	Head growth slows. Islets of Langerhans differentiated. Bone marrow forms, RBCs produced. Bladder sac forms. Kidneys make urine.
	Wt 14 g (½ oz) L 5–6 cm (2 in) crown–heel (C–H)	
	Week 11	Tooth buds appear. Liver secretes bile. Urinary system functions. Insulin forms in pancreas.

*Vulnerable to teratogenic effects.

the developing fetus. A teratogen has the greatest effect on an organ during that organ’s period of differentiation and development. Brain development occurs throughout the pregnancy, and teratogens can affect mental development throughout gestation.

Embryonic Assessment

Continual improvements in the area of prenatal diagnosis are making the availability of testing relatively safer, more acceptable, reliable, and accessible. Transvaginal sonography is one diagnostic procedure that can be used for early evaluation of the embryo. This procedure gives fairly accurate estimates of gestational age by measuring the biparietal diameter of the head, head circumference, and ab-

dominal circumference. This procedure is considered safe and is not invasive.

Embryoscopy can be used in early pregnancy (around 6 weeks). This procedure requires the insertion of a minute viewing scope into the mother’s abdomen through a canula about the size of a needle used to draw blood. This procedure is gaining acceptance for use in embryonic diagnosis and, in some cases, fetal surgery. This is an invasive procedure; the mother requires extensive support in preparation for the procedure and counseling on the possible risks and benefits gained from undergoing this test. The ultimate decision rests with the parents; however, they need current and accurate information to make the most appropriate decision for their family. The nurse should maintain a nonjudgmental and emotionally supportive approach to families who undergo embryoscopy.

Critical Thinking

Medical History

Review obstetric and medical history for risk factors (detrimental lifestyle, abusive relationship, inappropriate use of medications, and potential teratogens, such as alcohol or nicotine). Which of these factors is most likely to produce birth defects, and why?

3 Weeks

In the third week, the embryonic disk becomes elongated and pear-shaped, with a broad cephalic end and a narrow caudal end. The ectoderm forms a long cylindrical tube called the notochord, from which brain and spinal cord develop. The most advanced organ is the heart, which appears as a single tube outside the embryo’s body cavity. The heart muscle is able to contract, and peristaltic waves pass along the heart tube. The cardiovascular system begins to form and blood begins circulating in the primitive heart. The gastrointestinal tract, created from the endo-

Client Education

Healthy Pregnancy

Help your clients achieve a healthy pregnancy.

- Educate parents on critical stages of embryonic development; this helps the client understand the importance of maintaining a healthy lifestyle to ensure optimal fetal growth and development and the importance of early prenatal care to ensure adequate nutrition for both mother and fetus.
- Ascertain the client's knowledge level of dietary needs; fetal and maternal well-being depend on maternal nutrition during pregnancy and, in certain conditions, for approximately 2 years before the pregnancy (folic acid). Also ascertain iron intake; increased levels of iron are necessary during pregnancy for developing maternal and fetal tissue and fetal iron stores.
- Provide general information about antepartum testing that may be ordered and the specific times during pregnancy when these tests are most accurate. Many clients want to know how safe the tests are and how much discomfort they may cause. Review the procedures and explain why some tests may need to be repeated. Provide simple and clear explanations of what the tests measure.

derm, appears as a tube-like structure that communicates with the yolk sac.

4 Weeks

During the fourth week, **somites** form on either side of the embryo's midline. Somites are formed by the division of the mesoderm next to the midplane and eventually form the vertebrae and the spinal column. The main divisions of the central nervous system (CNS) are established. The pharyngeal arches, which will form the lower jaw, hyoid bone and cartilage of the larynx, develop at this time. The pharyngeal pouches appear; they will form the eustachian tube and cavity of the middle ear, the tonsils, and the parathyroid and thymus glands. The primordia of the ear and eye are also present. By the end of 28 days, the tubular heart is beating at a regular rhythm, and the contractions are efficient enough to produce circulation

through the main fetal blood vessels. The stomach begins as a spindle-shaped bulge in the lower part of the foregut, and the pancreas begins as two small buds of endodermal cells growing out of the foregut. The liver starts as a small bud, forming at the lower end of the foregut. Before the fourth week, arm and leg buds are not visible, but the tail bud is present.

5 Weeks

By this time, the brain has differentiated into five areas, and ten pairs of cranial nerves are recognizable. During the fifth week, the optic cups and lens vesicles of the eye form and the nasal pits develop. Partitioning in the heart begins with the dividing of the atrium. The heart, circulatory system, and brain show the most advanced development. The embryo has a marked C-shaped body, accentuated by the rudimentary tail and the large head that is folded over a protuberant trunk. By day 35, the arm and leg buds are well-developed, with paddle-shaped hand and foot plates.

6 Weeks

At six weeks, the head structures are more developed, and the trunk is straighter than in earlier stages. The upper and lower jaws are recognizable, and the external nares are formed. The trachea has developed, and its caudal end is bifurcated, heralding the beginning of lung formation. The lung buds extend into the abdomen. The upper lip is present and the palate is developing. The ears continue to develop. The heart now has most of its definitive characteristics, and fetal circulation begins. The liver starts to produce blood cells. The arms have begun to extend ventrally across the chest, and both arms and legs have digits, although they may be webbed. There is a slight bend in the arms, which are more advanced in development than the legs. At this stage of development, the prominent tail begins to recede.

Client Education

Drug Use

Assess fetal gestational age and counsel clients regarding drug use to prevent teratogenic problems in the developing embryo and fetus.

7 Weeks

During the seventh week, the head of the embryo is rounded and nearly erect. The eyes have shifted from their original lateral position to a forward location, in which they are closer together, and the eyelids are beginning to form. The palate is almost complete, and the tongue is developing in the formed mouth. The diaphragm begins to divide the thoracic cavity from the abdomen. The lung buds migrate up into the chest cavity. If the diaphragm fails to close, the fetus is born with a diaphragmatic hernia. The gastrointestinal and genitourinary tracts undergo significant changes during the seventh week. Before this time, the rectal and urogenital passages formed one tube that ended in a blind pouch; now they begin to separate into two tubular structures. The intestines enter the extraembryonic coelom in the area of the umbilical cord (called umbilical herniation). At this point the beginnings of all essential external and internal structures are present.

8 Weeks

At eight weeks, the embryo is approximately 1.2 inches (3 cm) long and resembles a human being. **Organogenesis** is complete. The facial features continue to develop. The eyelids begin to fuse. Auricles of the external ears begin to assume their final shape, but they are still set low. The circulatory system through the umbilical cord is well-established. External genitals appear, but the embryo's sex cannot be determined visually. The rectal passage opens with the perforation of the anal membrane. Long bones are beginning to form, and the large muscles are now capable of contracting.

Fetal Stage

By the end of the eighth week, the embryo is sufficiently developed to be called a fetus. Every organ system and external structure that is found in the full-term newborn is

COMMUNITY RESOURCES

Inform the clients of the resources in the community that assist clients who need further support and information regarding problems identified through antepartal testing.

present (England, 1996). The remainder of gestation is devoted to refining structures and perfecting function.

Fetal Assessment

There are several tests that can be used to assess fetal well-being. These tests may provide information about the fetus's development, fetal lung maturity, and the location of the placenta in the uterus. Some of the tests that can be used to determine fetal status are diagnostic ultrasound (intermittent high-frequency sound waves used to create an image of the fetus), fetal stress tests, chorionic villus sampling (CVS) for chromosome analysis, and amniocentesis for lung maturity.

9 to 12 Weeks

By 10 weeks, the fetus reaches 2 inches (5 cm) in length and weighs about ½ ounce (14 g). The head is large and comprises almost half of the fetus. The neck is distinct from the head and body, and both the head and neck are straighter than in previous stages of development.

By 12 weeks, the fetus reaches 3.2 inches (8 cm) in length and weighs about 1.6 ounces (45 g). The face is well-formed: the nose protrudes, the chin is small and recedes, and the ears are acquiring a more adult shape. The eyelids close at about the 10th week and do not reopen until about 28 weeks. Some reflex movements of the lips, suggestive of the sucking reflex, have been observed as early as 12 weeks. Tooth buds now appear for all 20 of the

Nursing Tip

FETAL TESTS

Be aware of available fetal tests and support the family in preparing for the tests (ultrasound, amniocentesis, triple-marker screening [analysis of maternal serum for abnormal levels of alpha-fetoprotein, hCG, and estriols]) that may predict chromosomal and neural tube defects.

REFLECTIONS FROM A CLIENT

"I really didn't even realize I was pregnant until I heard my baby's heartbeat. Then I saw her heart beating on ultrasound and found out it was a girl. I'm amazed to think my baby has all her systems developed and functioning so early."

Nursing Tip

FETAL DEVELOPMENT

To provide clients with education and support, you must know and understand the stages of embryonic and fetal development, such as when fetal heart tones (FHTs) can first be heard. FHTs confirm the presence of a fetus and rule out gestational trophoblastic disease (hydatidiform mole).

child's first teeth (baby teeth). The liver primarily produces red blood cells. The heart rate is 120 to 160 beats/min. The urogenital tract completes its development, well-differentiated genitals appear, and the kidneys begin to produce urine. The limbs are long and slender, with well-formed digits. The fetus can curl the fingers toward the palm and make a tiny fist. Ossification centers begin to form in the bones. The legs are still shorter and less developed than the arms. Ultrasonographic devices can easily ascertain spontaneous movements between 6 and 12 weeks.

13 to 16 Weeks

At 13 weeks, the fetus weighs 2 to 2½ ounces (55 to 60 g) and is about 3.6 inches (9 cm) in length. Fine hair (**lanugo**) begins to appear, especially on the head. The skin is transparent and the blood vessels are clearly visible. Active movements are present; the fetus stretches and exercises its arms and legs. The fetus begins making sucking motions, swallowing amniotic fluid, and producing meconium in the intestinal tract. Bronchial tubes are branching out in the primitive lungs, and sweat glands are developing. Fetal heart tones may be heard for the first time with a doppler device. The liver and pancreas begin to function. By the beginning of week 16, skeletal ossification is clearly identifiable. Muscle tissue and the body skeleton are developed, resulting in the fetus being straighter in body position.

17 to 19 Weeks

This is a period of somewhat slower growth, but the fetus becomes more active. The mother may feel fetal movements. Rapid brain growth occurs during this time, and myelination of the spinal cord is initiated. The fetal heart tones may be heard through a stethoscope. The fetus actively sucks and swallows amniotic fluid. The kidneys continue to secrete urine into the amniotic fluid.

20 to 23 Weeks

The fetus now measures about 8 inches (19 cm). Fetal weight is between 15.2 to 16.3 ounces (435 and 465 g).

The head is covered with fine hair, and the eyebrows and eyelashes are beginning to form. Lanugo covers the entire body and is especially prominent on the shoulders. Subcutaneous deposits of brown fat, which has a rich blood supply, makes the skin less transparent. Nipples appear over the mammary glands. The fetus has nails on both fingers and toes. The fetus begins to produce antibodies, and passive antibody transfer between the mother and fetus is established. **Meconium** is present in the upper intestines. Muscles are well-developed, and the fetus is active. Fetal movement is now strong enough to be felt by the mother.

24 Weeks

The fetus at 24 weeks reaches a length of 11 inches (28 cm) and weighs about 1 lb, 10 oz (780 g). The hair on the head is longer, and the eyebrows and eyelashes are formed. The eye is structurally complete and soon opens. The alveoli of the lungs are just beginning to form, and surfactant is present. The fetus has a reflex handgrip and, by the end of 6 months, a startle reflex. Skin covering the body is reddish and wrinkled, with little subcutaneous fat. Skin on the hands and feet has thickened, with skin ridges on the palms and soles, forming distinct footprints and fingerprints. The skin over the entire body is covered with a protective cheese-like, fatty substance secreted by the sebaceous glands, called vernix caseosa. Meconium is present in the rectum.

25 to 28 Weeks

At 6 months, the fetal skin is red, wrinkled, and covered with vernix caseosa. The fetus at 28 weeks is about 14 to 15 inches long (35 to 38 cm) and weighs 2 lb, 10 oz to 2 lb, 12 oz (1200 to 1250 g). During this time, the brain is developing rapidly, and the CNS is complete enough to provide some degree of regulation of body functions. The eyelids open and close under neural control. The alveoli of the lungs mature, and surfactant is present in the amniotic fluid. Even though the lungs are still physiologically immature, they are sufficiently developed to provide gas exchange. A fetus born at this time requires immediate and prolonged intensive care to survive. If the fetus is a male, the testes begin to descend into the scrotal sac.

29 to 32 Weeks

The fetus is gaining weight from an increase in body muscle and fat and weighs about 4 lb, 6 oz (2000 g) with a length of about 15 to 17 inches (38 to 43 cm). The CNS has matured enough to direct rhythmic breathing movements and has partial control of body temperature. At 30 weeks, the pupillary light reflex is present. The fetus responds to sounds outside of the mother's body. The fetus begins storing iron, calcium, and phosphorus. Bones are now

Research Highlight

Fetal Hemodynamic Changes

Purpose

To assess the relationship between the pressure pulses and flow velocity in the fetal descending aorta in fetuses with intrauterine growth retardation compared with fetuses with normal growth development.

Method

A serial study done between the 21st and 40th weeks of gestation was conducted on 22 pregnant women who had normal fetal growth, 25 pregnant women with fetuses who were small for gestational age (SGA), and six women with fetuses that were large for gestational age (LGA). Echocardiographic tracking was used to measure resistance and changes in fetal blood pressure.

Findings

Normal fetal growth was associated with an increase in systolic and diastolic diameters in the fetal descending aorta and advancing gestational age. SGA fetuses also had the similar pattern; however, there was a definite increase in both the systolic and diastolic pressures with increasing fetal weight.

Nursing Implications

It may be possible to measure the pressure pulse in relationship to velocity, thus identifying potential circulatory abnormalities. Ultrasound technology can be used to measure fetal blood circulation and systolic and diastolic pressure and velocity. This may help in identifying fetuses who are at risk.

Mori, A., Iwabuchi, M., & Makino, T. (2000). Fetal haemodynamic changes during fetal development evaluated by arterial pressure, pulse, and blood flow velocity. *British Journal of Obstetrics and Gynecology*, 107, (5), 669–677.

fully developed but are soft and flexible. In males, the testicles may be located in the scrotal sac but are often still high in the inguinal canal.

33 to 36 Weeks

The fetus is less wrinkled because of increasing deposits of subcutaneous fat. At 36 weeks, the fetal weight is usually 5 lb, 12 oz to 6 lb, 11.5 oz (2500 to 2750 g), and the crown-heel length of the fetus is about 16 to 19 inches (42 to 48 cm). Lanugo is beginning to disappear, and the nails reach the edge of the fingertips. By 35 weeks, the fetus has a firm grasp and exhibits spontaneous orientation to light. An infant born at this time has a good chance of surviving but may require some special care.

38 to 40 Weeks

The fetus is considered full-term at 38 weeks after conception. The length can vary from 19 to 21 inches (48 to 52 cm). The weight at term is approximately 6 lb, 10 oz to

7 lb, 15 oz (3000 to 3600 g) (Figure 20-7). The skin is pinkish immediately after birth. African American infants' skin color darkens within 1 to 2 hours after birth. There is a small amount of lanugo left on the upper arms and shoulders. Vernix caseosa is present, with heavier deposits remaining in creases and folds of the skin. The body and extremities are plump, with good skin turgor, and the fingernails extend beyond the fingertips. The chest is prominent but still a little smaller than the head, and mammary glands protrude in both genders. As the fetus enlarges, amniotic fluid diminishes to about 500 ml or less, and the fetal body mass fills the uterine cavity. The fetus assumes what is referred to as its position of comfort. The head is generally pointed downward, following the shape of the uterus (and also possibly because the head is heavier than the feet). The extremities and often the head are flexed. After 5 months, feeding patterns, sleeping patterns, and activity patterns became established, so the fetus at term has its own body rhythms and individual style of response. The testes are in the scrotum or are palpable in the inguinal canals.

Figure 20-7 Fetal size by gestational age.

Web Activities

- Visit the March of Dimes website to review fetal growth and development: <http://www.noah.cuny.edu/pregnancy/march-of-dimes/pre-preg.plan/babygrow.html>
- Identify two ways that you could incorporate the information provided at this site into your nursing care plan for mothers who are in the first trimester, second trimester, and third trimester.
- Identify two websites that can provide information on maintaining a healthy lifestyle during pregnancy. Evaluate the sites for their reliability and the scientific accuracy of data. Do the sites provide additional resources for individuals seeking more information?

Key Concepts

- ✿ Fertilization occurs in the uterine tube within 24 hours after ovulation, and implantation occurs approximately 6 days after fertilization.
- ✿ Organ systems and external features develop during the embryonic period (between third to eighth week after fertilization). The embryo is now most vulnerable to teratogenic exposure.
- ✿ Refinement of organ structures and function occurs from 10th week to the time of birth.
- ✿ The placenta carries out two major functions: transport and exchange of products between the fetus and the mother and hormone production.
- ✿ Fetal circulation is supported by the umbilical cord, ductus venosus, placenta, foramen ovale, and ductus arteriosus, and it is dependent on maternal placental circulation.
- ✿ Fetal development proceeds cephalocaudal and proximal to distal.
- ✿ Fetal development proceeds from generalization to differentiation.

Review Questions and Activities

1. When does implantation occur?
2. How is the embryo nourished before the placenta develops? After the placenta is developed?
3. When is the embryo susceptible to damage from teratogens?
4. What is the difference between the time of fertilization and implantation? Which time is used in calculating gestational age?
5. How does fetal development progress? Describe the sequence.
6. What is the function of amniotic fluid?
7. Attend an antepartal testing clinic: interview personnel that conduct antepartal testing and identify the preparation, purpose, process, and risks for each test. Ascertain what follow-up is routinely done for clients with abnormal test results.
8. Find a research article on fetal development and determine how the study results can be applied to your nursing practice.
9. View the film “Miracle of Life,” produced by WGBH for “NOVA.”

Environmental Risks Affecting Fetal Well-Being

Sometimes it is difficult to determine how much choice a woman has regarding her environment and lifestyle. Consider these questions as you reflect on your own feelings about reducing risks in pregnancy:

- *Have I ever tried to break an unhealthy habit, such as smoking or overeating? How difficult was it?*
- *Do I feel angry or disgusted when I hear about pregnant women using illegal drugs that may harm their fetuses? What would it be like for me to provide nursing care for a pregnant woman who uses drugs?*
- *How do I feel about making home visits to pregnant women in neighborhoods where violence occurs or where tuberculosis has been reported?*
- *If I were pregnant and my job increased my risk of miscarriage, would I stop working even if I were the only wage earner in my family?*
- *Is my home neighborhood at risk for a nuclear or chemical accident? How could I find out whether the soil or air has dangerous pollutants?*

Competencies

Upon completion of this chapter, the reader should be able to:

1. Describe contaminants found in air, water, food, and soil that may increase the risks to pregnant women.
2. Discuss threats to fetal well-being found in some workplaces and job requirements.
3. Explain how stress and strain may increase the risks to pregnant women.
4. Teach the client which food products and common medications to avoid during pregnancy.
5. Identify several types of resources that may assist a woman who has a chemical dependency to change her behavior.

Early physicians and scientists believed that the mother's body protected her fetus from harm and that the womb was a peaceful and safe setting for new life to begin. They believed that the mother's skeleton and integumentary system shielded the fetus from injuries. The placenta was considered a filter that would remove any dangerous substance before it diffused into the fetal bloodstream.

Although most pregnancies proceed normally and result in healthy newborns, we now know that some substances and events in the environment can increase the risk of death or injury to the developing fetus. Many chemicals diffuse readily from the maternal bloodstream into that of the fetus. Radiation and heat reach fetal tissue and can affect fetal development. Violent injury to a mother also may injure her fetus. Fetal growth and development are intimately affected by the mother's geographic location; chemical exposures; stresses at work and at home; use of medications and other substances, some of which are illegal; and infections, some of which may have been acquired by risky behavior.

Approximately 3% to 5% of newborns have some form of congenital anomaly. More than half of congenital malformations have an unknown cause. Genetic defects and inherited tendencies brought on by environmental risks taken together explain about a third of all defects.

The role of the registered nurse in caring for pregnant women is to:

- Assess clients for environmental and behavioral risks.
- Design individualized plans of care that support women in reducing risks in their lifestyles.
- Intervene using teaching, support, observations, and referrals to minimize environmental risks in pregnancy.
- Provide ongoing evaluation of maternal and fetal well-being so that care can be tailored to each client's changing needs.

This chapter begins by examining the larger picture of how regional geography and political environments can create risks for pregnant women. The focus then narrows to the workplace environment, centering on how a woman's job, which may be a means of economic survival, can increase risks to fetal survival. Last, home environment, personal lifestyle, and behavior are considered to determine how these factors can be modified through nursing interventions to reduce fetal risk.

RISKS RELATED TO GEOGRAPHIC LOCATION

A woman may be at risk for a poor pregnancy outcome simply as a result of the geographic location of her home or neighborhood. Conditions and substances in a woman's environment affect her health and that of her fetus. Many

women may be unaware of the risks faced from the environment. Nurses can identify women whose surroundings hold threats to well-being and intervene to promote safety during pregnancy.

Nuclear and Chemical Accidents

Residents in modern nations of the Western hemisphere are exposed daily to small amounts of **ionizing radiation** (energy in wave or particle form, such as X-rays) that is capable of releasing ions from irradiated tissue. Background radiation in the atmosphere has no measurable effect on health. In catastrophic industrial or warfare-related accidents, however, pregnant women can be exposed to large amounts of chemicals or radiation. Fortunately, these events are rare.

The fetal central nervous system (CNS) is vulnerable to high-dose radiation, particularly between 7 and 15 weeks' gestation when neurons are developing rapidly and the cerebral cortex is being formed. In the 1920s it was noted that women who received radiation to the pelvic area as part of medical treatment and later were found to be pregnant had increased risks of delivering newborns with microcephaly and CNS disturbances. Infants born to Japanese mothers in Hiroshima and Nagasaki after the atomic bombings of 1945 also had increased rates of microcephaly and mental retardation, with the risk of retardation increasing with the dose of radiation to which mothers were exposed. Children exposed to radiation also experienced retardation of growth and mental development after birth (Persaud, 1990).

In the late 1980s, a catastrophic nuclear power plant accident in Chernobyl, in the former Soviet Union, released large amounts of radioactive cesium, resulting in an unusually high incidence of neural tube defects and other malformations in infants born in the months after the accident (Persaud, 1990). Women living in the wider region surrounding the area of the accident also experienced greater than normal risks of spontaneous abortions and fetal growth retardation (Muratova et al., 1994).

Industrial chemicals also pose a danger to developing fetuses when released into the environment in large quantities. In 1984, at Bhopal, India, nearly 40 metric tons of methylisocyanate were released from a U.S.-owned pesticide plant. Among many other serious health consequences to residents was a spontaneous abortion rate in women in the region nearly four times above normal; perinatal and neonatal mortality rates also were higher, although the rate of birth defects did not increase (Bajaj, Misra, Rajalakshmi, & Madan, 1993).

Another chemical once produced for agricultural use in treating seed to prevent the growth of fungi is methyl-

mercury. In Iraq, in 1971 and 1972, the government distributed treated seed to farmers for planting the next spring. A severe drought had limited that year's harvest, however, and many families used the grain to bake bread. They soon showed signs of mercury poisoning, including paresthesias and other CNS disturbances. Close to 5,000 people died. Mothers who survived delivered children with severe CNS damage, including cerebral palsy and reduced brain growth.

Mercury played a role in another environmental disaster, in Minamata Bay off the coast of Japan in the early 1950s. An inorganic form of mercury used in chemical production had been released into the ocean, where microorganisms converted it to the deadly methylmercury. Fish became heavily contaminated. Japanese who ate these fish experienced the same health problems and fetal CNS damage as did the Iraqi victims of mercury poisoning. Since these two disasters, use of mercury in industry and agriculture has been more carefully controlled.

Pesticides

Pesticides are chemicals designed to kill insects, rodents, or other unwanted lower life forms harmful to crops or human habitation. **Herbicides**, chemicals designed to kill unwanted plant life, such as weeds, are often classified as pesticides. Humans are exposed to these chemicals through contact with contaminated air, soil, and water, and through consumption of foods treated during planting and cultivation. Humans also may eat fish or livestock that have ingested the chemicals from contaminated environments. Pesticides and herbicides are widely used not only in the agricultural industry but in homes, lawns, and gardens to destroy insects and weeds.

Over fifty pesticides have been identified as **teratogens**, substances that in doses of one thousand times or less the usual human exposure have been found to interfere with the formation or normal development of the human fetus. Some of the more commonly known harmful pesticides include Captan, copper sulfate, dichlorodiphenyltrichloroethane (DDT), and diethylmetatoluamide, the active ingredient in OFF. Herbicides include 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), used until 1970 along roadsides to control weeds; Agent Orange, used by U.S. military forces to destroy crops and remove leaves from trees in the Vietnam conflict; and dioxin, not an herbicide in itself but a long-lasting byproduct of the manufacture of other herbicides. Pesticides and herbicides appear to increase the risks of spontaneous abortion and fetal death and also can result in more subtle malformations, such as cleft lip or extra fingers (Needleman & Bellinger, 1994).

One group of women at particular risk of pesticide exposure during pregnancy is migrant workers and female members of agricultural laborer families. By living near

fields, vineyards, or orchards where pesticides are used, women may absorb high doses over time. The chemicals can accumulate in the liver and other body tissues, including fetal tissue. Women who are malnourished may face even greater maternal and fetal risks, if the maternal or fetal liver is not functioning well enough to detoxify the chemicals in the bloodstream (Needleman & Bellinger, 1994).

Another group of women at risk are those whose partners work with these dangerous chemicals. Either through the effects of the chemicals on male gametes or exposure of pregnant women to substances on their partner's clothing, paternal pesticide and herbicide exposure has been linked to spontaneous abortion and birth defects (Sever, Arbuckle, & Sweeney, 1997).

Although many dangerous pesticides have been banned by industrialized nations, risks still exist for women in agricultural regions of developing countries. As new pesticides are invented, their risks may emerge over time. All new products used in the United States must be tested for safety and approved by the Environmental Protection Agency. The human effects of chemicals are difficult to isolate because many substances are present in the environment, including residues from harmful products used in past years. Most products are tested on animals before being approved for human use; however, the effects on animal fetuses may be different from those on human fetuses. Testing must be adequate to ensure that these compounds are safe for human exposure. Nurses can advocate for complete safety testing of these products before they are released for public use.

Industrial Contaminants

Factories, machines, furnaces, and automobiles are among the many sources of pollution of soil, water, and air. Waste products or accidental spills of harmful products into the environment are a major complication of industrialization. Some of the effects of these products on human reproduction have been studied. Other substances have been studied only in animals.

Heavy Metals

Heavy metals, chemical substances such as lead or mercury, are byproducts of industry that may be found in the environment. Methylmercury, already discussed as a hazard when released accidentally, can be present in low levels in lakes. These low levels of mercury in lake water can accumulate in the tissues of fish. In some areas of the Great Lakes, the Adirondacks, Canada, and Florida, fish flesh has been found to contain 3 ppm of mercury, whereas 1 ppm is considered the level at which safety concerns should be raised. Women may consume large

amounts of these fish throughout pregnancy. In two studies, one of Cree Indians in northern Quebec and the other in New Zealand, the hair of mothers who consumed fish in large amounts during pregnancy showed evidence of mercury exposure. Their children were more likely than were other children to show delayed motor development or abnormal muscle tone and reflexes (Needleman & Bellinger, 1994).

Lead has been known to cause reproductive problems since the early twentieth century. Lead exposure can occur as a result of water or air pollution; from exhausts of cars using leaded gasoline; and in workplace exposure in industries such as smelting, battery and paint manufacturing, and typesetting. Exposures to high levels of lead during pregnancy can cause miscarriage, fetal demise, and prematurity and can lead to later developmental and growth delays in children (Needleman & Bellinger, 1994). Women whose male partners are exposed to lead also face increased risks of fetal malformations (Sever, 1994). Arsenic, lead, and mercury in mothers' drinking water have been linked to increased risks of cardiac defects and other adverse outcomes in newborns (Aschengrau, Zierler, & Cohen, 1993).

Critical Thinking

Activism to Reduce Harmful Substances in the Environment

Nurses have been active in advocating for public health since the profession was first recognized. Continuing in that tradition, the American Nurses Association (1996) issued a position statement on lead poisoning and screening in 1994. The Association stated its support of:

- Screening and intervention for lead poisoning in children.
- Efforts to make lead poisoning a reportable disease.
- Community outreach and funding to identify and clean up high-risk residences and neighborhoods.
- Legislation restricting the amount of lead in manufactured products.

Are you aware of activism taking place in the community of your home or college?

Are nurses among those in your state who are calling for a safer environment?

Polychlorinated and Polybromated Biphenyls

Polychlorinated biphenyls (**PCBs**) and polybromated biphenyls (**PBBs**), chemicals now banned but once produced in industry, are halogenated aromatic hydrocarbons used in the production of flame retardants, coolants, and sealants. These chemicals are highly stable and thus last for long periods of time in the environment and the human body. Exposure to PCBs and PBBs in pregnancy is hazardous, causing spontaneous abortion, growth deficits, and other fetal problems. In addition, there is some evidence that abnormal genetic syndromes may result from the father's exposure to vinyl chloride (Colie, 1993).

Although manufacture has been banned in the United States since 1979, these compounds still contaminate air, soil, water, and foods in some regions, including fish from the Great Lakes. These chemicals are present in electrical equipment manufactured before the 1979 ban and in landfills (Needleman & Bellinger, 1994). PCBs and PBBs are extremely fat-soluble, which results in concentrations in fatty tissue and breast milk of up to one hundred times those of maternal serum levels. In one incident in Japan, mothers who consumed PCB-contaminated cooking oil delivered infants with dark-pigmented skin, gum hyperplasia, and low birth weights (Office of Technology Assessment, 1985). Breast-fed infants whose mothers were exposed to PCBs and infants whose cord blood showed PCB exposure during pregnancy had lower cognitive performance and increased risk of developing attention and learning difficulties later in childhood (Needleman & Bellinger, 1994).

Solvents

Solvents, organic compounds widely used in industry to clean and manufacture mechanical or electronic components, are hazardous to fetal well-being. Solvents are found in dry-cleaning products, spray adhesives, paints, nail polish removers, felt-tipped pens, and many other products. Solvents may be used as mind-altering drugs by inhaling the agent. Either maternal or paternal exposure to toluene in the workplace has been associated with cardiovascular malformations (Sever, 1994), and paternal exposure to toluene has been linked to increased rates of miscarriage and anencephaly (Colie, 1993).

Carbon Monoxide

Carbon monoxide is a colorless, odorless, and extremely toxic gas. It is produced when burning occurs, including in internal combustion engines. The fetus may be exposed when a pregnant woman is exposed to automobile or furnace exhaust, or to cigarette smoke. Studies in animals have shown that maternal carbon monoxide exposure has

Critical Thinking

Environmental Racism?

Since the 1980s, Americans have been concerned that polluting industrial plants, toxic waste dumps, sewage discharge areas, and incinerators have been situated in communities whose residents are least able to speak out against these dangers—in low-income urban and rural areas populated by people of color and immigrants, and on Native American lands (Bullard, 1994; Szasz, 1994). In 1991, the First People of Color Environmental Summit gathered and put forth principles of environmental justice, and in 1994 then-President Clinton formed an Interagency Working Group charged with identifying and addressing disproportionately adverse human health or environmental effects of policies and programs on minority and low-income populations.

Can you identify areas of high pollution or environmental risks in your community that are located in low-income, minority-populated areas?

Is there any community resistance to the dangers?

Does the need for jobs and tax revenue from these industries outweigh the harms to the environment and human health?

What can nurses do to help educate people about the health effects of environmental hazards?

led to fetal death, neurologic abnormalities, and low birth weights (Needleman & Bellinger, 1994). The effects of cigarette smoke are discussed later in this chapter.

Rural or Urban Residence

Living in a rural or urban area may increase a woman's risks of pregnancy and birth complications. Women living in isolated rural areas may be hindered by distance or terrain from obtaining prenatal care or seeking help for problems that develop during pregnancy. These women also may have limited education and have received little assistance in improving hygiene and preventing disease. In contrast, urban living has its own unique stresses and dangers that create different types of pregnancy risks. Women living in urban areas who have low incomes are especially vulnerable to the harmful effects of poor living conditions, poor nutrition, and lack of health care.

Obstetrical care by family doctors and general practitioners in some rural areas is declining. For example, in

Mississippi, a 1993 survey revealed that although the number of obstetricians had remained steady over 8 years, a significant proportion of general and family practitioners either had stopped providing pregnancy care or were planning to stop. Doctors cited costs of malpractice insurance, concerns about litigation, and lack of time as reasons for terminating prenatal care services (Copeland et al., 1993). In many rural areas, women must travel long distances to obtain preventive care, including prenatal care and well-baby care.

Living in a rural area, however, does not always lead to poor pregnancy and birth outcomes. For example, although women in rural areas of Wisconsin were found to receive less prenatal care overall than did women in urban areas of the state, the urbanites with inadequate prenatal care were most likely to deliver low-birth-weight infants (Hueston, 1995). This study suggests that other problems in the urban environment had an especially harmful influence on these women.

Nurse researchers have determined that health behaviors and demographic risk factors such as low income and limited education were more important in predicting low birth weight than was urban or rural residence. Rural women were more likely than were urban women to be single, poorly educated, and of African American descent. They had lower incomes, lower pregnancy weight gain, and poorer nutrition than did the urban group. However, urban women were more likely to smoke and use illicit drugs. These factors rather than location alone created the risk of low birth weight (Alexy, Nichols, Heverly, & Garzon, 1997).

Health behaviors and health care use can be influenced by nurses who design and run outreach services and innovative health care agencies serving both urban and rural women. When nurses and others have developed comprehensive outreach programs to underserved rural areas, birth outcomes have improved (Boettcher, 1993; Carcillo et al., 1995). One well-known example of a nursing effort to bring safe maternity care to a very remote area is the Frontier Nursing Service, founded by Mary Breckinridge in Kentucky in 1925 (Figure 21-1). Nurse-midwives lived in remote mountain areas and provided comprehensive public health care to whole districts of poor families. Not only birth outcomes but the health of whole families was improved by this important service, which continues today (Frontier Nursing Service, 1997).

Warfare and Political Violence

Living in a frightening environment under threat of injury or death creates extreme risks for pregnant women. Both the injuries pregnant women have suffered as bystanders

Figure 21-1 Under the leadership of Mary Breckinridge, nurse-midwives of the Frontier Nursing Service have reduced the risks of geographic isolation and poverty for rural Kentucky families. (Courtesy of Frontier Nursing Service, Hyden, KY)

in armed conflicts and the deprivation and the extreme stress they have endured during war have been found to harm fetal development.

During World War II, women in Norway, the Netherlands, and other regions experiencing extreme food shortages and harsh conditions, along with women who received inadequate food in the third trimester of pregnancy, were at high risk for fetal growth retardation. Moreover, their daughters' pregnancies are now showing the long-term effects of malnutrition. Women who themselves were exposed to famine during the first and second trimesters of their mothers' pregnancies, although their own birth weights were normal, are more likely to deliver low-birth-weight and preterm infants (Lumey, Stein, & Ravelli, 1995).

The stress of living in a war zone affects prenatal health and newborn outcomes of otherwise healthy and well-nourished women. Maternal blood pressure was found to be increased by war stress during the Israeli Yom Kippur war, especially in young women whose husbands may have been serving in the front lines (Rofe & Goldberg, 1983). During civil war in Chile, women who lived in neighborhoods with high rates of bomb threats, political

demonstrations, military presence, and undercover surveillance were significantly more likely than were women from neighborhoods with low violence to experience pregnancy complications (Zapata et al., 1992).

In war-torn regions of Croatia, a slight overall increase in prematurity was seen. The greatest risk, however, was suffered by women who were expatriated or exiled from their native regions as a result of the conflict. Women refugees were twice as likely to deliver prematurely, probably due to fear, deprivation, and loss of prenatal services (Kuvacic et al., 1996). In babies born in a Sarajevo hospital during that war, perinatal mortality increased from 15.8 deaths per 1,000 to 36 per 1,000, and the rate of malformations increased from 0.4% before the war to 3.0% during the war (Simic et al., 1995).

The Persian Gulf conflict in 1990 and 1991 also revealed risks to pregnant women. In Kuwait, significant increases in the rates of spontaneous abortions, low birth weights, and major anomalies were observed in 1991 and 1992, and stillbirth and perinatal mortality increased in 1991 (Makhseed et al., 1996). In the neighboring country of Israel, which suffered Iraqi missile attacks during the Gulf War, transient fetal bradycardia was associated with air-raid sirens (Yoles et al., 1993). However, birth outcomes were not affected (Schenker & Mor-Yosef, 1993).

Effects on newborns of their fathers' exposures to chemicals during military activities has been a concern (Figure 21-2); however, no definite harmful effects have been observed. Men exposed to Agent Orange and dioxin during the Vietnam war had changes in sperm formation (Colie, 1993) but they could not be definitely linked to increased risks of delivering newborns with malformations or illnesses. However, these chemicals have been shown to cause reproductive problems in animals (Wolfe et al., 1995).

RISKS RELATED TO EMPLOYMENT

Most pregnant women are employed outside the home. Work itself does not appear to increase pregnancy risks; in fact, in one California county, employed African American women at all income levels were less likely than were unemployed African American women to deliver low-birth-weight infants (Poerksen & Petitti, 1991). Work may increase women's access to health care, sense of well-being, physical fitness, and financial autonomy and may have other healthy effects. However, work also may bring women into contact with harmful substances and physical dangers. Unfortunately, very few of the thousands of chemicals and other risks in modern workplaces have been studied for their effects during pregnancy. Predictions of possible risks often are based on assumed exposures, anecdotal evidence, and animal studies.

Figure 21-2 Exposure of either the male or female parent to harmful chemicals during war can increase pregnancy complications. This Persian Gulf War soldier is packing her gas mask before being deployed to Saudi Arabia for Operation Desert Storm. (Courtesy of Defense Visual Information Center)

Heat and Radiation

Work environments that include the presence of ovens or furnaces and outdoor work in hot climates expose the pregnant woman to excessive heat. As yet, no definite evidence exists of pregnancy harm specifically caused by exposure to heat, or cold, in the workplace (Gold & Tomich, 1994).

Radiation in the workplace comes from a variety of sources. Ionizing radiation is used in diagnostic and therapeutic x-rays studies. Radiation is also used during chemical processing, food and chemical preservation, and sterilization. Because some of these industrial processes are relatively new, the hazards to developing fetuses of women workers are not yet fully understood.

Diagnostic x-ray procedures are considered safe by some scientists when they involve less than 0.05 Gy of radiation; however, complete avoidance of X-ray exposure during the first 15 weeks of pregnancy is recommended.

Figure 21-3 Despite early concerns, radiation from computer monitor screens does not appear to increase the risk of pregnancy complications.

Exposure to greater than 0.2 Gy of radiation during pregnancy is known to cause birth defects, and lower-level exposures of 0.01 to 0.10 Gy have been linked to leukemia and mental retardation in children. Employers have been advised by federal agencies that exposure during any potential pregnancy should be limited to no more than 0.005 Gy (Office of Technology Assessment, 1985). Radiology workers in health care agencies and nurses working in areas where x-rays are frequently used should wear meters to detect cumulative radiation exposure.

Video display terminals, or computer monitor screens, are a potential source of exposure to low-level electromagnetic radiation for many employed women (Figure 21-3). Some clusters of spontaneous abortions and birth defects were reported in women computer workers in the early years of computerization; however, many subsequent studies using careful measurements and controls have shown no increase in the risk to pregnancy (Gold & Tomich, 1994).

Chemical Exposure

Heavy metals, solvents, pesticides, and other harmful chemicals are present in the workplaces where these products are manufactured or used in producing other products. Many chemicals are so new that their effects on pregnancy are not fully understood, although animal evidence is used to estimate human risks in pregnancy. In the United States, each workplace is required by law to maintain Material Safety Data Sheets (MSDS) listing all chemical substances to which workers may be exposed, their components, any toxic effect, and protective measures being taken; each workplace also must have in place a Hazard Communication Program that educates workers about these substances (Stanhope & Lancaster, 1996).

As described earlier, exposure to metals such as lead and mercury is hazardous in pregnancy, and these metals are present in some manufacturing plants. Other substances with potential risks include arsenic, which is produced as a byproduct of copper and lead smelting and is present in ceramics, paints and dyes, wood preservatives, and rat poison. In addition, pesticides and chemicals that are hazardous to women working in agricultural jobs are equally hazardous to women who work where these substances are manufactured.

When analyzed by occupation, certain job categories appear to have increased reproductive risks. Pulp and paper workers, laboratory workers, textile workers, and agricultural workers have been found to be at some increased risk, as have women exposed to solvents in factory work. Solvents include toluene, which was noted earlier as a hazardous substance in the environment and in some home products such as glues. Exposure to toluene and other solvents in the workplace has been linked to increased risk of spontaneous abortion along with fetal oral, renal-urinary, and gastrointestinal (GI) defects (Gold & Tomich, 1994). Solvents are used in many modern industries, including microchip manufacturing. Women may also be exposed in industrial settings where metal parts are cleaned or painted. Solvents also are present in some anesthetic gases such as trichloroethylene and ether.

Although it is difficult to measure women's exposures to these common chemicals, and not all studies have shown poor outcomes, animal studies have shown problems with development of the fetal nervous system. Infants of women exposed in workplaces (including operating rooms) and of women who used spray adhesives have had greater than normal incidences of fetal death and congenital defects. Nurses should advocate for extreme caution by employers using toluene and insist that manufacturers monitor worker exposure and minimize risks.

Anesthetic agents, including nitrous oxide, halothane, and cyclopropane, have been blamed for increased rates of spontaneous abortion and birth defects among operating room workers; however, the quantity of exposure is difficult to measure, and the effect is not consistent. Safety measures in the operating room that reduce leakage of gases and volatile liquids are important to minimize risks. Another area of risk in hospitals is where instruments are sterilized. Ethylene oxide is a gas used in sterilization as well as in the manufacture of antifreeze. This chemical is known to cause genetic mutations in laboratory experiments, and an increase in spontaneous abortion in sterilization workers has been found in several studies (Gold & Tomich, 1994).

Women who are employed in agriculture, spreading pesticides on crops or working in fields during crop-dusting, are at high risk. For example, in a study of infants born to over 34,000 licensed pesticide applicators in Min-

Critical Thinking

The Case of The Johnson Controls Company

The Johnson Controls Company manufactures lead-acid batteries. In 1982, the company adopted a policy to prevent exposure of pregnant women to lead. This policy barred all fertile women from jobs in which lead exposure was likely. One woman had a tubal ligation to keep her job; however, no fertile women, even those not planning to or likely to become pregnant, were permitted to continue to work. A male employee requested transfer out of the high-lead area to protect his ability to father a healthy child; however, his request was denied.

The U.S. Supreme Court ruled that The Johnson Controls Company policy constituted discrimination in employment based on sex, and that fetal protection, although a worthwhile goal, could not be pursued by discriminatory means. The Court stated that decisions about welfare of future children must be left to the parents, rather than to employers (Bertin, 1994). Women now have the choice to pursue an economic role even if it creates a threat to their reproductive role.

Do you think this decision solved the problem of employment risk?

Should companies protect all their workers from harmful chemicals, regardless of the possibility of pregnancy?

What is your role as a nurse in promoting healthy work policies in industry, and in educating workers?

nesota, the rate of birth defects between 1989 and 1992 was significantly greater than that in infants born to other Minnesota women during that time period. Circulatory, respiratory, urogenital, and musculoskeletal defects were increased, especially in regions where chlorophenoxy herbicides were used, and especially among fetuses conceived in the spring. Women living in these farming areas who were not employed as pesticide applicators also had a lesser but still increased risk of delivering infants with birth defects (Garry et al., 1996).

Fatigue and Physical Risks

Many jobs require women to stand for long periods, lift heavy objects, climb stairs, bend over for long periods (as in picking vegetables), and perform other physical exertion. Simply standing or sitting for an 8-hour workday can

cause significant fatigue. Strenuous activity also results in increased body temperature and thus creates concerns about **hyperthermia**, which is a dangerous elevation in body temperature resulting from fever or external heat sources.

For many women, and particularly for those in urban areas, getting to work involves long commutes on buses and trains, which also can be extremely tiring. Many women are not formally employed but still must engage in

Client Education

Reducing the Risks of Work in Pregnancy

Women who are employed outside the home during pregnancy or who have strenuous responsibilities within the home or family farm can reduce the risks of having infants with birth defects, and preterm infants, or low birth-weight infants by:

- Becoming aware of hazardous chemicals in the workplace and obtaining protective clothing or a work reassignment if exposure is unavoidable. At most companies, the Human Resources Department keeps a listing of hazardous substances information.
- Limiting heavy lifting and carrying at work and home after 20 weeks' gestation, including avoiding carrying children and heavy grocery bags up several flights of stairs. Request work reassignment and use family or home health aid assistance in the home.
- Reducing prolonged standing or sitting. A pregnant woman should take breaks in which she can change position, get up, and walk around if her job involves sitting, or rest with her feet up if her job involves standing. Women who stand at factory assembly lines or cash registers can request a high stool to sit on and a low stool to rest one foot on while standing. If this is not possible, work reassignment should be requested.
- Maintaining adequate food and fluid intake. Pregnant women should have access to drinking water in the workplace and should have at least one meal break and two snack breaks during an 8-hour shift.

Research Highlight

Reproductive Risks for Nurses

Purpose

To determine whether nurses face increased risks to their fetuses during pregnancy. The work environments of nurses may include hazards such as viruses, bacteria, anesthetic and sterilizing gases, antineoplastic drugs, and X-ray films.

Methods

Using data from 1968 to 1980, researchers in Atlanta, GA, analyzed the records of 4,915 babies born with congenital defects and 3,027 babies born without defects. The researchers compared the infants of nurses with infants whose parents had other occupations to determine whether having a nurse as a parent increased the likelihood of a defect.

Findings

Regardless of maternal age, education, and alcohol consumption, children whose mothers worked in nursing during early pregnancy were twice as likely as were those of nonnurses to be born with anencephaly, spina bifida, or coarctation of the aorta, and were more than three times as likely to have urinary system defects. There was no increase in defects among babies whose fathers worked in health care.

Nursing Implications

Because birth defects are quite rare in the general population (3%–5% of births), even if these findings hold true for nurses today, the risk of defects still is quite low. In addition, employers and nurses are better educated than they were in the 1970s about preventing hazardous exposures during pregnancy. Nonetheless, nurses should pay attention to hazards in their environments and alert their employers to potential risks.

Matte, T., Mulinare, J., & Erickson, J. (1993). Case-control study of congenital defects and parental employment in health care. *American Journal of Industrial Medicine*, 24, 11–23.

hard physical work to maintain a family farm, care for children, seek out financial assistance, and perform other activities. Therefore studies of formally employed women also may be relevant to other women.

The activities most likely to cause preterm birth and low birth weight are prolonged standing, long working hours, and lifting heavy objects (Simpson, 1993). Extreme physical effort at work was linked to fetal growth retardation in one study, although standing and walking were not (Spinillo et al., 1996). In another study, physical exertion did not increase miscarriage risks, except for women with a history of two or more previous spontaneous abortions. For these women, standing at work more than 7 hours a day greatly increased their risk of additional spontaneous abortion (Fenster et al., 1997).

In response to studies such as these, the American Medical Association has published guidelines for work limitations during pregnancy (AMA Council on Scientific

Affairs, 1984) that suggest prolonged standing (for more than 4 hours), repeated stooping and bending (more than twice an hour), climbing ladders, climbing stairs more than 4 times per shift, and repeated lifting of over 25 pounds should be restricted after 20 to 28 weeks' gestation. Nurses should make an individualized assessment of each pregnant woman's work-related risks as well as the personal beneficial factors related to work.

Stress

Job-related psychological stress may be as much of a burden to employed pregnant women as is physical exertion. Just as the stress and fear of living in a war zone may cause pregnancy risks, the pressure of a job with low rewards, high demands, low decision-making power, or other causes of worry and pressure may also place fetuses at risk. Some studies have suggested that pregnancy-

induced hypertension is more common in women with low-status jobs with limited decision-making, high job pressures, and little control over their work environment (Landisbergis & Hatch, 1996); for most pregnant women, however, job stress does not seem to lead to preterm delivery (Brett, Strogatz, & Savitz, 1997; Hickey et al., 1995). Clearly, more research is needed before nurses will be able to advise pregnant women on their stress-related pregnancy risks. In the meantime, however, nurses can provide emotional and practical support to employed pregnant women and facilitate support from others.

RISKS RELATED TO HOME ENVIRONMENT AND LIFESTYLE

Although industrial workplaces probably have the most intense concentrations of hazardous substances, the products produced in industry are used in the home. Foods are another source of harmful exposures. Medications and illicit drugs used in the home also can place the fetus at risk. Nurses can reduce some of the pregnancy risks related to home and lifestyle through teaching, home visiting, and ongoing support.

Food Additives and Contaminants

Food preparation and processing involve many chemical substances that serve as stabilizers, colorings, preservatives, leaveners, flavorings, sweeteners, and so forth. Some additives come from natural sources, such as red dye made from beets, and others are produced artificially. Whether an additive is natural or artificial has no bearing on its safety. In fact, artificial additives are often purer and more consistent than are natural ingredients (Food and Drug Administration, 1992).

In addition to compounds added directly to foods, indirect additives occur when a substance used in packaging, storage, or other handling becomes a part of the food in trace amounts. The Food and Drug Administration (FDA) must approve both direct and indirect food additives for marketing in the United States. The manufacturer must provide convincing evidence to the FDA in the form of animal or human studies to prove that based on the best scientific information available, this product is safe for human use. Evidence of safety in pregnancy must also be provided.

Pregnant women often are concerned about additives such as artificial sweeteners and preservatives. Preservatives have not been found to cause birth defects or other problems in pregnancy; however, the nutritional value of processed foods may be less than that of raw or home-

cooked foods. “Diet” soft drinks are a popular beverage for young women. Aspartame, the artificial sweetener in diet drinks, has not been found to cause harm in pregnancy (Briggs, 1995). Saccharin, another artificial sweetener, also is considered safe. Women who are concerned that consumption of these additives early in pregnancy may have caused harm to their fetuses can be reassured that the risk of harm is very low. However, sugar-free and artificially sweetened soft drinks have no beneficial nutritional value.

Caffeine, found in high concentrations in coffee, tea, and some soft drinks, has been linked to risk of spontaneous abortion in the past; however, recent studies indicate that caffeine consumption alone does not increase the risk of prematurity or low birth weight in infants. Many smokers consume more caffeine than do nonsmokers, however, and smokers who drink large amounts of coffee have an even greater risk of having an infant of low birth weight than do smokers who do not drink coffee (Cook et al., 1996; Peacock, Bland, & Anderson, 1995; Shu, et al., 1995).

Food contaminants are bacteria or chemicals that are present in foods in unsafe amounts. The U.S. Department of Agriculture and the FDA regulate and supervise foods for purity and safe processing. Occasionally, however, an accidental contamination occurs. Imported fruits such as raspberries may not undergo the same testing as do U.S.-grown fruit products and may be contaminated by viruses or bacteria. Poorly processed or stored meats also occasionally are found to have harmful levels of illness-causing bacteria, such as *Escherichia coli*. Pregnant women are subject to the same health risks as are nonpregnant women when contaminated food is ingested. Fortunately, there are no known direct risks to fetal development from food contaminated with bacteria.

Lead and mercury contamination of food may pose a greater risk to pregnant women than to the general population. Pregnant women should be advised not to drink hot acidic beverages on a regular basis from mugs that have been glazed improperly with high-lead glazes. The heat combined with the acid in coffee or tea speed the leaching of lead from the glaze into the liquid. Cracked or chipped ceramicware should be discarded. All ceramicware manufactured on a large scale in the United States is tested for safety. Pottery workers and craft groups in the United States currently are being educated about the importance of using safe glazes on all products made of clay that will contain food or drink (Foulke, 1997).

Mercury contamination occurs through consumption of fish from waters with a high mercury content, as noted in an earlier section of this chapter. All fresh, canned, and frozen fish processed and sold commercially, including tuna, is regulated and must meet safety standards. However, some pregnant women may consume fish caught by

sports fishing and thus not subject to testing. Nurses should advise pregnant women to contact local environmental protection or water safety agencies to determine whether high mercury levels have been found in specific fishing locations before consuming fish caught by friends or family (Foulke, 1994).

Medications

Medications are one of the many possible forms in which pregnant women may be exposed to teratogens. It was once thought that the placenta served as a barrier between the fetus and harmful substances in the mother's system. Now it is known that most medications pass to the fetus to some degree. Of the many thousands of medications available today, only a few drugs or certain drug classes have been proven to be teratogens: aminopterin; androgens; angiotensin-converting enzyme (ACE) inhibitors; busulfan, cocaine, when abused; coumarin derivatives; cyclophosphamide; diethylstilbestrol (DES); etretinate; isotretinoin; lithium; methotrexate; tetracycline; thalidomide; the anti-seizure medications carbamazepine, paramethadione, trimethadione, phenytoin, and valproic acid; and dosages of vitamin A over 18,000 IU/day (Briggs, 1995). Other drugs and drug classes have been linked only anecdotally to fetal problems. (Ethanol, also called grain or ethyl alcohol, also is a teratogen.)

Although it is wise to be cautious about taking medications, some pregnant women may require over-the-counter or prescription medications for chronic medical conditions, complications of pregnancy, or discomforts and common illnesses. In addition, women may take potentially harmful medications in the early weeks of gestation, before they realize they are pregnant. In order to provide preconceptual counseling for women who take medications on a regular basis for chronic illness such as diabetes, cardiovascular disease, or seizure disorders, and to provide current and accurate information for women who are pregnant, nurses must be aware of the many factors that affect how chemicals are metabolized during pregnancy.

The nature of the drug itself affects the rate at which it is diffused into the fetal circulation. Medications with high molecular weights, which are highly ionized, that are not readily fat-soluble, or that readily bind to proteins are less likely to diffuse across the capillary membranes between the maternal circulation and the placenta. The stage of pregnancy also affects fetal exposure. Early in pregnancy the membranes between fetal and maternal circulation are thick, making transport difficult; whereas at term the membranes are very thin, making transport easier. The volume of blood circulating through the placenta also greatly increases during pregnancy, which would increase the rate at which drugs are transferred to the fetus.

These factors would suggest that early in pregnancy the fetus is better protected from harm. To the contrary, however, the most vulnerable period for fetal malformations is in the first trimester, particularly weeks 3 through 8 after conception. Even a small amount of a harmful substance can cause damage during this time. Moreover, the blood-brain barrier, which protects the adult CNS from certain harmful substances, does not form until 20 weeks' gestation. Therefore, the CNS is more vulnerable early in pregnancy than it is later, although different periods of pregnancy have factors that increase fetal vulnerability.

Most medications are quite safe during pregnancy. Even during critical periods of organ formation, most drugs present less than 10% risk of fetal damage, compared with the 3% risk of birth defects in the general population. Although the risk of injury is low, nurses must use available information to minimize these risks whenever possible. Nurses should be aware of the major teratogens but also must consult up-to-date reference books and other resources before giving advice about medications to pregnant women. As shown in Table 21-1, prescription medications are rated for safety by the FDA based on available research to date. The ratings are included in all product information and in drug reference materials for physicians and nurses.

Vitamins

Most care providers advise pregnant women to take prenatal multivitamins, which contain the recommended daily allowances of many vitamins and minerals important for the pregnancy. The two minerals most essential to fetal development are calcium and iron. One B vitamin essential to normal CNS development is folic acid, or folate. Pregnant women should receive 0.4 mg/day or more of folic acid, most importantly during the early first trimester when the neural tube forms (Rose & Mennuti, 1994). Some medications, such as anticonvulsants and trimethoprim, increase the need for folic acid. Many health care providers advise nonpregnant women of childbearing age to take a multivitamin tablet daily, because the critical period for neural tube closure is soon after conception, when women may not realize they are pregnant.

Another vitamin, vitamin A, is healthy in therapeutic doses but is teratogenic in certain forms. When pregnant women took vitamin A for acne, in the isomer form of isotretinoin (Accutane®), a high rate of severe defects and spontaneous abortions occurred. In the topical form of the oral medication isotretinoin, tretinoin (Retin-A®), the dose is lower; however, some risk still may exist (Briggs, 1995).

Pain and Fever Relievers

Acetaminophen has been widely used in pregnancy to relieve minor pain and fever, and no fetal harm has been ob-

Table 21-1 Teratogenic Risks of Drugs: FDA Categories

Category	Risk
A	Controlled studies in women fail to demonstrate a risk to the fetus in the first trimester or later trimesters. Possibility of fetal harm appears remote.
B	Animal reproduction studies have not demonstrated a fetal risk, but there are no controlled studies in pregnant women. Or Animal studies have shown an adverse effect but the risk is not confirmed in human studies in the first trimester (and there is no evidence of risk in later trimesters).
C	Studies in animals have revealed adverse effects on the fetus, and there are no controlled studies in pregnant women. Or Studies in women and animals are not available. Drugs should be given only if the potential benefit justifies the potential risk to the fetus.
D	There is positive evidence of human fetal risk, but the benefits from use may be acceptable despite the risk.
X	Studies in animals or humans have demonstrated fetal abnormalities. And/or There is evidence of fetal risk based on human experience. The risk of use in pregnant women clearly outweighs any possible benefit. The drug is contraindicated in women who are or may become pregnant.

Adapted from Spratto, G., & Woods, A. (2002). *PDR nurses' handbook*. Albany, NY: Delmar.

served (Figure 21-4). Aspirin, on the contrary, although consumed inadvertently by many pregnant women, is less safe. Aspirin has been known to cause bleeding problems and premature closure of the fetal ductus arteriosus when taken daily in late pregnancy for chronic illnesses such as arthritis (Rayburn & Conover, 1993). In some special cases, however, it may be used to reduce the inflammatory process blamed for some forms of pregnancy-induced hypertension. Nonsteroidal anti-inflammatory drugs, or NSAIDs, such as ibuprofen (Motrin®) have not been linked to fetal harm; however, because of their similarity to aspirin, most practitioners do not recommend the use of NSAIDs during pregnancy. Narcotic pain relievers such as meperidine or morphine are safe in therapeutic doses but can cause problems when taken chronically or abused. When used in high doses late in pregnancy, fetal sedation, neonatal respiratory depression, and neonatal withdrawal may result (Briggs, 1995).

Figure 21-4 Nurses can help pregnant women recognize which over-the-counter medications are safe for use in pregnancy.

Antihistamines, Decongestants, and Cough Medications

Diphenhydramine (Benadryl®), an antihistamine sometimes taken for nausea, has been linked to malformations in a few cases; however, the evidence is not conclusive, and it may be safely used after the first trimester. Pseudoephedrine (Sudafed®) is considered relatively safe and is the best option for antihistamine use in pregnancy (Conover, 1994). Some decongestants have been linked to anomalies. Chlorpheniramine (Chlor-Trimeton®) has been taken without problems; however, some studies indicate an increased risk of anomalies when used in the first trimester (Briggs, 1995).

Cough medicines (such as Robitussin DM®) containing dextromethorphan and guaifenesin are considered safe when used in therapeutic doses. Medicines containing codeine, however, carry the risks noted previously for narcotics. Codeine also may increase the risk of respiratory tract malformations after first-trimester exposure. It is

Client Education

Medications for the Common Cold

Time, fluids, humidification of indoor air, rest, and good nutrition are perhaps the best medicines for a common cold. If these measures do not bring relief, you can suggest the following medications:

- For fever, body aches, and headache: acetaminophen (Tylenol®)
- For cough: syrup or lozenges containing dextromethorphan and guaifenesin (Robitussin DM®). Lozenges are preferred because they do not contain alcohol.
- For nasal and sinus congestion: pseudoephedrine (Sudafed®), an antihistamine. Decongestants are **not** advised.

important to note that cough syrups containing potassium iodine should be avoided because iodine can severely damage the fetal thyroid.

Gastrointestinal Medications

Constipation can be a major discomfort for many pregnant women. Increased fluid and fiber intake should be tried before medications are added. Stool softeners and laxatives, if needed, are not known to cause fetal harm. Laxative dependence generally is not a problem, because after childbirth the sluggish bowel usually returns to normal function.

Heartburn is another GI discomfort that affects many pregnant women. Antacid preparations containing calcium compounds as the main ingredient are considered safe. Those containing aluminum or magnesium are less well studied, and although no problems have been reported, a calcium-containing preparation is probably a better choice during pregnancy (Conover, 1994). Cimetidine (Tagamet®) and other systemic medications that reduce gastric acid production are fairly new but appear safe for use in pregnancy. Several types are available over the counter.

Sleep Medications

Sedatives such as secobarbital (Seconal®) and pentobarbital (Nembutal®) have been used in all trimesters of pregnancy without problems. Amobarbital has been linked to defects after first-trimester use, however, and neonatal respiratory depression can occur if the drug is given a short time before birth. Over-the-counter sleep aids such as

doxylamine (Unisom®) should be used with caution; however, no definite link to fetal malformations has been established (Briggs, 1995).

Antinausea Medications

Bendectin®, an antinausea medication containing pyridoxine (vitamin B₆) and doxylamine (now found in an over-the-counter sleep aid), was removed from the U.S. market after litigation about possible birth defects. Subsequent research could not prove this association. This medication still is available over the counter in England. Some women experience relief from nausea after taking oral or parenteral doses of B₆ and B₁₂.

Metochlopramide (Reglan®), an autonomic nervous system agent that works by speeding up GI motility to aid stomach emptying, is considered safe in pregnancy. Most other prescription antiemetics (such as perchlorperazine [Compazine®]) are from the phenothiazine group. In modest doses, they are considered safe for use during pregnancy.

Antibiotics

Most antibiotics are safe for use during pregnancy. Indeed, their use may be important because infection can cause serious complications, including preterm labor and fetal death. The penicillins, erythromycin, and many cephalosporins can be safely used in pregnancy. Several types of antibiotics are known or suspected teratogens, however, and their use should be carefully avoided.

Tetracycline and doxycycline can cause malformations early in pregnancy and produce tooth and bone discoloration after 20 weeks' gestation. They are considered teratogens. Drugs in the quinolone group, including ciprofloxacin (Cipro®) and norfloxacin (Noroxin®), should not be used because they may cause joint and bone problems in the fetus, as they have been found to do in infants and young children. Streptomycin, kanamycin, and gentamycin have been known to cause damage to the 8th cranial nerve, including hearing loss, in fetuses exposed during pregnancy. Chloramphenicol has been linked to a "gray baby syndrome" involving cardiovascular collapse in a newborn whose mother had taken it late in pregnancy, and therefore, this drug also should be avoided (Briggs, 1995).

Therapy for tuberculosis should be continued during pregnancy. Isoniazid and rifampin, common treatments, have been linked to isolated defects but overall are considered relatively safe. Women with resistant forms of tuberculosis who need other medications should be referred to a specialist in infectious diseases for treatment planning. Isoniazid and rifampin reduce the amount of vitamin K in the body. Therefore, vitamin K supplementation during labor for the woman and at delivery for the newborn is

Nursing Alert

DRUG THERAPY FOR TUBERCULOSIS

Treatment for tuberculosis requires taking daily antibiotics for a year, or longer. When clients do not take the medication properly, resistant strains can develop and the infection can be spread to others.

Nurses and assistive personnel working in nursing case management systems have been more successful than have other outreach workers at locating clients with tuberculosis in the community and ensuring that medications are taken properly. The American Nurses Association (1996) has called for use of nursing case management teams for all inpatient and outpatient management of tuberculosis treatment. Nurses working in maternal-child health care should refer all clients testing positive for tuberculosis to a case management program for treatment follow-up of both the client and family.

recommended to reduce the risk of **hemolytic disease of the newborn**. This disease results in destruction of the neonate's erythrocytes owing to either isoimmunization (Rh or ABO incompatibility) or an inadequate amount of vitamin K, which leads to an inability to produce clotting factors and consequent risk of hemorrhage (Briggs, 1995).

Anticonvulsants

Pregnant women with seizure disorders face an increased risk of birth defects, although it is unclear how much of these are linked to medications and how much to the disease being treated (Conover, 1994). In addition, to avoid injury during seizures, it is especially important for women with seizure disorders who take anticonvulsant medications to use effective forms of contraception and receive preconceptual counseling to minimize the risks to their fetuses. A change in drug type or dosage may be considered if pregnancy is planned. Folic acid supplementation also will be advised because antiseizure medications interfere with absorption of this vitamin, which is important to reduce the risk of neural tube defects.

Phenytoin (Dilantin®) is the most common antiseizure medication and is associated with a 10% risk of a definite syndrome of malformations. These malformations include growth retardation, hypoplasia of the fingers and toes, and craniofacial changes, such as a broad nasal bridge, a low hairline, epicanthal folds, and a short neck. Mental retardation sometimes is present. Phenytoin also causes a deficiency in vitamin K–dependent clotting factors in about half of exposed newborns. Mothers who take this medica-

tion should receive intramuscular vitamin K during labor, and newborns should receive an increased dose of vitamin K after delivery (Briggs, 1995).

Another common antiseizure medication is carbamazepine (Tegretol®). Although some consider this to be the best choice of an anticonvulsant during pregnancy, like phenytoin, it has been linked to a syndrome of malformations. A third type of antiseizure medication is valproic acid (Depakene®). This medication is considered especially harmful during pregnancy, and women who take this drug should seek consultation immediately with their neurologists to switch to another medication. A fourth drug is diazepam (Valium®), used to treat severe seizures. This drug should be avoided during pregnancy because it has been linked to many fetal problems, including anomalies and neonatal jaundice. Diazepam and related compounds also are used to treat anxiety disorders. They should be replaced with other less dangerous drugs.

All the anticonvulsants are believed to be potent folate **agonists**, drugs that block or reduce the action of this vitamin in the human body. Therefore folic acid supplementation is important, ideally beginning before conception. It is important to remember, however, that seizures are far

Nursing Alert

ANTISEIZURE MEDICATIONS

Women who take anticonvulsants for seizure disorders and who plan pregnancy or discover they are pregnant must take immediate action to reduce the risk of fetal anomalies from these medications. They should:

1. In consultation with their physician, begin taking a folic acid supplement of 0.8 to 1.0 mg/day to reduce the risk of neural tube defects. Most anticonvulsant medications greatly reduce the body's ability to use folic acid.
2. Consult their neurologist to ensure they are taking an anticonvulsant that will control their seizures with the lowest risk of fetal anomalies.
3. Work with their neurologist to determine the lowest dose of medication needed to stop the seizures. One drug rather than multiple drugs should be used whenever possible.

Preconceptual counseling is extremely important for women with seizure disorders. Effective and reliable contraception to prevent unintended pregnancy is another important topic of client teaching for these women.

more harmful to the fetus than is the risk of minor malformations, and women should be counseled about the benefits and risks of taking their medications.

Antianxiety and Antidepressant Medications

Medications used for mental health conditions have differing levels of safety during pregnancy. As already mentioned, antianxiety medications from the diazepam group should be avoided. Alprazolam (Xanax®), a related compound that is one of the most common drugs used to treat anxiety, has been linked to isolated cases of birth defects and neonatal withdrawal (Briggs, 1995) but when used very sparingly may be relatively safe.

Tricyclic antidepressants also have been associated with isolated defects and withdrawal symptoms in newborns but overall are considered fairly safe. The selective serotonin reuptake inhibitor, or SSRI, antidepressants such as fluoxetine (Prozac®), although fairly new, have not been reported to cause adverse effects and appear to be a good choice during pregnancy (Briggs, 1995; Conover, 1994). Lithium, used for bipolar disorder, has caused cardiac defects and neonatal problems for exposed fetuses (Briggs, 1995); however, the incidence of problems appears to be decreased when serum levels are monitored closely and the lowest therapeutic dose is maintained.

Cardiovascular Medications

Drugs used to treat cardiac function and hypertension on an outpatient basis generally are safe in pregnancy. These include digoxin, quinidine, nifedipine (Procardia®), and other calcium channel blockers. When used in therapeutic doses they have not been found to be harmful, and in fact, vasodilation may be important for hypertensive women to enable placental perfusion and fetal oxygenation. There is one exception, however. ACE-inhibitors, such as captopril (Capoten®), have caused severe fetal toxicity in the second and third trimesters of pregnancy, and should be avoided. Diuretics are not advised during pregnancy. By removing water from the plasma, they also reduce the circulating volume to the placenta, and thus place the fetus at risk.

Hypertension that arises during pregnancy or that is present before pregnancy can be treated safely with methyldopa (Aldomet®), labetalol (Normodyne®), or atenolol (Tenormin®); hydralazine (Apresoline®) also may be used. Bedrest is an important first step to manage high blood pressure and reduce edema. Fetal surveillance with regular nonstress tests and periodic biophysical profiles should be initiated for all pregnant women with hypertension regardless of medication use, to observe for

fetal compromise. The mother's renal and liver status also should be carefully monitored.

Anticoagulants

Warfarin (Coumadin®) should not be used in pregnancy because it is known to cause serious fetal defects. Women who need anticoagulation medication, such as those with artificial heart valves or clotting disorders, must be switched to heparin before pregnancy, if possible. This change must be made carefully while observing laboratory clotting values, because thrombosis may occur when drug levels are subtherapeutic. Heparin is a very large molecule and does not cross the placenta. Because heparin can cause bone demineralization when used in high doses, calcitriol should be added to a pregnant woman's medication regimen if heparin therapy will be needed throughout the pregnancy (Briggs, 1995).

Hormones and Steroids

Sex hormones in large dosages can be harmful in pregnancy. Diethylstilbestrol (DES), a potent estrogen given until the early 1970s to prevent miscarriage, is known to cause malformations and epithelial changes in the genital tracts of female offspring and altered semen, epididymal cysts, and other genital problems in male offspring. Estrogens therefore are contraindicated in pregnancy (Briggs, 1995). In very low doses, however, such as with accidental exposure to low-dose oral contraceptives, harm has not been observed (Raman-Wilms et al., 1995). Androgens such as danazol (Danocrine®) may cause masculinization of female fetuses.

Thyroid hormone is safe during pregnancy, and in fact, it is important that mothers with hypothyroidism take adequate thyroid replacement to avoid impaired motor and mental development in their newborns. Drug therapy can be monitored using laboratory values, and doses will need to be increased during pregnancy because thyroid hormone binding increases during pregnancy. The most common antithyroid treatment to reduce hyperthyroidism, propylthiouracil, is safe during pregnancy. Thyroid diagnostic or therapeutic agents containing iodides should not be used, however, because the iodide can destroy the fetal thyroid.

Steroid use during pregnancy generally is safe when needed to treat serious maternal conditions. For example, steroids can be used to control the inflammatory process in bowel disease, asthma, and systemic lupus erythematosus. Topical steroids for dermatologic inflammation can be used safely, as can hemorrhoid treatments containing cortisone. Some steroids cross the placenta more readily than do others. Betamethasone (Celestone®), used to enhance fetal lung maturity, crosses the placenta readily, whereas prednisone does not. When the desired target is not the

Figure 21-5 Pregnant women with asthma should continue to take their medications to prevent respiratory distress, which may also reduce oxygen to the fetus. Most asthma medications are safe in pregnancy.

fetus, the forms that cross the placenta less readily should be used.

Asthma treatments generally are safe in pregnancy. Bronchodilators, such as theophylline, can be used. **Sympathomimetic** agents, such as terbutaline (Brethine®) and isoproterenol (Isuprel®), that stimulate the sympathetic nervous system also are safe. Drugs that can be taken by inhaler are preferable to oral agents; however, oral or IV drugs should be used when needed. It is important to treat asthma promptly and effectively to maintain fetal and maternal oxygenation (Figure 21-5).

Immunizations

Pregnant women may need immunizations to protect against viral infections that threaten health during pregnancy. The inactivated polio vaccine, at one time given routinely in pregnancy, did not cause fetal malformations but did increase the risk of childhood cancers in offspring.

The oral vaccine, now most commonly used, has no known harmful effects to the fetus. Tetanus toxoid has been linked to a slight increased risk of malformations (Briggs, 1995).

The rubella vaccine has not caused fetal rubella syndrome when given accidentally during pregnancy. Because it is a live vaccine, however, its use is avoided in pregnancy, and it is given in the postpartum period instead. Influenza vaccines from live viruses should be avoided; however, newer inactivated virus forms may be safe and should be offered to pregnant women who are immunocompromized and others who may receive important benefits (Briggs, 1995). Likewise, the hepatitis vaccine may be given during pregnancy when a mother is at high risk of exposure to the disease, although immunization during the first trimester should be avoided whenever possible. Vaccines given for travel to tropical countries may be risky during pregnancy; the pregnant woman should consult a specialist in tropical medicine.

In general, few problems are reported with immunizations. However, they should be administered during pregnancy only when the benefits outweigh the risks. For example, for a pregnant woman at high risk of contracting varicella (chickenpox) from her young child who has the disease, the benefit of giving the varicella vaccine is prevention of stillbirth or preterm delivery if she were to develop varicella later in her pregnancy. In this case, the small risk of a reaction to the vaccination outweighs the risks to the fetus.

Alcohol Use

Although public concern tends to focus on illegal drug use during pregnancy, alcohol and tobacco use are much more common and are more common causes of harm to the fetus. Many women who use illicit drugs also use alcohol and tobacco, making it difficult to separate the effects caused by illegal drugs from those caused by the more commonly ingested legal substances. In the 1980s and 1990s, nurses and other health care professionals began to take seriously the risks of alcohol and tobacco use in pregnancy and to become involved in helping their clients to stop using these substances.

Women who use illegal drugs have been found to be much less likely than nonusers to obtain prompt and adequate prenatal care. These women may be afraid of being reported or stigmatized for their drug use, or of losing custody of their newborns. In addition, women involved in illegal drug use are more likely to have chaotic, violent, and risky lifestyles and be ambivalent about continuing their pregnancies (Kearney, 1995). Reaching and gaining the trust of pregnant women who use illicit drugs present special challenges for nurses employed in community health and prenatal care.

Prenatal alcohol use is the leading cause of childhood mental retardation, surpassing Down syndrome (Streissguth, Barr, Sampson, & Bookstein, 1997). Yet prenatal care providers probably spend more time counseling and testing women for fetal abnormalities such as Down syndrome than they do in assessing for and intervening in alcohol use. The National Institute for Drug Abuse has estimated that 18% of newborns are exposed to some alcohol during gestation (Young, 1997).

Heavy alcohol use throughout pregnancy (two or more drinks per day) has a 10% risk of producing **fetal alcohol syndrome** (FAS), which is a collection of physical and behavioral problems seen in children of women who drink heavily during pregnancy. Alcohol-related birth defects may include physical defects such as growth retardation; microcephaly; facial malformations, such as a flat midface, thin upper lip, and low or wide nasal bridge; malformations of joints and organs, such as the heart and kidney; and eye anomalies. FAS may also cause mental retardation, which is associated with microcephaly, and seizure disorders. Behavioral problems such as learning and attention difficulties and hyperactivity also have been associated with FAS. Fetal alcohol effect is a less severe form of alcohol-related problems.

A newborn exposed to alcohol during gestation with normal appearance and weight at birth still may have suffered brain damage. Newborns with low birth weight from maternal alcohol intake usually reach normal size by 8 months of age; however, CNS damage does not improve over time. Large amounts of alcohol cause physical malformations. Even small amounts consumed during pregnancy—so-called social drinking—can cause problems that persist into the teenage years and beyond: CNS damage; subtle cognitive delays; and motor, attention, and learning deficits (Streissguth, Barr, Sampson, & Bookstein, 1997). Thus, pregnant women and those planning pregnancy should be strongly advised to abstain from all alcohol use, because there is no known safe amount of alcohol consumption during pregnancy.

Tobacco Smoking and Passive Smoke

Approximately 20% to 30% of pregnant women report they smoke cigarettes with an average intake of about 14 cigarettes per day (Lawrance & Gruchow, 1996) (Figure 21-6). Tobacco use of over five cigarettes per day in pregnancy doubles a woman's risk of delivering a low-birth-weight infant (Lieberman, Gremy, Lang, & Cohen, 1994) (Figure 21-7). From 21% to 39% of low birth weights in infants are believed to be related to maternal smoking, and the effect on birth weight is proportional to the amount of tobacco used. The greatest effect is an in-

Figure 21-6 Estimated percentage of women who used selected substances in pregnancy, 1992. (Data from National Institute on Drug Abuse 1996. *National Pregnancy and Health Survey: Drug use among women delivering live births: 1992*. Rockville, MD: Author. NIH Pub. No 96-381 9, p. 36.)

creased risk of newborns who are small for gestational age; however, prematurity, infant mortality, and other pregnancy complications (such as spontaneous abortion, placenta previa, placental abruption, and premature rupture of fetal membranes) also are increased (Lieberman, Gremy, Lang, & Cohen, 1994). There is some evidence that prenatal tobacco exposure causes learning and atten-

Figure 21-7 Warnings of risk to pregnant women on packages of cigarettes and alcoholic beverages must be supplemented by nursing advice and support.

tion problems in children but less consistently than does alcohol exposure (Streissguth, Barr, Sampson, and Bookstein, 1997).

Both nicotine and carbon monoxide are thought to cause the problems resulting from cigarette smoking in pregnancy. Nicotine constricts blood vessels and reduces perfusion to the fetus. Carbon monoxide binds to hemoglobin, reducing its oxygen-carrying capacity. Some women may be at special risk from cigarette smoking. Although

more Caucasian than non-Caucasian women smoke cigarettes during pregnancy, the harm may be greater to African American women than to other groups. Cotinine, a metabolite of nicotine, is found in higher amounts in the urine of African American than of Caucasian smokers, even when their tobacco intake is the same (English, Eskenazi, & Christianson, 1994). Also, the older the woman, the more likely smoking will result in her having a low birth weight infant (Fox, Koepsell, & Daling, 1994).

Nursing Tip

ASKING CLIENTS ABOUT SUBSTANCE USE IN PREGNANCY

The most important point to remember is to ask *all* pregnant women about substance use. Do not make assumptions about which women are likely to be smokers or to use illicit drugs. Practice asking these kinds of questions and use them in assessment of all pregnant clients.

Keep these ideas in mind as you assess substance use:

1. Create a private setting to do a social assessment. The presence of other clients or family members may restrict the woman's willingness to discuss stigmatizing conditions such as substance use or domestic violence.
2. Ask about substance use in the part of the assessment that covers family, home life, and social environment. Linking these behaviors to the environment reduces the implication that they are personal failings of the woman. Ideally, ask them after you have established rapport with the client.
3. Consider asking, "Are you exposed to cigarette smoke in your home?" Then ask, "Who are the smokers in your home? Are you a smoker?" Inquire how many cigarettes the woman and her family members smoke each day and whether they have made any changes since the pregnancy began.
4. Use the same calm, warm tone of voice to inquire about alcohol use and then other drug use. Do not simply ask, "Do you use any other drugs?" Be specific: name illicit drugs, including heroin, cocaine, and marijuana.
5. Watch your body language. If you hurry through the questions, shake your head "No," or look away when asking these questions, the woman may assume you do not want to hear the answer.
6. If the woman admits substance use during pregnancy, do not give in to the urge to immediately explain all the risks of these substances and advise her to quit, which may alienate her. Unless she indicates a desire to continue to discuss it, simply say, "Thank you for sharing this, it is important to the health of you and your baby. We'll talk about this more later."
7. Complete the assessment, and then inquire, "You mentioned (substance use) earlier. I would like to review some of the effects of (this substance) during pregnancy and perhaps make some suggestions. Are you interested in discussing this?" If she declines, reply, "I will be happy to go over this information at any time." Offer printed literature on the topic.
8. Continue to treat her warmly and offer support and encouragement so that she develops trust in you. Over time, your positive relationship may enable you to revisit the topic. Your goal is to build her confidence and self-esteem, which will aid in her willingness to try to change her behavior.
9. Remember that she may be focusing on other personal priorities that seem much more urgent to her, such as surviving a violent relationship or keeping a job that her family depends on. She may value the stress reduction and sense of autonomy she gets from smoking more than protecting her fetus from a risk that seems small. Nurses are most effective when they work within the client's personal goals, helping the client see how improving health behaviors will help them meet their other goals as well.

One of the concerns of health care providers is whether pregnant women are reliable in their reports of how much alcohol and tobacco they use. In one study, only about half the women whose newborns had nicotine in their urine admitted to being smokers (Walsh, Redman, & Adamson, 1996). Nurses who conduct prenatal screening interviews must work to establish a secure, confidential environment for these assessments and develop rapport with their clients before asking potentially stigmatizing questions about alcohol, tobacco, and drug use in pregnancy.

When a woman's partner or work colleagues smoke cigarettes during her pregnancy, she is exposed to passive smoke. Passive smoke also causes low birth weight, although its effects may not be as severe as active cigarette smoking by the pregnant woman (Ellard et al., 1996). When a partner smokes cigarettes, it makes it more difficult for the woman to abstain from doing so during and after the pregnancy.

A woman who acknowledges cigarette smoking on an early prenatal visit may be encouraged to learn that it is not too late to avoid pregnancy risk. If she is able to stop by the third trimester, her risk of delivering a low-birth-weight infant decreases to normal levels (Lieberman, Gremy, Lang, & Cohen, 1994). However, many women who reduce or quit cigarette smoking during pregnancy resume their habit after giving birth, increasing the risk to the health of their newborns (Stotts, DiClemente, Carbonari, & Mullen, 1996). Nursing teaching and support are important to help women remain abstinent from cigarette smoking in the postpartum period.

Illicit Drug Use

Pregnant women who use illicit drugs often feel unwelcome in nursing care settings such as prenatal clinics. They fear they will be shamed or reported to legal or child protective authorities (Kearney, 1995). In order to provide nonjudgmental care and support for women who use illicit drugs, nurses must understand not only the effects of illicit drugs in pregnancy but how addiction affects a woman's lifestyle and self-concept. Nurses must conduct a complete and nonjudgmental assessment of each pregnant woman's use of all forms of legal and illegal drugs and provide accurate and unbiased teaching to pregnant women and their families. Ongoing support will be needed to help women use treatment resources, remain abstinent from substances, and continue and commit to avoiding relapse after giving birth.

Marijuana

Marijuana, also known as cannabis, is the illegal drug most commonly used in pregnancy. From 3% to 12% of preg-

nant women have traces of cannabis in their urine, with the higher rates found in women living in urban areas (Buchi, Varner, & Chase, 1993; Vaughn et al., 1993). Marijuana causes relaxation, euphoria, and sleepiness; may enhance appetite; and may reduce nausea and vomiting. Marijuana is not believed to be physically addictive or to cause withdrawal symptoms during periods of abstinence. Psychological dependence is possible, however.

The effects of marijuana smoking on pregnancy are not yet fully understood. There is some evidence that marijuana may cause decreased birth weight, birth length, and gestational age, as well as changes in infant sleep electroencephalograms and neurologic status; however, other studies do not support this evidence (Richardson, Day, & Goldschmidt, 1995). There are very few studies on the long-term effects of prenatal marijuana use on child development. Other factors in the lives of pregnant women who use marijuana, such as other substance use and poor nurturing from the home environment, seem to have as much impact on newborn and child health as does the drug itself.

Cocaine and Other Stimulants

Cocaine, a stimulant manufactured from the coca plant, is used by 0% to 12% of pregnant women, with the higher rates found in women living in urban areas (Vaughn et al., 1993; Young, 1997). Cocaine causes excitement, euphoria, and anorexia. Cocaine can be inhaled in powder form, injected, or smoked. The rates of perinatal cocaine use were highest in the late 1980s and early 1990s and declined in the late 1990s. Amphetamines, also known as "speed," "crank," or "ice," are other stimulants that can be injected, smoked, or taken orally. Their effects are believed to be similar to those of cocaine.

Cocaine is not physically addictive, meaning that use can be stopped without the risks of seizures or other life-threatening physical problems associated with withdrawal. Long-term use reduces the level of neurotransmitters produced in the body, however, resulting in intense behavioral dependence and producing psychological effects (such as depression) when cocaine use stops. Cocaine causes vasoconstriction, increased blood pressure, and tachycardia. Cocaine reduces placental blood flow. Chronic use in the second and third trimesters can lead to low birth weight, the most common effect of cocaine use in pregnancy (Bateman, Ng, Hansen, & Heagarty, 1993). Sudden decreases in placental blood flow may result in placental abruption. Scattered, rare reports link cocaine to congenital anomalies. Some infants exposed to cocaine in utero show increased irritability, difficulty in soothing, and changes in orientation and motor processes. These symptoms are not a result of physiologic withdrawal but of the effect of cocaine on the nervous system. These neurologic

effects are temporary in full-term infants (Richardson, Conroy, & Day, 1996).

Long-term effects of cocaine on development and cognition also have been found in some studies (Azuma & Chasnoff, 1993). Other studies, however, have not found differences between children who were exposed to cocaine in utero and those who were not who come from similarly deprived backgrounds, suggesting that the home environment may have an important influence on whether children outgrow the effects of cocaine (Richardson, Conroy, & Day, 1996; Weathers, Crane, Sauvain, & Blackhurst, 1993). Alcohol and tobacco are used heavily by many users of cocaine (Richardson, Day, & Goldschmidt, 1995), making it difficult to separate the effects of cocaine use from those of alcohol and tobacco use.

Heroin

Heroin is a narcotic related to morphine that causes sedation, relaxation, and euphoria. Less than 1% of pregnant women use heroin, its prescribed substitute methadone, or other opiates. Heroin can be inhaled or injected. It is physically addictive, and withdrawal in either mother or newborn can cause vomiting, diarrhea, diaphoresis, respiratory distress, seizures, or death. When pregnant women who are addicted to heroin withdraw use suddenly or sharply reduce their use, intrauterine fetal demise can occur.

The most common harmful effect of heroin on newborns is withdrawal, or **neonatal abstinence syndrome**. This collection of symptoms may include sneezing, vomiting, diarrhea, irritability, and seizures and is seen in newborns withdrawing from prenatal exposure to narcotics. In a few studies, heroin has been linked to anomalies and low birth weight. In some cases, children who are exposed to heroin or methadone in utero have shown deficits in developmental and cognitive testing; however, poor maternal-child interaction and other factors of the home environment probably contributed to this effect (Richardson et al., 1996).

Injection drug use—whether of cocaine, heroin, amphetamines, or other drugs—increases a woman's risk of exposure to the human immunodeficiency virus (HIV) through contaminated needles. Illegal drug use also carries the risk of acquiring a sexually transmitted disease (STD) because women may trade sex for drugs, provide sexual favors to earn money for drugs, or maintain relationships with drug users (Henderson, Boyd, & Mieczkowski, 1994). Prescribed oral methadone maintenance, given to reduce heroin withdrawal symptoms, can reduce exposure to HIV and other STDs if it helps the woman to stop injecting other drugs. However, methadone has the same withdrawal consequences for women and newborns as does heroin.

Critical Thinking

Caring for Pregnant Women who Abuse Substances

When caring for clients who abuse substances in prenatal or perinatal care, you may be faced with conflicting emotions. As a nurse, you spend your career working for healthy mothers and babies. When a mother places a child at risk, you may feel anger, dislike, or impatience. You may even wish the court system would place the mother under surveillance to prevent substance use. This is not currently legal in any state in the United States because a fetus does not have full legal status as a person with rights of its own.

You are facing a conflict among three ethical principles important in providing health care: *beneficence*, doing good; *paternalism*, taking care of those who are unable to use good judgment for themselves; and *autonomy* (self-determination), the right of an adult to make personal decisions about her own behavior even when it places a fetus at risk. Forcibly controlling a woman's behavior may further diminish her ability to make good decisions on her own.

To promote the health of the fetus while building the mother's confidence and self-esteem, think about how you could form a respectful and interested professional relationship with her. This will help her feel worthwhile and competent, and she may be more likely to continue in prenatal care and seek alternatives to substance abuse.

Infections

Infections during pregnancy can be acquired from humans, animals, or the natural environment. They fall into two broad categories: STDs, acquired through intimate sexual contact; and other infections, including rubella, *E. coli*, and hepatitis, that may be acquired through casual exposure to infected persons or animals or through food or water. Maternal infections, mainly rubella, toxoplasmosis, and cytomegalovirus, account for approximately 2% of major congenital malformations occurring during pregnancy (Briggs, 1995).

Sexually Transmitted Diseases

One potent route of infection during pregnancy is sexual exposure, which introduces harmful organisms into the maternal system by way of the genital tract (Figure 21-8).

Figure 21-8 Estimated rates of sexually transmitted diseases per hundred thousand population, 1960–1995. (Data from Centers for Disease Control and Prevention. 1996. *Sexually transmitted disease surveillance, 1995*. Atlanta, GA: CDC, U.S. Department of Health and Human Services, Public Health Service.)

Many diseases are known to be transmitted sexually. Although many cause discomfort or pose a risk to the mother, not all cause harm to the fetus. Examples of infections that do not seem to place the fetus at risk include trichomoniasis and candidiasis. Figure 21-8 displays incidence data concerning STDs.

Syphilis

Syphilis infection, caused by the spirochete *Treponema pallidum*, increases the risks of spontaneous abortion, stillbirth, and live birth with congenital syphilis. Congenital syphilis affects about 250 infants annually in the United States (Sweet & Gibbs, 1995). The longer the mother has been infected, the greater the risk to the fetus.

In the mother, a new case of syphilis causes a painless lesion in the area of contact, which soon disappears while the progress of the infection continues. In the newborn, congenital syphilis may have no symptoms. A distinctive rash on the palms and soles of the feet and around the mouth and anus usually appears 2 to 6 weeks after birth, along with rhinitis. By 4 months of age, bone problems can be detected, sometimes accompanied by meningitis and enlarged liver and spleen. Later in childhood, other changes are found, including perforated nasal septum, pointed or notched teeth, and facial abnormalities. Bone and joint problems, deafness, and CNS damage can occur.

All pregnant women should receive a blood serology test for syphilis as early as possible in pregnancy. Women

with evidence of active infection should have repeat VDRL (Venereal Disease Research Laboratory) testing during antibiotic treatment until the titer level decreases to a negligible one. Syphilis can be effectively treated during pregnancy using penicillin. Other substitute antibiotics (such as doxycycline or erythromycin) used for women who are allergic to penicillin and are not pregnant do not work as well during pregnancy. Pregnant women who have syphilis and are allergic to penicillin usually should undergo desensitization to be able to receive penicillin treatment (Sweet & Gibbs, 1995).

Gonorrhea and Chlamydia

Gonorrhea, caused by *Neisseria gonorrhoeae*, and chlamydia, caused by *Chlamydia trachomatis*, are transmitted sexually and cause no symptoms in 85% of infected women. If symptoms are present, they usually consist of vaginal discharge and dysuria (painful urination). Each disease affects about a half million women annually in the United States. The rate of chlamydia infection is increasing, and the rate of gonorrhea infection is slowly decreasing. Adolescent women and women of color are disproportionately affected by these infections (CDC, 1996).

If left untreated, these STDs can lead to pelvic inflammatory disease (PID) in up to 40% of women. In turn, PID leads to scarring of the reproductive tract that causes infertility in 20%, ectopic pregnancy in 9%, and chronic pelvic pain in 18%. Gonorrhea and chlamydia infections can

cause neonatal conjunctivitis and blindness, and chlamydia infection can cause neonatal pneumonia. Blindness can be prevented by prophylactic treatment of the newborn with ointment applied to the eyes at birth; however, prevention of pneumonia requires that chlamydia infection be treated during pregnancy (CDC, 1996).

Although not universally practiced, some health professionals recommend screening of all pregnant women for these infections, just as all women are screened for syphilis. The test for syphilis shows current and past infection. Therefore, tests for other STDs such as gonorrhea and chlamydia should be considered because unprotected sexual encounters also may have caused multiple infections. Women with chlamydia or gonorrhea infection should receive antibiotic treatment with a medication safe for use in pregnancy. Oral erythromycin is used to treat chlamydia, and intramuscular injection of cephtriaxone plus oral erythromycin is used to treat gonorrhea. Nurses should discuss with clients the likelihood of GI irritation with erythromycin therapy and the importance of contacting a health professional for an alternative plan if they are unable to complete the prescribed regimen. A reduced dosage for a longer treatment period may be prescribed.

Human Papilloma Virus

The human papilloma virus (HPV) is a common one that produces warts in the anogenital area known as the condyloma acuminatum. Because several subtypes of this virus have been implicated in cancer of the cervix, women with a history of this infection should have more frequent Pap smears, ideally every 6 months. Although the warts themselves are not harmful, when large they may block the passage of the fetus through the vagina or bleed excessively. In these cases, cesarean birth may be recommended. Exposure of the fetus to HPV during labor and birth has been linked to later development of laryngeal papillomas; however, the risk is less than 1 in 100. Although no treatment has been proved effective in permanently eradicating the HPV virus, the warts may be removed using laser, cryocautery, or topical chemicals that are safe during pregnancy. Maintaining a healthy immune system may help a pregnant woman fight off the infection (Sweet & Gibbs, 1995).

Herpes Simplex Virus

The herpes simplex virus (HSV) is a common one that causes painful, pruritic blisterlike lesions and is carried by 0.1% to 4% of pregnant women. Herpes is a chronic recurrent infection. The virus is shed heavily during the primary infection as well as during recurrences (Sweet & Gibbs, 1995). Fetal and neonatal risks from HSV occur mainly when a primary infection occurs in pregnancy. Rarely, the fetus may become infected through transplacental trans-

REDUCING RISKS RELATED TO THE HERPES SIMPLEX VIRUS

Isolation in a private room is no longer considered necessary for mothers and full-term newborns when the mother has HSV. Practicing and teaching good hand-washing technique are very important. The mother, all family members, and all visitors should wash their hands thoroughly before handling the newborn. The infant should be protected from exposure to herpes lesions. This includes advising the family not to kiss the infant if they have orofacial HSV lesions. Face masks may be worn by persons with orofacial herpes lesions to reduce the risk of spreading the virus in droplet form.

Protecting the newborn and other clients is important, as is treating the family with respect and understanding. The family will feel stigmatized if nurses avoid them or demonstrate a lack of enthusiasm in caring for them.

When the nurse has an orofacial herpes lesion, scrupulous handwashing and coverage of the lesion with a dressing is essential. Lesions are less contagious when crusted over, about 5 to 7 days after onset. Some institutions temporarily reassign nurses with herpes lesions to an area of the unit away from newborns.

mission or infection of the membranes, which can cause spontaneous abortion, preterm delivery, or intrauterine growth retardation. The most common route of transmission to the fetus is genital contact during vaginal delivery when the mother has a primary genital HSV infection. In this situation, neonatal HSV infection may occur in 25% to 50% of newborns; 40% to 60% of these newborns are at risk for death, and the remainder are likely to suffer CNS damage.

During a primary infection when the membranes are intact or have been ruptured for less than 4 hours, cesarean delivery may be recommended to reduce the exposure of the neonate to the virus. During a recurrent infection, the risk of transmission to the neonate is estimated at 0% to 4%; however, cesarean delivery may be performed as a precaution. Neonates also can be infected by hospital personnel or visitors with HSV lesions, and occasionally a newborn will develop an infection when the mother has no history of lesions but has a positive result on culture for HSV (Sweet & Gibbs, 1995).

Human Immunodeficiency Virus

Approximately 1 in 600 births in the United States are to women infected with the human immunodeficiency virus (HIV). At this time there is no cure for HIV infection. It leads to cancers and opportunistic infections, and ultimately death results as a result of depletion of the immune system. For childbearing women, a major concern is transmission of HIV to the fetus. Without antiviral therapy, approximately 25% of newborns of women infected with HIV will become infected with HIV. HIV in these infants causes growth retardation, repeated infections, and early death. Transmission risk is increased by advanced maternal disease and prolonged ruptured membranes. With zidovudine therapy during the second and third trimesters and treatment of the newborn for the first 6 weeks of life, infection of the newborn is reduced by as much as two thirds, to a rate of 8% to 11% (CDC Fact Sheet, 1996).

During pregnancy, nurses must focus on outreach to pregnant women who are HIV-positive to encourage them to obtain early and comprehensive prenatal care, including treatment with antiviral medications to maintain their own health and minimize the risk of perinatal transmission of the infection. Nutritional support, preventive care to avoid opportunistic infection, and other wellness promotion may reduce the risk of low birth weight and preterm delivery. Women who became infected with HIV through illicit drug use or unprotected sex should be offered referrals to treatment sources and teaching on prevention of sexual exposures.

Nursing Tip

HIV TESTING IN PREGNANCY

Although some practitioners believe that all pregnant women should be tested for HIV, regardless of consent, this practice would be contrary to the ethical principle of autonomy for health care clients. Voluntary counseling and testing has resulted in increased use of zidovudine therapy during pregnancy and reduced transmission of HIV to newborns (CDC Fact Sheet, 1996).

You must provide information and counseling on voluntary testing for HIV to all pregnant women. Explain that this testing will enable the detection of infection early enough to provide zidovudine and other important treatment. Advise women diagnosed with other STDs that they may also have been exposed to HIV. Repeated testing over 6 to 12 months is necessary to detect recent infection.

Nursing Alert

PREVENTING THE SPREAD OF HIV AND OTHER INFECTIONS

You must maintain standard infection control precautions during prenatal and perinatal procedures to minimize the risk of contamination of the environment with blood or body fluids containing the HIV virus and other pathogens. These precautions apply to all pregnant and postpartum women, not only those known to be infected with HIV.

You must remember that HIV and other infections may be present in any woman, including those whose HIV status was negative at the last test. If the infection is recent, antibodies may not have yet developed that can be detected with testing. Some women may have refused testing because of fear of stigma or loss of employment or insurance coverage if they are found to be HIV-positive. Others may never have been offered the HIV test. You should refrain from making judgments about which women are likely to be infected with HIV and use standard precautions for all clients.

During labor and birth, women known to be infected with HIV should receive the same consideration and level of support and care as do other mothers. These mothers may suffer fear and depression as they await the results of laboratory testing of their newborns for HIV infection. Because all newborns exposed to HIV will be born with maternal HIV antibodies, virologic tests must be performed to determine whether the virus itself is present in the neonatal system. Mothers with HIV should be counseled not to breast-feed their infants, because HIV can be transmitted to infants through breast milk.

Other Infections

Pregnant women may acquire infections from contaminated food, water, or nonsexual contact with infected persons. Although many kinds of infections may be contracted from these sources, some are known to have harmful effects on the fetus and newborn.

Hepatitis B

This viral infection is transmitted through blood and body fluids and predominantly affects the liver. The acute infection can be fatal or cause permanent liver damage or carcinoma. Infection in pregnancy may cause spontaneous abortion and has been linked to preterm labor. Maternal-infant transmission can occur transplacentally, through intrapartum or postpartum contact with

Nursing Tip

STANDARD PRECAUTIONS

When following Standard Precautions, you must:

1. Wear gloves to prevent transmission of blood-borne infections, such as HBV and HIV, when you are at risk of coming into contact with any bodily fluids that contain blood or amniotic fluid from the client, bedding, or instruments. You must also change gloves between clients. Do not reuse gloves.
2. Wear a mask, eye protection, a face shield, and a fluid-resistant gown in all situations in which bodily fluids are likely to be splashed or propelled onto you.
3. Wear a gown and gloves when handling newborns until all blood and amniotic fluid have been removed by bathing.
4. Do not recap, bend, or break needles. Do not remove needles from syringes. Store all sharps safely for disposal.
5. Perform resuscitation and suctioning using protective equipment rather than by mouth-to-mouth contact or use of a DeLee catheter.

contaminated surfaces, or through breast milk or colostrum. Approximately 5% to 10% of newborns of infected mothers will become infected unless they receive treatment in the neonatal period, and the rate is much higher if the mother carries a virulent form of the disease caused by the hepatitis B e (HBeAg) antigen (Sweet & Gibbs, 1995).

All pregnant women should be tested for hepatitis B surface antigen (HBsAg), the surface antigen indicating infectivity with hepatitis B. Women who are HBsAg-positive should receive careful instruction as to blood and body fluid precaution to prevent infection of family members. Public health service referrals may be used to assist in notifying all sexual contacts of a pregnant woman infected with hepatitis B and providing immunoglobulin and immunization therapy to family members to reduce the risk of infection. The neonate of a mother with hepatitis B should receive hepatitis B immune globulin and the first of three injections of hepatitis B vaccine before being discharged from the hospital. Most states require that all parents be offered the opportunity to have their newborns receive the first hepatitis B immunization injection during the nursery stay.

Varicella Zoster

The varicella virus causes the chickenpox infection. Chickenpox is a common childhood disease causing fever, malaise, and pruritic pustules. It is highly contagious, and more than 90% of adults show evidence of past infection and are immune. For this reason, infection during pregnancy is rare, only about 5 cases per 10,000 pregnancies. The most severe complication for adults with chickenpox is varicella pneumonia, which can be fatal. In most cases, however, adult chickenpox is a fairly low-risk disease.

In pregnancy, however, varicella can be extremely harmful. Varicella infection in the first trimester of pregnancy has approximately a 10% risk of causing congenital varicella syndrome, which includes limb and digit hypoplasia, eye anomalies, mental retardation, and growth retardation. Infection of the mother late in pregnancy can cause preterm labor and stillbirth and places the newborn at risk for life-threatening neonatal varicella infection. The risk of death can be averted by giving exposed newborns varicella-zoster immune globulin (VZIG), although some may still show signs of infection (Sweet & Gibbs, 1995).

When a woman who does not believe she has had chickenpox is exposed during pregnancy, blood for a varicella antibody titer should be drawn. If the results are negative, VZIG may be given to prevent or minimize infection. If the titer level is moderate, the woman is immune. If the titer level is high, current infection probably is present. Varicella vaccine is now available and can be given to pregnant women with negative results on varicella titer tests before exposure occurs. Immunization will prevent the serious sequelae of infection during pregnancy.

Cytomegalovirus

Cytomegalovirus (CMV) has been linked to serious neonatal infection and malformations. CMV causes mild flulike symptoms in the healthy adult or no symptoms at all, and as many as 75% of adult women have antibodies to CMV. Primary infection occurs in 1% to 2% of susceptible women during pregnancy and may be completely asymptomatic for the mother. The virus can be detected for long periods after infection and may be shed intermittently through body fluids. CMV can be transmitted to the fetus transplacentally and at the time of birth. Pregnancy may reactivate CMV infection in women who carry the virus. When CMV is present on the cervix at birth, 30% to 50% of neonates acquire the virus (Sweet & Gibbs, 1995).

Newborns infected with CMV have a 10% risk of symptomatic disease at birth. The infection can cause hepatosplenomegaly, jaundice, deafness, and eye problems. Mental retardation, chorioretinitis, cerebral calcifications, and microcephaly or hydrocephaly are long-term effects. Unfortunately, although antiviral treatments are used to

Nursing Tip

TORCH SCREENING

To collect data prenatally or in the postpartum period when viral infection is suspected you can use the TORCH screening panel, which tests for antibodies to certain infections that have been linked to fetal or neonatal harm. This includes testing for:

1. Toxoplasmosis
2. Other infections including hepatitis
3. Rubella
4. Cytomegalovirus
5. Herpes

limit the extent of disease, no fully effective treatments are available.

Pregnant women can be tested for immunity or current infection using the **TORCH** serum screening panel (see Nursing Tip). For an asymptomatic disease such as CMV, expensive serial titer testing would be needed to detect the presence of primary infection; however, no effective treatments are known for women diagnosed with primary CMV. Nurses should be prepared to counsel pregnant women about this difficult situation and provide support. Some women who have CMV infection may choose to terminate the pregnancy even though the likelihood of a healthy outcome is 90% (Sweet & Gibbs, 1995).

Parvovirus

Also known as Fifth disease, parvovirus causes erythema infectiosum in childhood, a disease involving low-grade fever and erythema of the cheeks. Parvovirus can have more serious effects in adults, including pneumonia and hemolytic anemia. One strain, human parvovirus B19, has been found to cause severe fetal anemia, cardiac failure, nonimmune hydrops fetalis, and intrauterine fetal death. Approximately 1% of pregnant women are infected with B19, which can be diagnosed with antibody testing. Fetal damage is believed to occur in 30% to 40% of pregnancies. Treatment is limited at the present time. Serial ultrasonography can detect early signs of heart failure and hydrops, and intrauterine transfusion may be used to treat fetal anemia (Sweet & Gibbs, 1995). Some women infected with B19 may choose therapeutic abortion.

Toxoplasmosis

Toxoplasma is an intracellular parasite that is found in animals, including sheep and mice. It is transmitted in the

feces of cats who have consumed infected mice and in meat from infected animals. The disease in humans may have no symptoms or may cause lymphadenopathy, fever, fatigue, sore throat, eye pain, and rash. It may be mistaken for influenza or mononucleosis.

At least half of all pregnant women in the United States have antibodies to toxoplasma. The rate of infection in pregnancy is fewer than 1 in 1,000 births. When infection does occur, spontaneous abortion, preterm delivery, and intrauterine growth retardation may result. At least half of all neonates born to mothers infected with toxoplasma during pregnancy show laboratory evidence of infection. The most severe effects occur when the mother is infected in the first trimester. These effects can include **chorioretinitis** (inflammation of the membrane of the retina of the eye), anemia, liver damage, CNS abnormalities, and perinatal death. Toxoplasmosis can be treated with antibiotics if infection is diagnosed early; however, some neonatal disease may still occur. Nurses play an important role in home assessment and prenatal teaching to prevent this infection.

This preventive advice has significantly reduced the incidence of toxoplasmosis in areas where it has been used systematically (Sweet & Gibbs, 1995).

Other Parasitic Diseases

Pregnant women in underdeveloped countries and tropical areas may be exposed to a variety of parasites in the environment. Many parasites have primarily GI effects, and some cause systemic infection.

Protozoans are the cause of amebiasis, giardiasis, leishmaniasis, trypanosomiasis, and malaria. Amebiasis causes ulcerative disease of the colon, giardiasis affects

Client Education

Preventing Toxoplasmosis Infection

You should advise clients who are pregnant and those planning pregnancy to:

- Avoid undercooked meat.
- Wash hands after handling cats.
- Have someone else change the cat's litterbox daily.
- Prevent cats from eating wild animals or raw meat.
- Avoid contact with stray animals.

Box 21-1 Home Visit Guidelines

1. Before the visit, gather information about environmental hazards present in the neighborhood of your client, such as toxic waste dumps, incinerators, factories with dangerous emissions, unsafe water supply, and other risks.
2. As you approach the residence, observe for potential pregnancy risks (and hazards to your own safety) in the social environment, such as street violence, drug dealing, and unsafe housing.
3. During your visit, observe the home for hazards such as peeling paint, toxic chemicals such as bug killers or lawn chemicals, or homemade ceramic mugs that may contain lead glaze.
4. During your nutritional assessment, ask to see the contents of cupboards and the refrigerator. Inquire about imported fruits and any fish or game that may not have been inspected.
5. Ask permission to look in the medicine cabinet. Point out over-the-counter medications that are unsafe for use in pregnancy.
6. Observe for the odor of tobacco, cigarette butts, and ashtrays. If a family member smokes, inform the pregnant woman about the risks of passive smoke to herself and her baby both before and after birth. Help the woman to problem-solve to reduce her exposure to tobacco smoke. Provide information for her and her family on stop-smoking classes and other resources.

While completing a nursing assessment of a client's medical and obstetrical history and risk factors, you should explore these other important areas through nursing observations and questioning the client on the following topics.

1. Geographic risks:
 - a. Are you or have you been exposed to violence, urban poverty, or chemical or nuclear accidents?
 - b. Are pesticides and herbicides used in agriculture present in your residential area?
 - c. Are there industrial wastes such as heavy metals, solvents, PCBs, or PBBs in the food and water where you live?
 - d. Is geographic isolation an obstacle that prevents you from obtaining prenatal care?
2. Employment-related risks
 - a. Are you exposed to extreme heat, radiation, chemical, or gas exposures at work?
 - b. Are you an agricultural worker exposed to pesticides or herbicides?
 - c. Does your job entail long hours of standing, heavy lifting, extreme physical exertion, or psychological stress?
3. Risks in the home environment
 - a. Do you frequently drink hot beverages from ceramic mugs that may contain lead?
 - b. Do you eat fish caught by sports fishermen that may contain high levels of lead or mercury?
 - c. Do you live in an area where waterborne or insectborne parasites are a threat, or have an untested well as your source of drinking water?
 - d. Do you have cats as pets?
 - e. Have you traveled to or emigrated from an area in which parasitic infections are common, such as a tropical climate?
4. Medication risks
 - a. What prescribed medications do you take for chronic or intermittent medical conditions?
 - b. What over-the-counter medications do you use on a regular basis, and what have you taken since the time of conception of the current pregnancy?
5. Recreational drug and tobacco risks
 - a. Do you smoke cigarettes, and if so, how many per day? Do other household members smoke?
 - b. Do you drink alcohol recreationally or regularly? How much and how often? How much since conceiving this pregnancy?
 - c. Have you ever tried cocaine, marijuana, heroin, or other drugs? How recently? How much have you used since conceiving this pregnancy?
6. Risks from STDs
 - a. Do you have one sexual partner or more than one? Do you practice safe sex?
 - b. Do you or your partner have any symptoms of vaginal or perineal infection, such as itching, discharge, burning, sores, or growths on the perineal area?

(continued)

Box 21-1 continued

- c. Have you or your partner ever been diagnosed with an STD?
 - d. Have you ever experienced PID? If so, do you have any symptoms of ectopic pregnancy, such as pelvic pain, vaginal bleeding, or shoulder pain that may be caused by internal bleeding?
 - e. Does your prenatal laboratory tests indicate infection with syphilis, parvovirus, toxoplasmosis, HIV, hepatitis B, gonorrhea, or chlamydia?
 - f. Have you been immunized against or have a history of past infection with rubella and varicella (chickenpox)?
7. Knowledge level, behavior, and social conditions
- a. Are you aware of the more common risks to the fetus, including those from over-the-counter medications, tobacco, and alcohol?
 - b. Are you motivated to change your behavior if you are a habitual user of substances that are dangerous in pregnancy? Have you made changes since your pregnancy was diagnosed, such as quitting smoking or avoiding alcohol?
 - c. What resources such as support and treatment are available to you? What is the level of family support present for behavior change such as stopping tobacco, drug, or alcohol use?
 - d. What is your overall nutritional and physical health status, which reflects your body's resistance to infections and ability to provide nourishment to a fetus?
 - e. What are your financial constraints that might affect your ability to change your employment setting if hazards are present?
 - f. What are your home responsibilities that may affect your ability to rest and care for yourself if you must continue to do strenuous work?

the duodenum, and leishmaniasis causes ulcers of skin and mucous membranes. Trypanosomiasis has two forms: Chagas' disease, which causes cardiac disease and intestinal problems and can be transmitted prenatally and through breast milk; and African sleeping sickness, which has rapidly progressive, fatal CNS effects and usually causes death of the woman before the pregnancy reaches full term. Malaria, the most common protozoan worldwide, is spread by mosquitoes and causes recurrent fever and chills, nausea, vomiting, liver damage, and sometimes rupture of the spleen. In pregnancy, malaria can cause spontaneous abortion, intrauterine growth restriction, and preterm delivery, as well as congenital infection of the newborn (Sweet & Gibbs, 1995). Protozoan infections can be treated with antibiotics during pregnancy.

Helminths are worms capable of parasitizing humans. Helminths include GI nematodes (roundworms), such as ascariasis, pinworms, and hookworms. Helminths also include tissue nematodes, such as filariasis, transmitted by mosquitoes, and trichinosis, spread by consuming infected meat. Trematodes, or flatworms, include schistosomiasis, a bloodborne infection that can penetrate skin in contact with infected water. Schistosomiasis can be fatal, and the drugs used for treatment are not advised during pregnancy. Cestodes, or tapeworms, inhabit the GI tract and are acquired by eating infected meat. Although cestodes cause unpleasant symptoms and treatment is available, it

usually is delayed until after delivery to avoid exposure to harmful medications (Sweet & Gibbs, 1995). Although the fetus is not harmed directly by these parasites, nutritional deficits and loss of body fluids in the mother may produce intrauterine growth restriction.

Nurses should counsel pregnant women who travel to tropical and undeveloped areas to avoid exposure to insects, bodies of water, water that has not been treated for drinking, and meat that is not fully cooked. Women who come to prenatal care from these areas should be assessed for signs of parasitic disease and treatment provided when appropriate. Blood and stool cultures can be used to detect many parasites. It is important for the nurse to teach women about the low risk to the fetus of many parasitic conditions and to provide emotional support and instructions on hygiene if treatment must be delayed until after childbirth.

NURSING PROCESS

Nurses are the ideal health care provider to identify and intervene with women exposed to environmental risks during pregnancy. Nursing's holistic focus on clients within the context of their families and environments promotes sensitivity to factors in addition to medical and obstetrical risks that may threaten the well-being of pregnant women and their fetuses.

Assessment

When providing care for pregnant women in acute, ambulatory, or home care settings, you must be aware of and assess for environmental and lifestyle risks that may endanger the mother and fetus. These assessments can take place in a health care setting or during a home visit.

Nursing Diagnoses and Outcome Identification

Nursing diagnoses along with expected outcomes are listed in Table 21-2.

Table 21-2 Common Nursing Diagnoses, Causes, and Outcomes

Nursing Diagnosis	Cause	Expected Outcomes
Risk for (or present) infection	Unsafe sexual practices, preexisting sexually transmitted disease, lack of immunity to childhood diseases that place the fetus at risk, environmental hazards such as parasites	Fetus is protected from infection by immunization, maternal antibiotic treatment, maternal safer sex practices and lifestyle precautions, and safe food handling and preparation.
Risk for injury (fetal)	Industrial waste, employment conditions that expose pregnant woman to dangerous chemicals or activities	Fetus is protected from injury by removing hazards from environment, protecting pregnant woman from exposure, and modification of employment or household conditions.
Ineffective tissue perfusion (placental)	Cigarette smoking, cocaine use, stress	Placental perfusion is adequate, as demonstrated by appropriate fetal growth and reassuring fetal assessments.
Impaired gas exchange (placental-fetal)	Cigarette smoking, carbon monoxide exposure, maternal anoxia from seizures	Fetus demonstrates adequate oxygenation by reactive nonstress tests and other assessments. Risk is reduced by reduction in maternal cigarette smoking and maintenance of therapeutic level of anticonvulsants.
Delayed growth and development (fetal)	Inadequate nutrition or malformations from chemical or drug exposure	Alterations are diagnosed promptly. Chemical exposures are minimized or eliminated. Pregnant woman and family are informed of risks and supported in decision-making. Pregnant woman and family have adequate support and preparation for birth of an infant with possible altered development.
Imbalanced nutrition, less than body requirements	Substance abuse and consequent anorexia, cognitive alterations, lifestyle disruption	Pregnant woman who abuses substances demonstrates adequate weight gain and fetal growth. Adequate support and teaching are provided to reduce substance abuse and promote healthful lifestyle.
Fatigue	Strenuous employment demands	Pregnant woman demonstrates moderation in physical activity and adequate rest periods.
Ineffective role performance	Role burdens (work and home) changing roles	Employment conditions and role expectations are modified to promote prenatal health.
Fear	Possible birth of damaged infant from exposure to a hazardous substance or infection	Pregnant woman and family report reduction in fear, and demonstrate knowledge of likelihood of fetal harm and measures to minimize fetal damage.
Deficient knowledge	Lack of information about pregnancy, hazards, risk reduction strategies	Pregnant woman and family can state potential risks of their environmental conditions for fetal health, and describe and demonstrate risk reduction strategies.
Ineffective individual and family coping	Substance abuse	Pregnant woman and family demonstrate improved safety in behavior and home management and increased motivation toward healthful behaviors.

Planning

For each nursing and medical diagnosis that applies to a pregnant woman and her family, you should work with the client to develop a plan of care that addresses health needs within the goals, capabilities, and context of the family. In planning to address each health issue, you should:

1. Consider the values behind the health goal, and clarify that the values are compatible with the client's choices. For example, a pregnant woman who smokes a pack of cigarettes per day may not value prevention of low birth weight as much as she values the autonomy and stress reduction of smoking.
2. Provide the education needed to convey the benefits of behavior or lifestyle changes. For example, if a pregnant woman works in an agricultural environment, explain the relative risks of harm from pesticide exposure and heavy lifting, and the reduction in risk that would be achieved if she were able to eliminate these exposures and activities.
3. Select interventions to reduce risks that are feasible within the client's unique situation and context. These may be client-initiated or nurse-initiated, or initiated by referral to another helping professional. Client-initiated interventions might include preparing meats at home in a different way to reduce the risk of trichinosis or other parasites. Nurse-initiated interventions might include weekly supportive phone calls to help a woman maintain abstinence from alcohol, or performing nonstress tests weekly to monitor reactivity in the fetus of a woman who uses cocaine. Referral-initiated interventions include actions such as providing information about Alcoholics Anonymous (AA) meetings, helping the woman make an appointment with a family counselor if a partner's substance abuse is placing her at risk, or sending a pregnant woman with a chronic illness to her specialist medical provider to have type and dosage of medications adjusted to maintain safety during pregnancy.

Nursing Intervention

Nurses should focus on the whole pregnancy, not just the present time, as they intervene to help pregnant women reduce environmental risks. Many actions may be initiated as a result of the initial assessment; however, follow-up is extremely important. Behavioral changes such as stopping smoking are extremely difficult to sustain, reducing activities at work may not be permitted over the entire course of pregnancy, and other conditions may increase the chance of reverting to the prior risk status. The nurse must main-

tain an active problem list and through telephone, home visits, and scheduled ambulatory care appointments, let the pregnant woman know that support is always available as she maintains these difficult changes.

One way of monitoring successful behavioral change is through voluntary testing. A pregnant woman may appreciate the motivating influence of regular testing of urine for alcohol, drugs, or cotinine. Testing should not be initiated without her knowledge or against her will, because doing so would constitute criminal assault and violate the principle of informed consent and client autonomy. Another type of periodic testing is monitoring of blood levels of prescribed medications to ensure adequate dosages and avoid excessive fetal exposure. A third type of continual monitoring is fetal assessments initiated in the third trimester to ensure fetal growth, oxygenation, and normal development.

Evaluation

Interim evaluations should be made of client knowledge, behavior, environmental conditions at work and at home, and maternal and fetal physical and psychosocial well-being. The ultimate outcome of nursing care to reduce risks during pregnancy is the birth of a healthy infant. Parents must be counseled that some exposures do not reveal their effects until later in childhood. For example, alcohol exposure may cause subtle learning and attention difficulties that are not detected until school age. Parents should also be advised that a nurturing, interactive, and educationally stimulating home environment can minimize the developmental effects of many prenatal exposures.

FUTURE DIRECTIONS: IMPROVING PUBLIC AWARENESS AND POLICIES FOR PREGNANCY SAFETY

Much more research is needed to fully understand the effects of many environmental influences during pregnancy. Because experimental studies cannot ethically be conducted on humans, information will continue to be gathered retrospectively from human experiences of exposures to newly identified hazards. Sadly, it is only after damage has occurred that many substances are labeled as harmful. With rapid development of new chemicals and forms of radiation for use in industry and health care, research on pregnancy safety must keep pace.

Yet, we do know a great deal about the impact of many environmental influences. Nurses have an important role to play in educating clients and families about reducing environmental risks during pregnancy and in advocating for clients with their employers, landlords, other social service providers, and families. In addition, much more

Case Study/Care Plan

SUBSTANCE USE IN PREGNANCY

Janice Lord is a 31-year-old (gravida 3, para 2) single Caucasian woman who arrives for her first prenatal visit. She is 16 weeks pregnant. Her first pregnancy ended with delivery of a healthy full-term male infant who is now 3 years old. Her second pregnancy ended in a spontaneous abortion at 18 weeks owing to placental abruption. She has no chronic diseases or known exposures to industrial chemicals or radiation. She lives with her son in a public housing project where gang fighting and public intoxication is common. She is employed full-time as a house cleaner.

Janice smokes 20 cigarettes per day, drinks two or three 12-ounce beers each night to relax after work, and smokes crack cocaine on weekends with her boyfriend. Her mother, also a cigarette smoker, watches Janice's son during the day. Her boyfriend does not live with her but spends most of each weekend in her apartment.

Janice was originally ambivalent about continuing the present pregnancy and also was delayed in seeking prenatal care because she did not have health insurance. She tells you that she believes the previous pregnancy loss was due to a cocaine binge, and she wants to do her best to protect the present fetus from harm. She hopes to move out of public housing sometime soon and relocate to a suburban area with less street violence.

Janice's initial physical examination is within normal limits, with the exception of a foul-smelling vaginal discharge and mild hypertension (140/90 mm Hg). Wet prep slide of discharge reveals *Trichomonas* infection; other culture results are negative. Fetal heart tones are normal, and fetal activity is palpated.

Assessment

Based on nursing knowledge of obstetrical, public health, and psychosocial risks, the nurse determined that the following assessments indicated need for nursing intervention:

1. History of late spontaneous abortion, violent home area, smoking by both Janice and her mother, cocaine use, and hypertension, all of which may increase the risk of vasoconstriction and inadequate blood supply to the placenta and fetus.
2. Reported alcohol and cocaine use in early pregnancy, suggesting an increased risk of fetal injury from these substances.
3. *Trichomonas* infection, suggesting unsafe sex practices and risks of other STDs and HIV.
4. Self-reported substance use, indicating ineffective coping strategies.

Nursing Diagnosis

Ineffective tissue perfusion (placenta) related to vasoconstriction from cigarette smoking, cocaine use, hypertension, and chronic stress.

Expected Outcomes Maintain adequate fetal-placental perfusion, as demonstrated by appropriate fetal activity and growth; absence of drugs in maternal urine; and self-reported reduction in cigarette smoking.

Planning

Adequate perfusion demonstrated by stable activity counts and reactive non-stress tests.

Normal fetal growth demonstrated by fundal height and ultrasonography.

Reduced risk, as measured by absence of substance in urine screening sample and self-reported reduction in substance use.

Pregnancy continues to term without evidence of preterm labor or placental abruption.

(continued)

Nursing Interventions**Rationales**

1. Educate about effects of nicotine, carbon monoxide from cigarettes, and neurologic and vasoconstrictive effects of cocaine in pregnancy, as well as effects of passive smoking on her and her son's health. Offer referrals to stop-smoking and substance abuse treatment programs. Provide ongoing emotional support to maintain behavior change. Engage mother and boyfriend in educational and stop-smoking programs.
2. Monitor placental function with activity counts, non-stress tests. Monitor blood pressure.
3. Provide letter to employer requesting activity limitations as recommended by the American Medical Association, and follow-up with phone call, if needed.

1. Information about health risks along with a referral to resources are important to begin change.
2. Monitoring the pregnancy is part of prenatal care.
3. Interventions may need to be taken at the workplace to facilitate a healthy environment.

Evaluation Janice describes reduction in smoking to 5 cigarettes per day, and abstinence from alcohol and cocaine. Her partner and mother attend stop-smoking classes sporadically. Janice expresses appreciation for support from the nurse as she continues to work on making changes at home and work. Activity counts and nonstress tests are within normal limits. Blood pressure decreases to normal levels as smoking decreases. Janice denies preterm contractions, uterine pain, and vaginal bleeding.

Nursing Diagnosis

Risk for fetal injury; risk factors include prenatal alcohol and cocaine exposure.

Expected Outcomes Minimize risk to fetus of further substance exposure, as demonstrated by Janice's understanding of the risks of drugs and alcohol use in pregnancy, her reports of abstinence from alcohol and drugs, and negative urine screening.

Planning Client will be able to state risks to fetus of alcohol and cocaine use in pregnancy.

Alcohol and cocaine intake will stop for remainder of pregnancy, as demonstrated by negative urine screening results and client self-reporting.

Nursing Interventions**Rationales**

1. Educate client and family about effects of cocaine and alcohol, as well as impairment of parenting interactions when intoxicated.
2. Refer to AA or Narcotics Anonymous for peer support; refer to formal drug and alcohol treatment, if desired.
3. Provide ongoing support and encouragement.
4. Discuss advantages of regular screening for substances.
5. Provide assessment and intervention for newborn alcohol and cocaine effects, if present.

1. Knowledge of effects of substance abuse on family and parenting abilities may motivate client to modify behaviors.
2. Education and referral provide the client the tools to make lifestyle changes.
3. Client may be more inclined to adopt healthy behaviors if nurse is a strong supporter and change agent.
4. Knowledge of the benefits of regular screening may encourage client to have frequent contact with a health care provider, resulting in better and more consistent prenatal care.
5. Continued assessment and monitoring of newborn risks allows for early intervention and treatment.

(continued)

Evaluation Janice reports abstinence from alcohol and cocaine since the time of committing to continue the pregnancy. She attends AA meetings weekly where she has met another pregnant woman who has become a friend. Janice's boyfriend continues to drink and use drugs but not in her apartment. Ultrasonography shows no apparent anomalies.

Nursing Diagnosis

Risk for fetal and maternal infection; risk factors include maternal exposure to STDs.

Expected Outcomes Complete treatment for current infection, consider HIV testing for self and partner, and use safer sex to prevent future infection.

Planning Client will complete treatment for documented infection.
Client will report safer sex practices to prevent future infection.
Client will report her decision regarding HIV testing in pregnancy.

Nursing Interventions

Rationales

- | | |
|--|--|
| 1. Educate client about implications of <i>Trichomonas</i> infection—not harmful in itself but a sign of other possible STD exposure. | 1. Client needs to understand the risks and implications of STDs on her health and that of her developing fetus. |
| 2. Provide treatment with metronidazole (safe after first trimester), and recheck for cure after completion of treatment. | 2. Complete course of medication is effective in fighting the infections. |
| 3. Discuss with client and partner importance of safer sex practices and merits of testing for HIV and other STDs. Advise partner to be treated. | 3. Treatments will be most effective if involved partner also undergoes treatment and therapy. |

Evaluation Janice reports she took all medication. Repeat testing is negative for *Trichomonas* infection. Boyfriend obtained medication, but Janice is unsure about his completion of therapy. Janice reports she has insisted on condom use since learning of risks of STDs in pregnancy. Other STD tests and HIV test are negative. Boyfriend has not yet agreed to HIV testing.

Nursing Diagnosis

Ineffective coping related to lack of alternatives to harmful substances, environmental prevalence of substance use, fatigue, and lack of social support.

Expected Outcomes Replace ineffective coping strategies (substance use) with alternative activities.

Planning Client will demonstrate abstinence from substance use or progress toward abstinence and can describe alternative methods of coping with fatigue and stress.

Nursing Interventions

Rationales

- | | |
|---|---|
| 1. Provide reading materials and refer for counseling to uncover alternative means of recreation and relaxation such as walking, movies, games, playing with her son, and naps in late afternoon while grandmother watches her son. | 1. Client may need help in identifying alternatives to substance use as a means of recreation; activities that involve her son and family may help strengthen family bonds. |
| 2. Discuss new sources of social support such as women's groups, religious groups, family, or clubs. | 2. Offering client an array of choices will allow her to choose those options most appealing to her, thereby increasing the likelihood of compliance. |

(continued)

Evaluation Janice remains abstinent from all substances except cigarettes. She has found a friend at a local AA meeting held in a church. She and her son have discovered friends at a playground of a local public library and have begun to go there in the evenings. She describes some distance between herself and her boyfriend but hopes that he will see the benefit of this healthier lifestyle.

can be done on a large scale to improve public health. More stringent federal and state policies for industrial waste emission and cleanup of toxic waste hazards are needed. Public education about safe food products and food preparation should be promoted by nurses. Nurses can advocate for safe housing for even the poorest residents of their communities to reduce stress from neighborhood violence and drug commerce, the risk of lead poisoning from unsafe paint, and the risk of infection from substandard water supplies.

A major area for nursing advocacy is that of federal policies for family work leave and work modification for pregnant and parenting women. Paid leave for the last 2 months of pregnancy and first 6 months postpartum is common in other industrialized nations, as is subsidized or free child care. Pregnant women should be able to change their job responsibilities during pregnancy to reduce risk without loss of income or fear of losing their jobs completely. Such family-friendly policies promote the health of mothers and children, reduce the risk of low birth weight, and foster strong and nurturing family bonds while maintaining financial stability.

Web Activities

- Visit some of the government web sites listed in this chapter. Can you locate specific information regarding avoiding hazards in pregnancy? Do these sites also contain guidelines for health professionals who counsel pregnant women and their families?
- Choose a specific toxin discussed in this chapter and search the web for information on its effects on a developing fetus.

Key Concepts

- Many substances found in air, soil, food, and water, as well as prescribed and over-the-counter medications, have potential effects on fetal development.
- A pregnant woman's living conditions, geographic location, work environment, and neighborhood activities can increase fetal risks. Neighborhood violence, proximity to chemical wastes, or isolation from adequate health care can create hazards and stressors while reducing a woman's ability to obtain help.
- Behaviors such as substance abuse may be hazardous to the developing fetus. Alcohol and tobacco use are responsible for widespread fetal risks.
- Nursing assessment of the pregnant woman must include careful and sensitive history-taking to reveal potential pregnancy risk in her neighborhood, home, work environment and activity, and personal behavior.
- Pregnant women must be educated to avoid all medications until advised by a health professional. They also can be reassured that most food additives are not harmful. Preconceptual counseling is important for women who must take medications to control chronic illnesses.
- Ongoing support and monitoring by the nurse will help pregnant women maintain a low-risk environment for fetal development. Lifestyle changes for substance users are difficult to make; outside support from counselors, social service workers, substance abuse treatment professionals, and others can assist the pregnant woman.

Review Questions and Activities

1. Contact the Environmental Protection Agency and the Centers for Disease Control and Prevention. Obtain information about potential hazards in your geographic area, including industrial wastes currently being discharged into the environment, toxic waste storage areas or contaminated land, and infection sources. Create a poster for a prenatal clinic to educate women and their families about local risk and how to protect themselves.
2. Visit a local factory or hospital. Ask for information on hazardous substances in that work environment. Prepare an educational pamphlet for pregnant woman in that work setting.
3. Visit an AA meeting. (Some are specified as open, and others may be limited to clients who abuse substances or restricted to specific members.) Note the personal circumstances and family histories of persons who disclose their past experiences. Analyze the difficulties and obstacles to substance abuse recovery. Explore other local resources for pregnant women who want to begin recovery from substance abuse.
4. Research the safety of use during pregnancy of medications commonly prescribed for chronic illnesses such as hypertension, asthma, epilepsy, diabetes, or multiple sclerosis. Use local teratology hotlines. Develop a guideline for nurses caring for this group of patients to advise them of which medications are safe and which may need alteration or substitution during pregnancy.
5. Prepare a travel advisory for pregnant women who plan to go to a particular tropical nation. Explore the tropical diseases prevalent in that area. Using reference materials, list the safe vaccinations and other recommendations for pregnant women to avoid infection.

Evaluation of Fetal Well-Being

Kristen is a 40-year-old woman who has been married to Jack for 6 months. This is a second marriage for both Kristen and Jack. Kristen has three children (aged 14, 11, and 8 years) from her previous marriage, and Jack has two teenagers with his first wife. Kristen was diagnosed with Crohn's disease five years ago. She has been experiencing irregular and infrequent menstrual cycles for the past 3 years. She was advised that in view of her chronic bowel disease and family history she was most probably experiencing premature menopause.

Kristen began to experience extreme fatigue and urinary frequency. She visited her primary care physician and, much to her surprise, discovered she was approximately 14 weeks pregnant. After the initial shock, Kristen and Jack were very happy. They viewed this pregnancy as a gift and a sign of their everlasting love and life together.

As part of her prenatal laboratory testing, maternal serum- α -fetoprotein (MS-AFP) and estriol levels were measured. When the results were returned, the MS-AFP level was low. Kristen was informed that this finding indicated that she was at greater than average risk for carrying a fetus with Down syndrome. Kristen was advised to have an amniocentesis for karyotyping of the fetus and a definitive diagnosis of whether or not the fetus had an extra chromosome 21.

Kristen and Jack were greatly distressed. Kristen states she could never have her pregnancy terminated, no matter what the test indicates, and Jack is supportive of her position. The physician is strongly advocating for an amniocentesis stating, "We need to know what we are dealing with." Finally, Kristen tearfully says, "I wish I never had that blood test!"

Key Terms

Amniocentesis	Fetal fibronectin (fFN) testing	Human placental lactogen (hPL)	Percutaneous umbilical blood sampling (PUBS)
Biophysical profile (BPP)	Fetal movement counting (FMC)	Magnetic resonance imaging (MRI)	Ultrasonography
Chorionic villus sampling (CVS)	Fetal tissue sampling	Maternal serum–alpha-fetoprotein (MS-AFP)	
Contraction stress test (CST)	Human chorionic gonadotropin (hCG)	Nonstress test (NST)	
Doppler blood studies			

Competencies

Upon completion of this chapter, the reader should be able to:

1. Discuss the clinical applications of ultrasonography.
2. Identify the role of the nurse in the evaluation of fetal well-being.
3. Identify the criteria for interpreting a nonstress test.
4. Explain fetal diagnostic techniques to families.
5. Differentiate between screening and diagnostic procedures.
6. Describe three procedures used to identify genetic alterations during pregnancy.
7. Teach the client how to perform fetal movement counts.
8. Describe a method to evaluate fetal maturity.

Technology and science have become prominent components of obstetrical care. Technology can provide useful information about the status of the pregnancy and condition of the fetus; however, it is imperative to balance technologic capabilities with responsiveness to the human needs of the woman and her family. Many of the fetal evaluation techniques described in this chapter are performed in outpatient settings. In addition, many of these procedures, especially those performed during the first half of pregnancy, are technically oriented and have minimal direct care responsibilities for the nurse during the procedure itself. However, the nurse does have a major role in identifying, preparing, counseling, supporting, and educating clients regarding the implementation and understanding of fetal evaluation throughout the period of gestation. Fetal evaluation is an interdisciplinary endeavor involving physicians, sonographers, laboratory technicians, and nurses. However, the nurse often is the only care provider who can establish a therapeutic and holistic relationship with the client and who has the opportunity to interact with the client before, during, and after the procedure. Consequently, nurses need to have a complete knowledge base of fetal diagnostic and screening technologies; the disease

processes that warrant fetal evaluation; and the meaning of the findings of these procedures to the woman, the pregnancy, and the family. The counseling, support, and education provided by the nurse are vital interventions to assist the woman during the experience of fetal evaluation.

EVALUATION OF FETAL WELL-BEING

A variety of diagnostic techniques and monitoring parameters are used to evaluate *fetal well-being*, that is, the growth and health of the developing fetus as well as its ability to tolerate the physiologic stresses of pregnancy, labor, and birth. Fetal development is a complex and, at times, mysterious process. The introduction of fetal evaluation technologies has allowed health care providers to peer into the intrauterine environment and gather data related to some of the mysteries of fetal growth and development. Fetal surveillance techniques have dramatically affected the understanding of fetal anatomy, physiology, and behavior. In addition, technologic advances have facilitated the ability to diagnose anatomic abnormalities, growth failure, and the potential for fetal hypoxia and

neonatal sequelae. The rapid growth of technologic advances in evaluating fetal conditions, however, has introduced the possibility of the use of such technology without a comparable level of knowledge of its effects and implications.

The average duration of human pregnancy is 40 weeks, or 280 days after the first day of the last menstrual period. The gestational period typically is divided into the period of the embryo (the first 8 weeks) and the period of the fetus (9 weeks to birth). The embryonic period is a time of growth, differentiation, and organization of the cellular components of the developing being. During the embryonic period, evaluation is done primarily to assess for normal implantation, viability, and abnormalities with a genetic base. By the end of the 8th week of gestation, all body systems are present in at least a rudimentary form. During the remainder of the gestational period, the fetal period, these rudimentary body systems grow, change, and evolve into specialized tissues and organs in preparation for existence outside the uterus. During this period of pregnancy fetal well-being can be assessed and monitored using a number of biochemical, physical, and physiologic surveillance techniques.

Routine assessment of fetal well-being has included intermittent auscultation of fetal heart rate, measurement of fundal height, and maternal perception of fetal movement. These parameters provide indirect measures of fetal condition (Figure 22-1). As knowledge about the causes of fetal compromise has grown and technology has progressed, however, three areas of particular concern to

Figure 22-1 Literature should be made available to the expectant parents who will be undergoing fetal evaluation testing. The nurse should also help the client understand and interpret information and be ready to answer questions.

nurses regarding fetal surveillance techniques have emerged: purpose, process, and consequences.

Purpose

We examine the purposes of the proposed fetal evaluation technologies: for use as diagnostic testing, screening procedures, and reassurance procedures. Some of the testing modalities described in this chapter are diagnostic, for example, amniocentesis and chorionic villus sampling for determination of chromosomal complement. Diagnostic testing modalities confirm the presence or absence of a specific condition. Other testing modalities are screening procedures to identify clients at greater risk of having a condition than the general population. These screening procedures identify a fetus as being at greater risk than other fetuses but do not confirm or rule out the condition in either group. Examples of screening procedures used during the prenatal period are MS-AFP and fetal fibronectin measurements. Thus, a positive finding that results from one of the screening technologies opens the door to further use of fetal evaluation technologies in attempts to obtain diagnostic data. A third group of evaluation technologies is reassurance procedures. These procedures

PRENATAL SCREENING

When considering whether prenatal screening should be done, ask the following questions:

1. Is the screening procedure justified in this population?
2. What is the risk to the pregnancy?
3. What is the risk to the woman?
4. What will the results reveal about the status of the pregnancy?
5. Which options are available to the woman and her family if the results indicate increased risk?
6. Which resources are available to support the woman and her family?

include the nonstress test. This test provides data predictive of fetal health and well-being; however, when the results are abnormal, no concrete evidence of danger to the fetus is provided. The client must understand the purpose or goal of a particular fetal evaluation technology in order to provide consent to undergo the procedure.

Fetal surveillance procedures should be considered for women with one or more of the following risk factors: maternal age over 35 years; a family history of chromosomal anomaly; carrier status, including a balanced translocation; and an X-linked disorder or an autosomal recessive trait. Table 22-1 outlines certain risk factors and the related recommended assessment techniques. Prenatal determination of fetal gender is a valid indication for prenatal surveillance only when the possibility exists of the presence of an X-linked disorder.

Process

We discuss the process of implementing the chosen fetal evaluation technology. The overriding goal of fetal evaluation is to obtain information about the growth, development, and well-being of the fetus; however, it is impossible to do so without invading the woman's bodily

Critical Thinking

Gender Selection

How do you respond to a 36-year-old client (gravida 6, para 5) (all boys) who tells you she wants genetic testing done because if this baby is not a girl, she wants to terminate the pregnancy.

integrity. Whether it is drawing blood, obtaining amniotic fluid, or placing a transducer on the abdomen, the woman is physically impacted during the implementation of fetal evaluation. Consequently, the rights and autonomy of the woman as an individual are potentially in opposition to the rights and well-being of the fetus. Therefore, the decision by the client to undergo prenatal surveillance procedures requires careful consideration of the prevalence and severity of the condition under investigation, the sensitivity and specificity of the testing modality, and the economic

Table 22-1 Assessment for Increased Risk of a Genetic Disorder		
Risk Factors	Related Risks	Assessment Techniques
Maternal age	At the age of 35, the risk of fetal loss from invasive prenatal testing equals the risk of having a child with a chromosomal anomaly.	Collection of demographic data Interview and general survey
Ethnic background	Certain genetic diseases are found in populations with a specific ethnic background, e.g., <ul style="list-style-type: none">• Tay-Sachs disease: Eastern European Jews• Thalassemia: Mediterranean descent• Sickle cell trait: African Americans	Interview Pedigree or genogram to analyze patterns
Family history	The presence of certain diseases (hemophilia, Huntington's chorea, and cystic fibrosis), birth defects (neural tube defects and abdominal wall defects), or mental retardation in the family history increases the risk for future offspring.	Careful family history Pedigree or genogram to analyze patterns
Reproductive history	Previous poor perinatal outcomes, e.g., <ul style="list-style-type: none">• Stillbirths• Repeated spontaneous abortions• Children with birth defects or disorders	Careful family history Medical record review
Maternal disease	Some diseases have the increased risk of transmission from mother to fetus.	Careful review of past medical history, current health status, and medication ingestion
Environmental hazards	Exposure to chemicals, radiation, hot tubs, nutrition, or other potential teratogens	Behavior evaluation Preconception education about hazard exposure

and emotional costs. Table 22-2 provides an overview of the types of fetal surveillance procedures available.

Providing an explanation of the procedure and its risks, benefits, and implications from the perspective of the woman as well as from that of the fetus is important. The nurse needs to be a nondirective counselor, committed to helping the client make a well-informed decision. It is the client who should decide if she wants to have the pregnancy screened or the fetus tested. It is also the client who should decide which actions should be taken based on the results of these tests. The woman and her family need a clear and thorough explanation of all the problems and potential outcomes of the current pregnancy. They then need to examine the information in view of their

personal, social, religious, cultural, and familial beliefs and values. The client needs time to think carefully about the potentially serious implications of pregnancy screening and fetal testing, without feeling pressured to make a decision.

Attention to maternal physical and emotional well-being is equally important in evaluating fetal or uterine response to evaluation technologies. For example, the following should be considered in deciding to initiate fetal evaluation procedures and in selecting specific evaluation modalities:

- Comparison of the specific differential procedures and risks of termination of a first- versus a second-trimester pregnancy.
- The impact of a procedure-induced loss of pregnancy compared with the risk of having a child that is not affected by a specific condition.
- The risk of maternal physical or psychological injury from the procedure.
- The resources available to provide support to the client and family who may experience a loss.

The nurse often is in the position of being the client's advocate and is a key person in assisting the client in

REFLECTIONS FROM A NURSE

"My client, Svetlana, received early and consistent prenatal care. She had no complications during her pregnancy. She had a CVS and two ultrasound examinations, and she performed daily fetal movement counts from 28 weeks on. All test results were within normal parameters. When her infant was born, however, he had a rare congenital anomaly. Svetlana and her family were devastated, and as her primary nurse, I was surprised and saddened. She and her family asked again and again, 'How can this happen?'"

Critical Thinking

Client Preparation for Fetal Evaluation

When preparing a client for fetal evaluation procedures, be sure you are prepared to respond to all of the following questions:

- Why is the procedure being done?
- Is the procedure safe?
- How accurate is the test?
- What information will the test provide?
- Who will perform the procedure?
- Is any physical preparation necessary?
- What does the procedure involve?
- How much time will the test take?
- What will I feel?
- What is the recovery time after the procedure?
- Who will interpret the results?
- When will I be informed of the results?
- Who will talk with me about the results?
- Who will answer my questions and address my concerns about the test and the results?
- What other options are available?

Critical Thinking

Difficult Choices

What are the psychosocial implications of choosing to have prenatal diagnosis and the implied consideration of pregnancy termination on the development of family bonds and trusting relationships?

accessing and synthesizing the information necessary to make decisions. Also, as with any technical procedure, it is incumbent on the nurse to ensure that the appropriate equipment and resources are available in the event a complication necessitating emergency intervention arises.

Consequences

We discuss the consequences of fetal evaluation technologies. As with any procedure that generates information, one must think about how that information will be used. Information can have both positive and negative implications. Information obtained from fetal evaluation technologies may significantly alter the course of a pregnancy. Based on the information obtained from fetal evaluation technologies, women are faced with choices about terminating the pregnancy, pursuing fetal therapy or intrauterine surgical procedures, waiting and accepting the test results, or hoping the test was wrong. There are no right answers, and even more questions will arise as technology continues to advance. These questions and the consequences of each option need to be explored in a knowledgeable and supportive environment.

Considering the consequences of fetal evaluation when a problem is detected is as important as considering the impact of fetal evaluation when the postulate condition is not confirmed. A “good” result from fetal evaluation technologies can result in a false sense of security. Fetal evaluation technologies do provide data about a wide variety of fetal conditions; however, many other conditions and factors exist that can impact pregnancy outcome. Fetal evaluation does not guarantee a perfect baby; it only provides data that confirm the presence or absence of a specific condition for which the testing modality was searching (Raines, 1996).

GENETIC AND BIOCHEMICAL EVALUATION

Prenatal evaluation has become increasingly important since the development of amniocentesis in the 1950s. The

concept underlying genetic and biochemical testing is the application of biochemical techniques to fetal tissue or cells as a means of detecting potentially harmful alterations. These alterations may be genetic, such as alterations in chromosomal number, change in molecular structure, metabolic deviation, and hematologic variation (Table 22-3). Biochemical analysis also can provide information related to fetal maturity and placental function that, in turn, can provide the critical data needed to develop a therapeutic treatment plan for managing a high-risk pregnancy. Genetic and biochemical evaluation of pregnancy status can be grouped into invasive fetal diagnostic studies and maternal serum studies.

Invasive Fetal Diagnostic Studies

Invasive fetal procedures involve violating the integrity of the fetal-placental-uterine environment and include amniocentesis, chorionic villus sampling, percutaneous umbilical blood sampling, and other tests. These studies facilitate direct testing of fetal tissues and byproducts. Invasive fetal diagnostic studies can identify a number of fetal conditions. These diagnostic tests are the first steps in the development of fetal intrauterine surgical interventions and the implementation of gene therapy to correct potentially life-threatening or life-altering conditions detected during the gestational period.

Specific concerns, both maternal and fetal, related to the possible risks and complications are discussed for each testing modality. However, a general concern relevant to all invasive fetal procedures is the risk of maternal-fetal hemorrhage. Therefore, blood type should be obtained for all pregnant women undergoing invasive fetal testing

Table 22-3 Areas of Genetic and Biochemical Evaluation	
Type of Condition	Example
Alteration in chromosomal number	Trisomy 21, Down syndrome Trisomy 18, Edwards' syndrome Trisomy 3, Patau syndrome Klinefelter's syndrome Monosomy: Turner's (or Noonan's) syndrome
Molecular structure	Cystic fibrosis Hemophilia Duchenne muscular dystrophy
Metabolic	Tay-Sachs disease Gaucher's disease
Hematologic	Sickle cell disease β-Thalassemia

Nursing Alert

PREVENTING ANTIBODY FORMATION

Women who are Rh-negative undergoing invasive fetal evaluation techniques such as CVS, amniocentesis, or PUBS should receive RhoGAM[®] after the procedure to prevent antibody formation in the event of maternal-fetal bleeding.

procedures. Women who are Rh-negative are candidates for Rh₀(D) Immune globulin (RhoGAM[®]). Prophylactic RhoGAM minimizes the potential for maternal sensitization and prevents antibody formation in the event of a minor maternal-fetal bleeding.

Amniocentesis

Amniocentesis is one of the oldest invasive methods of fetal evaluation. Use of amniocentesis was first documented in the 19th century as a treatment for polyhydramnios (Romero et al., 1991). The first documented use of amniocentesis for prenatal diagnosis was in 1966 when Steel and Breg cultured amniotic cells and identified the karyotype of the resulting cells (Steel & Breg, 1966). Today, with the increased knowledge of molecular genetics, am-

niocentesis is used to obtain amniotic fluid for the diagnosis of a variety of disorders through enzymatic analysis and DNA testing (Reece, 1997). In addition, the fluid obtained by amniocentesis can be used to evaluate fetal hemolytic disease by measuring bilirubin levels and fetal lung maturity by analyzing phospholipid ratios later in pregnancy.

Description

Amniocentesis is the removal, collection, and analysis of a sample of amniotic fluid from the amniotic sac. Amniotic fluid has long been established as a commonly used medium for prenatal diagnosis. Amniotic fluid is fetal in origin. It contains a variety of chemical substances and electrolytes. Amniotic fluid also contains a mixture of cells shed by the fetus from its skin and the linings of its gastrointestinal, respiratory, and genitourinary tracts. The cellular and biochemical components of amniotic fluid change with gestational age and fetal maturation. Consequently, amniotic fluid analysis is useful to determine chromosomal disorders early in pregnancy and to evaluate fetal health and maturity later in pregnancy.

Timing and Indications

Amniocentesis can be performed at different times during pregnancy for a variety of indications. Amniocentesis was originally used and continues to be most commonly performed between 15 and 17 weeks' gestation. During this stage of the pregnancy the amniotic sac is more accessible because the uterus has migrated from the pelvis to the abdomen; the volume and continuous replacement of amniotic fluid are adequate for sampling and fetal protection; and the ratio of viable to nonviable cells is greatest (Reece, 1997). Amniocentesis performed at this time usually is referred to as a mid-trimester procedure. Multicenter studies have demonstrated the procedure to be relatively safe, with an estimated pregnancy loss of 1 in 400 (0.25%) (Davis 1993). Studies also have demonstrated that mid-trimester amniocentesis is not associated with problems related to birth weight, gestational age, or maternal-fetal complications (Davis, 1993). One of the major disadvantages of mid-trimester amniocentesis is the need to wait until 15 weeks' postmenstrual gestational age to perform the procedure. Combined with the time necessary to culture and grow cells, test results may not be available until the pregnancy is physically evident to others and the woman has felt fetal movement. In addition, when the decision for pregnancy termination is made, the client must accept the increased risk of morbidity associated with second-trimester termination procedures. As a result, early amniocentesis involving the aspiration of fluid at or before 14 weeks' gestation has been explored (Davis, 1993). Early amniocentesis is technically more difficult because the uterus is still positioned within the pelvis and a smaller

Nursing Tip

INDICATIONS FOR AMNIOCENTESIS IN THE FIRST HALF OF PREGNANCY

1. Maternal age over 35 years.
2. Previous offspring with abnormal chromosomal pattern.
3. Altered chromosomal pattern, including a balanced translocation, aneuploidy, or mosaicism in either parent.
4. Trisomy 21 (Down syndrome) or other chromosomal abnormality in close family members.
5. Pregnancy after three or more spontaneous abortions.
6. Elevated MS-AFP level.
7. Personal or family history leading to increased risk for a neural tube defect.

volume of amniotic fluid is present. The procedure-related loss rate for early amniocentesis is 2.0% to 3.0%, which is greater than the loss rate for mid-trimester procedures (Reece, 1997).

Throughout pregnancy, but most significantly before 18 weeks' gestation, analysis of amniotic fluid samples can provide information about fetal karyotype, metabolic disorders, DNA pattern, and other biochemical components. Because the desquamated cells found in amniotic fluid are fetal in origin, they contain genetic information identical to the fetus (Callen, 2001). The list of conditions identifiable through amniotic fluid analysis includes chromosomal disorders, such as translocation, aneuploidy, and trisomy; autosomal recessive disorders; X-linked disorders; metabolic diseases; enzyme defects; hematopoietic diseases; and immunodeficiencies. As the number of genes identified by the Human Genome Project continues to grow, the list of conditions identifiable through amniotic fluid analysis also will continue to grow and may include individual traits and attributes as well as medical conditions or syndromes.

In the second half of pregnancy, amniotic fluid analysis can be used to identify fetal hemolytic disease caused by maternal red blood cell (RBC) antigens. Isoimmune hemolytic disease of the fetus culminates in hemolysis and phagocytosis of fetal RBCs. As the fetus becomes increasingly anemic, the bilirubin level in the amniotic fluid increases. On spectrophotometry, bilirubin levels produce an optical density peak at 450 nm. Therefore, titers of bilirubin in the amniotic fluid can be measured and evaluated. Increased levels of ocular density indicate advanced hemolysis. The degree of fetal involvement is evaluated by graphing the ocular density measure of bilirubin correlated with gestational age to identify the severity of fetal hemolytic disease.

Amniotic fluid values also can be used to evaluate fetal well-being through the use of gram-staining techniques to identify intraamniotic infections and measurement of creatinine levels reflective of fetal kidney development and fetal muscle mass.

A common use of amniotic fluid analysis in late pregnancy is to evaluate fetal surfactant production and respiratory system maturity in anticipation of the transition to extrauterine existence. Evaluation of the lecithin-to-sphingomyelin ratio is the most widely used method of fetal lung maturity assessment. Sphingomyelin levels remain relatively constant throughout pregnancy, whereas lecithin levels increase dramatically with the production of mature surfactant. Consequently, pulmonary maturity is established when the lecithin-to-sphingomyelin ratio is 2:1 or greater. A specific phospholipid, phosphatidylglycerol (PG), found in the amniotic fluid also is an indicator of fetal lung maturity. The presence of PG takes on added significance in women with conditions such as gestational diabetes, blood incompatibilities, and methadone use. In

these conditions, the mature pathway for surfactant production is delayed and the lactase/sucrase ratio may be borderline, but the presence of PG almost ensures pulmonary maturity.

A newer technique for evaluating lung maturity by amniotic fluid analysis is counts of lamellar bodies. Lamellar bodies are excreted by type II alveolar cells, and the concentration of lamellar bodies increases exponentially with gestation (Greenspoon et al., 1995). Fetal pulmonary maturity is associated with counts of lamellar bodies of over 30,000 particles/ μL (Fakhoury, Daikoku, Benser, & Dubin, 1994).

Client Preparation

Amniocentesis usually is performed as an outpatient procedure. Informed consent procedures include a dialogue outlining the risks, benefits, and limitations of the procedure as needed. When amniocentesis is done in early pregnancy, the bladder may be filled to elevate the uterus and increase visualization of a fluid pocket. In the second half of pregnancy, the bladder is emptied to prevent confusion between it and the uterine sac. Maternal vital signs and fetal heart tones are evaluated before the procedure. During the procedure, the client is placed in a supine position. In late pregnancy, a hip roll may be used to prevent supine hypotensive syndrome. The client needs to know that some women experience a sensation of pressure, cramping, or both during the procedure.

Before and during amniocentesis, the nurse is a support person and patient advocate. The need for the procedure and the potential outcome are sources of anxiety and uncertainty for most women. Anticipating the client's anxieties and feelings and responding verbally and nonverbally are critical components of client preparation by the nurse.

Procedure

Amniocentesis is performed after ultrasound examination to identify an adequate pocket of amniotic fluid free of fetal parts, umbilical cord, or placental mass (Figure 22-2). The maternal abdominal wall is cleansed with an antiseptic solution and prepared and draped as a sterile field. In some situations, a local anesthetic may be used before amniocentesis is performed. Using an ultrasound probe with a sterile cover, the physician introduces a 20- or 22-gauge spinal needle through the abdominal wall and uterus and into the pocket of amniotic fluid. As the needle stylet is removed, amniotic fluid should freely flow from the needle. The initial fluid sample may be contaminated by maternal blood or cells and usually is discarded. In amniocentesis done early in the pregnancy, approximately 1 mL of fluid for each gestational week is collected. In amniocentesis performed at mid-trimester, approximately 20 to 30 mL of

A.

B.

Figure 22-2 A. An amniocentesis setup. B. During amniocentesis, a sample of amniotic fluid is aspirated for evaluation.

fluid is collected. In amniocentesis performed in the third trimester, the volume of fluid collected will vary based on the number and types of tests being performed. If the attempt to obtain amniotic fluid is unsuccessful, a second needle may be inserted at a different site. However, studies have indicated that fetal loss rates increase in proportion to the number of needle insertions. Therefore, no more than two attempts should be performed on any given occasion (Reece, 1997). After withdrawal the fluid is placed in culture tubes, labeled, and sent to the laboratory

Critical Thinking

“I Feel So Guilty”

How do you respond to a woman who, after having amniocentesis, states, “I feel so guilty. This test makes it seem as if I won’t love this baby unless it is perfect”?

for analysis. Culture tubes sometimes require special handling to protect the specimen. For example, specimens for bilirubin analysis must be placed in tubes covered with an opaque material to prevent breakdown of the bilirubin by light rays. After fluid collection the needle is withdrawn, pressure is applied to the site, and the site is dressed.

Follow-up

Maternal vital signs and fetal cardiac activity are documented at the conclusion of the procedure. When amniocentesis is performed before the age of viability, cardiac activity is an indicator of fetal survival. As gestational age of the pregnancy advances, monitoring of fetal tolerance to the procedure is increased and may incorporate other modalities to evaluate fetal well-being, such as a nonstress test.

Many women experience mild cramping for a few hours after the procedure. Women should be instructed to rest until the cramping subsides and then resume normal activity. However, women should refrain from sexual intercourse, heavy lifting, and strenuous physical activity for 24 hours. The abdominal puncture site should be kept clean, and no special skin care is required.

Maternal complications after amniocentesis, including vaginal spotting, fluid leaking, and uterine contractions, are uncommon and usually self-limiting (Tabor et al., 1986; Reece, 1997). Women need to report any vaginal discharge, severe or persistent uterine cramping, and increased temperature to the health care provider.

Women need emotional support and education during the interval between the procedure and availability of the results, especially when the purpose of the testing is for identification of a condition that may threaten the well-being and continuation of the pregnancy. The client needs to be informed of when the results will be available, who will contact her, and how she will learn the outcome. Ongoing support during this period of uncertainty is a critical role for the nurse.

Chorionic Villus Sampling

Chorionic villus sampling (CVS) is an alternative to amniocentesis. The primary stimulus for the development of CVS

technology was its use in earlier diagnosis, during the first trimester when the pregnancy is not yet physically visible to others. The major disadvantages of CVS are inability to diagnose the presence of a neural tube defect and higher rate of pregnancy loss.

Description

Chorionic villus sampling is a procedure to obtain fetal cells in the first trimester of the developing pregnancy. Chorionic villi cells are living cells fetal in origin, thereby reflecting the chromosomes, enzymology, and DNA content of the fetus. However, unlike amniocentesis, CVS cannot determine the presence of a neural tube defect because the level of α -fetoprotein can only be tested using serum or amniotic fluid.

Timing and Indications

Chorionic villus sampling is usually performed between 10 and 12 weeks' menstrual age of gestation (American College of Obstetricians and Gynecologists, 1995). At this gestational age, the amniotic sac does not fill the uterine cavity, thereby facilitating the passage of the sampling instrument into the uterus to remove a tissue specimen. A small tissue aspiration device is inserted into the developing placenta, allowing the chorion frondosum (which ultimately will form the placenta) to be biopsied. The chorion frondosum are mitotically active cells that provide tissue for karyotype determination and tissue cultures as well as fetal RBCs for identifying RBC antigens (Wapner, 1997). Because the chorionic villi are composed of spontaneously dividing cells, it is not necessary to grow cell cultures in the laboratory.

The chorion frondosum eventually will develop into the placenta, and can be visualized on ultrasonography. Only a small amount (10 to 20 mg) of villi is required for most diagnoses. This quantity of cells represents less than 1% of the villi destined to become the functioning placenta.

The greatest benefit of CVS is earlier diagnosis of fetal disorders and a shorter interval between test performance and availability of the results. CVS is performed in the first trimester of pregnancy, before the obvious changes in maternal physical appearance and before the experience of quickening. If the woman chooses to end the pregnancy based on the diagnosis, a first-trimester termination procedure, with a lower risk of complications and lower cost, is an option. The waiting time between obtaining the specimen of chorionic villi and test results also is decreased because the specimen consists of actively dividing fetal cells as opposed to the cells shed by the fetus that are grown in culture medium after amniocentesis.

The risks associated with CVS include spontaneous pregnancy loss. One confounding factor in calculating

pregnancy loss after CVS is the differentiation of loss related to the procedures and pregnancies that would have naturally terminated between 9 and 20 weeks' gestation. One study has demonstrated that 2% to 5% of pregnancies shown to be viable by ultrasonography at 7 to 12 weeks' gestation subsequently become nonviable or spontaneously abort before 20 weeks' gestation (Rodesch et al., 1987). Data from two collaborative studies have demonstrated that the risk of pregnancy loss is not significantly greater than that with the more established mid-trimester amniocentesis procedure (Canadian Collaborative Study, 1989; Rhoads et al., 1989). Concern has been voiced about the increased risk of fetal structural anomalies after CVS. Froster-Iskenius and Baird (1989) reported a greater than 1% incidence of oromandibular-limb hypogenesis in CVS sampled pregnancies. This syndrome has a prevalence of 0.057 per 10,000 births, thereby providing strong suspicion of an association between the procedure and the presence of anomalies (Froster-Iskenius & Baird, 1989). While the cause of this malformation is not clear, it appears that the association is related to the timing of the CVS procedure, between 55 and 65 days' gestation (Hsieh et al., 1995). While the association is unclear, the American College of Obstetricians and Gynecologists (1995) has made the following statement related to the use of CVS in the clinical setting.

Chorionic villus sampling is a relatively safe procedure when performed at 10–12 weeks and is an acceptable alternative to amniocentesis. Chorionic villus sampling is not recommended prior to nine weeks' gestation.

Client Preparation

Chorionic villus sampling usually is performed in an outpatient setting and takes approximately 20 minutes. However, the preparation and recovery time may require approximately 2 hours in the clinical setting. Before the procedure, the client and her family should receive genetic counseling and be informed about its benefits, risks, and limitations. Informed consent must be obtained. The client needs thorough education about what to expect during the procedure, and a comprehensive assessment of maternal-fetal status is completed. A full bladder is used to serve as an acoustic window. Some women experience discomfort during the procedure as a result of bladder fullness and pressure from the ultrasound transducer.

Procedure

Two techniques currently are in widespread use for performing CVS: the transcervical catheter aspiration technique and the transabdominal needle aspiration technique (Figure 22-3). The choice of a transvaginal or transabdominal approach usually is based on client preference

Figure 22-3 During chorionic villus sampling, a small tissue sample is aspirated from the fetal side of the placenta. Needle insertion is made either transabdominally or transvaginally.

and provider skill. In some situations, however, client-specific factors such as the presence of cervical polyps, uterine position and placental location, or active cervical or vaginal herpes infection determine the procedural approach. Both approaches require two practitioners, one performing the sampling and one providing the ultrasound guidance.

If the transcervical technique is selected, an ultrasound examination is completed to confirm fetal viability and to locate the chorion frondosum. The woman is placed in lithotomy position, and a sterile speculum is inserted to visualize the cervix. A transcervical catheter with a malleable obturator, capable of negotiating the cervicouterine angle and being directed to the biopsy site is selected. Under real-time ultrasound guidance, the physician passes the catheter through the cervix and into the chorion frondosum. Once at the selected site, the obturator is removed, a 20-mL syringe is attached to the catheter, and negative pressure is applied to aspirate the villi into the syringe. The catheter is removed with continuous negative pressure being applied to prevent leakage into the amniotic sac. If an inadequate sample is obtained, the procedure is repeated with a new sterile catheter. In general, no more than three attempts are made. The presence of fetal cardiac activity, appearance of the amniotic sac, and the chorion frondosum are verified after each attempt.

Ultrasound verification of fetal viability, gestational age, and location of the chorion frondosum is the first step in transabdominal CVS. After ultrasound examination, the maternal abdomen is draped and prepared with an antiseptic solution in a way similar to that of the amniocentesis procedure. Under ultrasound guidance, an 18- or 20-

gauge needle is inserted through the abdominal and uterine wall and guided into the chorion frondosum. A 20-mL syringe is attached to the hub of the needle, and negative suction is applied to aspirate the sample of villi. The tip of the needle is kept under ultrasound visualization at all times. If an inadequate sample is obtained, the procedure is repeated using a new sterile setup.

The specimen from either technique is inspected visually for the presence of villi, which have a distinctive frondlike appearance with budlike projections. The specimen is placed in a sterile medium for transport and cytogenic analysis.

Follow-up

After the procedure the woman's vital signs are evaluated and assessment of uterine status is completed. Uterine cramping should not occur. Vaginal spotting may occur after the transcervical approach, and usually resolves within 3 days. Heavy bleeding or passage of clots, tissue, or amniotic fluid is abnormal and should be reported to the health care provider. After the CVS procedure, the client is advised to avoid sexual activity and strenuous physical activity until all vaginal spotting has resolved. The client also needs to be informed to contact the physician if cramping, vaginal bleeding, or flulike symptoms are experienced within the week. Women usually have follow-up ultrasonography a week after the procedure and at 16 weeks' gestation to reconfirm integrity of the products of conception.

Percutaneous Umbilical Blood Sampling

Percutaneous umbilical blood sampling (PUBS), also known as cordocentesis, has expanded the possibilities for fetal surveillance and treatment. Improved ultrasound guidance techniques have enhanced the safety of this highly invasive technique. A major consideration in the decision to perform PUBS is whether premature birth and neonatal care would be more effective or associated with lower risk than this highly invasive prebirth procedure.

Description

PUBS is an evaluation technique that provides direct access to the fetal circulation and involves direct aspiration of fetal blood. The most common site for needle placement is the umbilical cord, within 2 cm of the placental insertion site. This site is preferred because it provides a relatively fixed target for puncture as opposed to a free-floating loop of cord. Conditions such as maternal obesity, marked hydramnios or oligohydramnios, or unfavorable fetal position may make the cord-placenta junction inaccessible. Thus, alternative sites include the fetal intrahepatic vein and the cardiac ventricle.

Timing and Indications

Percutaneous umbilical blood sampling can be performed any time after 17 weeks' gestation. Because the medium assayed is fetal blood, PUBS is useful in conducting a wide variety of blood studies and in diagnosing a variety of conditions including the following: chromosomal alterations; intrauterine infections; coagulopathy; hemoglobinopathies and RBC disorders; immunodeficiency states; and platelet disorders, including RBC counts for identifying isoimmune disease and fetal thrombocytosis levels. In cases of suspected intrauterine growth retardation, PUBS can be used to evaluate fetal hypoxia and determine fetal acid-base status. PUBS also can be used for intrauterine transfusion and fetal drug therapy.

Client Preparation

Percutaneous umbilical blood sampling can be performed in either an outpatient or inpatient setting. The actual sampling procedure takes approximately 10 minutes for specimen collection. Women must give informed consent because of the invasive nature of the procedure. The client needs to understand the reason, risks, benefits, and nature of the follow-up of the PUBS procedure. Depending on uterine size, a full bladder may be necessary. The client can be informed that physical discomfort during the procedure is minimal and similar to the pressure and cramping sensations experienced during other intrauterine procedures such as amniocentesis. Physical care of the woman includes documenting baseline vital signs and fetal cardiac activity. When PUBS is performed after the fetus is viable, preparation for a cesarean birth in the event of fetal distress must be discussed and considered by the client before the procedure is implemented. Preparation also involves ensuring that emergency equipment and personnel are available.

Procedure

Percutaneous umbilical blood sampling is performed under ultrasound guidance to identify the target sampling site. Antiseptic preparation of the maternal abdomen is completed and a local anesthetic may be used. A 20- or 22-gauge spinal needle is inserted through the abdominal and uterine walls and is directed into the umbilical vessel, most commonly the umbilical vein (Figure 22-4). A site approximately 1 to 2 cm from the insertion of the cord into the placenta is desirable. This site minimizes the risk of cord injury and the chance of obtaining maternal blood from the placenta. If fetal movement interferes with the procedure, a sedative can be administered intravenously to the mother, or intravenously or intramuscularly to the fetus. Once the umbilical vein is accessed, the blood sample can be aspirated and placed in the appropriate microtube for the desired testing. Confirmation that the blood

Figure 22-4 The percutaneous umbilical blood sampling technique is performed using ultrasound guidance and transabdominal aspiration of a sample from the fetal umbilical vessel.

sample is fetal in origin can be accomplished by assessing the mean corpuscular volume (MCV), which is greater in the fetus than in the adult.

Percutaneous umbilical blood sampling, or cordocentesis, also provides an access site for administration of medications or blood transfusion to the fetus. After the blood specimen is obtained or the infusion completed, the needle is removed, the site is inspected for bleeding, and fetal cardiac activity is confirmed by ultrasonography.

Follow-up

Postprocedure care includes monitoring maternal vital signs, fetal heart rate, and uterine activity. The fetal heart rate is evaluated for signs of reactivity and the absence of distress. PUBS is associated with a 2% risk of complications that include bleeding from the puncture site, fetal bradycardia, infection, thrombosis, and hematoma formation (Scott et al., 1994). Because of the increased risk of infection, some providers prescribe prophylactic antibiotics. The client also should be instructed to monitor her temperature twice a day to detect temperature elevation.

Other Genetic and Biochemical Evaluations

Fetal tissue sampling and fetal fibronectin are two of the lesser used modalities for evaluation of the status of a pregnancy.

Fetal tissue sampling involves a direct biopsy of fetal tissue. Collection of fetal tissue is accomplished using biopsy forceps through an angiocatheter or a double-needle system under ultrasound guidance. Tissue samples of fetal skin can be used to diagnose severe skin disorders such as epidermolysis bullosa, Harlequin ichthyosis, and oculocutaneous albinism; liver biopsies can identify inborn errors of metabolism such as glucose-6-phosphate dehydrogenase deficiency and alanine-glyoxalate aminotransferase deficiency; and lung biopsy can provide data about masses detected with ultrasonography (Chitty and Bobrow, 1994). Fetal tissue sampling is a highly invasive procedure and is not widely used in the clinical setting.

Fetal fibronectin (fFN) testing is a screening procedure for the prediction of preterm labor. Fetal fibronectin is a protein substance that helps connect the amniotic sac to the inside wall of the uterus. The FDA (Food and Drug Administration) has approved a test for fFN detection between 22 and 31 weeks' gestation. Determination of cervicovaginal fetal fibronectin as a marker for risk of preterm birth has been proposed for two uses: to test women identified as being at high risk and thus leading to reassurance that early birth is unlikely and to screen low-risk populations to identify women at higher than normal risk. The test for fFN involves obtaining a swab of vaginal and cervical secretions. It is believed that fetal fibronectin leaks into the cervix when the interaction between the fetal membranes and the uterine wall weakens. Consequently, a positive finding may predict the onset of labor. The more useful finding may be a negative result, which is correlated with a low incidence of labor onset in the next 7 to 14 days (Weismiller, 1999).

Maternal Serum Studies

The interaction of the maternal-placental-fetal unit, present from the earliest point of the pregnancy, forms the basis for genetic and biochemical screening through maternal serum studies. Maternal serum testing technologies examine byproducts of the gestational state found in the maternal system but do not invade the integrity of the uterine-placental-fetal unit. Before the technologic advances that now facilitate direct examination of uterine-placental-fetal cells, maternal serum analysis was the primary method of fetal surveillance in early pregnancy. Although more direct ways of examining the fetus have made some maternal serum studies less widely used today, this method is recognized as a valuable tool in screening women for high-risk pregnancies. Maternal serum studies measure maternal hormone levels, MS-AFP levels, and fetal cell isolation, with MS-AFP measurement being the most widely used prenatal screening modality today. Maternal serum studies are primarily screening procedures to identify pregnancies that are at high-risk for complications or negative out-

comes. In contrast, many of the invasive fetal studies described previously are diagnostic of specific conditions. Screening procedures simply identify pregnancies at risk for complications or alterations, whereas diagnostic procedures confirm the presence or absence of specific conditions. Therefore maternal serum screening techniques, if the results are altered, lead to more invasive diagnostic techniques.

Maternal Hormone Levels

Human chorionic gonadotropin, estrogen and estriol, and human placental lactogen are hormones associated with the state of pregnancy. Levels of these hormones can be measured in a sample of maternal venous blood. Maternal serum hormones are used in the diagnosis of pregnancy, differential diagnosis of intrauterine and ectopic pregnancies, and prediction of poor perinatal outcomes. With more accurate and more direct modalities to evaluate the status of a pregnancy, maternal hormone levels are not routinely used in the management of high-risk pregnancies. Follow-up includes referral for the appropriate diagnostic testing based on the results of maternal serum studies.

Human Chorionic Gonadotropin

Human chorionic gonadotropin (hCG) is a protein hormone secreted by the syncytiotrophoblast early in pregnancy. hCG is detectable in maternal serum 8 days after conception. hCG is exclusively produced during pregnancy and therefore is the basis for many pregnancy tests. Maternal plasma levels of hCG increase rapidly, doubling approximately every 1.5 to 2.5 days after conception, and then rapidly decline. Values that deviate from the expected pattern suggest an abnormally developing pregnancy: low or slowly increasing levels are associated with threatened abortion and ectopic pregnancies, and highly elevated levels are associated with hydatidiform moles. hCG levels that persist into the mid-trimester of pregnancy may be predictive of Down syndrome, when considered in conjunction with maternal age and MS-AFP and estriol levels (Palomaki et al., 1992).

Estrogen and Estriol

Maternal estrogen levels increase progressively over the course of pregnancy. The increased estrogen level is due primarily to estriol, which increases a thousand times over nonpregnant levels and accounts for 90% of total estrogen levels (Cunningham et al., 1997). Estriol precursors are secreted from the fetal adrenal cortex, and the conversion to estriol is accomplished in the placenta. Thus, compromise in either the fetus or placenta can result in decreased estriol production (Martin & Cowan, 1990). In the past, serum estriol levels were used as an indicator of fetal

condition in high-risk pregnancies. Decreased levels of estriol suggest fetal jeopardy. In multiple gestation pregnancies or pregnancies complicated by erythroblastosis, estriol levels may be elevated.

Human Placental Lactogen

Human placental lactogen (hPL) levels also increase progressively over the course of pregnancy. hPL is produced by the syncytiotrophoblast cell as early as the third week after ovulation and is detectable in the maternal serum 4 weeks after fertilization. The level of hPL is continually increasing throughout the gestational period and peaks at 35 weeks' gestation. hPL promotes fetal and placental growth. The level of hPL in the maternal circulation is directly related to fetal and placental weight. Therefore, alteration in maternal serum levels of hPL may indicate altered placental function, providing a basis for screening for complications.

Maternal Serum–alpha-Fetoprotein Screening

Maternal serum–alpha-fetoprotein (MS-AFP) testing is the basis for screening for neural tube defects (elevated levels) and trisomy 21 (decreased levels) during the second trimester of pregnancy. MS-AFP testing screens maternal blood for the presence and volume of AFP, which is the major serum protein of early fetal life. AFP is present as early as 6 weeks' gestation and initially is produced by the yolk sac and later by the fetal liver. Levels increase rapidly, with peak concentrations found at the end of the first trimester. The absolute level of AFP produced and secreted by the fetus remains constant throughout the remainder of the gestational period; however, the circulating concentration of AFP is diluted as the fetal blood volume increases. The presence of AFP in the amniotic fluid is largely maintained by fetal urination. Another source contributing to AFP in the amniotic fluid is leakage from fetal capillaries in the absence of keratinization of the skin (Ruoslahti, Engvall, Pekkola, & Seppala, 1978). AFP enters the maternal circulation by way of diffusion across the amnion. MS-AFP concentrations increase geometrically until 30 weeks' gestation and then decline. Normal ranges have been identified for each week of pregnancy. The optimal time for testing is 16 to 18 weeks' gestation (Cunningham et al., 1997). The American College of Obstetricians and Gynecologists (1996) recommends that all pregnant women be offered MS-AFP screening. Significant variations in the serum levels of AFP have been reported among different laboratories. Thus, to increase standardization, results are reported as multiples of the laboratory's median level (multiples of the median [MoM]) in unaffected pregnancies adjusted for gestational age. MS-AFP testing has high sensitivity but low specificity. Therefore, when al-

tered levels of MS-AFP are obtained, the first course of action is to repeat the screening. When abnormal levels persist, the client is referred for both ultrasonography to examine for structural anomalies and amniocentesis to further quantify AFP levels and obtain chromosomal analysis.

Several variables can affect the level of AFP in the maternal circulatory system: large women have lower levels, whereas African American women have higher levels than do Caucasian or Asian women. Other factors that can alter AFP levels include inaccurate gestational dating; multiple pregnancy; and maternal disease states such as diabetes, lupus, and blood group sensitization. High levels of AFP suggest an increased risk of an open neural tube defect, and low levels suggest an increased risk of Down syndrome. The specificity of MS-AFP in the diagnosis of Down syndrome is increased when serum levels of hCG and unconjugated estriol also are measured. This procedure is known as the triple Marker Serum Screen and detects 2.3 times more cases of Down syndrome than does MS-AFP testing alone (Haddow & Palomaki, 1993).

Before obtaining a specimen for MS-AFP analysis, informed consent needs to be obtained. Clients need to understand the nature of this procedure (a screening test, not a diagnostic test), the potential outcomes of the test, and the procedures that will be followed if the results are altered. Because of the wide variation of "normal levels" among healthy women, fetuses, and pregnancies, the possibility of a false-positive result should be discussed.

Fetal Cell Isolation

A promising development in prenatal genetic diagnosis is the retrieval of fetal cells from the maternal peripheral blood. Fetal cells that "leak" into the maternal circulation include trophoblasts, lymphocytes, and RBCs. Fetal nucleated RBCs appear to be a useful source for fetal diagnostic studies because they are unique to the adult circulation, express several unique antigens, produce fetal hemoglobin, have a short life span, and do not persist from one pregnancy to another (Steele & Berg, 1996). Fetal cell isolation is an attractive concept and the outlook for clinical application is promising; however, this method currently is in the investigational phase.

PHYSICAL AND PHYSIOLOGICAL SURVEILLANCE

Visualization of the physical size, structure, and movement of the fetus is possible with the use of ultrasonography, Doppler flow studies, and magnetic resonance imaging (MRI). Physiologic integrity of the placenta and of fetal compensatory mechanisms can be measured with elec-

tronic fetal monitoring and biophysical profile evaluation. Through the use of these technologies, practitioners can gather information about the physical status and structural anatomy and about the physiologic status and functional behavior of the fetus, respectively. Physical and physiologic surveillance of the fetus includes imaging, heart rate monitoring, and behavior studies.

Fetal Imaging

Fetal imaging is based on the belief that the ability to “see” the fetus and its environment profoundly shifts the factual and psychologic basis of the management of pregnancy (Manning, 1995). The primary means of fetal imaging include ultrasonography, Doppler studies, and MRI. Before the introduction of high-resolution imaging procedures, visualization of the fetus and intrauterine environment was limited to indirect measures such as fundal height assessments and manual palpation for fetal size. The introduction of fetal imaging has transformed the fetus from a hidden and mysterious being to a “patient” to be viewed, examined, evaluated, and in some situations treated.

Ultrasonography

Ultrasound technology has made possible direct noninvasive visualization of the fetus. Ultrasonography is the imagery modality most widely used to assess the pregnant client and developing fetus. In obstetrical settings, both the transabdominal and transvaginal approaches to ultrasound examination are used.

Description

Ultrasonography is the use of high-frequency (>20,000 Hz) sound waves to detect differences in tissue density and visualize outlines of structures within the body. Ultrasonography used in obstetrical settings to generate images operates on the pulse-echo principle. According to this principle, a short pulse is emitted by the transducer, the pulse is reflected from underlying fetal structures as an echo, and the rebounding echo is detected by the transducer and displayed as an image. The pulse or sound wave passes through various tissues at different speeds based on tissue density and elasticity. The pulse travels through tissue until it comes to a tissue interface or another tissue with a different density. The change in density causes a small proportion of the pulse to be echoed back to the transducer. The echo is converted into electrical signals and displayed as an image on the monitor. The time interval from emission of the impulse to detection of the echo determines the physical position of an underlying structure. Dense tissues produce a higher velocity of sound transmission, which translates to brightness of the image on the monitor. Most state-of-the-art ultrasound equipment

displays 128 shades of gray correlated with differences in signal strength. Differences among signals result in color gradient changes that indicate structure density:

- ✦ Bright white areas: strong echoes from high-density structures such as bone tissue.
- ✦ Gray areas: small echoes from intermediate density tissues, such as brain, renal, or cardiac tissue.
- ✦ Black areas: no echo related to a fluid-filled areas, such as a pocket of amniotic fluid or a filled bladder.

Therefore, ultrasonography provides physical measures of tissue density, size, and location. The translation of these physical measures into estimates of gestational age or fetal weight is based on data from clinical research (Docker, 1992). Real time or B-scan ultrasonography uses a multiple-pulse system of sound waves to note fetal movements, whereas conventional or M-mode scan ultrasonography uses a single pulse that produces a static image. Real-time ultrasonography is most commonly used in obstetrical practice because of its capability to display motion-picture-like two-dimensional sectional images. However, M-mode scan ultrasonography, or static images, is valuable in gaining information about individual structures, such as the dynamic changes occurring in the fetal heart.

INDICATIONS FOR ULTRASOUND DIAGNOSIS IN THE SECOND TRIMESTER

1. Estimation of gestational age for women with uncertain clinical dates.
2. Evaluation of fetal growth.
3. Estimation of fetal weight.
4. Vaginal bleeding of unknown cause.
5. Suspected multiple gestation.
6. Adjunct to amniocentesis or PUBS.
7. Adjunct to cervical cerclage placement.
8. Significant uterine size or clinical dates discrepancies.
9. Suspected uterine abnormality.
10. Suspected alteration in amniotic fluid volume.
11. Premature labor.
12. Abnormal AFP level.
13. Serial evaluation of fetal growth in multiple gestation.

Timing and Indications

Ultrasonography is used progressively throughout the gestational period for a variety of indications. According to the American College of Obstetricians and Gynecologists (1993) the ultrasound examination may take one of three forms: basic, or level I, examination; comprehensive, or level II, examination; and limited, or targeted, examination.

Level I, or basic, ultrasonography is used to:

- ✿ Detect the gestational sac as early as 5 weeks after the last menstrual period.
- ✿ Identify the number of fetuses.
- ✿ Document fetal life.
- ✿ Detect gross fetal structural anomalies.
- ✿ Estimate gestational age.
- ✿ Determine fetal position.
- ✿ Locate the placenta.
- ✿ Estimate amniotic fluid volume.
- ✿ Evaluate maternal pelvic masses.

The basic examination takes approximately 20 minutes and is a component of the obstetrical standard of care. The basic examination is the most common use of ultrasonography in obstetrical practice (Tucker, 2000).

A level II, or comprehensive, ultrasound examination is done when the provider suspects a client is carrying an anatomically or physiologically abnormal fetus. Indications for level-II ultrasonography include abnormal findings on clinical examination, history of an abnormal fetus, and validation of information obtained in the level-I examination. The focus of a comprehensive examination is to survey fetal anatomy for specific malformations. A level II, or comprehensive, ultrasound examination is used to:

- ✿ Evaluate gestational age.
- ✿ Measure fetal growth.
- ✿ Perform specific examinations of the brain, heart, kidney, and cord insertion.
- ✿ Quantify amniotic fluid volume.
- ✿ Determine placental location.

A level II examination usually is performed after 18 weeks' gestation and is done by a perinatologist.

The third type of examination, limited or targeted, is performed when specific information is needed but a complete survey of the fetus and intrauterine environment is not needed. Limited examination usually is performed in conjunction with another procedure or event. Limited ultrasound examinations are performed during amniocentesis, PUBS, or a biophysical profile to confirm fetal cardiac activity as a result of decreased fetal movement, and iden-

tify fetal presentation or locate the placenta after the onset of spontaneous bleeding or labor.

Client Preparation

As with any procedure the client needs to be informed about its purpose, content, and limitations. Before transabdominal examination, the client will need to fill her bladder. To establish adequate bladder filling the client should drink 1 to 2 quarts of water 1 hour before the procedure. Maintaining a full bladder can be a source of discomfort for many clients, especially in late pregnancy. When a transvaginal examination is planned, the client will be asked to empty her bladder before the procedure to minimize obscuring the view into the pelvic cavity.

Procedure

Obstetrical ultrasonography can be performed using either a transabdominal or transvaginal scanning approach (Figure 22-5). Transabdominal scanning is the more traditional approach and can be used throughout gestation but is most useful in the second and third trimesters. Transabdominal ultrasonography provides a clear view of the fetus and placenta. When this approach is used a filled bladder or an acoustic window is necessary to displace the gas-filled bowel, which obstructs pelvic structures, and to lift the uterus higher into the abdominal cavity. During transabdominal ultrasonography, a lubricating gel is applied to the abdomen and the probe is moved over the abdominal surface. The lubricating reduces friction and enhances transmission and reception of the sound waves by the probe.

Transvaginal ultrasonography is most useful in the first trimester of pregnancy. During this procedure, a handheld probe is inserted into the vagina, allowing detailed examination of the pelvic anatomy and earlier diagnosis of intrauterine pregnancy (Cunningham et al., 1997). Using a transvaginal approach an acoustic window is not necessary. Another advantage of transvaginal scanning is the closer proximity to the pelvic structures, facilitating clearer visualization and reducing interference by thick abdominal tissue. Therefore, this method is especially useful in clients who are obese. Transvaginal scanning has limited usefulness in visualizing fetal anatomy and obtaining fetal measurements after 16 weeks' gestation because the enlarging uterus moves into the abdominal cavity and away from the vaginal vault. Guzman and coauthors (1998), however, have used transvaginal ultrasonography as an adjunct to abdominal scanning in the second half of pregnancy to evaluate preterm labor.

The findings of an obstetrical ultrasound examination can provide valuable data to influence the management plan during the course of gestation. In addition to data about the physical status of the fetus (e.g., number of

fetuses, presentation, and anatomical survey), data obtainable from an ultrasound examination includes fetal cardiac activity, gestational dating and fetal growth, placental position and function, and amniotic fluid volume.

Critical Thinking

Is Ultrasonography a Routine Procedure?

A study by Berkowitz (1993) concluded that routine ultrasound screening for low-risk women did not improve pregnancy outcome. The author suggested that savings for prenatal care could total about \$1 billion if there was a decrease in the number of screening ultrasound examinations in routine pregnancy.

- Do you agree with this position?
- In your opinion, what are the risks of discontinuing routine ultrasounds?

Using an echo scanner, cardiac activity can be documented as early as 6 to 7 weeks' gestation. The lack of cardiac activity, in association with fetal scalp edema, and maceration are signs of fetal death. By 9 to 10 weeks' gestation, the lack of fetal cardiac activity and the proliferation of trophoblastic tissue are diagnostic of gestational trophoblastic disease.

Ultrasonography can be used to obtain gestational dating of a pregnancy. During the first 20 weeks' gestation, normal fetuses grow at approximately the same rate. The four methods use to determine gestational age are

- Determination of gestation sac dimensions at about 8 weeks' gestation.
- Measurement of crown-rump length between 7 and 14 weeks' gestation.
- Measurement of biparietal diameter (BPD) after 12 weeks' gestation.
- Measurement of femur length after 12 weeks' gestation.

In the second half of pregnancy, accurate determination of fetal age is enhanced by serial measurements. When three composite measures are obtained at least 2 weeks apart, between 24 and 32 weeks' gestation, a highly accurate estimate of actual age is achievable (Manning, 1999). These measurements can also be used to evaluate fetal growth. Serial evaluations of BPD and femur length can identify reduced fetal growth. Intrauterine growth restriction (IUGR) can be symmetric, reflecting a chronic insult to fetal growth, or asymmetric, indicating an acute state of deprivation impacting fetal growth.

Differentiation between placental and endometrial tissue is evident by about 14 to 16 weeks' gestation. However, determining the exact relationship of the placenta to the internal cervical os is difficult before the end

of the second trimester. Therefore, the diagnosis of placenta previa before 27 weeks' gestation is questionable because of the elongation and stretching of the lower uterine segment in late pregnancy.

Placental grading and classification of placental maturity are accomplished by ultrasound scanning. Grading of the placenta is based on the identification and distribution

of calcium deposits on the fetal surface of the placenta (Manning, 1999). A relationship has been established between placental grade and fetal pulmonary maturity (Manning, 1999).

Amniotic fluid volume (AFV) can be objectively quantified using ultrasound technology. The AFV is calculated by measuring the depth of the amniotic fluid pocket in the

Research Highlight

Effects of Symmetric and Asymmetric Fetal Growth on Pregnancy Outcome

Purpose

Obstetrical ultrasonography was used in a study to assess the prevalence of head-abdomen circumference (HC/AC) asymmetry among small for gestational age (SGA) infants and to determine adverse fetal outcomes among symmetric versus asymmetric SGA infants when compared with their average gestational age (AGA) counterparts.

Methods

A retrospective cohort study was undertaken in which antepartum sonography was completed on women within 4 weeks of delivery. Data were collected between January 1, 1989, and September 30, 1996, on 33,740 women who delivered live singleton infants without anomalies. A HC/AC normogram was derived from this database. Fetuses were considered to have HC/AC asymmetry if the normogram value was greater than or equal to the 95th percentile for gestational age. Neonatal morbidity and outcome data were based on diagnosis by neonatal intensive care faculty.

Findings

Of infants in the study, 16% (1,364) were at or below the 10th percentile (SGA). Among those, 80% (1,090) were symmetric and 20% (274) were asymmetric. Major anomalies were detected among asymmetric SGA infants. The mean birth weight was significantly lower in SGA infants. Preterm induction of labor was more common among asymmetric SGA fetuses. Intrapartum hypertension requiring delivery at or before 32 weeks' gestation was significantly more common in the asymmetric SGA group. Finally, cesarean delivery owing to nonreassuring fetal heart rate tracings was significantly more common in SGA than in AGA fetuses and was nearly twice as frequent among pregnancies complicated by asymmetric versus symmetric growth restriction.

Nursing Implications

A third trimester ultrasound can be a valuable diagnostic tool in identifying infants at risk for adverse outcomes related to birth weight and growth symmetry of HC/AC. Identifying those clients at risk for delivering SGA infants with asymmetrical growth patterns will afford the nurse the opportunity to educate the clients about their likelihood of delivering an infant with an anomaly. The nurse can also help prepare the clients mentally and emotionally for a change in birth plan, which might include the need for preterm induction of labor, an early delivery to control intrapartum hypertension, or a c-section delivery in the event of nonreassuring fetal heart rate tracings.

Dashe, J. S., McIntire, D. D., Lucas, M. J., & Leveno, K. J. (2000). Effects of symmetric and asymmetric fetal growth on pregnancy outcomes. *Obstetrics and Gynecology*, 96, 321–327.

four quadrants surrounding the maternal umbilicus. The measurements obtained from each quadrant are totaled to provide the amniotic fluid index. Values of 5 to 19 cm are considered normal, whereas values under 5 cm indicate oligohydramnios and over 20 cm indicate hydramnios (Chervenak & Gabbe, 1996). Altered AFV is a marker of a chronic fetal condition.

Follow-up

Ultrasonography is a noninvasive procedure. Follow-up care is primarily education, counseling, and support as referral for additional testing or treatment based on ultrasound findings is implemented.

Since its introduction more than 30 years ago the safety of ultrasonography, especially during critical periods of embryonic development, has been questioned. Although the use of ultrasonography is apparently free from physical danger to the mother and fetus when pulse intensity is within predetermined safety zones, no conclusive empirical findings or longitudinal data are available to support this claim (Sabbagha, 1994; Anthony, 1996).

Doppler Studies

An addition to ultrasound imaging technology is color-enhanced Doppler flow studies, also called umbilical vessel velocimetry. Based on recent data, The American College of Obstetricians and Gynecologists (ACOG, 1997) has endorsed the use and clinical value of umbilical vessel Doppler studies in high-risk pregnancies.

Description

Doppler blood studies, or umbilical vessel velocimetry, is the measurement of blood flow velocity and direction in major fetal and uterine structures. The Doppler effect provides information about blood flow in supplying vessels and reflects changes in the connecting fetal-uterine vascular system. The Doppler effect, or Doppler shift, occurs when a sound wave is reflected from a moving object, and there is a change in the frequency of the reflected wave relative to that of the transmitted wave. This principle can be applied to fetal RBCs moving through the umbilical vessels. The velocity of the RBC can be determined by measuring the change in the frequency of the sound wave reflected off the cell. Therefore, Doppler ultrasonography detects the movement of RBCs in vessels and is used to measure blood flow velocity.

Timing and Indications

Velocity waveforms can be detected as early as 15 weeks' gestation. With advancing gestation there is a progressive decrease in resistance in the umbilical vessels. Consequently, a high-velocity umbilical artery flow or a lower

systolic-to-diastolic ratio is found in normally growing fetuses. Decreased umbilical vessel flow is found in fetuses with intrauterine growth retardation (IUGR) and in pregnancies complicated by pregnancy-induced hypertension (PIH) or postdates, when a pregnancy exceeds its edc, usually 42 weeks. In addition, exposure to nicotine from maternal smoking has been shown to decrease blood flow velocity (Schulman, 1990).

Client Preparation

From the client's perspective, physical preparation is similar to the preparation for imaging ultrasonography. Additional counseling and education are needed specific to the indications for the addition of Doppler velocity.

Procedure

The technique of transabdominal ultrasound is used to obtain blood flow velocity measurements. A Doppler waveform of a vessel represents the systolic and diastolic flow velocities within the vessel. Doppler measurements include the systolic-to-diastolic ratio (systolic/diastolic measure), pulsatility index (systolic-diastolic/mean value of the maximum frequencies) and resistance or Pourcelot's index (systolic-diastolic/systolic). High values (>3) in the second half of pregnancy may indicate increased resistance of the placental vascular bed and decreased diastolic flow (Reed, 1995; Cundiff, Haubrick & Hinzman, 1990). Doppler waveforms can measure the blood flow velocity in several vessels, including the intracerebral, renal, femoral, and umbilical arteries. The most common application is measurement of blood flow velocity from the fetus to the placenta or in the umbilical artery. Doppler flow studies therefore primarily measure placental and not fetal health (Whittle, 1992). However, Doppler studies have been considered a valuable screening tool because abnormalities in the placental vascular status are theoretically associated with fetal problems or compromise. An abnormal flow is either an absent end-diastolic flow or a flow index greater than 2 standard deviations above the mean for gestational age.

Color-enhanced flow imaging is an extension of Doppler velocimetry. With color-flow instrumentation, multiple samples of blood flow velocity are obtained. A mean velocity is calculated and assigned a color by the instrument. An image of the vessel is displayed in color, and the direction and velocity of blood flow are represented by color changes coinciding with the cardiac cycle (Hung et al., 1997).

Follow-up

Follow-up care includes providing information and support to the client and her family, explaining the management plan, and making referrals as needed.

Magnetic Resonance Imaging

The newest imagery modality in pregnancy is magnetic resonance imaging (MRI). MRI generates excellent pictures of soft tissue, similar to those of computerized tomography (CT). Unlike CT, however, ionizing radiation is not used, thus eliminating any known biological risk.

Description

Magnetic resonance imaging (MRI) is a noninvasive diagnostic tool that provides high-resolution cross-sectional images of fluid-filled soft tissues. MRI produces a magnetic field that causes the hydrogen nuclei of the body to align and emit a signal, which is converted to a computer image (Fishbach, 2000). Similar to ultrasonography, MRI can provide images in a variety of planes. Unlike sonography, however, with MRI there is no interference from skeletal, fatty, or gas-filled structures and a full bladder is not necessary for imaging structures deep in the pelvis.

Timing and Indications

In pregnancy, MRI has been used as early as 10 weeks' gestation to demonstrate placental location and biparietal diameter, and the results are comparable with ultrasound imaging. However, MRI is specifically suited for the detection of soft-tissue abnormalities not easily identifiable on ultrasonography, such as hydatiform mole and fetal anomalies (e.g., cystic hygroma, urethral obstruction, and hydronephrosis) (Fishbach, 2000). The uses of MRI technology during pregnancy include evaluation of fetal structure, placental tissue, amniotic fluid quantity, maternal structures, biochemical status of tissue and organs, and soft tissue or functional anomalies.

Client Preparation

During the procedure, which can take 20 to 60 minutes, the client must lie completely still.

Procedure

The client is placed in a supine position on a table that is then moved into the bore of the main magnet. Because it takes a significant amount of time to produce magnetic resonance images, the probability of fetal movement during image generation is high. Movement leads to image distortion. Consequently, the major drawbacks of MRI imagery during pregnancy are the following: inability to select the plane of imaging, making true measurement of fetal structures impossible; and the relatively long time period needed to produce a single image, resulting in distortion secondary to fetal movement. MRI is advantageous in situations that are not conducive to ultrasound examination, such as maternal obesity and oligohydramnios. Thus, the utility of MRI during pregnancy may be increased in conditions such as oligohydramnios where fetal movement is limited and in which ultrasound examination of

the fetus and uterine contents is inhibited by the lack of amniotic fluid (Johnson, 1992). The overall cost and length of time required to complete imaging has reserved the use of MRI in pregnant women to situations in which the results of other imaging modalities are unacceptable.

The client will be given a follow-up appointment for results.

Fetal Heart Rate Monitoring

Fetal heart rate monitoring is integral to fetal surveillance. Intermittent auscultation of the fetal heart rate has been a basic component of fetal physiologic surveillance for many years and is a standard component of each prenatal visit (Figure 22-6). The introduction and widespread acceptance of electronic fetal monitoring techniques have allowed the development of testing modalities to evaluate fetal condition over time and in response to intrauterine events. The goal of fetal evaluation with electronic fetal monitoring in late pregnancy is to determine whether the intrauterine environment continues to be supportive of the fetus. Antenatal electronic fetal monitoring can identify the gradual deterioration of placental function, ultimately resulting in fetal hypoxia. As the fetus experiences sustained hypoxemia, cardiac output, arterial blood pressure, and cerebral and cardiac blood flow are decreased (Parer, 1999). These physiologic alterations are manifested as characteristic changes in fetal heart rate patterns.

Fetal heart rate variability or rhythmic change in baseline heart rate values is a reassuring indicator of a supportive intrauterine environment. Variability is designated as a nonperiodic fetal heart rate change because it is not related to changes in fetal or uterine activity. Periodic fetal heart rate changes are defined as alterations in the fetal heart rate pattern in response to fetal movement or uterine contraction. The major designations of periodic changes

Figure 22-6 Fetal heart rate monitoring is a routine factor in each prenatal visit.

are accelerations and decelerations. An acceleration is a responsive or stimulated increase of fetal heart rate by a minimum of 15 bpm with a duration of at least 15 seconds. A deceleration is a decrease in fetal heart rate in response to fetal or uterine activity. Decelerations in response to uterine contractions are further differentiated by their relationship to the onset, peak, and resolution of the contraction. Analysis and classification of the fetal heart rate pattern are the foundation of antenatal fetal heart monitoring evaluation. The methods of electronic fetal monitoring used for fetal evaluation include nonstress tests with or without the addition of fetal acoustic stimulation (FAS) and contraction stress tests (CST).

Nonstress Test

A nonstress test (NST) is a noninvasive method that combines detection of fetal heart rate accelerations and presence of spontaneous or evoked fetal movement. A NST is a relatively inexpensive procedure and has no known contraindications. NSTs are performed by nurses in a variety of settings including outpatient, inpatient, and home environments.

Description

A **nonstress test (NST)** is the evaluation of fetal heart rate in response to an increase in either spontaneous or stimulated fetal activity.

INDICATIONS FOR THE NST

1. Suspected postmaturity
2. Maternal diabetes mellitus
3. Maternal hypertension: chronic and pregnancy-related disorders
4. Suspected or documented intrauterine growth restriction (IUGR)
5. Sickle cell disease
6. History of previous stillbirth
7. Isoimmunization
8. Older gravida
9. Chronic renal disease
10. Decreasing fetal movement
11. Severe maternal anemia
12. Multiple gestation
13. High-risk antepartal conditions: premature rupture of fetal membranes, preterm labor, bleeding

Figure 22-7 A client undergoing a nonstress test is asked to depress a button when fetal movements are felt.

Timing and indications

Nonstress testing can be reliably performed after 28 weeks' gestation, when maturity of the fetal autonomic nervous system is achieved. A positive relationship between fetal heart rate acceleration and fetal movement is dependent on the integration of peripheral receptors, the autonomic nervous system, and myocardial function (Paul & Miller, 1995). In the healthy fetus with a functional central nervous system (CNS), 90% of fetal body movements are associated with accelerations in fetal heart rate (Tucker, 2000).

Client Preparation

The NST is a noninvasive procedure that can be performed in an outpatient setting. The client's blood pressure is taken and documented. The woman is placed in a reclining position or a Semi-Fowler position with a lateral tilt to avoid supine hypotension. An external mode of fetal monitoring is placed on the abdomen. The woman may be instructed to depress an event button to mark episodes of fetal movement on the monitoring strip (Figure 22-7).

Procedure

The fetal heart rate is detected and recorded by the Doppler transducer. Fetal movement is documented either by the event button or use of the tocotransducer to document fetal movements as intermittent changes in uterine pressure. The test usually is completed in 20 minutes but may take longer if the fetus is in a sleep state.

The criteria for a reactive NST are two accelerations in a 20-minute test period and a normal baseline fetal heart rate. Failure to fulfill the criteria as a reactive pattern over a total of a 40-minute test period is deemed a nonreactive NST. A nonreactive result is the absence of accelerations during the test period (Figure 22-8). The 40-minute time frame for observation accounts for fetal sleep-wake cycles. A third result is an inconclusive, or equivocal, test

Figure 22-8 A. A reactive nonstress test pattern shows fetal heart acceleration with movement. B. The nonreactive pattern shows absence of accelerations during the test period.

result. An inconclusive test result is the finding of less than two accelerations in the 20-minute test window, accelerations that do not meet the criteria of an amplitude increase of 15 bpm for a duration of 15 seconds, or a poor-quality recording that is inadequate for interpretation.

When the NST is reactive, it is highly predictive of fetal health and well-being. However, the use of the NST in identifying the fetus at risk for a poor perinatal outcome is less reliable. NSTs have a significantly high false-positive rate of over 75%; in other words, more than 75% of fetuses with nonreactive NSTs are in fact healthy (Gauthier, 1979; Smith, 1995).

In an attempt to reduce the incidence of false-positive results on NSTs and to differentiate a healthy fetus at rest from one who is sick or asphyxiated, vibroacoustic stimulation has been used. An artificial larynx that provides acoustic and vibratory stimuli has received FDA approval for prenatal use between 28 and 42 weeks' gestation. Vibroacoustic stimulation usually is initiated after 10 minutes of nonreactivity during the NST. To provoke fetal activity, the stimulation is applied to the maternal abdomen for 1 second. The stimulus startles the fetus, causing a behavioral state change, and generates a state of reactivity. If the fetus does not respond, the stimuli can be repeated twice. After stimulation, the fetus is observed until a reactive pattern is attained or until 40 minutes have elapsed. Fetuses exposed to vibroacoustic stimulation exhibit more movements and therefore are more likely to have a reactive test pattern (Marsden et al., 1997).

REFLECTIONS FROM A NURSE

"I recently worked with a woman who was 33 weeks pregnant and eager to see the end of a rough pregnancy marked by daily nausea, a great deal of back pain, and swollen feet. After a nonreactive NST, the woman emphatically stated: 'I want to have a cesarean birth right now, so the nursery can take care of my baby!' Being a mother of three myself, I empathized with her plight, but took it upon myself to gently remind her of the benefits of seeing a pregnancy through to at least 38 weeks. I also made some suggestions for exercise and diet changes, which I thought could help relieve some of her discomforts"

Follow-up

When the NST is reactive, most practitioners will repeat the examination twice weekly. The pregnancy is continued if the results remain reassuring. When the results are inconclusive or equivocal, either the NST is repeated within 12 to 24 hours or further testing is scheduled, based on the evaluation of the clinical situation. A nonreactive test result is followed by a decision to perform a contraction stress test or a biophysical profile to further evaluate fetal well-being.

Contraction Stress Test

The contraction stress test (CST) is one of the original forms of fetal testing. It is a graded fetal stress test based on the principle that a stage of fetal compromise can be identified by exposing the fetus to gradual stress. Stress is applied by uterine contractions that cause intermittent interruption of oxygenated blood into the villus spaces, resulting in a transient decrease in the partial pressure of oxygen to the fetus. If the fetus has a baseline oxygen deficit, it will be manifested as a change in the fetal heart rate pattern.

Description

A **contraction stress test (CST)** stimulates uterine contractions for the purpose of assessing fetal response. It evaluates the presence or absence of fetal heart rate de-

Figure 22-9 A. Negative contraction stress test. B. Positive contraction stress test.

celerations in the presence of uterine contractions (Figure 22-9). The presence of a late deceleration pattern of the fetal heart rate during a uterine contraction is indicative of uteroplacental insufficiency and altered fetal cardiorespiratory reserves. In a healthy fetus, cardiorespiratory reserves are adequate to tolerate the decreased or interrupted intravillous blood flow associated with uterine contraction whereas inadequate fetal cardiorespiratory reserves lead to decreased tolerance of altered uteroplacental blood flow that is manifested as late decelerations.

Timing and Indications

A CST usually is performed after a nonreactive finding on a NST. Although a NST is noninvasive, with no known contraindications, the CST is not. The potential for preterm labor after a CST has led to it being contraindicated in clients with a predisposition to preterm labor or a gestation age at which the risk for preterm birth is greater than the benefit of the information provided.

Client Preparation

Because the CST is an invasive procedure, informed consent must be documented. A discussion of potential risks should include the possibility of the need for preterm vaginal or abdominal birth.

Procedure

A CST is an invasive procedure because it stimulates uterine contractions. To perform a CST, the client is placed in a Semi-Fowler position and baseline maternal vital signs and fetal heart rate tracings are obtained. Uterine contractions can be induced by either nipple stimulation or administration of exogenous oxytocin. The results of a CST are documented as follows:

- ✱ **Negative:** no late decelerations with three adequate uterine contractions in a 10-minute window, normal baseline fetal heart rate, and accelerations with fetal movement.
- ✱ **Positive:** Late decelerations with more than half the uterine contractions.
- ✱ **Suspicious:** Late decelerations with fewer than half the uterine contractions.
- ✱ **Unsatisfactory:** Inadequate fetal heart rate recording or less than three uterine contractions in 10 minutes.

A CST is a lengthy procedure, averaging 90 minutes. It also is an invasive surveillance measure that carries the risks of labor and premature delivery of the pregnancy as a result of stimulation of the uterus. Consequently, these risks must be considered in the decision to undertake a CST. Similar to the NST, the CST also has a high false-positive rate of 50% to 75% (Gauthier, 1979, Paul & Miller, 1997). Therefore, external fetal monitoring as a surveillance technique identifies the healthy well-oxygenated fetus but is of limited use in identifying the at-risk or compromised fetus.

Follow-up

If the CST is negative, the oxytocin source is discontinued. Intravenous fluids are continued until uterine activity has returned to preprocedure status. A negative CST is reassuring that the fetus is likely to survive labor should it occur within 1 week if there are no other changes in either maternal or fetal condition. Immediate retesting is needed if any change in maternal condition occurs. If the CST is positive, continued monitoring and assessment of fetal well-being are needed. A positive result may lead to a decision to end the pregnancy and care for the newborn in the nursery.

Fetal Behavior Studies

Documenting the woman's perception of fetal movement is the traditional method for evaluating fetal behavior. Whereas maternal perception of fetal activity provides valuable data, the addition of ultrasound technology has provided direct measurements of fetal behavior.

Critical Thinking

Development of Mothering

What is the impact of multiple fetal evaluation procedures on the developmental experience of pregnancy and mothering?

Fetal Movement Count

Fetal movement counting, also known as kick counting, is a simple noninvasive form of surveillance that can be done anywhere.

Description

Fetal movement counting (FMC) is the daily maternal assessment of fetal activity by counting the number of movements within a specified time period. The pregnant woman's observation of fetal movement has been validated through an 80% to 90% correlation of maternal perception of movement with movement detected on real-time ultrasonography (Moore & Piacquadio, 1989).

Timing and Indications

The American College of Obstetricians and Gynecologists ACOG (1994) recommends daily fetal movement counting beginning at 28 weeks' gestation for pregnant women at increased risk for antepartal fetal death. Because of the simplicity of this surveillance, however, all pregnant women could benefit from instruction in fetal movement counting.

Maternal perception of fetal movement usually is related to motion of the trunk or limbs and total body movements, such as flips. During the second half of pregnancy, fetal movement becomes more organized and movements become stronger. The frequency of fetal movement peaks at 32 weeks' gestation and gradually decreases as the pregnancy approaches 40 weeks' gestation (Rayburn, 1995). A number of other factors can influence fetal movement: time of day, glucose loading, and maternal smoking, alcohol, or medication consumption.

Maternal perception of fetal movement correlates with fetal well-being. Decreased fetal movements may be associated with chronic as opposed to acute states of fetal distress (Rayburn, 1995). As the fetus experiences intrauterine compromise, the decreased activity leads to decreased oxygen requirements manifested as altered growth and oxygenation patterns.

Client Preparation

Fetal movement counting is a no-cost noninvasive method used to heighten the pregnant woman's awareness of fetal activity and behavior. Fetal movement counting can be initiated with all pregnant women after 28 weeks' gestation. Pregnant women should be taught the significance of fetal movement, the procedure for counting, how to record the findings, and when to report changes to the health care provider.

Procedure

A variety of counting methods exist. Two of the most widely used are the following:

- ✦ Record a start time. Place the hands over the abdomen to palpate fetal movement. Count until 10 movements are palpated, and record the time.
- ✦ Select a predetermined time interval. Place the hands on the abdomen to palpate fetal activity. Count the number of movements within the selected time period.

To perform fetal movement counts, the woman should be in a relaxing environment and a comfortable position, that is, semi-Fowler, reclining, or side-lying. A side-lying position promotes placental circulation and increases detection of fetal movements. Fetal movement counting should be done at the same time each day, preferably after a meal or when the fetus is most active.

Follow-up

Neither an ideal number of fetal movements nor an ideal interval for fetal movement counting has been established. A trend toward decreasing motion should be reported. In general, a count of less than three fetal movements within 1 hour necessitates further evaluation, usually with a NST or biophysical profile.

Biophysical Profile

The biophysical profile (BPP) is a dynamic noninvasive surveillance technique that combines the strong points of ultrasound imagery and external fetal monitoring technologies.

Description

The **biophysical profile** is a noninvasive dynamic assessment of the fetus and fetal environment. The BPP is based on the premise that the predictive accuracy of observing a number of biophysical variables is greater than the predictive value of a single observation. The BPP consists of five parameters: fetal heart rate reactivity, fetal breathing movements, gross body movement, fetal tone, and amniotic

Table 22-4 Biophysical Profile Variables and Scoring Criteria

Variable	Normal (Score = 2)	Abnormal (Score = 0)
Fetal breathing movements	One or more episodes of 30 seconds' duration during the 30-minute test period	Absent or breathing movement is <30 seconds' duration
Gross body movement	A minimum of three discrete body or limb movements during the 30-minute test period (active continuous movement is considered one movement)	Less than three fetal movements during the test period
Fetal tone	One or more episode of active extension with return to flexion of fetal limbs or trunk, or opening and closing of the hand	Slow extension with return to flexion, movement of limb in full extension, or absence of fetal movement
Amniotic fluid volume index	One or more pockets of amniotic fluid measuring ≥ 1 cm in two perpendicular planes	Pockets of amniotic fluid are <1 cm or absent
Nonstress test	Reactive	Nonreactive

Adapted from: Manning, F. A. (1995). Dynamic ultrasound-based fetal assessment: The fetal biophysical profile score. *Clinical Obstetrics and Gynecology*, 38, 26–44.

fluid volume (Manning, 1995). Each area receives a score of 0 (absent) or 2 (present) based on established criteria (Table 22-4). Therefore, BPP evaluates fetal status using a methodology modeled after the *Apgar score*, a numerical expression of the condition of a newborn.

Timing and Indications

The decision to perform a BPP usually is the sequella of a nonreassuring finding on a NST. BPP scoring is based on the assessment of both acute and chronic markers of fetal compromise. In response to systemic hypoxia the fetus demonstrates alterations in movement, muscular tone, breathing, and heart rate pattern. Therefore, normal biophysical activities are a proxy measure of a functional CNS (Manning 1995).

Client Preparation

The BPP is indicated as a result of a nonreassuring finding from a previous fetal surveillance technique. Therefore, a

primary area of client preparation is emotional support, education, and counseling in the face of a potential pregnancy crisis.

Procedure

Level II, or comprehensive, ultrasonography is used to examine the variables of fetal breathing movements, gross body movements, fetal tone, and amniotic fluid volume. A NST is completed before the ultrasound examination.

A BPP score of 8 to 10 is normal, a score of 6 is equivocal, and a score of 4 or less indicates fetal compromise. The biophysical activities of the fetus provide a reflection of CNS activity because the CNS is among the tissues most sensitive to altered oxygen supply. Based on the gradual hypoxia principle, therefore, progressive fetal hypoxia is manifested as loss of biophysical function. The multiple-variable input of the BPP scoring system improves the specificity and sensitivity of the technique compared with the use of a single surveillance variable. BPP has a low false-negative rate of less than 1 infant per 1,000 (0.726 per 1,000) pregnancies with adequate BPP scores. Therefore, the incidence of fetal compromise is not underestimated with BPP testing. Thus, the BPP is an accurate indicator of impending fetal crisis and should be acted on (Manning, 1995).

Follow-up

The BPP is an accurate indicator of impending fetal demise. When the BPP score is low, induced labor is considered. When the BPP score is normal, intervention is indicated only for specific obstetrical or maternal factors.

Critical Thinking

Fetal Behavior Studies

How do you respond to a client who has a nonreactive NST and BPP score of 4, but is refusing a cesarean birth because she is afraid of having surgery?

NURSING PROCESS

In the area of fetal evaluation interdisciplinary collaboration and coordination of the client's care is a significant component of nursing care. Some of the fetal evaluation technologies discussed in this chapter are not within the scope of nursing practice; however, the nurse's role in the care of the client surrounding the procedure is essential and needs to be a component of the nursing management plan for the woman's pregnancy.

Assessment

A comprehensive nursing assessment is completed during the initial prenatal contact to identify risk factors or indications of the need for fetal evaluation. An interrelationship among biophysical, psychosocial, sociodemographic, and environmental variables can impact maternal response to the pregnant state, fetal development and well-being, desirability of the intrauterine environment, and the ultimate pregnancy outcome. The initial comprehensive assessment may reveal indicators for immediate testing or may uncover indicators for testing at some future point in the pregnancy.

The nursing assessment needs to include physical and physiologic factors as well as cultural and emotional ones that influence the woman's need for and perception of fetal evaluation technologies. Nurses must be aware and knowledgeable about predisposing conditions along with

procedures and resources available for prenatal fetal surveillance. The assessment process should result in collection of an individualized database that facilitates selection of fetal evaluation modalities within the context of the client's situation.

Once the need for a fetal evaluation procedure has been identified, the nurse often is the primary liaison between the pregnant client, testing facility, and associated specialist and staff. At the time of the procedure, a focused assessment of both maternal and fetal status is completed. The purpose of this assessment is to identify factors that may alter or contraindicate the performance of a fetal evaluation procedure. For example, the presence of a vaginal infection would contraindicate transvaginal CVS, the inability to auscultate the fetal heart tone would lead to additional assessment to confirm fetal viability before amniocentesis, and the presence of uterine irritability or cervical change would necessitate an evaluation of the decision to perform a CST.

A significant component of the nursing assessment is to evaluate the client's psychosocial status to identify the levels of stress and anxiety being experienced. Stress and anxiety can interfere with the client's ability to make decisions and cope with test procedures and outcomes.

Stress and anxiety also can impact the client's level of understanding. The client's ability to take, assimilate, and process information about the need, risks, benefits, and limitations of the procedure and its outcomes must be assessed. When faced with the crisis of a problem pregnancy, clients may be unable to absorb information about the procedure, diagnosis, follow-up, and options for alternative modes of evaluation and interventions. Consequently, in addition to a complete physical and psychosocial assessment, the nurse needs to assess the client's ability to participate in the informed decision-making process (Figure 22-10).

Client Education

Fetal Evaluation

To encourage critical thinking by the client, the nurse may ask the following questions:

- What do you know about the status of your pregnancy and fetus?
- How did you learn this information?
- How do you explain this concern to yourself?
- What do you think will help you to deal with your concern?
- How does this situation affect your daily life?
- If you could have one question answered, what would it be?
- How much control do you think you have over this situation?

Figure 22-10 Part of the nurse's responsibilities during fetal evaluation procedures is to ensure the client is fully informed and able to participate in the decision-making process.

The woman's individual belief system also is an integral component of the assessment. Racial, ethnic, and cultural differences are particularly important in assessing clients. A recent study has revealed that African American and Hispanic women are less likely to use fetal diagnostic testing compared with Caucasian and Asian women, suggesting that the meaning of testing, pregnancy termination, and raising a disabled child may be unique within cultural groups (Kuppermann, Gates, & Washington, 1996). The meaning of pregnancy, the status ascribed to the fetus, beliefs about disability and disease, attitudes about pregnancy termination, family dynamics, and decision-making patterns must be analyzed within the context of the client's dominant cultural paradigm. The cultural role of women, the perception of childbearing as a developmental process or a role-gender responsibility, a choice versus a fate, and the choice of being an active participant and decision-maker or a follower and producer of offspring have profound influences on the client's perception and use of fetal evaluation technologies. It is important to avoid cultural stereotyping however; that is, the nurse must recognize that not all clients of a specific cultural origin will hold the same values and beliefs. Therefore, assessing the client's cultural perspective is essential in developing a plan of care that is culturally sensitive and congruent.

A comprehensive holistic assessment is essential to identifying the client's need for fetal evaluation and to developing an individualized plan of care. Because the fetal environment can change quickly and the woman's physiologic response to the pregnant state can vary from adaptive to maladaptive, assessment needs to be an ongoing process throughout the duration of the gestational period.

Nursing Diagnoses

Appropriate nursing diagnoses are based on clustering, interpreting, and validating client-specific assessment data to determine mutually agreed on client needs. Consequently, a thorough assessment and knowledge base about fetal evaluation procedures are essential in formulating reliable and valid nursing diagnoses. A list of nursing diagnoses is provided to give some insight into the types of health care needs typically associated with fetal evaluation testing. The following nursing diagnostic labels can be applied to most of the procedures discussed in this chapter. The cause and supporting data components of the diagnostic statement, however, must be individualized based on the context of the testing situation and client-specific assessment data.

- ✱ Risk for injury of the invasive diagnostic technique.
- ✱ Powerlessness related to feeling inadequate to properly care for the fetus, inability to control events impacting fetal well-being, and inability to protect the fetus.

- ✱ Pain related to manipulation during the diagnostic procedure.
- ✱ Anxiety related to the possibility of an abnormal test result and uncertainty.
- ✱ Fear related to possible complications of the procedure and possible pregnancy loss.
- ✱ Ineffective coping related to stress and the inability to control or influence events.
- ✱ Spiritual distress related to the possibility of a negative outcome of the testing procedure and association of the outcome with pregnancy termination.
- ✱ Anticipatory grieving related to the loss of a "perfect" pregnancy.

Outcome Identification

The outcomes reflect the needs and desired goals for the woman, fetus, and family. Consistent with a variety of theoretic frameworks, goals are initially prioritized to reflect physiologic needs followed by psychosocial and emotional needs. However, pregnancy is a developmental episode in the client's life. Therefore outcome identification specific to fetal evaluation technologies needs to be formulated within the context of the pregnancy experience and the individualized client database. Consequently, because the priority outcome may be related to a psychosocial or emotional state, the risk of physical complications may be considered a secondary outcome by the woman. The important point is that the rationale for the designated priority be based on scientific principles yet be consistent with the values and beliefs of the client and mutually agreeable to all involved in the care-giving situation. Because of the amount of time required by some fetal evaluation procedures, the expected outcomes for each proposed group of nursing interventions should be documented in the client's medical record to allow for continuity of care. Possible outcomes for the client experiencing fetal evaluation include the following:

- ✱ The woman and fetus experience no injury or complication from the procedure
 - The fetal heart rate is audible and within normal parameters based on gestational age.
 - The client has no uterine cramping, or uterine cramping resolves within 24 hours.
- ✱ The fetus maintains a state of well-being.
 - Fetal movement level is unchanged.
 - Fetal heart rate is consistent with the norms for gestational age, and accelerations are present.
- ✱ The compromised fetus is identified, and timely referral for follow-up is made.
- ✱ The woman participates in the decision-making process related to the selection and use of fetal evaluation procedures.

- She verbalizes concerns and questions related to fetal evaluation technologies.
 - She verbalizes the meaning of the fetal evaluation testing results.
 - She states her options based on the testing results.
- The woman and family psychologically adapt to the process and results of fetal evaluation procedures.

Planning

The nurse is responsible for planning client care in accordance with established standards of care as defined by state nursing practice acts, professional scope of practice statements, professional education, and employer policies and guidelines. Some fetal evaluation procedures such as CVS, amniocentesis, PUBS, and BPPs are performed by sonographers, laboratory specialists, and physicians. In these situations, the planning component of the nursing process involves facilitating communication and coordination among activities, settings, and practitioners.

RECOMMENDATIONS OF THE U.S. PREVENTIVE SERVICES TASK FORCE: STRATEGIES IN HEALTH EDUCATION AND COUNSELING

1. Frame the teaching to match the client's perception.
2. Fully inform clients of the purpose and expected effects of the intervention and when to expect these effects.
3. Be specific.
4. Use a combination of strategies.
5. Involve others.
6. Refer.
7. Monitor progress through follow-up contacts.

Ask yourself:

- How do you feel about women who come for pre-natal care but refuse to undergo fetal evaluation testing?
- How do your personal values and beliefs about pregnancy, children, and disability influence your interactions with these clients?

U.S. Preventive Services Task Force. (1996). *Guidelines to clinical preventive services* (2 ed.). Philadelphia: Williams & Wilkins.

Other fetal evaluation technologies, such as NSTs and CSTs, are performed by the nurse. Not only does the nurse need the competencies to carry out the procedure but the skill to recognize nonreassuring patterns and to initiate interventions and notification of appropriate personnel.

An important component of planning is ensuring that the persons significant to the client are included in the procedure and decision-making process, as desired by the client. An assessment of family dynamics and communication patterns consistent with the client's cultural values and beliefs will assist the nurse to empower the client to include those persons important to her.

A growing number of nurses are performing ultrasound scans, BPPs, and other fetal evaluation procedures. Nurses who have training and competence, usually in the form of additional education, can perform these procedures if it is within the scope of practice as defined in the practice act of their state (Treanor, 1998).

Nursing Intervention

Nursing interventions are concentrated primarily in the area of counseling, support, and education. Before the procedure, nursing interventions encompass explaining the indications, risks, accuracy, technical aspects, rationale, and limitations of the specific evaluation modality. Performance of fetal evaluation procedures such as CVS, amniocentesis, PUBs, and MRI are not within the scope of nursing practice. The nurse is integrally involved in preparing the client, however, and may be present during the procedure. In these situations the nurse plays a vital role in explaining the technical and sensory aspects of the procedure. When the nurse is present during the performance of the procedure, her role is twofold: assisting the physician and supporting the client. During the procedure, the nursing activities may include assisting with skin preparations, positioning the woman, and specimen collection and labeling. The more significant role of the nurse, however, is as client advocate and a source of support. During the procedure, the nurse should be in continuous contact, verbal or nonverbal as appropriate, with the client. The nurse can provide anticipatory guidance about what will happen next, provide comfort measures, use anxiety reduction techniques, and monitor for potential and real problems.

After the procedure, nursing interventions include monitoring the pregnancy for complications that include amniotic fluid leakage; bleeding; uterine irritability; fetal distress, including changes in fetal cardiac activity; and maternal physiologic parameters of distress, such as fever, pain, and changes in baseline vital signs. Facilitating the client's verbalization of her perception of the experience, her concerns, and her coping strategies and support systems while awaiting the results are vital interventions.

Case Study/Care Plan

CLIENT IN A SECOND PREGNANCY

Maria presents for her first prenatal visit. Maria, who is 40 years old, is accompanied by her husband of 14 years, Alex. Maria is a loan officer and Alex is a 43-year-old stockbroker. Both Maria and Alex are very religious. They have not used contraceptive methods during their marriage. They had begun to explore adoption during the past year, with the belief that pregnancy was not in God's plan for their lives.

This is Maria's second pregnancy. Her first pregnancy was at aged 16 and produced a 3-pound male infant at 39 weeks' gestation. The infant was placed for adoption, and Maria has had no contact with him.

Assessment

The client reports she has missed two menstrual periods and has had a positive home pregnancy test.

Both Maria and Alex are excited about this pregnancy and the prospect of being parents. They state that they desire this baby and are certain everything will be okay since they have waited so long.

Family history is significant because Maria's older sister gave birth to a stillborn infant with an "open sore on her back" 20 years ago. Alex's family history is without evidence of genetic or birth-related conditions.

Maternal vital signs and prepregnancy weight are within normal limits.

Maria is referred for an amniocentesis for karyotyping and evaluation of AFP level. Maria and Alex tearfully agree to the procedure stating, "We love this baby. There can't be anything wrong. Please tell us everything will be okay."

Nursing Diagnosis

Deficient knowledge related to unfamiliarity with the testing procedures and lack of understanding of genetic predisposition.

Expected Outcome Client will understand importance of family history related to risk factors.
Client will understand general parameters of the procedure.
Client will feel empowered during the procedure.

Planning Referral for comprehensive ultrasonography specifically to examine for neural tube closure, movement of lower extremities, and bladder filling. In later pregnancy, Maria will need to be monitored for IUGR based on a previous history of a low-birth-weight infant and a family history of a stillbirth.

Nursing Interventions	Rationales
1. Teach the client about the indications, risks, benefits, and limitation of amniocentesis for fetal karyotype and AFP analysis.	1. Client acceptance of the procedure is based partly on an understanding of how it works and what it does.
2. Provide emotional support during the procedure.	2. The client's fears and feelings of loss of power can be kept in check with thoughtful and sensitive nursing care.
3. Encourage consultation with clergy or presence of religious article, as desired by the client.	3. Show respect for the client's preferences by considering factors that are important to her during the decision-making process.

Evaluation

1. The client is able to state the purpose, process, and alternatives to the chosen procedure.
2. The client's spiritual needs are met consistent with her beliefs and values.

Some fetal evaluation procedures, such as fetal movement counts, are completely within the scope of nursing practice. Nurses can initiate the procedure by teaching the client the purpose and process of fetal movement counting. When a decrease in fetal movement is detected, the nurse collaborates with and refers to the physician or certified nurse-midwife for further evaluation and testing.

Evaluation

The woman, pregnancy, and family unit need to be reevaluated in the context of the results of fetal evaluative procedures and the individual client's values and choices. Depending on the results of the testing procedure, evaluation of nursing interventions and achievement of nursing care goals may lead to formulation of a new nursing care plan focused on promoting a healthy pregnancy or adapting to and coping with an affected fetus, a high-risk pregnancy, or perinatal loss.

FUTURE DIRECTIONS

Support for the continued use and further dissemination of fetal surveillance technologies was identified in the objectives of Healthy People 2000, which stated, "increase to at least 90% the proportion of women enrolled in prenatal care who are offered screening and counseling on prenatal detection of fetal anomalies" (U.S. Department of Health and Human Services, 1991). Prenatal fetal testing is becoming increasingly recommended during pregnancy. Combined with continued technologic advances in genetics and instrumentation, this trend is not likely to be reversed. In addition, the wide dissemination of information about fetal evaluation modalities has resulted in consumers who request procedures, sometimes based on incomplete knowledge or information. Another practice that can influence the use of fetal surveillance procedures is the practice of defensive medicine. The use of fetal evaluation technologies to prevent a potential legal action as opposed to using it to promote maternal well-being

should be a point of concern. Much of the literature related to emerging technologies is focused on safety, accuracy, and financial costs of different procedures and not on the broader implications of the use of that knowledge within the context of society. As patient advocates, nurses must ensure that decisions are made consistent with the client's values and not directed solely by technology or the dominant values of the health care system.

Fetal surveillance technologies can produce a sense of anxiety and a feeling of powerlessness in women and their families. Decisions related to the use of fetal surveillance can alter family dynamics and can impact the bond between mother and the fetus or infant (Raines, 1996). Simply because the technology is available does not mean that every procedure is right for every pregnancy. Questions about the purpose, process, and consequences of fetal evaluation are critical to holistic nursing practice and individualized, quality nursing care. Sometimes a little mystery is a good thing.

Web Activities

The following web sites have information concerning assessment of fetal status. Visit these sites for additional information.

Key Concepts

- Most fetal evaluation procedures have benefits and risks to both mother and fetus. There are limitations to the amount of information provided from these testing modalities.
- Reactive NST and negative CST are reassuring signs of fetal well-being.
- A BPP is an evaluation of fetal well-being and condition of the intrauterine environment.
- Ultrasonography is a commonly used imaging modality during pregnancy with no known side effects.
- Amniocentesis is performed throughout pregnancy for differing indications: from 15 to 18 weeks' gestation for identification of chromosomal alteration or altered AFP level, in the second trimester for elevated bilirubin levels, and in the third trimester for a lung maturity profile.

- ✿ Alterations in AFP levels are not detectable by CVS.
- ✿ MS-AFP is a screening procedure that identifies pregnancies at increased risk for a neural tube defect.
- ✿ The nurse's role in fetal surveillance includes teaching, counseling, and supporting the client and family.

Review Questions and Activities

1. Identify nonreassuring fetal heart rate patterns using electronic fetal monitoring and discuss the physiology and nursing interventions for each pattern.
2. What are the characteristics of a reassuring fetal heart rate pattern?
3. What is the difference between a screening test and a diagnostic test? Provide examples of each type of test used in the care of the pregnant woman.
4. What are the indications for a NST and how are the results interpreted?
5. Compare and contrast the NST with the BPP.
6. What is the purpose of a CST?

UNIT VI

Childbirth

Processes of Labor and Delivery

One evening, a group of women began talking about their labor experiences. Each woman could clearly remember the details. It did not matter if it was her first or her fourth child, she could recall many of the details of the labor and delivery, even when the events had occurred decades before. This fact represents how significant the process is and how important it is for the nurse to have a thorough understanding of the physiologic and psychologic changes that occur during labor. Because the labor nurse often is the person who has the most contact with the client during labor, this knowledge can help assist the nurse in making the experience a positive and safe one for both mother and baby. The labor and delivery process is a pivotal point in a woman's life, a time when she is making the transition to her role as mother. A positive experience can have major effects on the key people in the woman's life, such as her spouse or partner, other children, parents, and friends.

Key Terms

Active phase	Dystocia	Fourth stage of labor	Parturition
Amniotomy	Effacement	Labor	Placental stage
Augmentation of labor	Fetal attitude	Labor induction	Primary powers
Bloody show	Fetal lie	Latent phase	Pushing stage
Braxton Hicks contraction	Fetal position	Leopold's maneuvers	Recovery stage
Cervical dilation	Fetal presentation	Lightening	Second stage of labor
Cesarean section	First stage of labor	Maternal role attainment	Secondary powers
Crowning	Flexion	Molding	Station
Descent	Fontanel	Nesting (energy spurt)	Third stage of labor
	Forceps	Oxytocin	Transition

Competencies

Upon completion of this chapter, the reader should be able to:

1. Understand the theories of the onset of parturition or labor.
2. Define the signs and symptoms of impending labor.
3. Define the five Ps of labor.
4. Describe the psychologic response of the mother during labor.
5. Define the four stages of labor.
6. Explain the maternal adaptations to labor.
7. Explain the fetal adaptations to labor.

Labor is the bridge between pregnancy and motherhood, and for the laboring woman it often is the most intense experience of the pregnancy. Most nulliparous women can readily visualize themselves as pregnant and their future role as a mother; however, most women cannot or do not visualize what labor is or can be. Labor is both a physical process for the mother and an emotional passage. Family members and friends often are involved in the labor process, introducing additional emotional experiences for all those participating in the labor experience. Finally, the neonate is going through the transition between intrauterine and extrauterine life.

In this chapter we explore the physiologic and psychological processes of labor, the various stages associated with childbirth, and how labor affects both mother and child. The signs and symptoms of impending labor will be examined and the maternal and fetal adaptations reviewed. The medical and surgical interventions and indications for labor induction, augmentation, and cesarean sections will be discussed.

Because the nurse often is the caregiver who spends the most time with the laboring woman, it is important for the nurse to understand fully the physiologic process of

labor and how it affects both the woman and neonate. Knowing the normal process, the nurse can assist the woman and her support group through the experience, ensuring the well-being of all involved.

PHYSIOLOGY OF LABOR

The physiologic process by which the fetus, placenta, and membranes are expelled through the uterus is called **labor** or **parturition**. Labor has four stages. Stage I begins with the onset of labor and continues until full cervical dilation occurs, typically lasting 12 hours for primigravida and 8 hours for multigravida. Stage II begins at the point of complete dilation of the cervix and is complete when the fetus is expelled, usually lasting 50 minutes in primigravida and 20 minutes in multigravida. Stage III begins with the delivery of the fetus and ends with delivery of the placenta and membranes, usually within 8 to 10 minutes of delivery of the neonate. Stage IV begins when the placenta and membranes are delivered and is complete 4 hours later. When labor fails to ensue or situations arise that do not allow a spontaneous vaginal delivery, labor induction, augmentation, assisted delivery, and cesarean section must be considered.

Theories for the Onset of Labor

Blackburn and Loper (1992) emphasize that the exact cause of the onset of labor still is not completely understood but no doubt involves both maternal and fetal factors. Progesterone withdrawal or binding, increased estrogen levels, prostaglandins, and oxytocin sensitivity are believed to have a part in the onset of labor. Fetal factors such as cortisol levels also are thought to play a role in the onset of labor.

Maternal Factors

Maternal hormone levels are partly responsible for initiation of labor.

Estrogen and Progesterone

It is believed that progesterone causes relaxation of the myometrium, whereas estrogen stimulates myometrial contraction. Estrogen levels begin to increase at about 34 to 35 weeks gestation; a decrease in uterine responsiveness to progesterone also occurs, changing the effect of the estrogen-progesterone ratio. The changes in these steroid levels are responsible for the increased number of myometrial gap junctions. *Gap junctions* are proteins that connect cell membranes, facilitating coordinated uterine contractions and myometrial stretching (Ulmsten, 1996). Estrogen also stimulates the production of prostaglandin in the decidua and fetal membranes, which increases stimulation of smooth muscle contraction of the uterus.

Prostaglandins

Prostaglandins, which act as paracrine hormones, are derived from arachidonic acid and are essential for the onset of labor. Increases in prostaglandin production occur late in pregnancy and are thought to play an important role in the onset of labor. The two most important prostaglandins associated with parturition are PGE_2 and $\text{PGF}_{2\alpha}$. Prostaglandins are produced in the myometrium, cervix, fetal membranes, and placenta. $\text{PGF}_{2\alpha}$ exerts a stimulatory effect on the myometrium, whereas PGE_2 has a stimulatory effect on the cervix. The effect of PGE_2 on the cervix causes remodeling of the connective tissue in the cervix, allowing the cervix to soften, efface, and dilate during labor.

Oxytocin

Produced in the posterior pituitary, **oxytocin** is a hormone that plays a major role in the onset and maintenance of labor. Maternal oxytocin levels increase throughout pregnancy. As a gestation nears term the number of oxytocin receptors in the uterus increases, creating increased sensitivity to oxytocin. Estrogen also increases myometrial sensitivity to oxytocin. In the absence of these end-organ

changes, even external administration of oxytocin will not be successful in precipitating labor. Fetal production of oxytocin also occurs, which is thought to stimulate prostaglandin production (Blackburn & Loper, 1992).

Fetal Factors

An increase in fetal adrenocorticotrophic hormone levels at term is speculated to have an effect on uterine sensitivity to oxytocin and prostaglandins, thus stimulating the onset of labor (Ulmsten, 1996). Increased cortisol levels also decrease the production of progesterone by the placenta, therefore aiding in the relaxation of the myometrium.

Mechanisms of Labor

Five important factors affect the process of labor:

1. Passageway, or the birth canal.
2. Passenger, the fetus and placenta.
3. Powers, the uterine contractions.
4. Position of the mother.
5. Psychological response of the mother (Box 23-1).

Passageway

The bony pelvis is an important structure in the birthing process to accommodate the fetus as it passes through the birth canal. The bony pelvis is composed of four bones, two innominate (each consisting of the ilium, ischium, and pubis), the sacrum, and the coccyx. The effects of hormones associated with pregnancy, relaxin and estrogen, are to soften cartilage and increase the strength and elasticity of the pelvic ligaments. These changes cause the pelvic joints to separate slightly, allowing some movement of the pelvic joints. As the pregnancy progresses, the symphysis pubis separates slightly, allowing room for the fetal head.

The pelvis is divided into the false pelvis and true pelvis. The *false pelvis* is the shallow upper section of the pelvis. The *true pelvis* is the lower curved bony canal, including the inlet, cavity, and outlet, through which the fetus must pass in the birth process (Seidel et al., 1999).

Box 23-1 The Five Ps of Labor

- **Passageway**
- **Passenger**
- **Powers**
- **Position**
- **Psychologic response**

Figure 23-1 Station or relationship of the fetal presenting part to the ischial spines. The station illustrated is +2.

Station refers to the relationship between the ischial spines in the passage and the presenting part of the fetus (Figure 23-1). The ischial spines are station 0 and in the normal pelvis signify the narrowest diameter the fetus encounters during a vaginal birth.

There are four types of female pelvis: gynecoid, android, anthropoid, and platypelloid. These various pelvis types can play a large role in determining the ease of a vaginal delivery. The most common type of female pelvis is the gynecoid pelvis found in about half of women. The least common type of female pelvis is the platypelloid pelvis found in about 3% of women. Figure 23-2 compares the four female pelvis types. Wide suprapubic arches (gynecoid and platypelloid) tend to allow normal vaginal delivery, whereas narrow arches (android and anthropoid) increase the risks for forceps and cesarean deliveries.

Passenger

The ease with which the passenger goes through the pelvis is determined by many fetal factors: head size, presentation, lie, attitude, and position.

Fetal Head Size

The fetal head is composed of bony parts consisting of a frontal bone, two parietal bones, two temporal bones, and an occipital bone. The skull bones are united by membranous sutures, and the points of intersection of these are called **fontanels**. The two most important fontanels for delivery are the anterior and posterior fontanels (Figure 23-3). The diamond-shaped anterior fontanel is the largest of the two and lies at the juncture of the sagittal, coronal, and frontal sutures. This fontanel generally stays open until about 18 months of age, allowing brain growth. The posterior fontanel is triangular shaped and is formed by the intersection of the sagittal and lambdoid sutures; it closes about 6 to 8 weeks after birth. During a vaginal examina-

Figure 23-2 Female pelvis types.

tion, the fetal presentation can be determined by locating these fontanels.

The fontanels are important during the birth process because they allow molding to occur. **Molding** is the overlapping of the fetal skull that helps the fetal head to adapt to the size and shape of the maternal pelvis. Molding can be extensive, causing the fetal head to appear misshapen at birth. The effects of molding on the shape of the head usually resolve completely in 3 days.

Fetal Presentation

Fetal presentation refers to the anatomic part of the fetus that is either in or closest to the birth canal. Presentation is determined by performing a vaginal examination and feeling the part through the cervix. There are three major presentations. Cephalic or fetal head presentation is the most common, occurring in 96% of births, and is most likely to lead to a vaginal birth. Breech or buttock presentation occurs in 3% of births. Shoulder presentation occurs in the remaining 1%. These last two presentations are associated with a complicated birthing process and often require cesarean section.

Fetal Lie

The **fetal lie** describes the relationship of the fetal long (head to foot) axis to that of the maternal long axis or spinal cord (Figure 23-4). In a breech or cephalic presentation, the lie is longitudinal. With a shoulder presentation, the lie is transverse, making vaginal birth unlikely. An oblique lie indicates the fetus is at a 45-degree angle to the maternal long axis and is considered an unstable lie; the oblique lie often converts to longitudinal or transverse lie during labor.

Figure 23-3 Fetal skull—sutures and fontanelles. A. Superior view. B. Lateral view.

Figure 23-4 Fetal attitude and fetal lie. A. Fetal attitude flexion, fetal lie longitudinal. B. Fetal attitude flexion, fetal lie transverse.

Fetal Attitude

Fetal attitude refers to the relationship of fetal body parts to one another. The typical fetal attitude includes flexion of the head wherein the chin rests on the sternum, the arms and legs are flexed against the chest, and the back is bowed out. Throughout the pregnancy, the fetus assumes various attitudes through movement and stretching of the fetal extremities. The available space within the uterine cavity can cause changes in fetal attitude; large for gestational age infants tend to be flexed more than are normal-sized infants owing to lack of room inside the uterus.

Fetal attitude can affect the birth process. For example, when the fetal head is slightly extended (sinciput or brow presentation), it presents a larger diameter to pass through the maternal pelvis and thus increases the difficulty of labor and delivery (Figure 23-5).

The largest transverse diameter of the fetal head is the biparietal diameter, which at term is about 9.25 cm. The suboccipitobregmatic diameter is the most critical anteroposterior diameter, which is about 9.5 cm at term. If the fetal head is not fully flexed at delivery, the anteroposterior diameter increases and may prevent the head from entering the true pelvis or the deeper cavity below the inlet (Figure 23-6).

Fetal Position

Fetal position refers to the relationship of the fetal presenting part to the left or right side of the maternal pelvis. If the cephalic presentation is vertex, the position landmark is the posterior fontanel or occiput; similarly, in a

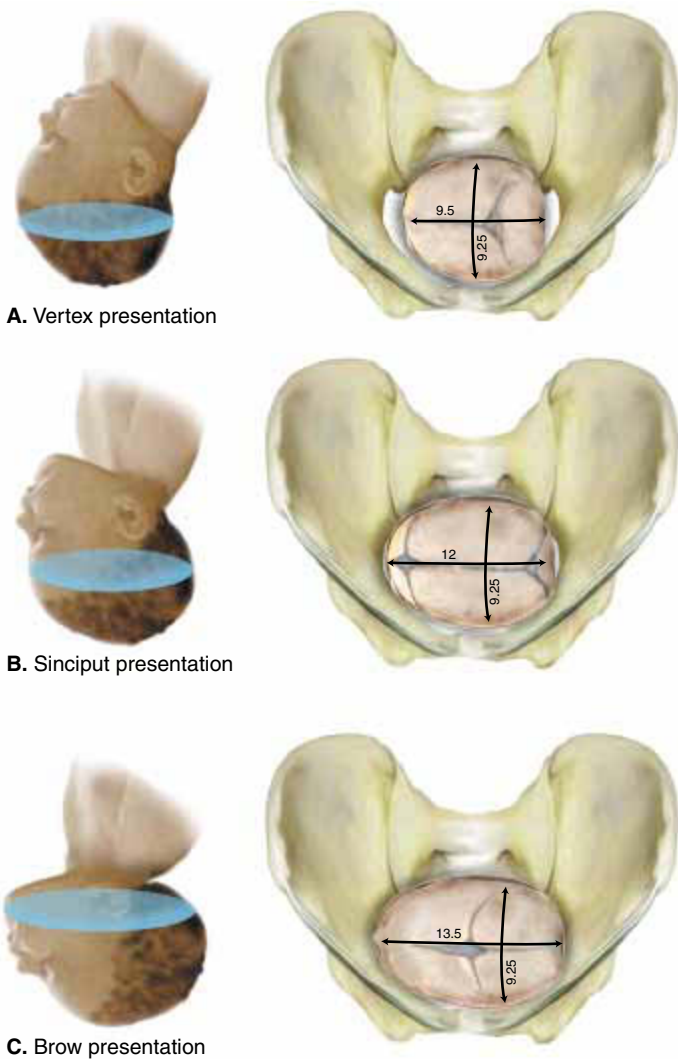

Figure 23-5 Diameter of presenting part in vertex, sinciput, and brow presentations.

cephalic face presentation, the mentum or chin is the presenting part. In breech and shoulder presentations, the sacrum and acromion are the landmarks, respectively. The landmark of the presenting part of the fetus is described in relation to the four quadrants of the maternal pelvis (left anterior, right anterior, left posterior, and right posterior) or the transverse portion (Figure 23-7). In a posterior position, a larger part of the head must pass through the pelvis, causing a long labor and often more back pain owing to increased pressure on the sacral nerves.

The positions for fetal presentation follow:

- ✦ Position in Vertex Presentations:
 - ROA, right-occiput-anterior
 - ROT, right-occiput-transverse
 - ROP, right-occiput-posterior
 - LOA, left-occiput-anterior
 - LOT, left-occiput-transverse
 - LOP, left-occiput-posterior
- ✦ Position in Face Presentations:
 - RMA, right-mentum-anterior
 - RMT, right-mentum-transverse
 - RMP, right-mentum-posterior
 - LMA, left-mentum-anterior
 - LMT, left-mentum-transverse
 - LMP, left-mentum-posterior
- ✦ Position in Breech Presentations:
 - RSA, right-sacrum-anterior
 - RST, right-sacrum-transverse
 - RSP, right-sacrum-posterior
 - LSA, left-sacrum-anterior
 - LST, left-sacrum-transverse
 - LSP, left-sacrum-posterior

Figure 23-7 Positions of a vertex presentation.

Assessment of Fetal Presentation and Position

There are two primary means for determining the presentation and position of the fetus. The first and less invasive way is through Leopold's maneuvers; the more invasive way is through a vaginal examination.

Leopold's Maneuvers or Abdominal Palpation. **Leopold's maneuvers** refer to a method of abdominal palpation to determine fetal presentation and position. These maneuvers need to be performed in a consistent and systematic fashion to be as reliable as possible. These maneuvers are a reliable method to determine position and presentation but are very limited in the obese client or the client with an anterior placenta. The examiner should stand at the side of the bed that is most convenient and face the client's head for the first three maneuvers and the client's feet for the last maneuver (Figure 23-8).

First Maneuver

With both hands, the examiner outlines the shape of the uterus, gently palpating the fundus with the fingertips to determine which fetal pole is present in the fundal area. The fetal buttocks give the sensation of a large nodular body, whereas the head is more firm, round, and ballotable.

Second Maneuver

After determining the fetal part in the fundus, the examiner's palms are placed on either side of the client's abdomen, exerting deep but gentle pressure. In a vertex or breech presentation, one side will feel smooth and firm,

Figure 23-8 Leopold's maneuvers.

indicating the back; whereas the other side will have numerous small irregular mobile parts, indicating the fetal extremities. Both increased amniotic fluid and maternal obesity will make feeling the individual extremities more difficult, and in some cases only the back may be palpated. Determining the location of the back more anteriorly or transversely will give the examiner a more accurate idea of the fetal lie and presentation.

Third Maneuver

The third maneuver will help determine whether the previously detected presenting part is *engaged* (deep in the pelvis), and the attitude of the fetal head is in a cephalic presentation. With the thumb and fingers of one hand, the examiner attempts to grasp the lower portion of the client's abdomen, just above the symphysis pubis. If a body part moves easily, the presenting part is not engaged. The fetal attitude can be determined in a cephalic presentation by assessing if the cephalic prominence is on the same side as are the small parts, indicating that the head is flexed and the fetus is in vertex presentation. When the cephalic prominence is on the same side as is the back, the fetal head is extended.

Fourth Maneuver

The examiner will face the client's feet to assess further the fetal attitude. This maneuver will use the fingertips of the palmar surface of the examiner's hands to outline the cephalic prominence of the fetus. When the presenting part is deeply engaged, only a small portion may be outlined.

Vaginal Examination. The vaginal examination during the labor process is done to obtain valuable information about the mother's progression during labor and the position of the fetus. Vaginal examination often can determine the fetal station and presenting part. The mother's cervix also can be assessed vaginally for how open, thin, and short it is and for the amount of dilation and effacement. Vaginal examination can help determine the adequacy of the pelvic size and shape for a vaginal delivery.

Powers

Two important types of powers are involved in the labor process, which are characterized as primary and secondary powers. The **primary powers** are the involuntary uterine contractions. The **secondary powers** are the mother's intentional efforts to push out the fetus.

Primary Powers

Uterine contractions are involuntary and generally are independent of extrauterine control. During labor, the uterus forms what is called the physiologic retraction ring, dividing itself into two portions. The upper contractile segments become thicker as labor advances. The passive lower uterine segment and the cervix expand and thin out as labor progresses. Uterine contractions are responsible for the effacement and dilation of the cervix, allowing the descent of the fetus. Uterine contractions are measured by their frequency, from the beginning of one to the beginning of the next contraction. The length of a contraction is how long it lasts in seconds. The intensity or strength of a contraction also is evaluated by external palpation of the firmness of the uterus and the level of pain perceived by the client.

As the uterine muscle contracts, the upper uterine segment shortens and causes longitudinal traction on the cervix. This leads to **effacement**, or shortening and thinning, of the cervix. Before labor, the cervix generally is 2 to 3 cm long and about 1 cm thick. The degree of effacement is described in terms of a percentage. For example, a cervix that is halfway effaced would be described as being 50% effaced.

The widening of the cervical opening that occurs from myometrial contractions in labor is referred to as **cervical dilation**. In general, before labor the cervix is closed, progressing to 10 cm open as labor advances. Dilation accom-

modates passage of the fetal head through the birth canal. When the cervix is fully dilated and retracted into the lower uterine segment, it is no longer palpable (Figure 23-9). The uterus elongates with each contraction, causing the fetal body to straighten. This fetal change exerts pressure on the fundus of the uterus, pushing the presenting part onto the cervix and assisting in dilation; this phenomenon is called *fetal axis pressure*. In the primigravida, the effacement of the cervix usually begins before dilation. In a multipara, effacement and dilation generally progress together.

Secondary Powers

After the woman is fully dilated and effaced, the presenting part of the fetus descends to the pelvic floor. The uter-

Figure 23-9 Effacement and dilation. A. Primigravida. B. Multigravida.

ine contractions begin to change and become more expulsive. The laboring woman begins to feel an involuntary urge to bear down or push. This begins the use of secondary, more voluntary efforts of labor. With each uterine contraction, the woman contracts her abdominal muscles to compress all sides of the uterus to aid in expelling the fetus. The woman's ability to push has an important role in the progression of the vaginal birth of the fetus.

Position

Maternal position in labor can have an effect on both the mother and fetus. Much disagreement exists regarding the influence of maternal position on labor progress, pain perception, and fetal well-being. During the first stage of labor, it may be psychologically beneficial for the mother not to be confined to lying supine in bed. If a client has an intravenous line in place, a movable pole should be used to allow ambulation. If a mother chooses to remain in bed, she should be encouraged to find her most comfortable position. A lateral recumbent position often is the most comfortable one and best for fetal well-being, particularly during the first stage of labor. The optimal position for an individual client, however, may range from sitting in a rocking chair to using a labor ball or being in a semi-reclined position. All positions have advantages and disadvantages. For example, although the squatting position may increase the size of the pelvic outlet, it may be difficult for a woman with an epidural to assume this position.

Many studies have examined the effects of maternal position on pain and duration of the second stage of labor. In some cultures, women give birth in an erect, kneeling, or squatting position, which has been associated with less maternal pain. A study by Gardosi, Hutson, & Lynch (1989) found that assuming a modified squatting position resulted in a shorter second stage of labor and fewer subsequent perineal lacerations.

In the absence of a clear-cut "best" position during labor, it is important to consider maternal needs, both physical and psychologic, as well as fetal well-being.

Psychological Response of the Mother

Few reports exist in the nursing literature about the psychological response to labor. Clark and Affonso (1978) identified some factors that make labor a meaningful positive event or the antithesis, a negative event for the mother. The first factor is the role of one's culture, that is, how a particular society views childbirth, which incorporates the woman's attitudes toward the labor process. Another factor that can negatively or positively affect the childbirth experience is the expectation and goals for the labor process. If the expectations about labor are realistic

and can be met, the outcome is more likely to be positive; in contrast, if the expectations are unrealistic and unattainable, the experience is more likely to be negative. Finally, feedback from other people participating in the labor and birth process can add positive or negative aspects to the experience.

It is important for the nurse to assess these factors as soon as the client arrives in the labor suite. The nurse should communicate with the client and significant others involved in the labor experience and explore cultural ideas, attitudes, expectations, and goals. For example, a specific cultural need of the client that could be explored is the role of labor coach being taken on by the laboring woman's mother instead of the husband. These needs should be met when possible, even if the nurse providing care has different cultural attitudes.

A positive labor and birth experience can help the woman more easily transition into the maternal role. **Maternal role attainment** as defined by Rubin (1984) is the process by which a woman acquires knowledge of maternal behavior that aids in transforming her maternal identity. The first developmental stage of maternal role attainment is for the mother to seek a safe passage for herself and her child during pregnancy, labor, and delivery. Many factors contribute to maternal role attainment such as age, culture, support system, childbirth preparation, and previous birth experiences. Williams, Kramma, & O'Brian (1997) describe proper childbirth preparation as a valuable tranquilizer during the birth process that can lead to decreased need for analgesics to be administered during labor.

The labor and delivery nurse should provide a supportive and caring environment for the client and should respect the client's and family's needs and attitudes. Delivery of such care is attained through therapeutic communication and assessment of client needs.

Cultural Perceptions of Childbirth

Leininger (1985) defines culture as a "particular group's values, beliefs, norms and practices that are learned and shared and that guide thinking, decisions and actions in a patterned way." In examining this definition and relating it to childbirth, culture is one of the biggest influences on childbirth perceptions and the role of motherhood. A study by Callister, Vehvilainen-Julkunen, & Lauri (1996) compared childbirth perceptions among women who were American Mormon, Canadian Orthodox Jew, and Finnish Lutheran. The results showed that Finnish Lutheran women felt that motherhood was one of many roles women would encounter in life. In contrast, Canadian Jewish women and American Mormon women felt that motherhood was their purpose in life. The author points out that family structures are different in that husbands in

Finland take a more active role in parenting. In contrast, American and Canadian fathers of these religious affiliations believe the mother's role is paramount and thus are less involved.

SIGNS AND SYMPTOMS OF IMPENDING LABOR

The signs and symptoms of impending labor are different for every woman, and an individual woman may experience all, some, or none of them. Some of the premonitory signs and symptoms of labor may include lightening, cervical changes, Braxton Hicks contractions, bloody show, an energy spurt, and gastrointestinal (GI) upset. Education of the woman and assessment of these signs and symptoms can help the nurse to provide anticipatory guidance for the onset of labor and delivery.

Lightening

Lightening is the movement of the presenting part of the fetus into the true pelvis. In primigravidas, lightening usually occurs about 2 weeks before the onset of labor. Clients often will describe a feeling of being able to breathe more easily because of less pressure on the diaphragm from the gravid uterus. Other discomforts however may become more apparent:

- ✦ Increased pelvic pressure and congestion, resulting in increased vaginal secretions and pelvic discomfort.
- ✦ Increased urinary frequency from extrinsic pressure on the bladder.
- ✦ Neuropathic pain related to the pressure of the presenting part on the nerves in the pelvis, particularly in the obturator foramen.
- ✦ Edema of the lower extremities and increased venous stasis from inhibition of blood return by the pelvic pressure of the presenting part.

Cervical Changes

As a pregnant woman approaches term, her cervix changes from being long and closed with a firm consistency to shortened (or effaced), thinned, dilated, and soft. The cervix of a multipara normally can be dilated 2 cm or more before the onset of labor. Primigravidas often will experience effacement before dilation, whereas multiparas will have concurrent effacement and dilation (Seidel et al., 1999).

Cervical changes are thought to occur from the remodeling of connective tissue secondary to the effects of prostaglandins. Braxton Hicks contractions also play a role in cervical change. Because cervical ripeness varies at the onset of labor, it does not predict when the woman will go

into labor. However, cervical ripeness can help predict that a client will go into labor when contractions begin and can help in deciding who is ready for induction of labor (Varney, 1987).

Braxton Hicks Contractions

Throughout the pregnancy a woman may experience painless irregular contractions called **Braxton Hicks contractions** or false labor. These contractions produce no cervical changes. As true labor approaches, Braxton Hicks contractions may become more noticeable, frequent, painful, and difficult to differentiate from true labor without cervical examination. These contractions may be annoying and confusing to the pregnant woman, who often will come to the physician's office or hospital for evaluation. A woman experiencing false labor needs reassurance that true labor will eventually ensue.

Bloody Show

Soon after conception, thick tenacious mucus forms inside the cervical canal to act as a protective barrier. Before the onset of labor, as the cervix begins to soften and dilate, this mucous plug often is expelled. These blood-tinged secretions are referred to as **bloody show**. Labor usually ensues within 24 to 48 hours of expelling the mucous plug. It may be difficult to identify bloody show if a vaginal examination has been done within the past 24 hours, given the increased friability of the cervix near term.

Energy Spurt

Although no physiologic basis is known for this, many women experience a burst of energy, known as **nesting**, 24 to 48 hours before going into labor. Many women report having the energy to do things that they recently have not had the ability to do because of the fatigue of pregnancy, for example, cleaning the house or washing windows. In providing anticipatory guidance, the nurse should warn clients of the possible energy spurt and how they need to conserve their energy for labor.

Gastrointestinal Disturbances

Diarrhea, indigestion, nausea, and vomiting sometimes are reported just before the onset of labor. There is no known physiologic explanation for these symptoms.

STAGES OF LABOR

There are four stages of the labor process. The first and longest stage of labor occurs between the onset of true labor and the point of complete cervical dilation and ef-

facement. The second stage of labor is expulsion of the fetus, and the third stage of labor is delivery of the placenta. The fourth stage is the first 4 hours after delivery of the placenta.

First Stage

The **first stage of labor**, which is the longest in duration, begins with regular contractions and ends when the cervix is completely dilated. This stage is divided into three phases: latent, active, and transition phases.

Latent Phase

The **latent phase** of labor begins with the onset of regular contractions, which usually are mild. During this phase, contractions may be 15 to 20 minutes apart, lasting 20 to 30 seconds. As this phase progresses, however, the contractions will occur every 5 to 7 minutes and the duration will lengthen to 30 to 40 seconds. Many women remain at home during the early parts of the latent phase. This phase usually begins with little or no cervical dilation and ends when the cervix is 3 to 4 cm dilated. For the primigravida, the latent phase lasts an average of 9 hours; whereas in the multigravida, the latent phase generally lasts an average of 6 hours. Although the woman may exhibit some anxiety during this phase, she often is comfortable enough to verbalize her concerns.

Active Phase

The **active phase** of labor begins when the woman is 3 to 4 cm dilated and ends when she is 8 cm dilated. During this phase, contractions occur every 2 to 3 minutes and last up to 60 seconds. The intensity of each contraction begins as moderate and continues to increase as the woman gets closer to the transition phase. The average length of the active phase in the primigravida is 6 hours and in the multigravida is 4.5 hours. Dilation rates should be at least 1.2 to 1.5 cm/h (Troyer & Parisi, 1993). This often is the period when pain relief is requested by the laboring client.

Transition Phase

The last and shortest part of the first phase of labor is **transition**, which typically is the most intense phase for the laboring woman. In transition, contractions occur every 1.5 to 2 minutes, with a duration of 60 to 90 seconds. The intensity of the contractions is very strong in the transition phase. The woman often becomes very restless and agitated and may have difficulty focusing during contractions. Many women exhibit anger at the coach, voice a desire to leave the hospital, request a cesarean section, hyperventilate, complain of nausea and vomiting, tremble, and experience rectal pressure. The nurse plays an impor-

tant role for the client and her coach because the laboring woman often begins to withdraw from her coach's support. The coach may feel useless, and both the client and her partner will look to the nurse for reassurance and support. During this time the nurse will need to prepare the woman for the second stage of labor.

Second Stage

The **second stage of labor** begins when the cervix is completely dilated and effaced and ends when the fetus is expelled; it also is known as the **pushing stage**. The average length of the second stage of labor in a primigravida is 1.1 hours and 24 minutes in the multigravida. Many factors influence the length of the second stage of labor, including maternal parity, fetal size, uterine contractile force, presentation, position, pelvic size, method of anesthesia, and magnitude of maternal expulsive effort.

During contractions, the woman will bear down, causing the abdominal muscles to contract and helping the fetal head to descend through the birth canal. As the fetal head continues into the birth canal, the perineum begins to bulge. **Crowning** is defined as the point at which the fetal head is visible at the vulvar opening. When crowning occurs, birth is imminent.

Many women feel relief at the developing urge to push, partly because it signifies that the birth is very close. Other women, particularly those without support or child preparation classes, feel overwhelmed when it is time to push. Some women describe intense pain and burning of the perineum as the pressure increases on the vulva. Women are in various positions during the second stage of labor; the lithotomy position is the most common in the United States. Epidural anesthesia may interfere with the woman's perception of pushing and her ability to push forcefully. Nurses need to be aware of prolonged second stages of labor (Table 23-1) because intervention may be required.

Cardinal Movements or Mechanism of Labor

During the birthing process, the position of the fetal head and body must change to accommodate the maternal pelvis. These changes in fetal position are called *cardinal movements* or *mechanism of labor* (Figure 23-10). The cardinal movements are descent, flexion, internal rotation, extension, restitution, external rotation, and expulsion.

Descent

Descent is the progression of the fetal head into the pelvis, which occurs because of three forces: the pressure of the amniotic fluid, direct pressure of the contracting uterus, and effects of the contractions on the maternal

Table 23-1 Average Length of Labor Stages 1 and 2

Characteristic	First Stage			Second Stage
	Latent Phase	Active Phase	Transition Phase	
Primigravida	8–10 h	6 h	2 h	1 h
Multigravida	5 h	4 h	1 h	15 min
Cervical dilation	0–4 cm	4–8 cm	8–10 cm	
Contractions				
Frequency	10–20 progressing to 5–7 min	3–5 min	2–3 min	2–3 min
Duration	15–20 progressing to 30–40 sec	40–60 sec	60–90 sec	60–90 sec
Intensity	Mild progressing to moderate	Moderate progressing to strong	Strong	Strong

diaphragm and abdominal muscles. The head generally enters the pelvis in the transverse and oblique position. The degree of descent is measured by stations.

Flexion

Flexion occurs when the fetal head meets resistance from the pelvic floor and walls as well as the cervix, causing the head to flex with the chin against the fetal chest. This position achieves the smallest fetal diameters coming into the maternal pelvis.

Internal Rotation

The widest part of the maternal pelvis is the anteroposterior diameter because the fetal head must rotate to accommodate the pelvis. The pelvic muscles, levator ani muscle, and the fascia cause resistance to the fetal head, forcing it to rotate from the left to right and aligning the fetal head with the long axis of the maternal pelvis. This occurs mainly during the second stage of labor.

Extension

As resistance is met by the pelvic floor, the fetal head pivots beneath the symphysis pubis. The head emerges through extension, led by the occiput, then the face, and finally the chin.

Restitution

Internal rotation causes the shoulders of the fetus to enter the pelvis in an oblique position. When the head is delivered in the extended position, the neck is twisted and the head realigns with the long axis of the fetus.

External Rotation

As a continuation of the restitution, the shoulders align in the anteroposterior diameter, causing the head to continue

to rotate. The trunk navigates through the pelvis with the anterior shoulders descending first.

Expulsion

As the shoulders extend under the symphysis pubis, the anterior followed by the posterior shoulders are delivered by the woman's pushing effort. Once the shoulders are delivered, the trunk easily follows.

REFLECTIONS FROM A LABORING MOTHER

"During my pregnancy, my labor lasted almost 48 hours. I had an epidural and felt pretty good but was getting more and more tired. The nurses couldn't believe how long I was taking to dilate (since they saw me—unusually—on more than one rotation). Finally, after about 40 hours, a new nurse came in and reviewed my chart. She introduced herself and said, 'You are going to have this baby on my shift.' She instructed me to turn every half hour, and she came into my room to make sure I did it. She was calm yet in control. I did have my baby on her shift and I whole-heartedly believe it was because she worked with me to make it happen."

Figure 23-10 Mechanisms of labor.

Third Stage

The **third stage of labor** or **placental stage** begins as soon as the fetus is delivered and lasts until the placenta is delivered. The mechanism of placental separation is a combination of uterine contractions and involution. After expulsion of the fetus, the uterus continues to contract every 3 to 4 minutes. As the uterus contracts and begins

the process of involution, shrinkage of the site of implantation of the placenta occurs. Within 10 to 15 minutes after delivery of the infant, most of the placenta has detached from the uterine wall. At this point, vaginal bleeding from the uncovered implantation site increases, and delivery of the placenta generally soon follows. The classic signs of placental separation are rounding up of the uterus, upward

movement of the fundus, lengthening of the umbilical cord, and a rush of blood from the vagina. Once the placenta is delivered, the uterus continues to contract, closing off the spiral arterioles. As the uterus continues to shrink, the bleeding decreases.

Fourth Stage

The **fourth stage of labor** or **recovery stage** is defined as the first 4 hours after delivery of the placenta. During this time, many maternal physiologic readjustments are occurring. The average blood loss from a vaginal delivery is 250 to 500 mL. Because of the blood loss and the return of a more normal abdominal anatomy as the uterus returns to a more normal size, there is a decrease in blood pressure and slight tachycardia. The fundus is midline and usually is halfway between the umbilicus and the symphysis pubis. The fundus should remain firm and contracted. Most of the discomforts of labor, such as nausea and vomiting, should be gone or clearly subsiding.

INTERVENTIONS OF LABOR

Interventions of labor are those techniques that facilitate the progress of labor or provide an alternate birthing mechanism.

Labor Induction

Labor induction is the stimulation of uterine contractions before the spontaneous onset of labor for the purpose of accomplishing delivery (ACOG, 1995). There are multiple medical and obstetric reasons for induction of labor, the most common being postterm gestation. Other indications for induction of labor include pregnancy-induced hypertension (PIH), diabetes mellitus, intrauterine growth restriction, intrauterine fetal demise, and various other maternal-fetal complications. Before induction of labor is

performed, the benefit of delivery must be compared with the risks of continuing the pregnancy and the induction process itself (Bernstein, 2000). Contraindications to labor induction include placenta previa, transverse fetal lie, prolapsed umbilical cord, a previous classical uterine incision scar, and active genital herpes virus infection (ACOG, 1995).

In attempting to ensure the safety and ease of labor induction, Bishop (1964) established a cervical scoring system based on the clinical assessment of the cervix. Developed in the 1950s, the Bishop score has been studied extensively and compared with other methods of evaluation. Some authors have reported that cervical examination alone proves to be a more predictive value than does the Bishop score (Williams, Krammer, & O'Brian, 1997; Friedman et al., 1966; Harrison, Flynn, & Craft, 1977). The Bishop score however remains standard practice.

Success with induction of labor is improved when the cervix is favorable or inducible. The Bishop scoring system (Table 23-2) is a 13-point scoring scale in which points are awarded (or subtracted) after clinical evaluation of cervical dilation, effacement, position, consistency, and the station of the presenting fetal part. The Bishop score originally was designed for use with multiparas but over time has been used with primigravids. Although many clients with lower scores have successful inductions, induction of labor is more likely to be attained if the total score is greater than eight. Low Bishop scores have been associated with failure of induction, prolonged labor, and higher cesarean section rates (ACOG, 1995).

Cervical Ripening Methods

For those clients with low Bishop scores requiring induction of labor, there are methods to enhance the readiness of or ripen the cervix. MacKenzie and Embrey (1979) found that the intravaginal administration of 0.5 mg of the

Table 23-2 Bishop Scoring System

Factor	0	1	2	3
Cervical dilation	Closed	1–2 cm	3–4 cm	5+ cm
Cervical effacement	1–30%	40–50%	60–70%	80+%
Fetal station	–3	–2	–1	+1, +2
Cervical consistency	Firm	Med	Soft	+
Cervical position	Posterior	Mid	Anterior	+

Predictive value:
Score: 0–4 45–50% induction failure rate
5–9 10% induction failure rate
10–13 0% failure rate
Bishop, E. H. (1964). Pelvic scoring for elective inductions. *Obstetrics and Gynecology* 24:266.

prostaglandin gel (PGE₂) dinoprostone (Prepidil) shortened the length of labor and improved the cervical condition, thus reducing the risk for cesarean section. Approved by the FDA in 1992, Prepidil gel is administered into the cervical canal through a catheter-tipped syringe or applied to a diaphragm placed next to the cervix. Doses may be applied every 6 to 12 hours, with ripening of the cervix occurring most often after two to three doses.

The vaginal insert Cervidil contains 10 mg of PGE₂, generic name, that is slowly released over 12 hours. One benefit of Cervidil is that the insert may be removed if hyperstimulation or active labor begins. Hyperstimulation of the uterus can be described as an inadequate rest between contractions and is a potential hazardous side effect of using any kind of PGE₂ for induction of labor. Maternal side effects of PGE₂, including vomiting, diarrhea, and fever, are avoided with local vaginal applications.

According to Keirse (1993), prostaglandin treatment can increase the spontaneous vaginal delivery rate by 33% as a result of a decrease in cesarean section and instrument-assisted delivery. Monitoring of the client after receiving PGE₂ includes 30 minutes to 2 hours of external fetal monitoring for uterine contractions and reassuring fetal heart tones. Bed rest should be maintained for 30 minutes to ensure proper placement of the medication. If regular uterine contractions persist, fetal heart rate (FHR) monitoring should be recorded hourly for at least the first 4 hours (ACOG, 1995).

Osmotic cervical dilators can be placed into the cervical canal under direct visualization using aseptic technique. As many dilators as possible are placed in the cervical canal and swell when left in place (usually overnight) to cause cervical dilation. Initially made of dried seaweed (*Laminaria*), there are now synthetic versions available (Dilipan). *Laminaria* has shown to be a cost-effective and safe method of cervical ripening; however, one study has shown *Laminaria* to be associated with a high incidence of increased peripartum infection (Kazzi, Bottoms, & Rosen, 1982).

Misoprostol (Cytotec) is a synthetic PGE₁ used for the treatment and prevention of peptic ulcer disease. Although its use for the induction of labor is not approved by the FDA, studies have been conducted using the drug intravaginally to soften the cervix. ACOG (1999) outlined strict guidelines for the use of Cytotec in labor induction stating that for cervical ripening, one quarter of a 100- μ g tablet should be used for the initial dose; doses should not be given more frequently than every 3 to 4 hours; oxytocin should not be given within 4 hours of the last dose; and Cytotec should not be used in clients with a previous cesarean delivery or a previous uterine scar. Wing, Lovett, & Paul (1998) also discourage use in clients with a previous uterine scar owing to the increased incidence of uterine rupture in his randomized trial of labor.

Nursing Alert

OXYTOCIN

An accidental bolus of oxytocin can be life-threatening for both the mother and fetus. To avoid this potential hazard, oxytocin should always be administered through an infusion pump and inserted by piggyback through the main intravenous line at the port closest to the client.

Intervention for Uterine Hyperstimulation

- Turn off the pitocin.
- Change the client's position (left side-lying is best).
- Administer oxygen.

Oxytocin (Pitocin) is a hormone used to help induce labor, continue labor, or control bleeding after delivery. Pitocin is produced naturally by the posterior pituitary gland and stimulates contraction of the uterus. For those clients with low Bishop scores, cervical ripening may be initiated before using Pitocin.

Oxytocin usually is diluted with 10 U in 1 L of an isotonic electrolyte solution (ACOG, 1995), although many hospital protocols may call for 20 U of oxytocin in a 1-L

Client Education

Pitocin

Explain the following to the client:

- The medication and reasons for use: induction of labor and improvement of contractions.
- The reactions to expect: increased intensity and frequency of contractions.
- The route of administration and the rate.
- The monitoring of the fetal heart rate and contractions, including frequency, intensity, and resting tone.
- The monitoring of the maternal blood pressure, pulse, and temperature.
- The expected outcome.
- That expectations may vary according to the Bishop score and other maternal-fetal factors.

Research Highlight

Membrane Sweeping

Purpose

To determine whether cervical membrane sweeping (stripping) during labor is beneficial.

Methods

Randomized trial of labor outcomes after induction. Experimental group with membrane sweeping. Control group without membrane sweeping. Outcome measures included duration of labor, maximum dose of oxytocin used, induction-labor interval, and mode of delivery.

Findings

130 nulliparas (64 swept, 66 nonsweep); 118 multiparas (60 swept, 58 nonsweep). Among nulliparas who received intravaginal prostaglandin and oxytocin, those who had sweeping had significantly shorter induction-labor interval ($P = 0.048$), lower doses of oxytocin ($P = 0.01$), and increased normal vaginal delivery rates ($P = 0.01$). Sweeping also had a favorable effect on nulliparas who received oxytocin alone ($P = 0.04$). There were no differences on outcome measures in multiparous women.

Nursing Implications

Sweeping the membranes during induction of labor had a beneficial effect on labor and delivery of nulliparas with unfavorable cervixes who required cervical priming with PGE_2 . Membrane stripping is a technique physicians occasionally undertake. It is not a generally accepted practice for nurses.

Foong, L. C., Vanaja, K., Tan, G., & Chua, S. (2000). Membrane sweeping in conjunction with labor induction. *Obstetrics and Gynecology*, 94, (4), 539–542.

bag. Regimens for the initial dose and dose increases vary according to hospital protocols. Starting dosages of 0.5 to 2 mU/min with increases in increments of 1 to 2 mU/min every 20 to 60 minutes are acceptable dosages (ACOG, 1995).

Oxytocin does not cross the placenta; therefore, no direct effects on the fetus are seen. FHR deceleration as a result of uterine hyperstimulation is the most common adverse effect (ACOG, 1995). Adverse effects for the mother include uterine rupture and hyperstimulation. Hypotension and diuresis have been shown with oxytocin use; however, these effects usually occur with a large bolus dose.

Amniotomy

Amniotomy (artificial rupture of membranes) can stimulate and reduce the duration of labor. Amniotomy may be performed early in labor for urgent inductions (e.g., for preeclampsia), or later once cervical dilation has advanced for routine inductions. The longer the membranes have been ruptured the greater the possibility of infection; therefore, amniotomy often is used in conjunction with oxytocin.

Augmentation of Labor

Augmentation of labor is the stimulation of uterine contractions after labor has begun. Indications for augmenta-

Nursing Tip

STRIPPING THE MEMBRANES

Stripping of the membranes can assist the commencement of spontaneous labor. Performed during a sterile vaginal examination, the technique entails placing the examining finger through the cervical os and sweeping in a circular motion to separate the chorioamniotic membrane from the internal surface of the lower uterus. Risks associated with the procedure include infection, bleeding, and accidental rupture of membranes. This procedure is done by physicians.

INTERVENTIONS DURING AMNIOTOMY

1. Explain the procedure to the client and family.
2. Assure the client the procedure is painless to her and her baby.
3. Assess the fluid color, odor, and consistency.
4. Note the time of rupture.
5. Note and document the fetal heart rate before and after the procedure.
6. Assess the client's temperature every 1 to 2 hours to check for infection.
7. Frequently assess the client's level of comfort.
8. Maintain adequate intake and output records.
9. Document maternal and fetal assessments in the medical record.

tion include prolonged labor, failure of cervical dilation to progress, or dysfunctional labor. Procedures for the augmentation of labor are the same as are those for induction. Nursing assessment and management of the client undergoing augmentation also are the same as are those for induction.

Forceps-Assisted Birth

Forceps are metal instruments used on the fetal head to provide traction or to provide a method of rotating the fetal head to an occiput-anterior position. There are several types of forceps. Some forceps have fenestrated (open) blades and some solid blades. All forceps have a locking mechanism that prevents the blades from compressing the fetal skull (Figure 23-11).

Forceps may be applied as follows:

- **Outlet forceps**—when head is crowning (Figure 23-12).
- **Low forceps**—when head is at +2 station or lower but not yet crowning.

According to Cunningham, et al (1999), the indications of forceps-assisted birth are classified as maternal and fetal. Maternal indications include; heart disease, acute pulmonary edema, intrapartum infection, certain neurological conditions; exhaustion or a prolonged second stage labor. Fetal indications are prolapse of umbilical cord, premature separation of the placenta, and worrisome FHR patterns.

Figure 23-11 Types of forceps.

Before forceps are applied, the cervix must be completely dilated, membranes must be ruptured, and position and station of the fetal head must be known. The FHR must be checked, reported, and recorded *before* forceps are applied and again *after* forceps are applied to make sure the cord is not being compressed by the forceps. It may help the mother to understand about the forceps if it is explained that the forceps blades fit around the baby's head like two teaspoons fit around an egg (Lowdermilk et al., 1999). Traction is applied to the forceps only during contractions. Rotation is performed between contractions.

Figure 23-12 Forceps-assisted birth; traction is applied downward and outward during contractions.

After the birth of the infant, the mother must be assessed for vaginal and cervical lacerations, hematoma, and bruising. The newborn infant may have facial bruising or edema.

Vacuum-Assisted Birth

A cup connected to suction is placed over the occiput on the fetal head. After the suction (negative pressure) is attained, traction downward and outward is applied during contractions (Figure 23-13). Indications are the same as for forceps-assisted birth.

Maternal risks include vaginal and rectal lacerations. Fetal risks include cephalhematoma, brachial plexus palsy, retinal and intracranial hemorrhage, and hyperbilirubinemia (O'Brian & Cefalo, 1996).

The FDA (1998) issued a public health advisory on the need for caution in vacuum-assisted deliveries. Two life-threatening complications have been reported; subgaleal hematoma (subaponeurotic hematoma) and intracranial hemorrhage. In response to the FDA report, the American College of Obstetrics and Gynecology (ACOG, 1998) recommends the continued use of vacuum-assisted deliveries when indicated. ACOG emphasizes the importance of appropriate training concerning the indications and use of all vacuum extraction deliveries.

Figure 23-13 Vacuum-assisted birth.

Cesarean Section

Cesarean section, commonly called C-section, is the birth of the fetus through a surgical incision made in the mother's abdomen (Figure 23-14). The classical cesarean section involves a vertical incision through the skin and uterus and usually is performed only in cases of emergent delivery. The classical incision usually extends from the pubic hairline to the navel. The low transverse cesarean section is a horizontal (Pfannenstiel) incision of the skin and uterus. The incision scar from a low transverse cesarean section is a horizontal crease under the pubic hairline. Occasionally, the physician may perform a horizontal skin incision with a vertical uterine incision. Owing to the increased risk for uterine rupture in future pregnancies associated with a vertical uterine scar, it is important to maintain adequate documentation of both the skin and uterine incisions.

Indications for cesarean section are varied. **Dystocia** (failure of labor to progress), repeat cesarean section, breech presentation, and fetal distress are among the more common indications. Other indications for cesarean section include active genital herpes infection, placenta previa, placental abruption, prolapsed umbilical cord, PIH, and other maternal-fetal complications.

Cesarean section may be performed under regional (epidural or spinal) or general anesthesia. Because most surgeons use the low transverse cesarean section, vaginal birth after cesarean section is common practice. Risk for uterine rupture increases dramatically after a vertical uterine incision and therefore is a contraindication for vaginal delivery in subsequent pregnancies.

Counseling the client in preparation for cesarean section should include information about the surgery, anesthesia, and expected course of recovery. Clients undergoing cesarean section may express feelings of loss of a natural birth. Support and emphasis on a healthy baby may enhance the client's sense of well-being. Refer to the accompanying photo story on a cesarean delivery.

MATERNAL ADAPTATIONS TO LABOR

Maternal physiologic adaptations to the process of labor are complex and change rapidly throughout labor and delivery. To assess the client's status adequately, the nurse needs to understand the changes that occur during labor in the following systems: hematologic, cardiovascular, respiratory, renal, GI, and endocrine systems.

Hematologic System

During labor, maternal hemoglobin levels increase slightly in response to the hemoconcentration. The increased hemoconcentration is related to the increases in erythro-

Figure 23-14 Cesarean incisions: A. Skin and uterine incisions classic, vertical skin incision with uterine incision; seldom used except in emergency situation; B. Horizontal skin incision with low vertical uterine incision; C. Horizontal skin incision with horizontal uterine incision.

poiesis, muscular activity, and dehydration from blood and fluid loss. An increase in the leukocyte count is seen owing to an increase in neutrophils related to the stress response. It is not uncommon for a woman to have a leukocyte count from 25,000 to 30,000 mm^3 immediately after delivery, which often makes diagnosing an infection difficult.

The coagulation system is activated both before and after placental separation. The placenta and decidua are rich in thromboplastin, accounting for activation of the coagulation system. Because of all the changes in the coagulation system that occur during labor and immediately postpartum, the mother is in a hypercoagulable state. This is a compensatory mechanism to help protect the woman from postpartum hemorrhage (Blackburn & Loper, 1992).

Cardiovascular System

During labor a significant increase in maternal cardiac output occurs. Many factors contribute to this increase, including uterine contractions, pain, anxiety, and maternal position. During the first stage of labor, with each contraction approximately 400 mL of blood is emptied from the uterus into the maternal vascular system, increasing cardiac output by 10% to 15%. In the second stage of labor the increase in cardiac output is 30% to 50% (Blackburn & Loper, 1992).

An increase in blood pressure occurs during contractions, again related to the increase in blood flow to the maternal vascular system. An increase in systolic blood pressure of 10 mm Hg can be expected with contractions in the first stage of labor. In the second stage of labor, systolic blood pressure may increase by 30 mm Hg with each contraction. The diastolic pressure may increase by 25 mm Hg with each contraction. It is important to carefully assess clients with underlying hypertension. Hypotension can occur in the supine position owing to compression of the ascending vena cava and descending aorta. In addition, medications used for anesthesia in labor sometimes can cause hypotension.

During the second stage of labor, the woman often is inclined to hold her breath and tighten her abdominal muscles, called the Valsalva maneuver, when pushing. The Valsalva maneuver can cause fetal hypoxia because the maternal pulse slows and cardiac output and blood pressure increase.

Respiratory System

An increase in oxygen consumption is associated with the increase in physical activity associated with labor. In addition, mild compensatory respiratory acidosis occurs to accommodate for mild metabolic alkalosis. By the end of the second stage of labor, the respiratory system can no longer fully compensate for the metabolic acidosis. Hyperventilation, which is common in labor, can cause

One Couple's Cesarean Section Delivery and Tubal Ligation

*W*hen the operating room is set up and the client is secure on the table, anesthesia personnel monitor the client while the surgical team gathers.

Nursery personnel arrive and check neonatal equipment and supplies in preparation to receive the newborn.

Identification bands are prepared for mother and infant.

The circulating nurse performs a surgical scrub of the client's abdomen followed by a rinse with sterile water.

The client's abdomen is painted with an antiseptic solution to further reduce the risk of infection.

Sterile drapes are applied to provide a sterile field for the surgery.

The surgeon marks the targeted incision line along the previous C-section scar.

A Pfannensteil incision is made.

The central muscle is retracted and dissected to access the fascia.

With routine C-sections, an attempt is made to control bleeding through cauterization.

The father supports his partner and observes as the surgical team works.

Prior to incision into the uterus, the bladder must be dissected away; a bladder blade is inserted into the abdominal cavity to retract the bladder.

The infant's head is delivered through the incision, followed by the remainder of his body.

The infant's mouth and nose are suctioned immediately to remove amniotic fluid from the airway.

The infant's umbilical cord is cut and clamped.

The infant is handed to the nursery personnel, who receive him in a sterile blanket.

Nursery personnel place the infant in a warmer and dry him to prevent heat loss by evaporation.

Cord blood samples are obtained.

The placenta is removed and the uterine cavity is examined for fragments of retained membranes.

The fundus of the uterus is removed from the abdominal cavity to assist the surgeon in visualizing the lower uterine segment for closure.

The surgeon sutures the lower uterine cavity to close the incision and control the bleeding.

Once the major bleeding has been controlled, the smaller vessels are cauterized.

The circulating nurse and scrub nurse count lap sponges as the uterus is closed. A second sponge count occurs later, prior to closure of the peritoneum.

The bladder flap is repaired.

To begin the tubal ligation, the right fallopian tube is grasped with a Babcock clamp near the middle of the tube.

Kelley clamps are placed on each side of the Babcock.

A suture is placed and tied to occlude the tube proximally and distally.

A segment of the tube between the two ligatures is removed.

After the segment of tube is removed and the ligature is placed, the proximal end of the tube may be buried as an extra precaution.

The contracted uterus is replaced into the abdominal cavity.

The abdominal cavity is irrigated to remove any blood clots and reduce infection.

Each layer of tissue is reapproximated and sutured.

Care is taken to cauterize small bleeders during closure.

The abdominal opening is ready to be closed.

Skin staples are used to reapproximate the surface incision.

The lower abdomen is cleaned and a pressure dressing is applied.

Since the mother has been awake for this procedure, she and her husband have time to bond with their new son.

respiratory acidosis, which can result in a decrease in the partial pressure of carbon dioxide in arterial blood. Symptoms of hyperventilation include dizziness and tingling. Nursing intervention includes counting the client's respirations aloud and informing her when a contraction is ending to help her relax. The acid-base disturbance quickly resolves after delivery because the respiratory rate returns to normal.

Renal System

During pregnancy the uterus displaces the bladder anteriorly, thus making it an abdominal organ, which causes a decrease in venous return, thus making it edematous. Edema and pressure placed on the bladder during labor can make voiding during labor very difficult and can cause overdistension of the bladder, often making urinary catheterization necessary.

Increased maternal and plasma renin levels as well as increased angiotension levels are thought to be important in the control of uteroplacental blood flow (Blackburn & Loper, 1992).

Gastrointestinal System

During labor there are significant decreases in gastric emptying and gastric pH. The implication of these changes is the risk of vomiting with aspiration pneumonia. The use of narcotic pain medication can further decrease gastric emptying (Blackburn & Loper, 1992). Hyperventilation related to mouth breathing that occurs during labor can cause dehydration; however, because of the decreased gastric emptying it is important for the nurse to be cautious about the amount and type of oral fluids administered. With complete cervical dilation it is common for the client to experience nausea, belching, and sometimes vomiting. Diarrhea often is experienced at the onset of labor.

Endocrine System

As discussed previously, many changes occur within the endocrine system. In addition to the hormonal changes that occur during labor, metabolic change also occurs. An increase in the metabolic rate occurs related to the pain and work associated with labor, which is reflected by the decrease in glucose levels during labor.

FETAL ADAPTATIONS TO LABOR

Although the fetus experiences many mechanical and hemodynamic changes during parturition and birth, the full-term healthy infant can withstand these changes without adverse effects.

Fetal Heart Rate

During pregnancy the average FHR decreases from 140 to 160 beats per minute (bpm), to the normal range of 120 to 160 bpm. Although a normal fetus may have a baseline heart rate below 120 bpm, it is important to be aware that a prolonged FHR below 100 bpm during labor is likely to indicate fetal jeopardy. During labor, FHR monitoring provides a predictable and reliable measure of fetal oxygen status and well-being. Deceleration associated with fetal head compression can be as low as 40 to 50 bpm; this represents the hypoxic depression of the central nervous system, which is under vagal control. Other factors, such as movements, vaginal examinations, and contractions, can cause accelerations and decelerations of the FHR that can be normal (Figure 23-15).

Figure 23-15 Based on Leopold's maneuvers, the fetal heart rate will best be heard in the marked areas for the various positions.

Fetal Respiratory System

The incidence of fetal breathing movements decreases before the onset of spontaneous labor. During active labor, fetal breathing movements continue to decrease. Fetal blood gases and pH change throughout the labor process. During early labor a gradual decrease in the capillary blood pH occurs; toward the end of labor this decrease is more rapid. The pH continues to decrease during the few minutes after birth. As the fetus passes through the birth canal, 7 to 42 mL of amniotic fluid is squeezed out of the fetal lungs. All of these changes help stimulate chemoreceptors in the aorta and carotids to prepare the fetus for spontaneous respirations after delivery (Manning, 1995).

Fetal Circulation

During the birth process the fetal circulation converts to that of an adult configuration within 60 seconds of the birth. The completion of this event may take up to 6 weeks. During this transition period the fetal oxygenation

is transferred from the placenta to the lungs. As the placenta ceases to be the source of fetal circulation there is an increase in pulmonary blood flow and closure of the fetal cardiovascular shunts (Blackburn & Loper, 1992).

Web Activities

- Search under the Iowa Health Book: Obstetrics and Gynecology's Patient Information by Department, at www.vh.org/Patients/IHB/ObGyn.html. Create a list of client teaching tips for the primipara and multipara.
- Visit the website of the National Library of Medicine at the National Institutes of Health at www.nlm.nih.gov. What time frames are outlined for the stages and phases of labor?

Key Concepts

- The physiology of the onset of labor is a complex process involving many fetal and maternal factors.
- There are many premonitory signs and symptoms of labor, which may include lightening, Braxton Hicks contractions, cervical change, bloody show, energy spurts, ruptured membranes, and GI disturbances.
- The five Ps of labor are important factors that may affect the labor process: passageway, passenger, powers, position of the mother, and psychologic response of the mother.
- The latent phase of the first stage of labor begins with the onset of labor and lasts until the woman's cervix is 3 to 4 cm dilated.
- The active phase of labor begins when the woman's cervix is 3 to 4 cm dilated and ends when it is 8 cm dilated.
- The transition phase of the first stage of labor begins when the woman's cervix is 8 cm dilated and ends when it is fully dilated.
- The second stage of labor begins when the cervix is completely dilated and effaced and ends when the fetus is expelled.
- The third stage of labor begins when the fetus is expelled and ends when the placenta is expelled.
- The fourth stage of labor lasts for 4 hours after the placenta is expelled.
- Labor requires the adaptation of every body system of the mother.
- There are many fetal adaptations during the labor process.

Review Questions and Activities

1. How do hormones and prostaglandins affect the onset of labor?
2. Discuss the premonitory signs and symptoms of labor.
3. Name the five Ps of labor and explain how each affects the labor and delivery process.
4. Describe some aspects of the maternal attainment theory and how it is applied to labor.
5. Describe some of the maternal adaptations during the process of labor.
6. Name the different stages of labor, including the definition and the length of each.
7. Describe the fetal adaptations during the labor and delivery process.

Analgesia and Anesthesia in Labor and Delivery

There are both supporters and opponents to the use of drugs for pain relief during labor and delivery. In order to support your client during labor and delivery you must first

- *Examine your own opinions and preferences regarding the use of drugs during childbirth.*
- *Review your own knowledge of all available options for pain relief for the client in labor.*
- *Be objective regarding education of the client about all options for pain relief.*
- *Acknowledge the right of the client to choose or decline options for pain relief.*

Key Terms

Analgesia
Anesthesia
Anesthesiologist

Certified Registered
Nurse Anesthetist
(CRNA)
Dermatome
Epidural

General anesthesia
Intrathecal

Opioid
Parenteral
Pudendal block
Regional anesthesia

Competencies

Upon completion of this chapter, the reader should be able to:

1. Define and differentiate analgesia and anesthesia.
2. Describe three main types of anesthesia.
3. Explain the different options of analgesia for labor.
4. Discuss the advantages and disadvantages of specific options.
5. Describe the nursing actions necessary to prepare a client for placement of an intrathecal narcotic, epidural catheter, or both.
6. Indicate the common side effects of intrathecal and epidural analgesia.
7. Indicate the treatment of side effects of intrathecal and epidural analgesia.

The discomforts of childbirth have been acknowledged for thousands of years. For centuries it was thought that pain during childbirth was inevitable and to be endured. In comparison, the idea of pain relief during childbirth is a new concept (Morrison, Wildsmith, & Ostheimer, 1996). The advent of anesthesia in childbirth occurred in the mid-19th century in Great Britain and the United States. Dr. James Young Simpson, professor of midwifery at Edinburgh University is credited with being an early user of ether, and then chloroform, in obstetrical practice (Cohen, 1996). In 1849, the Committee on Obstetrics of the American Medical Association recommended the use of anesthesia in obstetrics, stating that pain relief in labor was justified (Morrison, Wildsmith, & Ostheimer, 1996). After the early use of anesthesia in obstetrics, debate continued. Objections included medical concerns, need for physiologic pain during childbirth, and religious reasons. Medical concerns related to the newness of the field and safety of the mother and child. Some obstetricians regarded the mother's reaction to pain as a valuable guide to the progress of labor and therefore believed pain should not be relieved (Morrison, Wildsmith, & Ostheimer, 1996). The religious objections were based on the interpretation of Genesis 3, verse 16, which was thought to imply that God had decreed that in pain would woman bring forth children (Cohen, 1996).

Rabbi Abraham De Sola, Canada's first rabbi, was asked to clarify the meaning of Genesis 3:16; in 1849, he published a three-part article detailing the interpretation. He concluded that the verse referred to the uterine contractions of labor and not the somatic sensation of pain, and therefore, the use of anesthetics for pain relief in labor was not opposed by scripture (Cohen, 1996). The controversy died in Great Britain after Dr. John Snow administered chloroform to Queen Victoria, in 1853, for the birth of her ninth child, Prince Leopold (Morrison, Wildsmith, & Ostheimer, 1996; Cohen, 1996; Kyle & Shampo, 1997; Ball, 1996). Because the Queen was the head of the Church of England and defender of the faith, her use of anesthesia led to the end of the controversy on religious grounds, at least in Great Britain. Arguments continued over the safety of the practice (Connor & Connor, 1996). By 1862, however, chloroform and ether were in general use for anesthesia in obstetrics practice (Morrison, Wildsmith, & Ostheimer, 1996).

During this same period, development proceeded in the use of parenteral opioids, first morphine and later meperidine, and the use of both parenteral and inhalation anesthesia (Morrison, Wildsmith, & Ostheimer, 1996). The early 20th Century saw an increased use of twilight sleep, a result of the addition of scopolamine to morphine, with resultant analgesia, amnesia, and maternal restlessness.

The high incidence of neonatal respiratory depression caused this technique to fall into disrepute (Morrison, Wildsmith, & Ostheimer, 1996). Although a movement known as natural childbirth began in the 1940s and 1950s, it did not become prevalent in the United States until the 1960s when the Lamaze method of prepared childbirth was introduced (Sandelowski, 1984).

The technique of epidural anesthesia was known in the first half of the 20th century; however, its use in obstetrics was limited. Refinement of the technique and improvement in the available equipment and drugs led to an increased use of epidural anesthesia (Morrison, Wildsmith, & Ostheimer, 1996). Research continues to make further refinements in techniques and medication combinations. Today, clients facing childbirth have a vast array of options for pain relief in labor and delivery.

THEORIES OF PAIN AND PAIN MANAGEMENT

Pain has been the subject of interest for centuries. By the middle of the 20th century the specificity theory of pain was prevalent. The specificity theory states that pain is a pure sensation with its own specific receptor organ and pathways for the conduction of nociceptive information to the brain, with little or no modification (Morrison, Wildsmith, & Ostheimer, 1996). Further research led to modifications of the specificity theory, yet there were still areas of pain that were not well explained by the theory. In 1965, the gate-control theory of pain was proposed by Melzak and Wall (Morrison, Wildsmith, & Ostheimer, 1996). The gate-control theory proposed that pain is a result of activity in several interacting neural systems. Each of these nervous systems, peripheral and central, has different functions. Nociception is made up of four processes: transduction, transmission, modulation, and perception. Transduction is the receiving of noxious stimuli and converting them to electrical activity at the sensory endings of peripheral nerves. Transmission is the continuation of those electrical impulses throughout the nervous systems. Modulation is the alteration of the transmissions by neural influences. Perception is the development of the sensory, subjective, and emotional experience identified by the person as pain (Fine & Ashburn, 1998). In the gate-control theory, sensory information can only pass from the peripheral nervous system to the central nervous system (CNS) when the physiologic “gate” is open. When the gate is closed due to the release of inhibitory neurotransmitters, endogenous opioids, or lock, then sensory information is blocked. This mechanism explains the effectiveness of both physical (e.g., rubbing, massage, transcutaneous electrical nerve stimulation [TENS], and water therapy) and psychological (e.g., focus points, breathing exercises, and

Nursing Alert

OVER-THE-COUNTER MEDICATIONS

Remember to ask clients about over-the-counter medications and dietary supplements, including herbal preparations. Clients often do not volunteer this information unless specifically asked. Many of these preparations can interact with analgesic and anesthetic agents.

encouragement) methods of pain relief (Nichols and Hamenck, 2000).

Pain is an individual experience. It can be influenced by a number of factors such as cultural practices, anxiety, fear, previous experiences with pain, and psychological support. These factors also are present during the experience of childbirth. It is useful for the nurse to identify in advance the most frequently seen client ethnic groups and develop profiles of culturally specific childbirth practices, including pain behaviors (Weber, 1996). However, the nurse should be concerned about stereotyping clients or failing to adapt to individual clients. The nurse must be aware of and sensitive to individual variations in a client's choices for dealing with pain in labor and delivery. The client may choose to use pharmacologic methods, nonpharmacologic methods, or both to meet her needs. The nurse must be able to teach, review, and assist the client to implement a variety of pain relief methods. The nurse also must respect the client's prerogative to choose, as long as the method chosen is safe for the mother and child at that time.

ANALGESIA AND ANESTHESIA

It is important to have a clear understanding of the concepts of analgesia and anesthesia. **Analgesia** is the relief of pain. This can be complete relief or some lesser degree of relief. Analgesia can be provided by a variety of techniques, including administration of medications. **Anesthesia** is the absence of sensation. Whereas the absence of sensation could imply complete relief of pain, the opposite is not necessarily true. Anesthesia also can be provided by a variety of techniques.

Types of Anesthesia

Anesthesia techniques fall into three categories: local, regional, and general anesthesia. The different types of anesthesia have different applications, actions, effects, and requirements. Some types of anesthesia are instituted by the

obstetrician or Certified Nurse Midwife (CNM); others require the assistance of a provider whose specialty is anesthesia. The specific applications, effects, and administration of the techniques are discussed subsequently.

Local Anesthesia

Local infiltration anesthesia refers to the loss of sensation from a small area of the body after infiltration with a local anesthetic. **Local anesthetic** refers to a class of drugs that produce reversible blockade of electrical impulses along nerve fibers (Williams, 1997). Blockade is produced by preventing sodium ions from passing through selective channels in the membrane of the nerve (Stoelting & Miller, 1994). There are different types of nerve fibers, which have different functions and carry impulses that are interpreted differentially by the brain. Table 24-1 illustrates the classifications and functions of nerve fibers. Williams (1997) notes that these fibers are blocked in a specific order. B-fibers are affected first, causing autonomic blockade. Then C-fibers and A-delta fibers are affected, causing loss of superficial pain, touch, and temperature. Finally, A-alpha, A-beta, and A-gamma fibers are blocked, causing loss of motor function and proprioception. This differential blockade is very important in the technique of epidural anesthesia, which will be discussed subsequently.

Regional Anesthesia

The second category of anesthesia techniques is **regional anesthesia**, which is the loss of sensation from a large area of the body owing to blockade of neural impulses. The most common regional anesthesia techniques in obstetrics are the subarachnoid block, or spinal, and the epidural. Pudendal nerve blockade is another form of regional anesthesia found in obstetrics and also will be discussed subsequently.

Table 24-1 Nerve Fibers and Functions	
Fiber Type	Function
A-alpha	Proprioception Large motor
A-beta	Small motor Touch Pressure
A-gamma	Muscle tone
A-delta	Temperature Sharp pain
B	Preganglionic
C	Dull pain Temperature Touch

General Anesthesia

The third category of anesthesia techniques is **general anesthesia**, which is the loss of sensation from the entire body secondary to the loss of consciousness produced by intravenous (IV) or inhalation anesthetic agents. Unconsciousness does not prevent the transmission of neural impulses of pain and other sensations; rather, it prevents the brain from interpreting the neural impulses into conscious awareness. Unconsciousness is not the only factor involved in general anesthesia. Other aspects—amnesia, analgesia, and muscle relaxation—also need to be provided through administration of other medications.

Types of Anesthesia Providers

Both nurses and physicians provide anesthesia services in the United States. These providers have undergone additional and extensive educational preparation in this specialty. There are institutions with only one type of provider; however, currently most anesthesia services are delivered by an anesthesia care team. This team of nurses and physicians work together to provider safe, high-quality anesthesia care to clients in a variety of situations.

Nursing anesthesia is considered the oldest nursing specialty, with a documented history of service of over 100 years (Bankert, 1989; Jordan, 1994). The **Certified Registered Nurse Anesthetist** (CRNA) is an advanced practice nurse who has completed an accredited educational program (now only at the graduate level) and passed the National Certification Examination. CRNAs administer 65% of the over 26 million anesthetics given in the United States each year. CRNAs are the sole providers of anesthesia services in 85% of America’s rural hospitals (Garde, 1997). These nurses practice in a variety of arrangements, in collaboration with other legally authorized and qualified providers (Jordan, 1994). The American Association of Nurse Anesthetists (AANA) was founded in 1931. There currently are over 26,000 CRNAs nationwide, and over 96% are members of the AANA (Garde, 1997).

An **anesthesiologist** is a physician who has completed a postgraduate residency in anesthesia (and then has the option of taking the board certification examination). The American Society of Anesthesiologists was founded in 1935 and currently has over 30,000 members (Stoelting and Miller, 1994).

PAIN IN LABOR AND DELIVERY

In order to understand the requirements for analgesia or anesthesia it is necessary to briefly review the nature and transmission of pain in the process of labor. Pain is a

highly individualized experience with painful stimuli interpreted within the brain (Fiedler & Shaw, 1997). The philosophy behind prepared childbirth or psychoprophylaxis is that ignorance, misinformation, fear, and anxiety appear to intensify pain (Santos, Pederson, & Finster, 1997). Education of the client regarding expectations of labor increases her ability to deal with the stress of labor. The intermittent nature of pain in labor is a primary contributor to the challenge in providing analgesia through some options. These challenges include the contrast in pain levels between the peak of a contraction and the period between contractions. What would be an appropriate blood level of medication for pain relief at the peak of contractions would be too much for the periods between contractions.

Types of Pain

The pattern of pain in labor is fairly predictable (Nichols & Humerick, 2000) (Figure 24-1). During the first stage of labor, pain results from cervical dilation and uterine contractions. These pain impulses are carried via C-fibers through the lower thoracic dermatomes T-10 to L-1

(Fiedler & Shaw, 1997). A **dermatome** is an area of the body innervated through a specific spinal nerve (Figure 24-2). The degree of pain changes as dilation progresses, and maternal tolerance of the changes vary but often are impacted by the duration of labor. Exhaustion from loss of sleep or prolonged labor contributes to increased pain perception (Youngstrom, Baker, & Miller, 1996; Morrisson, Wildsmith, & Ostheimer, 1996). When tired, a person may have less energy and a poor ability to deal with pain.

As labor progresses, with descent of the fetal head into the pelvis, another pathway appears to be the primary one (Fiedler & Shaw, 1997). The second stage of labor includes distention of the vagina and perineum by the fetal head, resulting in pain impulses being transmitted through the pudendal nerve. The pudendal nerve is composed of fibers that enter the spinal column through the sacral nerves S-2 to S-4 (Santos, Pederson, & Finster, 1997).

If the fetal head is descending in the occipitoposterior position, the force of contractions will push the fetal head into the client's sacrum and coccyx. The sacrum is in a relatively fixed position, and pressure exerted against it will result in the client perceiving pain to be in her lower back.

Figure 24-1 Intensity and distribution of labor discomfort during various stages of labor: A. First stage; B. Early second stage; C. Late second stage and birth.

Figure 24-2 Pain pathways.

The stretching of the perineum just before delivery of the fetal head often is described by clients as an intense, burning sensation. Other specific pain sensations may be indicative of an abnormal presentation, such as an occipitoposterior position, or a different problem, such as uterine rupture (Fiedler & Shaw, 1997).

Considerations in Medication for Pain

Above all else, the first consideration regarding medication for pain in pregnancy, labor, and delivery is the safety of the mother and baby. Early in pregnancy the focal concern is the teratogenic effects of medications on the developing fetus. The critical period of fetal exposure to medications is from 4 to 10 weeks' gestation (Visconti & Rathwell, 1998). Unfortunately for many clients the critical period occurs before confirmation of a pregnancy.

In labor and delivery the focal concern is respiratory depression of either the mother or neonate and the possible complications as a result of maternal or neonatal depression. Therefore careful monitoring of clients choosing to use medications is necessary. The nurse must be vigilant and knowledgeable about the medications being used and the individual nature of the response of the client to them.

ANALGESIA IN LABOR

Clients currently have a number of options for analgesia during labor. The nurse plays an important role in client education, that is, in conveying and confirming information regarding the advantages and disadvantages of many available options to the client. The client may enter the labor process with little or no understanding of the course or expectations of labor and delivery, or the client may be highly educated and well informed but seek the opinion of those she expects to have greater knowledge and experience. An understanding of the impacts of parenteral and regional analgesia in labor will allow the nurse to anticipate problems that might, if undetected, jeopardize the safety of the mother and baby.

Nonpharmacologic Methods

Nonpharmacologic options are discussed in Chapter 17, Childbirth Preparation, and the reader is directed there for information on techniques such as focal points and controlled breathing. The reader is directed to Chapter 4, Alternative Therapies, for more information on touch therapies, visual imagery, and other relaxation techniques. Transcutaneous electrical nerve stimulation (TENS) involves transmission of electrical energy by way of skin electrodes to relieve pain (Davies, 1997). The electrical stimulation is thought to produce an inhibitory effect on transmission of

impulses that are interpreted by the brain as pain. The four electrodes are placed in pairs, with one on either side of the spine (Figure 24-3). The top pair is placed with the top edge at the level of T-10, and the lower pair is placed with the top edge at the level of S-2. The nurse should review all the information from the manufacturer before instructing the client in use of the device. TENS appears to be most helpful in the latent and early active phases of labor. Other techniques for pain management, with the exception of water therapy, may be used in conjunction with a TENS unit.

Parenteral Analgesia

Parenteral analgesia, or administration of drugs by intramuscular (IM) or IV route, has a long history of use in ob-

Figure 24-3 Placement of electrodes for transcutaneous electrical nerve stimulation.

stetrics to provide some degree of analgesia to the client in labor. There are two broad groups of medications administered parenterally to clients in labor: opioids and sedatives (Schnider & Levinson, 1994). Registered nurses can easily administer parenteral analgesia, which is an advantage of this method.

The disadvantages of parenteral analgesia are inadequate pain relief, neonatal CNS and respiratory depression, and maternal nausea or vomiting (Fiedler & Shaw, 1997). The route, dosage, and timing of administration are the primary factors impacting the amount of neonatal depression present at birth (Stoelting & Miller, 1994). Most drugs administered to the client will cross the placenta by simple diffusion. Molecular weight, lipid solubility, degree of protein binding, and speed of maternal metabolism will impact placental transfer of drugs (Visconti & Rathmell, 1998). Drug uptake, distribution, metabolism, and elimination by the fetus will determine the impact of medications (Schnider & Levinson, 1994). The advantages and disadvantages of parental analgesia are outlined in Table 24-2 and the factors impacting placental drug transfer are highlighted in Box 24-1.

Opioids

An **opioid**, also known as a narcotic, possesses analgesic properties because it is derived from or modeled on morphine (Hawkins, Chestnut, & Gibbs, 1996). Morphine provides excellent analgesia but its long duration of action and depressive effects in the neonate have relegated its use to the client in the prolonged latent phase of labor when delivery is not anticipated for many hours (Santos, Pederson, & Finster, 1997). Side effects include a high frequency of nausea and vomiting; possible histamine release, with resultant orthostatic hypotension; and occasional bradycardia.

Meperidine (Demerol) is probably the most frequently used opioid analgesic in labor (Santos, Pederson, & Finster, 1997). It appears to cause a lesser degree of neonatal respiratory depression than does morphine; however, its

Box 24-1 Factors Impacting Placental Drug Transfer

- Non-protein-bound amount
- Concentration gradient

- Un-ionized amount
- Uterine blood flow

metabolite normeperidine has a half-life of 30 hours and may impact neonatal behavioral assessment scores (Fiedler & Shaw, 1997; Santos, Pederson, & Finster, 1997). The dosage and elapsed time from administration of meperidine can predict to some extent the degree of neonatal respiratory depression exhibited at birth.

The greatest degree of neonatal depression is seen when delivery occurs 1 to 4 hours after administration (Hawkins, Chestnut, & Gibbs, 1996). When this occurs the nurse must be prepared to carefully assess the neonate for signs of respiratory depression. The neonate with opioid-induced depression may be sleepy and not breathe properly. Appropriate care of the neonate includes stimulation, ventilation (if needed), and oxygenation. If these measures are not successful then administration of appropriate doses of an opioid antagonist naloxone (Narcan, 0.1 mg/kg) may be given IV, IM, or subcutaneously (SQ) (Hawkins, Chestnut, & Gibbs, 1996).

Naloxone should not be administered to the client just before delivery in an attempt to avoid respiratory depression in the neonate. Doing so reverses the analgesic effects when they are most needed, and there have been reported cases of maternal pulmonary edema and cardiac arrest as a

	Drowsiness	
	Possible histamine release	

Nursing Alert

NEONATAL RESPIRATORY DEPRESSION

- Opioids may cause respiratory depression in clients.
- Opioids administered to the woman cross the placenta.
- Neonates can exhibit drug-induced respiratory depression at birth. The greatest degree of drug-induced respiratory depression is seen when delivery occurs 1 to 4 hours after administration of meperidine (Demerol).

Nursing Tip

ASSESSMENT AND TREATMENT OF THE NEONATE WITH OPIOID-INDUCED RESPIRATORY DEPRESSION

1. Place infant under warmer and dry thoroughly, removing wet linen.
2. Position and open airway, if needed.
3. Suction mouth and nose.
4. Evaluate respiratory efforts.
5. Provide tactile stimulation: rub back, flick the heel, or slap the foot briefly if infant does not have adequate respirations.
6. If neonate has no respirations or only gasping respirations, begin positive-pressure ventilation with a bag and mask to deliver 100% oxygen.
7. Evaluate heart rate.
8. If heart rate is below 60, continue ventilation and begin chest compressions.
9. If heart rate is 60 to 100 and increasing, continue ventilation.
10. If heart rate is below 80 and not increasing, continue ventilation and begin chest compressions.
11. If heart rate is above 100, watch for spontaneous respirations and discontinue ventilation.
12. If heart rate remains below 80 after 30 seconds of positive-pressure ventilation with 100% oxygen, medications may be needed and additional help should be summoned.
13. Evaluate color; if blue, continue to provide 100% oxygen.
14. If pink or there is peripheral cyanosis, observe and monitor.
15. Note: Careful observation of the neonate with suspected drug-induced respiratory depression continues after this period of stimulation because the decrease in stimulation may result in hypoventilation at this point.
16. If severe respiratory depression is present or maternal opioid has been administered in the past 4 hours, naloxone (Narcan) may be needed. The dosage is 0.1 mg/kg, preferably IV, or through an endotracheal tube. IM or SQ routes are acceptable but onset of action will be delayed.
17. Note: Duration of opioid may exceed duration of naloxone. Infant will need continued observation and assessment for return of respiratory depression. Notify nursery personnel of administration.

result of sudden opioid reversal (Santos, Pederson, & Finster, 1997). The placental transfer is unpredictable. This affects the amount of drug delivered to the neonate and therefore its effectiveness in reversing opioid activity in the neonate (Hawkins, Chestnut, & Gibbs, 1996). It is vital to inform nursery personnel of the administration of naloxone, because its duration of action is shorter than that of some opioids. The difference in duration of opioids and naloxone results in the need for careful observation and repeated doses, if needed, for the reappearance of respiratory depression (Harmer & Rosen, 1996; Hawkins, Chestnut, & Gibbs, 1996).

Fentanyl, like meperidine, is a synthetic compound modeled on morphine (Hawkins, Chestnut, & Gibbs, 1996). Fentanyl is more potent but has a shorter duration of action than does morphine, which may limit its usefulness as a parenteral opioid except in situations where rapid onset and short duration may be advantages, such as forceps application (Santos, Pederson, & Finster, 1997). The lack of active metabolites may offer some advantage

because the duration of fentanyl is not impacted by the cumulative effects of repeated doses as is the duration of other opioids (Camann, 1996).

Patient-controlled analgesia (PCA) is a method of mechanical delivery of small doses of an opioid by IV on patient demand. PCA may or may not include an underlying continuous basal rate of medication. The safety features incorporated into the PCA device include a time interval lockout and set doses that are not accessible by the client. These are safeguards against the possibility of self-administration of an overdose. The nurse should remember that these mechanical devices are not a substitute for continued vigilance and assessment. Two advantages to this method are the sense of client autonomy and the ability of clients to tailor drug administration to their perception and tolerance of pain during the course of labor. The disadvantage is the need for PCA pumps and pharmacy-prepared medications. Studies show conflicting results regarding an increase or decrease in total opioid dose used with this method (Hawkins, Chestnut, & Gibbs, 1996).

Research Highlight

A Randomized Trial of Epidural versus Patient-Controlled Meperidine Analgesia during Labor

Purpose

To assess the effects of epidural analgesia on the incidence of cesarean delivery.

Methods

In a prospective randomized trial, 715 women received either epidural analgesia or PCA IV meperidine analgesia.

Findings

Epidural analgesia was not associated with an increased incidence of cesarean delivery when compared with PCA using meperidine.

Nursing Implications

Understanding the research regarding the incidence of cesarean delivery associated with epidural analgesia is important in client education regarding this option for pain management in labor and delivery.

Sharma, S. K., Sidawi, J. E., Ramin, S. M., Lucas, M. J., Leveno, K. J., & Cunningham, F. G. (1997). A randomized trial of epidural versus patient-controlled meperidine analgesia during labor. *Anesthesiology*, 87, (3), 487–494.

Sharma et al. (1997) concluded that PCA with meperidine was a safe and effective method of analgesia during labor but noted the increased need for neonatal naloxone administration. In this study, the mean and maximum doses of meperidine were 139 ± 100 mg and 500 mg, and the authors noted that 24% of women received over 200 mg. PCA has gained in popularity in recent years but may not be in use in all hospitals (Cheek & Gutsche, 1997).

Another type of opioid drugs is known as agonist-antagonists. Two drugs of this type, butorphanol (Stadol) and nalbuphine (Nubain), are still occasionally seen in obstetrics practice. These drugs produce analgesia but also a degree of maternal sedation and dizziness (Hawkins, Chestnut, & Gibbs, 1996). The apparent ceiling effect for maternal respiratory depression (increasing doses do not appear to increase respiratory depression) is the advantage cited by some proponents (Cheek & Gutsche, 1997). These drugs appear to have a lower incidence of nausea and vomiting (Hawkins, Chestnut, & Gibbs, 1996; Santos, Pederson, & Finster, 1997). Because there is some association of fetal respiratory depression with the use of these drugs, the nurse should be prepared to assess and respond to problems at birth.

Sedatives

Sedatives or tranquilizers usually are co-administered with opioids (Cheek & Gutsche, 1997). Pentobarbital (Nembutal) occasionally is used, in combination with morphine in the prolonged latent phase of labor when delivery is not anticipated for over 12 hours (Schnider & Levinson, 1994). Promethazine (Phenergan) is the most widely used drug of this class (Hawkins, Chestnut, & Gibbs, 1996). Promethazine or hydroxyzine (Vistaril) are co-administered with meperidine to reduce narcotic requirements, decrease nausea and vomiting, and allay anxiety (Schnider & Levinson, 1994; Cheek & Gutsche, 1997). Because of the strong sedative effect of benzodiazepines such as diazepam (Valium) and midazolam (Versed), they are only used in specific situations, for example, as anticonvulsive agents in the presence of seizures (Schnider & Levinson, 1994). The nurse should be aware that benzodiazepines have amnesic properties.

Client Experience with Pain

The nurse must always recognize that pain is a very individual experience. It is subjective in nature and can only

REFLECTIONS FROM A LABORING MOTHER

"My husband and I had been to childbirth preparation classes and had toured the hospital where I was planning on delivering our first baby. We were very excited and practiced the techniques we learned in the classes. Two days before my due date we had some friends over for a barbecue, and as we sat around afterward I found myself restless and kind of achy. I found that if I changed my position or rubbed my abdomen I felt better. That night I just kept feeling like I had to go to the bathroom, even if there was nothing there. I spent a couple of hours getting up and down, and finally my husband grumbled, 'Why don't you call the doctor?' I didn't think this was labor because it really wasn't painful. I called and was sent to the hospital. But I was only dilated to 1 cm. I thought the pain wasn't too bad. Little did I know what it would be like in the next couple of hours. The contractions got closer together and hurt more, and after awhile I couldn't walk any more. At 5 cm dilated I was exhausted from being up all night and ready for some pain relief. I was unprepared for the intensity of the pain, and although I had hoped for a drug-free delivery, I was most relieved when the medications began to take effect."

be defined by the client experiencing the pain, who may communicate in many different ways that are interpreted by the nurse. Misunderstandings may arise if the nurse is not aware of the personal beliefs and biases regarding pain and pain behaviors, particularly in clients from other cultural backgrounds (Weber, 1996).

Nursing Implications

Nurses and clients should discuss plans regarding pain relief early in labor. Assessment of the client's understanding

of different methods of pain relief can illustrate educational needs. The nurse should convey information or act as the client's advocate to acquire needed information regarding pain relief methods. If the client asks for medication the nurse should inform her of what to expect regarding the onset, duration, and side effects of the individual medication.

Regional Analgesia

Regional techniques, alone or in combination with other techniques, are commonly used to provide analgesia for labor pain (Ellis, 1997). Regional analgesia options for labor include the use of intrathecal opioids, epidural blocks, and spinal-epidural combination. One other regional technique, paracervical block, is not in common use but will be reviewed for the sake of completeness.

A review of the anatomy of the spinal column and epidural space is needed to fully understand the mechanism by which these techniques provide analgesia or anesthesia to the client (Figure 24-4). The spinal cord ends approximately at the level of the first or second lumbar vertebrae, L-1, L-2 (Ostheimer & Leavitt, 1996). It is protected by the dural sac and lies within the vertebrae.

REFLECTIONS FROM NURSES

"Before epidurals were available I gave Demerol to clients in labor. There were some things that I could watch for because they happened a lot. I always put an emesis basin within reach because a fair number of the women would be nauseated or vomit. I had to really watch the multiparas when I gave them Demerol at 5 cm dilated, because after they threw up a couple of times they would look at you with eyes the size of dinner plates and say 'The baby is coming.' You had better believe them, because often they were right. The increased intraabdominal pressure created by vomiting would push that baby down against the cervix, and they would go from 5 cm to complete in minutes. It didn't happen all the time but often enough to watch for it."

Critical Thinking

Client and Partner Conflicts Regarding Analgesia and Anesthesia in Labor and Delivery

It is not unheard of for clients to change their minds regarding options for pain relief in labor and delivery, especially as pain intensifies.

- What will you do if the client requests medications or anesthesia and the partner disagrees?
- What if the client has had medications and now wants an epidural but her partner disagrees?
- Can the client give informed consent while under the influence of medication?
- What will you do?

Below L-1, L-2 the dural sac contains spinal nerve roots. The epidural space lies between the dura and vertebral canal (Benards, 1997). Nerves and blood vessels travel through the epidural space, which is occupied by fat globules (Luyendijk, 1996). The epidural spaces are discontinuous. Addition of fluid volume to the epidural space opens up the areas that appear unoccupied (Figure 24-5).

The major factors involved in analgesia or anesthesia provided by regional techniques include the types of drugs used, dosages, anatomic level and area of placement, and patient position. Individual differences in these factors impact the analgesia produced in a specific client.

Figure 24-4 Cross-section of the spinal canal area.

Figure 24-5 Discontinuous nature of epidural space.

Preparation of the Client

The nursing actions to prepare the client and assist the anesthesia provider during initiation of intrathecal, epidural, or combined techniques are virtually identical. When applicable, slight differences will be discussed in the sections on specific techniques.

The client's desire for regional analgesia should be confirmed and the obstetrician notified before the procedure. IV access must be obtained, if not already available, and a bolus of fluid should be given just before the procedure. The CRNA or anesthesiologist must assess the client

Client Education

Important Information for the Anesthesia Provider

Before administration of medication, the anesthesia provider must ascertain the client's health history on the following:

- Drug or other allergies
- Smoking history
- Breathing problems
- Cardiac problems
- Other health problems
- Previous anesthetics
- Difficulties with nausea or vomiting with previous anesthetics

requesting regional analgesia. The client's medical history; physical status; understanding of the procedure, including risks and benefits; and consent for the procedure must be obtained (Fiedler & Shaw, 1997). It is very important to answer any questions the client may have regarding the risk and benefits of regional analgesia before the procedure is begun to create an atmosphere of trust and confidence and to fulfill conditions of informed consent.

After all questions of the client have been answered and informed consent has been obtained, the client is assisted to a sitting position (feet over the side of the bed, or cross-legged in front and hunched forward) or side-lying position (with knees and feet drawn up toward her chest), depending on the preference of the anesthesia provider (Figures 24-6 and 24-7). The client's gown or fetal monitor belts must be moved away from the area of the back where the needle will be placed.

The back is palpated for the appropriate landmarks and prepared with an antiseptic solution. A small wheal of local anesthetic is made, and the epidural needle is placed between the vertebrae and the epidural space identified. (When an intrathecal opioid alone or spinal anesthesia is planned, a spinal needle is used and the epidural space is not identified.) There are two methods of identification, "hanging drop" and "loss of resistance." In the hanging

drop method a drop of saline is placed in the hub of the epidural needle once the needle has entered the ligaments near the spinal canal. When the epidural needle enters the epidural space, a slight degree of negative pressure will pull the drop into the needle (Ostheimer & Leavitt, 1996). In the loss of resistance method, a 5- to 10-mL syringe filled with saline is attached to the hub and the needle slowly advanced. Keeping a steady pressure on the plunger of the syringe as the needle is advanced, resistance will be felt until the epidural space is entered, at which point the saline will be suddenly and easily injected (Ostheimer & Leavitt, 1996). Regardless of the method, the most important task of the nurse is to assist the client in not moving and remaining in an optimal position during the procedure. A knowledgeable nurse is a great asset to the anesthesia provider performing regional analgesia and anesthesia techniques (Fiedler & Shaw, 1997). The anesthesia provider will indicate when it is safe for the client to move. At this point in the administration the techniques vary slightly and will be covered in the individual sections.

Intrathecal Opioids

The technique of **intrathecal** opioid administration is a variation of the subarachnoid block, or spinal. The difference lies in the type of medication (opioid instead of local

Figure 24-6 Sitting position for insertion of spinal or epidural anesthesia.

Figure 24-7 Side-lying position for insertion of spinal or epidural anesthesia.

anesthetic) deposited just inside the dural sac. This method provides analgesia through opioid activity at the receptors located in the spinal nerves. A small amount of an opioid, such as morphine, fentanyl, or sufentanil, is placed in the cerebrospinal fluid through a small-gauge spinal needle after puncture of the dural membrane. Refer to Table 24-3 for the advantages and disadvantages of this method.

Table 24-3 Advantages and Disadvantages of Intrathecal Opioids

Advantages	Disadvantages
Rapid onset (fentanyl or sufentanil)	May not last as long as labor
No motor block (able to ambulate)	Pruritus
No sympathetic block (no hypotension)	Nausea (morphine)
	Vomiting (morphine)

The intrathecal opioid technique using fentanyl or sufentanil has the advantages of rapid onset (often less than 5 minutes) and of providing excellent analgesia without autonomic or motor blockade (Mullins & Johnson, 1996). The client's ability to ambulate without orthostatic hypotension or motor coordination is preserved (Rawal, 1996). Because there is no autonomic blockade, maternal blood pressure decreases slightly but usually not below prelabor levels. In the absence of the autonomic blockade, the IV fluid bolus requirement usually is less than 500 mL. There are drawbacks to this technique. Labor duration is highly individualized and not easily or accurately predictable and thus may outlast the duration of pain relief afforded by the dose of intrathecal opioid. Mullins and Johnson (1996) reported that 40% of clients required additional analgesia owing to duration of labor. Additional disadvantages can include sedation, nausea and vomiting, and pruritus. The incidence, duration, and severity of these symptoms are related to the drug and dosage used. Use of intrathecal morphine alone is limited due to the high incidence of side effects and the more serious occurrence of maternal respiratory depression. Fentanyl is more

Client Education

Intrathecal Opioids

Teach your clients what to expect after administration of an intrathecal opioid:

- Rapid (one to two contractions later) onset of relief.
- Contractions that feel more like pressure and less like pain.
- Itching that could be located anywhere but usually is mild and resolves in 30 to 40 minutes.

frequently given because of the lower incidence and decreased severity of side effects. It is beneficial to inform the client that she may experience itching shortly after administration of intrathecal fentanyl and that it usually will resolve over the next 30 to 40 minutes. Extreme cases of pruritus can be managed by the administration of naloxone; however, treatment rarely is required (Mullins & Johnson, 1996). Most clients will indicate that they prefer itching over pain.

Clients also should be educated regarding other sensations they will experience after intrathecal opioid administration. Although they still may be aware of the uterine contraction, the pain will be more like a pressure sensation, possibly rectal, than pain. Clients should be instructed to report an increase in rectal pressure sensation or a feeling of continuous pressure. Either may be an indication of progression of labor. When clients begin to feel pain again, the anesthesia provider should be notified in a timely manner because once the intrathecal opioid activity begins to diminish it may wear off quickly.

Epidural Anesthesia

The technique of lumbar **epidural** analgesia for relief of labor pain was first used during the 1940s (Ostheimer, Shea, & Van Zundert, 1996). Currently, epidural use of a dilute solution of a local anesthetic (often in combination with a small amount of opioid) is the standard against which all other modalities of pain relief in labor are measured (Vincent & Chestnut, 1996). The combination of a dilute solution of local anesthetic and an opioid appears to result in the best combination of quality analgesia and minimal side effects (Table 24-4) (Fiedler & Shaw, 1997).

An *absolute contraindication* refers to the idea that in the face of a particular condition there is no valid reason for proceeding to place an epidural. A *relative contraindication*

Table 24-4 Advantages and Disadvantages of Epidural Analgesia

Advantages	Disadvantages
Indefinite duration	Confined to bed
Titratable	Frequent vital signs
Excellent analgesia	May interfere with pushing
	Possible postdural puncture headache

cation means that although there may be some valid reason for placing an epidural, it is not likely to offer significant benefit versus the risks involved the procedure. There are few absolute contraindications to the use of epidural analgesia and some relative contraindications (Box 24-2).

After identification of the epidural space the anesthesia provider may either give a test dose of a small amount of local anesthetic and epinephrine or pass an epidural catheter through the needle (Figure 24-8), withdraw the needle, and give the test dose through the catheter.

The combination of local anesthetic and epinephrine is designed to test for accidental placement of the needle or catheter into the subarachnoid space or into an epidural vein (Fiedler & Shaw, 1997). If the needle or catheter is in the subarachnoid space, the small amount of local anesthetic will produce a degree of spinal block. If the client indicates that her legs are heavy or feet are numb, the needle or catheter is in the subarachnoid space and will need to be withdrawn. If the needle or catheter is in an epidural vein, the small amount of epinephrine in the test dose will cause a rapid but transient increase in maternal heart rate. Continuous pulse oximetry or other assessment of mater-

Box 24-2 Contraindications to Regional Analgesia and Anesthesia

- Absolute
 - Patient refusal
 - Severe hemorrhage
 - Significant coagulopathy
 - Infection at the site
- Relative
 - Sepsis
 - Neurologic disorder
 - Heparinization
 - Spinal deformity
 - Extensive spinal surgery or hardware
 - Metastatic disease in the lumbar spine

Figure 24-8 Epidural catheter passed through the needle.

nal pulse should be used to detect changes. When the results of the test dose are negative, either a bolus of medication is given through the needle or, if preferred, the catheter is passed through the epidural needle, the needle withdrawn, and the bolus administered through the catheter. The catheter is carefully passed through the epidural needle and the needle withdrawn. The anesthesia provider is careful not to move the needle forward once the catheter has been passed because doing so could result in breakage or shearing off of the catheter tip and thus

an inability to remove the catheter after use. The catheter is securely taped to the client's back, and she is assisted to a lateral position. Maternal blood pressure and fetal heart tones are assessed frequently in the initial 20- to 30-minute period after the procedure.

Local anesthetic creates a degree of autonomic blockade, which relaxes the blood vessels in the lower body and results in decreased maternal blood pressure. An adequate preload or bolus of IV fluid (500 to 1,000 mL non-dextrose-containing solution) and the judicious use of small increments of ephedrine by anesthesia providers when necessary will counteract the effects of the autonomic blockade.

Whereas epidural analgesia offers excellent analgesia and versatility for providing differing levels of analgesia for different conditions, this technique may have side effects or complications. It should be noted that complications occur very rarely. If the epidural needle accidentally punctures the dura, the larger size will make a bigger hole, which may increase the incidence of postdural puncture headache (also known as a spinal headache). The large fluid bolus needed for epidural analgesia may decrease uterine contractions; however, this side effect often is transient and responsive to oxytocin administration (Hawkins, Chestnut, & Gibbs, 1996). Epidural analgesia may contribute to prolonging the second stage of labor when the block is dense enough to obliterate the bearing-down reflex or diminish maternal ability to push (Vincent & Chestnut, 1996).

Nursing Alert

POSSIBLE SIDE EFFECTS AND COMPLICATIONS OF EPIDURAL ANALGESIA

- Hypotension
- Urinary retention
- Total spinal anesthesia
- Neurologic injury
- Unsatisfactory block
- Unintentional subarachnoid (spinal) block

It is possible to use a single shot or repeated bolus technique for epidural analgesia and anesthesia; however, uncertainty regarding the duration of labor has led to these techniques being abandoned in favor of the continuous infusion technique. In the continuous infusion technique, an infusion of dilute local anesthetic and opioid is prepared and administered by way of a syringe pump or other infusion-controlling device. As the client nears full dilation or begins to push, her motor function is assessed and the infusion rate adjusted downward, if needed (Fiedler & Shaw, 1997). Infusions may be adjusted but rarely are discontinued because doing so is likely to result in return of pain, which is unnecessary, unjustified, and counterproductive (Youngstrom, Baker, & Miller, 1996).

Combined Intrathecal-Epidural Technique

The newest of the regional techniques seeks to combine the rapid onset of pain relief of the intrathecal opioid with the ability to provide analgesia over an indeterminate period, as with a continuous epidural infusion (Cheek & Gutsche, 1997). In the combined technique the epidural space is identified and the dura punctured using a spinal needle through the epidural needle (Figure 24-9). Combination needles are available commercially. These consist of an epidural needle with an additional port and centering sleeve on the spinal needle. A small amount of fentanyl (usually 25 µg) or sufentanil (10 µg) is injected and the spinal needle withdrawn (Vincent & Chestnut, 1996).

An epidural catheter is threaded through the epidural needle and the needle is withdrawn. The catheter is securely taped to the client's back. At this point the client is monitored as described previously. After 30 minutes of monitoring and assessing for postural hypotension the client may ambulate with a support person, if desired (Cheek & Gutsche, 1997). The duration of analgesia varies from 1 to 2 hours. When the client is again uncomfortable (if ambulating, she returns to bed) the catheter is tested (as previously described) and a bolus of local anesthetic and opioid is administered and a continuous epidural infusion begun. When ambulation is not desired (or permitted) and delivery does not appear imminent, a continuous epidural infusion may be begun immediately. Thus, a seamless course of analgesia is created. By the time the analgesia

Figure 24-9 Spinal-epidural needle combinations.

provided by the intrathecal opioid decreases, the continuous epidural infusion will have built up sufficient volume in the epidural space to provide analgesia.

The combined technique also has disadvantages. In theory, administration of a solution into the epidural space, in the presence of a dural hole, could result in accidental subarachnoid administration. Cheek and Gutsche (1997), however, argue a pressure gradient exists that is unlikely to be overcome by slow epidural injection.

Paracervical Block

A paracervical block involves submucosal injections of local anesthetic in the vaginal wall, lateral to both sides of the cervix (Figure 24-10). A blockade of the visceral sensory nerves of the uterus, cervix, and upper vagina is produced. Because a paracervical block does not block sensory nerves from the perineum, it is not effective in the second stage of labor (Schnider & Levinson, 1994). This technique is rarely used because of the high incidence of severe fetal bradycardia, fetal asphyxia, and poor neonatal outcome (Santos, Pederson, & Finster, 1997; Schnider & Levinson, 1994). It is suggested that the fetal bradycardia is a result of the proximity of the uterine artery to the area of local anesthetic administration, which causes constriction that results in decreased placental blood flow. It also has

Figure 24-10 Paracervical block.

been suggested that high fetal blood levels of local anesthetic, as a result of absorption into the uterine artery or fetal scalp, are the cause of the fetal bradycardia (Schnider & Levinson, 1994).

Possible Complications with Regional Anesthesia

Numerous long-term complications from regional anesthesia are possible but very rare. Knowing about such problems, however, should result in rapid recognition by the nurse. Trauma to a nerve root or spinal cord is possible. Administration of lumbar puncture below the level of L-1, L-2 decreases the risk of spinal cord trauma because the spinal cord usually ends above this level. Trauma to the nerve root is possible but extremely rare (Concepcion, 1996). An intraneural injection of local anesthetic causes immediate pain and is a signal to the anesthesia provider to stop injecting. Paresthesias or hyperalgesia in the area innervated by that nerve root indicates damage to the nerve root. Fortunately, this type of injury generally resolves within weeks to several months (Concepcion, 1996).

Drasner and Swisher (1996) indicate that risk factors for postdural puncture headache include age, body habitus, specifics of the needle, and multiple insertion attempts (Box 24-3). Postdural puncture headache occurs when the dura mater of the spinal cord is punctured. The puncture can be deliberate, such as in administration of intrathecal opioids or spinal anesthesia, or accidental, such as in the case of epidural anesthesia.

Headaches after childbirth are not uncommon; they may be due to a number of causes other than regional anesthesia. The distinguishing characteristic of a postdural puncture headache is the association between client position and headache severity. A true postdural puncture headache causes severe pain when the client is in an upright position, sitting, or standing, and is minimal or disappears completely when the client assumes a horizontal position (Chadwick & Ross, 1992). The onset usually is

within the first 5 days after the procedure. The headache may last for days and usually is not responsive to minor analgesics. The cause of the headache is tension on the meninges of the brain as a result of the loss of cerebrospinal fluid through the puncture site. The lower level of cerebrospinal fluid allows the brain to shift more than usual when the client assumes the upright position, causing more severe pain when the client is sitting or standing. Treatment of postdural puncture headache includes hydration to assist the body in replacing the cerebrospinal fluid; analgesics, which may provide some relief; and oral or IV caffeine for cerebral vasoconstriction. When these treatments are unsuccessful, the next step is an “epidural blood patch.” This technique is successful in over 95% of clients. It is an invasive technique, however, and carries the risks of additional puncture of the dura, which will result in worsening of headache, and arachnoiditis (if the blood is injected into the subarachnoid space). The technique involves placement of an epidural needle, preferably in the same vertebral interspace as the original puncture, and venipuncture and withdrawal of 20 mL of the client’s blood by an assistant, often the nurse. The anesthesia provider then slowly injects the blood through the epidural needle into the epidural space. The client is instructed to lie quietly for the next 30 minutes and curtail activities over the next several hours. The epidural blood patch appears to work by two different mechanisms: the blood clots and plugs the hole in the dura; and the volume of blood in the epidural space increases the pressure within the spinal canal, which increases the cerebrospinal fluid level surrounding the brain (Fiedler & Shaw, 1997).

Hematoma in the spinal canal is a rare complication but one that can result in spinal cord compression or ischemia (Drasner & Swisher, 1996). The damage may range from sensory or motor weakness to quadriplegia and death. Presenting symptoms may include lower body muscle weakness, back pain, and sensory deficit. Delays in recognition, diagnosis, and treatment have been correlated with more severe damage (Drasner & Swisher, 1996). Concern about this complication is one of the reasons that spinal and epidural anesthesia methods are contraindicated in the presence of severe coagulopathies.

Epidural analgesia may contribute to some neurologic injuries. Because of the relaxation and decreased pain sensation provided by the epidural, it is possible to excessively flex the client’s legs while positioning during pushing. Overstretching of the nerves passing through the pelvis may result. Clients may report paresthesias or numbness in one foot or leg that can be severe or last long enough to require the use of a cane or walker for weeks to months. Any report of numbness, paresthesia, or weakness that lasts longer than the expected duration of the regional or epidural analgesia should be referred to the anesthesia provider for further evaluation.

Box 24-3 Factors Associated with Increased Risk of Postdural Puncture Headache

- Age: younger women are at greater risk than are older women
- Body habitus: obesity carries a greater risk
- Previous postdural puncture headache
- Multiple attempts: increased number of punctures
- Needle size: large needle, more leakage
- Needle design: beveled needles, more than conical needles

The diminishment of uterine contractions after IV fluid boluses has been noted previously. Studies have indicated some diminishment in uterine activity in women receiving epidural analgesia with epinephrine-containing solutions (Chantigian & Chantigian, 1996).

An increased duration of the second stage of labor is common enough that the American College of Obstetricians and Gynecologists revised the guidelines for defining prolonged second stage of labor. In the presence of epidural analgesia, prolonged second stage of labor is defined as more than 3 hours in nulliparous women and more than 2 hours in parous women. These guidelines encourage careful assessment of the clients' motor and sensory functions as she is preparing to start pushing. It has been recommended that pushing should be delayed if the client lacks motor or sensory function (Hawkins et al., 1995).

Hawkins et al. (1995) reviewed the records of over 14,000 deliveries before and after implementation of epidural service. These authors found an increased incidence of the use of forceps for delivery in multiparous women with epidural analgesia. The nurse is reminded that association does not imply causation.

The impact of epidural analgesia on the progress of labor and modes of delivery is a topic that has been studied by numerous researchers in the past and continues to be studied today. There are multiple studies with results that support both sides of the controversy. There is no definitive answer to the questions raised; however, research continues toward improving our understanding and refin-

ing techniques. The nurse should be aware of the ongoing research to further her own knowledge and assist the client in fully understanding the risks and benefits involved in the vast array of options currently available for pain relief in labor and delivery.

Client Experience with Pain

The nurse should be sure to educate the client regarding the onset of pain relief with regional analgesia, the expected side effects, and safety concerns.

Nursing Implications

Nurses must assess the client's response to regional anesthesia; a baseline assessment of physical status is important for comparison after administration. Maternal responses can include hypotension, hypoventilation, nausea and vomiting, pruritus, and urinary retention. IV fluid boluses should be administered before an epidural with local anesthetic is performed. Evaluation of pain relief is needed to determine the level of analgesia appropriate for the stage of labor. Fetal well-being also must be assessed.

ANESTHESIA FOR DELIVERY

Anesthesia options for delivery include local anesthetic infiltration; regional techniques, such as a pudendal nerve block, a spinal, or an epidural; and general anesthesia. Without subjecting the client or fetus to unnecessary risks, the goal is to provide analgesia and anesthesia to meet the client's wishes and the requirements of the mode of delivery (Hawkins, Chestnut, & Gibbs, 1996). Modes of delivery include spontaneous vaginal, forceps (outlet, low, or mid), vacuum extraction, and cesarean section. Table 24-5 lists the specific modes of delivery and appropriate anesthesia techniques. The accompanying photo story highlights the technique of spinal anesthesia administration.

Local Infiltration

Infiltration of the perineal tissues with 10 to 20 mL of a local anesthetic (usually lidocaine) provides anesthesia during vaginal delivery to facilitate cutting or repair of the perineum and vagina. Episiotomy usually is performed by the obstetrician just before delivery of the fetal head (Schnider & Levinson, 1994). From a safety standpoint, local perineal infiltration has the least likelihood of complications (Hawkins, Chestnut, & Gibbs, 1996).

Regional Anesthesia

Regional anesthesia may be used for delivery as a continuation of the analgesia provided during labor or administered just before delivery, if required, for a specific mode of delivery.

REFLECTIONS FROM A LABORING MOTHER

"When I got to the hospital I was 4 cm dilated. Although I had managed pretty well so far, I knew what was coming. With my first baby, once I got to be 6 cm the contractions started to hurt a lot worse and that's when I got the epidural. Talk about the difference between day and night! I felt the contractions as pressure, but they were not as painful as they had been before the epidural. With my second baby, I asked for the epidural as soon as I just got into the labor-delivery room. I didn't want to miss getting one because my labor was moving too fast."

Table 24-5 Modes of Delivery and Appropriate Anesthesia Techniques

Modes	Local Infiltration	Pudendal	Spinal	Epidural
Spontaneous vaginal	X	X		X
Vacuum extraction	A	X		X
Outlet forceps		X	X	X
Low forceps		A	X	X
Cesarean section	B		X	X

A = Some clients may tolerate

B = Known technique but not used frequently

Pudendal Block

A **pudendal block** is a minor regional block that is reasonably effective and also very safe owing to its lack of fetal effects (Hawkins, Chestnut, & Gibbs, 1996). This block is administered by the obstetrician through the vagina by placing a local anesthetic in the area of the pudendal nerve, behind the sacrospinous ligament and near the right and left ischial spines (Cunningham et al., 1997; Hawkins, Chestnut, & Gibbs, 1996; Schnider & Levinson, 1994). (Figure 24-11). A pudendal nerve block can be used for spontaneous vaginal, outlet, and sometimes low forceps delivery. It also has been used effectively in some cases of vacuum extraction.

Spinal Anesthesia

Spinal anesthesia is rarely used for spontaneous vaginal delivery. It is likely to be used in low or midforceps delivery and vacuum extraction. It is often used for cesarean delivery. A list of the advantages and disadvantages of spinal anesthesia is provided in Table 24-6. Differences in the levels of spinal anesthesia for vaginal and cesarean delivery are created by the dosage of medication administered and the position of the client after placement of the local anesthetic in the dural sac (Figure 24-12).

For a vaginal delivery, the client will remain in a sitting position for a brief period (1 to 2 minutes) after the spinal anesthesia has been administered so that the hyperbaric local anesthetic solution will migrate downward toward the sacral area. *Hyperbaric* refers to the local anesthetic solution as being heavier than the cerebrospinal fluid it is placed in, and therefore, gravity pulls it downward. This block also has been referred to as a “saddle block,” although the term is technically incorrect because the anesthetized area is larger than that which would be in contact with a saddle (Cunningham et al., 1997).

Cesarean section requires sensory blockade to at least the level of the xiphoid process, the T-8 dermatome (Cunningham et al., 1997). To obtain these levels a greater dosage of medication is required. The client is assisted immediately to a supine position, with left lateral tilt, after administration of the spinal anesthesia. The tilt causes a more cephalad spread of anesthesia, resulting in a higher level of sensory blockade. Hazards include maternal hypotension and the possibility of complete spinal anesthesia (Hawkins, Chestnut, & Gibbs, 1996). Preloading with 1,500 to 2,000 mL of fluid may help decrease maternal hypotension (Ostheimer & Leavitt, 1996). Incremental doses of ephedrine may be administered if maternal hypotension occurs (Schnider & Levinson, 1994; Stoelting & Miller, 1994).

**Figure 24-11** Pudendal block.**Table 24-6 Advantages and Disadvantages of Spinal Anesthesia**

Advantages	Disadvantages
Rapid onset	Finite duration
Dense block	Possible severe hypotension
Less shivering	Possible total spinal
Less systemic medication	
Little placental transfer	
Awake client	

Administration of Spinal Anesthesia

This 29-year-old female is a gravida 4, para 3 who is being prepared for a repeat C-section. She will sit on the operating table with the nurse's assistance and support while the anesthesiologist assesses physical landmarks.

Upon identification of landmarks, preparations are made to cleanse the injection site.

The nurse has the responsibility to promote client comfort and limit motion during the procedure.

Once the area surrounding the injection site is cleansed, a sterile sponge is used to remove Betadine from the injection site.

The anesthetic agent is prepared for injection using sterile technique.

Epinephrine is added to the anesthetic agent to produce local vasoconstriction and to prolong the action of the substance.

A local anesthetic is administered prior to the spinal to increase client comfort.

When the local anesthesia is completed, an 18-gauge introducer is inserted and the hub of the needle is left in place.

The stylus guide wire is removed from the hub of the needle and inspected for drops of spinal fluid.

The syringe containing the anesthetic is connected to the hub of the needle.

The anesthetic agent is administered.

The anesthetic equipment is removed. The nurse assists the client in remaining seated until anesthesia personnel indicate the time is appropriate for the client to lie down. It is important to avoid vena cava syndrome by inserting a wedge or pillow under the right side of her back.

Anesthesia personnel will document the procedure and continue monitoring the client's condition.

The nurse's responsibility in assisting with an epidural is the same as assisting with a spinal. The difference is the epidural needle is inserted lower (L4–L5), a larger needle is used, and a catheter remains in place for continuous dosing or reinjection.

Epidural Anesthesia

The epidural anesthesia technique provides the versatility required for all modes of delivery. This versatility is a result of differences in types, volumes, and concentrations of

local anesthetics administered through a functioning epidural catheter (Figure 24-13). For a spontaneous vaginal delivery, additional local anesthesia can be administered just before delivery of the fetal head. Local anesthesia also may provide additional analgesia and anesthesia for episiotomy repair.

A slightly larger dose of local anesthetic can be administered for forceps or vacuum extraction delivery. The anesthetic should be administered 5 to 10 minutes before attempting forceps or vacuum extraction. It should be noted that the voluntary expulsive effort may be diminished with increased doses and longer elapsed time between administration and delivery. Two distinct advantages of epidural anesthesia are the ease and rapidity by which the anesthesia level can be increased to levels sufficient for cesarean delivery when forceps or vacuum extraction

Figure 24-12 Anesthesia levels for vaginal and cesarean births. A. Anterior view. B. Posterior view.

Figure 24-13 Side view of the anatomy of the spine. A. Epidural needle placed in the epidural space. B. Epidural catheter placed in the epidural space.

attempts are unsuccessful. The advantages and disadvantages of epidural anesthesia are summarized in Table 24-7.

The fact that epidural anesthesia can be used to increase the level of sensory blockade in slow increments can be an advantage in certain cases. In clients with pregnancy-induced hypertension (PIH), epidural anesthesia offers a number of advantages: reduction of maternal blood pressure secondary to autonomic blockade, with possible improvement in uterine blood flow. Reduction in circulating maternal cat-

echolamines through relief of pain may also improve uterine blood flow. When cesarean section is needed, gradual increases in sensory blockade levels help avoid maternal hypotension and resultant decreases in placental perfusion. Use of epidural anesthesia avoids airway stimulation, owing to tracheal intubation for general anesthesia, which could precipitate hypertension and thus possibly contribute to maternal cerebral bleeding (Fiedler & Shaw, 1997).

Except in the case of severe fetal distress, an epidural usually can be used to provide sufficient surgical levels of anesthesia in a short enough period of time for urgent cesarean section. General anesthesia is the technique of choice for true emergency cesarean sections such as in cases of severe fetal distress and substantial maternal hemorrhage (Santos, Pederson, & Finster, 1997).

Table 24-7 Advantages and Disadvantages of Epidural Anesthesia

Advantages	Disadvantages
Slower onset	Placement takes longer
Titratable level and duration	Possible systemic toxicity
Less hypotension	Larger placental transfer
Awake client	Higher incidence of inadequate block

General Anesthesia

General anesthesia for delivery involves rendering the client unconscious and intubation of the trachea with a cuffed endotracheal tube. Afterward, ventilation, oxygena-

Table 24-8 Advantages and Disadvantages of General Anesthesia

Advantages	Disadvantages
Total pain relief	Awareness is impossible
Optimal operating conditions	Slight risk of fetal depression

tion, unconsciousness, analgesia, and muscle relaxation are maintained. Emergence, or waking up the client, and extubation follow. The advantages and disadvantages of general anesthesia are given in Table 24-8). The possible maternal and fetal complications of general anesthesia are listed in Table 24-9.

All anesthetic agents, whether given by IV or inhalation, cross the placenta and affect the infant. Muscle relaxants are the exception owing to their large molecular size. Resuscitation of an infant with respiratory depression should be anticipated, with adequate equipment and personnel present at delivery.

The two major causes of maternal morbidity and mortality from general anesthesia are failure to intubate and pulmonary aspiration (Hawkins, Chestnut, & Gibbs, 1996). Pregnancy-induced changes contribute to airway management problems and are listed in Table 24-10.

Management of the airway, including tracheal intubation, is in the hands of the anesthesia provider; however, the nurse should be aware of the possible difficulties in airway management. To be able to render assistance, the nurse also must know the necessary steps to be taken by the CRNA or anesthesiologist in the case of difficult intubation. Figure 24-14 provides an algorithm for failed intubation. The nurse may be required to assist the anesthesia provider by calling for additional help, especially other anesthesia providers, if readily available because extra experienced hands can be invaluable (Johnson, Lawlor, & Weiner, 1994). The nurse also may be needed to hold cricoid pressure or hand an endotracheal tube to a solitary anesthesia provider. To maintain cricoid pressure, use the thumb and forefinger to firmly compress the cricoid ring

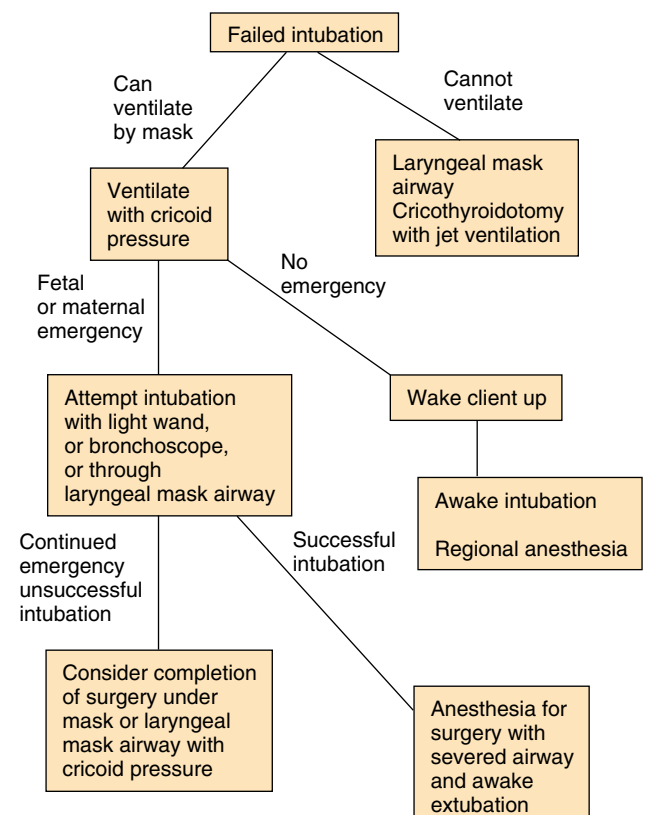

Table 24-9 Possible Maternal and Fetal Complications of General Anesthesia

Breast enlargement	Mechanical obstruction to insertion of laryngoscope; may need short-handled scope

downward (Figure 24-15) (Chipas, 1997). The cricoid ring is the first and only tracheal cartilage ring that is a complete circle. Compression of this ring closes off the esophagus, helping to prevent passive regurgitation (Schnider & Levinson, 1994). The most important part the nurse must remember is that *cricoid pressure is not released* until after the cuff of the endotracheal tube is inflated, with proper placement confirmed or the anesthesia provider indicating it can be released (Chipas, 1997).

**Figure 24-14** Failed intubation algorithm.

Nursing Alert

CRICOID PRESSURE

- The cricoid ring is located just below the thyroid bone.
- The cricoid ring is the only tracheal cartilage that forms a complete ring.
- With client in the supine position, downward compression (with thumb and forefinger) will cause the cricoid cartilage to close off the esophagus and help protect the client against aspiration of gastric contents.

Pulmonary aspiration of gastric contents can result in obstruction of lower airways, pneumonitis, pulmonary edema, and death (Cunningham et al., 1997). Two factors impact the severity of aspiration pneumonitis: volume

greater than 25 mL and pH less than 2.5 (Fiedler & Shaw, 1997). There are methods to decrease the risk of maternal aspiration or severity of a possible aspiration. The oral administration of a nonparticulate antacid (such as sodium citrate) just before induction of general anesthesia increases the gastric pH level and should be given routinely. Particulate antacids (such as Maalox) are not recommended because the particulate matter in the antacid can produce severe pulmonary reaction if aspirated (Fiedler & Shaw, 1997). Additional medications such as histamine blockers (cimetidine or ranitidine) also may be administered to decrease the gastric pH level and volume.

All pregnant clients are considered to have “full stomachs” even if they have been in labor or have not eaten for hours. The physiologic changes in the gastrointestinal system due to pregnancy that increase the likelihood of regurgitation and aspiration are shown in Table 24-11 (Bassell, 1996). The best defenses against pulmonary aspiration are use of medications, rapid sequence induction with cricoid pressure, immediate intubation and inflation of the cuff of the endotracheal tube, and extubation only after the client is awake and has regained the protective airway reflexes.

Special Considerations for Cesarean Section

After securing of the airway, the obstetrician is directed to proceed with the cesarean section. Unconsciousness of the client is maintained through the use of a volatile anesthetic agent and oxygen. After delivery of the infant, nitrous oxide is often added to enhance the anesthesia. Additional doses of muscle relaxant are given as needed to maintain surgical conditions. After the procedure the client is awakened. Once she is responsive, is spontaneously breathing with sufficient rate and tidal volume, and has the protective airway reflexes including swal-

Figure 24-15 Downward force of the cricoid cartilage will compress the esophagus.

Pepsin production	X	

lowing, the oral cavity is suctioned, the cuff deflated, and the client extubated. At this time she is taken to the recovery room.

The two other complications listed in Table 24-9 are awareness during general anesthesia and uterine atony. It is possible for the client to have some degree of awareness under general anesthesia; this may be attributed to the attempt to minimize drug-induced depression of the neonate (Chadwick & Ross, 1992). Addition of nitrous oxide to the oxygen-volatile agent mixture can help decrease awareness but is not advocated by some practitioners until after the delivery of the fetus. Many anesthesia providers think that delivery 100% oxygen until delivery of the infant is preferred because doing so should result in the highest level of oxygen available to the fetus. After delivery of the infant, additional doses of opioids and amnesics such as midazolam (Versed) as well as increased levels of volatile agents and use of nitrous oxide can help prevent maternal awareness. If the client describes incidences of awareness the nurse should take this seriously and notify the anesthesia providers so that the client can receive further assessment and explanation of the incident.

Uterine atony is possible in all deliveries regardless of the presence of anesthesia. The volatile agents used to maintain general anesthesia can produce a degree of dose-related decrease in uterine contractility and tone (Chadwick & Ross, 1992). At the level of volatile anesthetic agents and other drugs normally used, the uterus is responsive to the administration of oxytocin to induce contractions (Schnider & Levinson, 1994).

POSTDELIVERY CARE FOR THE CLIENT RECEIVING ANESTHESIA

The care needed in the recovery period by the client who has received anesthesia varies greatly according to the type of anesthesia. The care related to the birth process itself is covered in Chapter 25. Care of the client related to analgesia and anesthesia in labor and delivery is discussed subsequently.

Local Anesthesia

The client with local infiltration anesthesia of the perineum requires little additional recovery care owing solely to the anesthetic. The nurse must be aware that the client may be unable to feel hot or cold in the area that has been anesthetized. She must ensure that ice or other sources of cold are not placed directly on the skin of the perineum because it is possible to cause cold thermal injury owing to impaired cold and pain perception in this area.

Regional Anesthesia

In the recovery of a client with regional anesthesia, the type and extent of the regional anesthesia will determine necessary care. The client with a pudendal nerve block requires the same care as does a client with local infiltration. One additional caution applies: the perineal area should be carefully assessed for swelling, which may indicate the development of vaginal wall or perineal hematoma. The impaired sensory perception may mask pain and delay the recognition of a developing hematoma.

The recovery of a client with spinal or epidural anesthesia requires careful attention to vital signs and the declining spinal level (sensory block). Monitoring of vital signs includes blood pressure, electrocardiogram, and pulse oximetry. Oxygen by nasal cannula may be needed if the client has received sedation or other depressive medications. A low spinal or saddle block has a lower sensory level and causes less maternal hypotension than does a spinal block for cesarean section. Positional changes from supine to semi-Fowler's to Fowler's position should be done incrementally, with assessment of the client for tolerance and hypotension. It is not necessary for the client to remain supine after regional anesthesia. The nurse should be aware that the sensory blockade recedes from the chest toward the feet. Analgesia for incision or episiotomy pain should be considered and administered before the block is completely gone. The client's ability to urinate may be impaired. The bladder should be assessed and catheterized if the client is unable to void.

The client with epidural anesthesia may need the care indicated above if epidural anesthesia has been used to provide sensory blockade for vaginal forceps or cesarean delivery. The type of local anesthetic used through the epidural greatly impacts the client's status in recovery. Bupivacaine is frequently used for its properties of sensory blockade with preservation of motor control. Clients who did not receive additional analgesia for delivery may not require specific care other than a warning that they will not have complete control of their legs for several hours and that full sensation does not mean full control. All clients should have assistance the first time they ambulate from the bed; however, the nurse should be even more cautious when helping to ambulate clients who have had regional anesthesia (consider additional help).

General Anesthesia

Recovery of the client from general anesthesia requires close observation and complete monitoring. Assessment of the client involves all major systems and preparations for immediate response to problems encountered. Respirations should be observed for rate and depth. Oxygen should be administered by nasal cannula or by mask

(when higher concentrations are needed.) Pulse oximetry should be employed to determine changes in oxygen saturation. Continuous electrocardiogram and frequent intermittent blood pressure monitoring are done. Suction equipment should be functioning and ready in case of vomiting. The nurse should be aware that the client should not be left alone at any time and that the most dangerous time in the recovery period can be that few minutes after the initial flurry of activity involved in admission to the recovery area. After the initial stimulation of monitor placement and assessment is over, the patient may drift back to sleep and hypoventilate. Vigilance is the key word for safe recovery of the client from general anesthesia.

Web Activities

- Visit the sites listed above for both client and professional educational materials. Check out www.childbirth.org and the section Epidurals—Frequently Asked Questions. Type in the terms “childbirth” and “analgesia” in any web search engine, such as Lycos, HotBot, AltaVista, Excite, or Goto.com. You will get lists of thousands of websites. Check out a few just to see what is out there. Some information may be excellent and some may not be.

Key Concepts

- Theories of pain suggest that pain is a very individual experience influenced by cultural practices, previous experience with pain, and available support systems.
- Types of anesthesia include local (small area of the body), regional (large area of the body), and general (loss of consciousness).
- The primary consideration for use of pain medication during labor and delivery is always the health and well-being of the mother and baby.
- Sources of pain in labor and delivery include cervical dilation, uterine contractions, distension of the vagina and perineum, and pressure on the sacrum; perception of pain can be influenced by cultural expectations, exhaustion, loss of sleep, and duration of labor.
- Parenteral analgesia options during labor include opioids and sedatives. Options for regional analgesia in labor include intrathecal opioids, epidural, combined intrathecal-epidural, and paracervical analgesia.
- During delivery, pudendal, spinal, and epidural blocks are the pain relief options of choice.
- The nurse’s role in caring for the client recovering from anesthesia emphasizes close observation, complete and frequent monitoring, and assessment; the nurse may also provide assistance to the client when ambulating.

Review Questions and Activities

- Which of the following is not a process involved in nociception?
 - Transduction
 - Transmission
 - Transudation
 - Modulation
 The correct answer is c.
- Which of the following types of anesthesia involves the loss of sensation from a large area of the body?
 - General
 - Regional
 - Inhalation
 - Local infiltration
 The correct answer is b.
- Which of the following types of anesthesia does only a CRNA or anesthesiologist provide?
 - General
 - Regional
 - Inhalation
 - Local infiltration
 The correct answer is a.
- In which stage of labor is the conduction of pain impulses through T-10 to L-1?
 - Third stage
 - Second stage
 - First stage
 - Fourth stage
 The correct answer is c.

5. In which stage of labor is the conduction of pain impulses through S-2 to S-4?
- Third stage
 - Second stage
 - First stage
 - Fourth stage

The correct answer is b.

6. Which opioid is most frequently used in labor and delivery?
- Fentanyl
 - Morphine
 - Sufentanil
 - Meperidine

The correct answer is d.

7. Which of the following methods of pain management is the gold standard?
- Intrathecal opioids
 - Parenteral analgesia
 - Epidural

- d. Combined spinal and epidural

The correct answer is c.

8. Which of the following is one of the major causes of maternal morbidity and mortality from anesthesia?
- Emergency cesarean section
 - Epidural catheter breakage
 - Pulmonary aspiration
 - Postdural puncture headache (spinal headache)

The correct answer is c.

9. Which of the following is the most dangerous period for a client after general anesthesia?
- During transportation from the operating room to the recovery room.
 - After the initial flurry of activity on arrival to the recovery room.
 - Thirty minutes after arriving in the recovery room.
 - Just before transportation to the postpartum unit.

The correct answer is a.

Intrapartum Nursing Care

Childbirth is one of the most meaningful, unique, and exciting times for the laboring woman and her partner, yet it also can be a time of stress and anxiety. Essential components of nursing care include a comprehensive knowledge of the processes of labor and delivery, competence in providing care that conforms with current standards, and provision of support for the childbearing family through this major event. Good interpersonal skills, including listening to the client, will complement technical skills. A positive perception of the birthing experience and a feeling of empowerment are fostered by the nurse who gives sufficient information to the woman and her partner, in language they can understand, and who shows nonjudgmental support for their efforts.

A good intrapartum nurse is one who not only is skilled and knowledgeable but who deems it a privilege to provide care to a family during this momentous time. Many women remember every nuance of their labor and childbirth for many years afterward. These women especially remember the actions and demeanor of the major caregiver. Attentive and effective support, therefore, can make childbirth a satisfying experience for everyone and a treasured memory for the family.

Key Terms

Acceleration	Effacement	Meconium	Preterm premature
Acme	Emergency childbirth	Montevideo units	rupture of membranes
Acrocyanosis	Episiotomy	Multipara	(PPROM)
Active phase	Fern test	Nitrazine test	Reactive nonstress test
Amnihook	Fetal heart rate (FHR)	Nonperiodic fetal heart	Resting tone
Amnioinfusion	First stage of labor	rate changes	Saltatory pattern
Amniotomy	Frequency	Nuchal cord	Second stage of labor
Apgar score	Gravidity	Oligohydramnios	Short-term variability
Baseline fetal heart rate	Hypertonic contractions	Overshoot	Shoulder
Beat-to-beat variability	Hyperventilation	Parity	Station
Bloody show	Increment	Parturient	Striae gravidarum
Chorioamnionitis	Intensity	Periodic fetal heart rate	Third stage of labor
Contraction	Intrauterine pressure	changes	Transition phase
Crowning	catheter (IUPC)	Placenta previa	True labor
Deceleration	Inversion of the uterus	Polyhydramnios	Uterine atony
Decrement	Labor	Precipitous delivery	Uteroplacental
Dilation	Laceration	Premature rupture of	insufficiency
Doula	Late onset deceleration	membranes (PROM)	Variable deceleration
Duration	Latent stage	Presenting part	Variability
Early onset deceleration	Long-term variability	Preterm birth	Vertex

Competencies

Upon completion of this chapter, the reader should be able to:

1. Describe the initial assessment of the woman in labor.
2. Describe the subsequent maternal-fetal assessment during the four stages of labor.
3. Define the normal course of all four stages of labor.
4. Describe the primary nursing interventions in all four stages of labor.
5. Identify changes in client-fetal status that may alter the course of labor and delivery.
6. Discuss episiotomy use and subsequent nursing considerations.
7. Accurately document events and nursing interventions.

The nursing care of the woman experiencing an uncomplicated vaginal birth is discussed. All maternity clients have their individual expectations and reactions to labor and delivery. Emphasis on each of the varied roles of the nurse, as client advocate, support person, and expert caregiver, will depend on the client's particular circumstances and specific needs. For example, the young teenager who has received no childbirth preparation will need a great deal more teaching than will the client who is giving birth to her fourth child and has attended childbirth classes. A middle-class woman with a planned pregnancy, good preparation, and a supportive family is more likely to find the experience joyful and rewarding than is the single woman with an unwanted

pregnancy. The actions of the intrapartum nurse are described step-by-step through the labor and delivery process, beginning with the admission procedures and continuing with the ongoing observation and support of the client until completion of the fourth stage, or stabilization period. This is the sequence of events as the nurse encounters them. Although this chapter deals with uncomplicated vaginal delivery, every labor and delivery nurse must be able to recognize symptoms of complications that might develop and must know the appropriate nursing interventions.

Most women in the United States give birth in a hospital birthing room called a labor, delivery, and recovery room (LDR). In that setting, the woman is not transferred

Figure 25-1 Many hospitals offer a pleasant, family-centered atmosphere for the birthing experience.

from a labor room to a delivery room, unless the need develops for operative intervention; she remains in the LDR for at least 1 hour after delivery. During this recovery period the woman can hold and feed her infant and thus begin the bonding process. After the recovery hour, the woman is transferred to the postpartum unit. In some hospitals the woman remains in the same room (labor, delivery, recovery, and postpartum room [LDRP]) until discharge. With the introduction of LDRs, LDRPs, and birthing rooms, hospitals have attempted to create a family-centered homelike appearance that promotes an ambience of normalcy rather than a clinical atmosphere (Figure 25-1).

ASSESSMENT OF THE PHYSIOLOGIC PROCESSES OF LABOR

Most women who arrive at the labor and delivery unit are excited about the birth of their baby but also anxious that everything should progress well. A woman often is concerned about whether she really is in labor, whether she will appear foolish if sent home again, and if she is in true labor, how she will cope with the pain and stress of contractions and giving birth. The nurse can allay much of this anxiety by adopting a friendly and interested manner and by keeping the woman and her support person fully informed. Teaching plays a major role in easing anxiety and should include events of labor and what to expect in the way of procedures. Care must be taken to maintain the client's privacy and confidentiality to promote trust and avoid undue stress. The nurse is perceived as powerful but should not be controlling. The **parturient**, that is the

Critical Thinking

Who Delivers the Infant?

It is the woman who delivers the infant, not the physician or midwife. The laboring woman is the key player in this event. The health care team safeguards the mother and infant by providing a therapeutic environment, appropriate interventions, encouragement, reassurance, and feedback.

What do you believe is the most appropriate role for the professional nurse in providing care for the laboring woman and her fetus?

How do you think the nurse fits into the health care team?

woman in labor, is the person of central importance in this situation, not the nurse, doctor, or nurse-midwife.

Maternal Status

Women come to the hospital or birthing center at different stages of labor and with different levels of wellness. Thorough initial and ongoing assessment by the nurse is critical to the well-being of mother and infant. Certain information is needed immediately for the nurse to establish appropriate priorities when developing the plan of care. Initial admission observations are aimed at establishing the fact that true labor has begun, ascertaining the imminence with which the birth might be expected, and alerting team members to existing or developing complications or risk factors. It is desirable for the prenatal care provider to transmit the client's health history, physical findings, and laboratory data to the hospital toward the end of the third

INTRODUCTIONS

When meeting a client for the first time, it is wise to bear in mind that first impressions are lasting. The nurse should introduce herself, ask the names of the client and those accompanying her, and conduct them to the triage room or the assigned labor, delivery, and recovery room.

Table 25-1 True versus False Labor

Qualifier	True Labor	False Labor
Contractions	Regular Intervals shorten Intensity increases Intensify with walking	Irregular Intervals do not shorten Intensity remains unchanged Do not intensify with walking
Cervix	Dilates and becomes effaced	Does not dilate or efface
Sedation	Does not stop true labor	Tends to stop false labor
Show (blood-tinged mucus from the cervical canal)	Often is present	Usually is absent

trimester so that when the client is admitted to the labor and delivery unit her prenatal record can be reviewed and pertinent information recorded in the Admission Record.

Labor Onset

One of the most critical diagnoses in obstetrics is the accurate diagnosis of labor onset. The hallmark of true labor is cervical change; however, the woman at home has no way of knowing whether her cervix is dilating. Many women come to the hospital believing that they are in labor, only to be discharged home, still pregnant, after a few hours. To conserve the use of LDRs, many hospitals have a triage room in which the client's labor status is first evaluated before she is either discharged or moved to an LDR.

Although making a differential diagnosis between true and false labor sometimes is difficult, it usually can be done on the basis of certain very specific criteria (Table 25-1).

Initial Status Assessment

During the initial assessment the client is observed closely for clues to her status. Postures, facial expressions, and gestures can suggest tension, anxiety, or pain. Perspiration, varied breathing patterns, and frequent position changes also can indicate stress and discomfort. Grunting or breath-holding may signal the start of the second stage of labor. If the client is in active **labor** (the process by which the fetus is expelled from the uterus) the nurse may have to shorten the initial assessment and prioritize the questions (between contractions) to focus on her current labor status. Certain information is needed immediately to evaluate the extent of the woman's labor and to become alert to the woman with a history of rapid deliveries or problems denoting risk. The client should not have to guess the information that is important for the nurse to know; therefore, skillful interviewing is essential. Questions that the nurse should ask include the following:

1. What is your reason for coming to the hospital?

Information obtained: Presenting complaint (e.g., urge to push, back pain, "water" broke).

2. When is your baby due, and how many babies have you had?

Information obtained: Expected date of delivery and parity, possibility of a rapid labor if the woman is a **multipara**, that is, a woman who has had two or more pregnancies that reached viability.

3. When did your labor begin? How far apart are the **contractions** (tightening and shortening of the uterine muscles during labor)? Have they become stronger? Information obtained: The length of time the woman has been in labor, and the frequency and perceived **intensity** (strength of the contraction at its peak) of the contractions.

4. Has the bag of water (membranes) broken? At what time? What color was the fluid? Have you noticed any bleeding?

Information obtained: Possible presence of abnormal bleeding (bloody discharge without mucus) or **bloody show** (a blood-tinged mucous discharge from the vagina that occurs as the cervix starts to dilate), whether membranes have ruptured, time of rupture of membranes, possible presence of meconium-stained amniotic fluid (**meconium** is fetal stool found in the bowel of a term neonate). Presence of meconium-stained amniotic fluid indicates that the fetus has experienced an episode of hypoxia.

5. How has your pregnancy been? Have you been hospitalized during this pregnancy? Is there anything else about you or your pregnancy that I should know?

Information obtained: Any condition or information that may have an impact on labor, delivery, and the neonate.

6. Are you allergic to any foods or medicines that you know of? Are you allergic to latex? Have you ever had a bad reaction to a blood transfusion?

Information obtained: Any known allergies to medications, latex, or blood.

Other pertinent information can be outlined on the Obstetric Admitting Record (Figure 25-2).

Informed Consent

The fact that the woman comes to the birthing facility gives the implication of consent to treatment; nevertheless, informed consent should be obtained in the form of a signature before any invasive procedures are carried out. It is the physician's responsibility to give the client information and rationale for the type of interventions that may be performed, including benefits, possible risks, and available alternatives. Typically, however, it is the nurse who obtains and witnesses the client's signature on the consent form. An informed consent form should be signed before any treatment is carried out, particularly administration of medications that might impair the woman's ability to make decisions. Each hospital or birthing center may have its own variation of an informed consent form; however, all forms should cover delivery of the infant and include procedures that may be necessary in an emergency, for example, general anesthesia, cesarean delivery, blood transfusion, and hysterectomy.

Risk Factors

If the prenatal record is available, it should be reviewed before the client arrives at the unit. The nurse reviews the prenatal history and antenatal care and notes identified risk factors. To make appropriate nursing diagnoses, a comprehensive nursing database must be compiled. To achieve an optimal perinatal outcome, factors that put the woman or infant at high risk for morbidity must be recognized early so that appropriate and timely intervention can be made, including consultation with specialists in other medical departments. Early intervention can minimize fetal and maternal complications.

Many conditions in either the mother or fetus, some preexisting and others that have developed during the

Box 25-1 Pregnancy Risk Factors Identified from the Mother's Medical History

- | | |
|---|---|
| • Diabetes mellitus | • Renal disease |
| • Sickle cell disease | • Infection, e.g., hepatitis B, syphilis, gonorrhea |
| • Prior cesarean delivery | • human immunodeficiency virus group B |
| • Chronic hypertension | • <i>Streptococcus</i> , active herpes virus |
| • Heart disease | |
| • Anemia | • Previous perinatal loss |
| • Cigarette smoking, alcohol use, substance abuse | • Age under 16 or over 35 years |

pregnancy, can result in a high-risk classification (Boxes 25-1 and 25-2).

Cunningham (1997) listed three major categories that can be identified antepartum that put the client at increased risk: preexisting medical illness; previous poor pregnancy outcome, such as perinatal mortality, preterm delivery, fetal growth retardation, malformations, placental accidents, and maternal hemorrhage; and inadequate maternal weight gain owing to malnutrition.

Expected Date of Delivery

The expected date of delivery (EDD) is noted in the Admission Record and the gestation calculated in weeks and days; for example, 38 weeks and 3 days would appear as 38 3/7 weeks. If the EDD is not known, the nurse may cal-

Critical Thinking

Noncompliance

RL has phenylketonuria. Her doctor advised her to follow a diet low in phenylalanine before becoming pregnant and throughout the pregnancy to protect the fetus. RL refused to follow the low-phenylalanine diet and gave birth to a baby boy with severe neurologic damage. You overhear another nurse say, "People like her should be put in the hospital and obliged to follow the diet so that the baby would not be harmed."

What would be your response to this nurse?

Box 25-2 Specific Risk Factors Developing During This Pregnancy

|-------------------------------------|------------------------------------|
| • Pregnancy-induced hypertension | • Gestational age 42 weeks or more |
| • Polyhydramnios or oligohydramnios | • Preeclampsia |
| • Preterm labor | • Multiple gestation |
| • Bleeding in the third trimester | • Placenta previa |
| • Placenta abruption | • Abnormal presentation |
| • Prolonged rupture of membranes | • Inadequate prenatal care |
| • Gestational diabetes mellitus | • Intrauterine growth retardation |
| • Fetal congenital anomalies | • Isoimmunization (Rh or ABO) |

PARITY

Parity is determined by the number of *pregnancies* of viable duration, not the number of fetuses delivered. For example, a primigravida who previously delivered stillborn triplets at 29 weeks gestation is a para 1.

calculate the EDD from the date of the woman's last menstrual period using Nägele's rule (see Chapter 15). **Gravidity**, the number of times the woman has been pregnant, and **parity**, the number of pregnancies that have reached viability regardless of outcome, are noted.

Two methods are used to document gravidity and parity:

5-digit method:

- Number of times the woman has been pregnant (gravidity).
- Number of term births (parity).
- Number of **preterm births**, that is, births after 20 weeks' gestation and before 37 weeks' gestation.
- Number of abortions (spontaneous or elective).
- Number of living children.

GTPAL: G6P4014 = 5 pregnancies, 4 to term, 0 premature, 1 abortion, 4 living.

2-digit method:

- Number of times the woman has been pregnant (gravidity).
- Pregnancies that have reached a gestation of viability, regardless of outcome.

G₃P₂: 2 pregnancies and two live births. G includes current pregnancy prior to delivery.

Problems with Present Pregnancy

The client is asked about any problems she may have had, particularly those requiring hospitalization, pertaining to the current pregnancy. Problems such as preterm labor, vaginal infections, vaginal bleeding, gestational diabetes, and pregnancy-induced hypertension (PIH) are of particular importance.

Findings of a preliminary history and screening serve to ascertain whether the woman is, in fact, in labor and whether there are any obvious problems. Relevant information includes but is not necessarily limited to the EDD; blood pressure; temperature; pulse; respirations; pattern and amount of weight gain and present nutritional status; symptoms experienced; deep tendon reflexes; edema; and urine screening for protein, glucose, and ketones.

Health History

The nurse obtains pertinent information from the prenatal record and by interviewing the client. Risk factors that may increase morbidity or mortality are evaluated. In order to make this evaluation, the nurse must possess a knowledge of factors and chronic physical conditions that might put the pregnancy into a high-risk category. Childhood diseases, emotional problems, and genetic defects are noted in the Admission Record. Chronic illnesses, such as hypertension, diabetes, positive human immunodeficiency virus (HIV) status, cardiac disease, phlebitis, renal disease, and seizure disorders, are conditions that place an additional burden on the body; therefore, these illnesses put the client and fetus at greater than normal risk for mortality or morbidity. Surgical operations are noted, particularly uterine surgeries (e.g., cesarean delivery, myomectomy) that would leave a weakened portion of the myometrium and thus a higher than normal risk of uterine rupture.

Demographic and Psychosocial History

Demographic and psychosocial information includes age; religious and cultural factors; and use of substances such as alcohol, tobacco, and illicit drugs. If the woman smokes cigarettes, she should be asked how many are smoked per day. If the woman admits to using illicit, so-called recreational, drugs she should be asked for details such as the specific substance used and the amount taken. A drug screening should be done on any client who admits to or displays evidence that leads the caregiver to suspect substance abuse. Signs suggestive of substance abuse, such as needle marks or bruising, should be noted.

If the woman is admitted in an advanced stage of labor and is experiencing strong contractions, it may not

Critical Thinking

Cigarette Smoking During Pregnancy

Women who smoke cigarettes during pregnancy face serious health risks, including increased perinatal mortality, increased risk for placental abruption, low-birth-weight infants, small for gestational age infants, and preterm deliveries (ACOG, Sept. 1997).

If you were a nurse caring for a pregnant woman who smokes cigarettes, what would you tell her about cigarette smoking during pregnancy?

Would your advice differ if you were a cigarette smoker?

be appropriate for the nurse to make an in-depth health history record. Priority assessments, however, include the following:

Is the woman able to ask for what she needs?

Is there a language barrier?

Does she talk freely with the nurse and her partner?

Does she avoid eye contact?

How much rest has she had lately?

The woman's culture and socialization as well as her perception of previous birth experiences are likely to influence her attitude toward her current situation and her postpartum emotional adjustment (Lowe, 1996).

The woman should be encouraged to ask about practices during labor and delivery that are important to her culture, and these requests must be entertained with respect and sensitivity. When a request is made that contradicts usual practice, nurses should ask themselves the following questions: How important is this to the client? Is it safe? Is it feasible to incorporate this request into the plan of care?

Safety Screening

Estimates of the prevalence of abuse during pregnancy, developed from clinic-based studies, range from 0.9% to 20.1%, with the bulk of studies reporting a prevalence of 3.9% to 8.3% (Gazmararian et al., 1996). Many studies report that violence may begin or escalate during pregnancy (Hilliard, 1985). Thus, it is crucial for the nurse to enquire of all female clients as to the safety of their domestic situa-

tion, because hospitalization during childbirth may provide the only window of opportunity for an abused woman to seek assistance. Studies have revealed that women who are anxious during pregnancy compared with women who are not tend to have infants of lower birth weight; studies also have shown that women with high levels of stress hormones compared with those with low levels are more likely to deliver preterm (Teixeira, Fisk, & Glover, 1999; Wadhwa et al., 1998).

A client may not want to confide in the nurse about domestic violence until a relationship of trust has developed between the nurse and the client. Even then, the client may not volunteer information unless she is asked outright and is assured of confidentiality. Safety screening should always be performed in absolute privacy, when the client is alone with the nurse. Sometimes it is necessary for the nurse to ask the partner to step out into the waiting room. An Abuse Assessment Screen should be completed and placed in the client's medical record (Figure 25-3). If the client screens positive for abuse, the nurse must discuss possible options that are available, provide phone numbers of local shelters, and notify the hospital social worker. If there are overt signs of abuse, such as bruises or abrasions, the nurse should describe them and take photographs, which are then placed in the client's medical record.

Obstetric History

When this is not the woman's first pregnancy, the characteristics of previous births are noted. The number of previous deliveries and length of the client's last labor is information that might help to predict progress of the current labor. Useful details of the previous births would include birth weights, the type of anesthesia used, the kind of birth (spontaneous vaginal, forceps-assisted, vacuum-assisted, or cesarean birth), and whether there was postpartum hemorrhage.

Fetal Status

Initial assessment of fetal status gives reassurance of well-being and must be recorded appropriately. The fetal heart rate (FHR) may be evaluated by auscultation with a fetoscope or electronically by means of an ultrasound stethoscope or by electronic fetal monitoring (EFM). EFM has become routine in most labor and delivery units in the United States. The character of uterine activity and the response of the FHR to contractions are of considerable interest. Leopold's maneuvers are performed by the nurse between contractions to assess fetal presentation, lie, position, and engagement (see Chapter 23) and also to ascertain the appropriate location for auscultating the FHR. Success of external fetal monitoring depends largely on correct positioning of the transducer.

Critical Thinking

Domestic Violence During Pregnancy

Complications of pregnancy, including low weight gain, anemia, infection, preterm labor, chorioamnionitis, and first and second trimester bleeding are significantly higher in women who are abused compared with women who are not abused (Parker, McFarlane, & Soeken, 1994; Berenson et al., 1991). Also significantly higher are maternal rates of depression; suicide attempts; and use of tobacco, alcohol, and illicit drugs. Some studies report appreciably lower mean birth weights for infants born to women abused during pregnancy (McFarlane, Parker, & Soeken, 1996).

What responsibility does the nurse have in screening for domestic violence in pregnancy?

CONFIDENTIALITY

The client's partner may be unaware of past pregnancies, infants given up for adoption, abortions, or a positive human immunodeficiency virus status. A client's desire for confidentiality must be respected. Therefore, some questions are best asked when the partner, all family members, and all other support persons are out of the room.

The **fetal heart rate (FHR)** is the number of times the fetal heart beats per minute (Cunningham, 1997). The Association of Women's Health, Obstetrics, and Neonatal Nurses (AWHONN) (1998) establishes guidelines for competency validation for FHR monitoring and the American College of Obstetricians and Gynecologists (ACOG) publishes technical bulletins to guide clinical practice issues such as FHR monitoring (ACOG, 1995).

Perinatal nurses are responsible for familiarizing themselves with practice guidelines regarding FHR monitoring. The FHR should be evaluated as soon as possible after the woman arrives at the labor and delivery unit (Box 25-3). The method and frequency of assessment will depend on risk factors and departmental policy. Monitoring can be continuous or intermittent.

Auscultation

Auscultation is an auditory method of monitoring the FHR. It is performed intermittently and usually with a DeLee-Hillis obstetric stethoscope or a Doppler device. Auscultation should be done during and immediately after a contraction. For the low-risk client in the active phase of the first stage of labor, auscultation should be performed at least every 30 minutes (ACOG, Dec. 1995). The Doppler ultrasound device is handheld and amplifies the sound of the FHR. The advantage of auscultation is that it allows for greater freedom of the client because she is not attached to a machine and does not have to wear belts to secure the ultrasound transducer and the tocotransducer. However, auscultation does not provide a printed record of the FHR for other medical professionals to see, nor does it provide an assessment of variability or other subtle changes in FHR.

Electronic Fetal Monitoring

Electronic fetal monitoring (EFM) is an auditory and visual monitoring method and provides a paper strip printout of

Box 25-3 Nonstress Test

1. Place the fetal monitoring device on the client.
2. A **reactive nonstress test** is:
2 accelerations of the fetal heart rate that are at least 15 beats above the baseline and last 15 seconds or more within 10 min.
3. If unable to obtain a reactive nonstress test within 30 min:
Change the client's position.
Administer oral or intravenous fluid.
Use acoustic stimulation.
4. Continue to monitor for 30 more minutes.
5. If the fetal heart rate is not reactive after this time, inform primary care giver.

FHR and variability, as well as a record of contraction frequency and duration (Figure 25-4, Box 25-4). EFM is used more frequently than is any other method; research has shown that EFM has increased the rate of surgical intervention and decreased perinatal mortality owing to fetal hypoxia (Vintzileos et al., 1995). Using EFM, the FHR can be assessed externally, or internally after the membranes have ruptured.

In external electronic monitoring, the quality of the FHR strip depends on correct placement of the transducer

Critical Thinking

Fetal Monitoring Interpretation

Intrapartum nurses are legally responsible for interpreting the fetal heart rate (FHR) pattern and initiating appropriate nursing interventions. Timely notification of the primary caregiver in the event of a nonreassuring FHR pattern and documentation of all interventions and subsequent outcomes are nursing responsibilities. Should a difference of opinion arise between the intrapartum nurse and the physician or nurse-midwife regarding the appropriate intervention, the intrapartum nurse is responsible for initiating the institutional chain of command (AWHONN, 1998).

As a labor and delivery nurse, you have a client who has what you consider to be an ominous FHR pattern. You voice your concern to the physician several times, with no response. What is your duty as a nurse to provide for the safety of your client and her infant?

Figure 25-4 External fetal heart rate monitoring. A. Ultrasound transducer in place over the fetal heart. B. Tocotransducer in place over the uterine fundus.

Box 25-4 General Approach to External Fetal Monitoring

1. Explain the procedure to the client.
2. Place the client in a position in which she feels comfortable and that is a semi-Fowler's, side-lying, or semi-recumbent position, with one hip tilted to the side.
3. Perform Leopold's maneuver to ascertain the position of the fetal back.
4. Apply water-soluble gel to the underside of the transducer for conduction of the fetal heart sounds.
5. Place the Doppler transducer on the maternal abdomen over the location of the fetal back (Figure 25-5).
6. Check that the fetal heart rate (FHR) appears on the monitor screen.
7. Check that the paper strip of the FHR monitor is being printed and that the correct time appears on the strip.

Figure 25-5 Lateral view of correct placement of Doppler and the tocotransducer on the maternal abdomen.

8. Mark the FHR monitor strip with the following information: client's name and medical record number, name of the physician or nurse-midwife, date, time, diagnosis, estimated date of delivery, and weeks of gestation.

(sometimes called a *Doppler*) on the maternal abdomen and the position of the fetus. The ultrasound waves strike the fetal heart, detecting the opening and closing of the valves, and direct a signal back to the transducer (ACOG, July 1995). The FHR can be observed from the bedside monitor or from a centrally located screen. Internal EFM requires a fetal scalp electrode (FSE) that attaches to the fetal scalp after rupture of the membranes (Figure 25-6).

The method and frequency of FHR and contraction monitoring depend on the stage of labor, maternal and fetal risk factors, and the client's preference. The nonstress test is the first line of antepartum fetal assessment (Salamalekis et al., 1997). Parameters for normal and abnormal FHR baseline in the term fetus are shown in Table 25-2 (Cunningham, 1997).

Electronic fetal monitoring gives data that are slightly more objective than does intermittent auscultation, and EFM provides a continuous graphical printout of rate pat-

Table 25-2 Classification of Fetal Heart Rates

Normal range	110–160 beats per minute (bpm)	
Tachycardia	Mild	161–180 bpm
	Severe	>180 bpm
Bradycardia	Mild	100–110 bpm
	Moderate	80–100 bpm
	Severe	<80 bpm

terns and periodic changes. If the FHR is to be monitored electronically, a 20-minute strip should be obtained on admission for evaluation.

Labor Status

The client's labor status should be assessed in terms of uterine activity, fetal membrane status, cervical status, and fetal descent.

Uterine Activity

In addition to asking the client when her contractions began and whether they are getting stronger, the nurse can evaluate the intensity of contractions by palpating the fundus. Uterine activity is assessed to identify frequency, duration, and intensity of contractions. Uterine resting tone also is evaluated. The presence of uterine irritability or strong and prolonged contractions, that is **hypertonic contractions**, is noted. Assessment of uterine contractions by palpation requires no special equipment but, rather, nursing skill and touch sensitivity. The nurse rests the palmar surface of the hand and fingertips on the fundus, where contractions start, and notes the changing firmness of the uterus as the contraction increases in intensity and then recedes. The firmness of the uterus at the **acme**, or peak, of the contraction is used to determine the intensity, which can be described as mild, moderate, or strong (Figure 25-7).

During mild contractions, the fundus can be indented easily by the fingertips. During moderate contractions, the fundus indents less easily and feels more rigid. During strong contractions, the fundus is firm and resists indenting by the slightly spread fingertips.

The **resting tone**, that is, the firmness of the uterus between contractions, should be soft. The **frequency** of contractions is measured from the beginning of one to the beginning of the next contraction. **Duration** of a contraction is the time from the beginning of a contraction until the end of the same contraction.

Electronically, contractions can be monitored by means of a tocotransducer, which is a pressure-sensing

A.

B.

Figure 25-6 A. Fetal scalp electrode. B. Placement of a fetal scalp electrode for fetal heart rate monitoring.

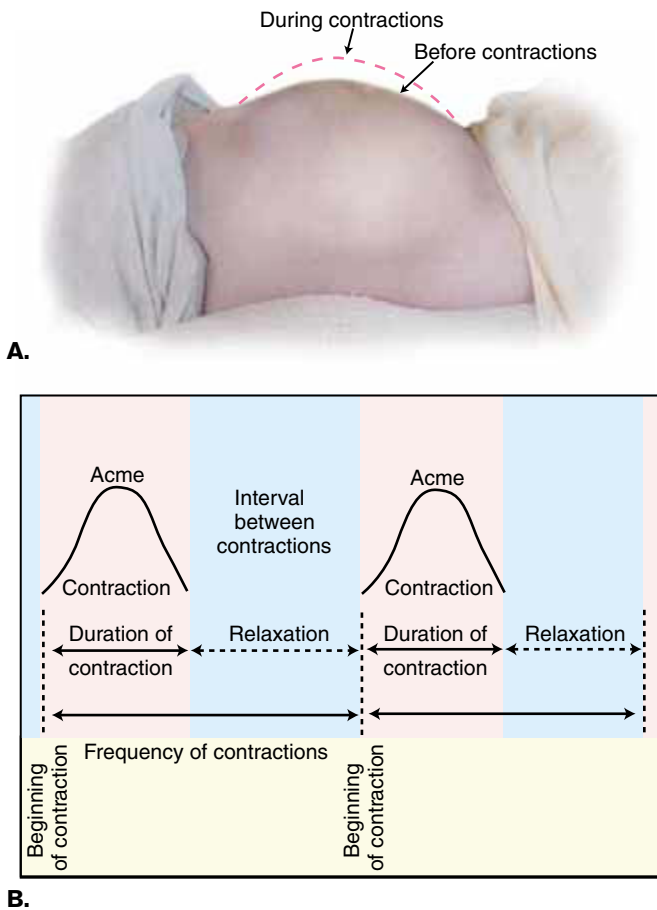

Figure 25-7 A. Abdominal contour before and during a uterine contraction. B. Wavelike pattern of contractions on the fetal heart rate strip.

device placed on the fundus. The tocotransducer detects changes in the shape of the abdominal wall directly above the fundus as each contraction occurs. This noninvasive method gives the nurse information about the frequency and duration of the contractions but not the intensity. Because many women feel contraction pain in the lower back, or in the lower abdomen, they might question why the toco is placed over the fundus instead of where the pain is felt. The nurse should explain that contractions begin at the fundus even though the woman may not experience pain in that particular area.

Accurate information concerning the intensity of contractions only can be obtained internally by means of the **intrauterine pressure catheter (IUPC)**. The IUPC is a fluid-filled catheter that is inserted directly into the uterine cavity through the cervix after the membranes have ruptured (Figure 25-8). In addition to the frequency and duration of contractions, the IUPC records contraction intensity by measuring the pressure of the amniotic fluid inside the uterus in millimeters of mercury (mm Hg). Occasions that might necessitate the use of an IUPC include induction of labor, vaginal birth after cesarean section, and in the very

Figure 25-8 Placement of the intrauterine pressure catheter (IUPC) and fetal scalp electrode (FSE).

obese client for whom attempts at external monitoring have been unsuccessful.

Fetal Membrane Status

By the end of pregnancy the uterus contains about 1 L of amniotic fluid (Cunningham, 1997). In abnormal conditions the amount of fluid within the amniotic sac may vary from a few milliliters to several liters. The presence of more than 2 L of amniotic fluid is called **polyhydramnios** and less than 300 mL of fluid is referred to as **oligohydramnios** (Cunningham, 1997). Normal amniotic fluid is colorless and clear, and contains particles of vernix. The odor is characteristic (not foul). As the nurse observes the perineum during physical examination, there may be pooling of amniotic fluid. It is important to establish the time of membrane rupture because a delay of 24 hours or more between membrane rupture and birth, greatly increases the risk for intrauterine infection (Cunningham, 1997). Rupture of membranes may be confirmed by performing a **nitrazine test**, in which a dye-impregnated paper is dipped into a pool of suspected amniotic fluid or is touched to a cotton-tipped applicator soaked with vaginal secretions (Box 25-5). The color of the nitrazine paper is then compared with a color chart showing varying degrees of blue and the corresponding pH number (Table 25-3). Nitrazine paper that turns dark blue (pH of 6.5) on contact with the alkaline amniotic fluid is consistent with ruptured membranes (Cunningham, 1997).

If a Nitrazine test is not definitive and doubt still exists as to membrane status, a **fern test** may be done (Box 25-6).

The nitrazine test and the fern test may be done in conjunction with a vaginal examination. Most women will go into labor spontaneously within a few hours after membranes rupture. **Premature rupture of membranes (PROM)** is the term used to describe rupture of membranes before labor begins. **Preterm premature rupture of membranes (PPROM)** describes rupture of membranes in a preterm pregnancy (less than 38 weeks gesta-

Box 25-5 Procedure for Nitrazine Test for Presence of Amniotic Fluid

1. Explain the procedure to the woman and her partner.
2. Wash your hands, and put on sterile gloves. Do not use lubricating jelly.
3. Use a sterile cotton-tipped applicator to obtain fluid from the vagina. Touch the applicator to the test paper. Alternatively, a strip of nitrazine paper may be touched to the perineum when there is profuse drainage of clear fluid.
4. Compare the color of the nitrazine paper to the color chart.
5. Discard the gloves, and wash your hands.
6. Explain your findings and their implications to the client.
7. Document the numerical result.

tion) in the absence of contractions. Abnormal findings after rupture of membranes include meconium staining, foul odor, and dark-red fluid.

Meconium, when present in the amniotic fluid in a cephalic presentation, often is an indication that the fetus has experienced an episode of hypoxia. Meconium turns the amniotic fluid to yellow or greenish-brown, depending on the amount of meconium present in the fluid. Meconium staining in the presence of a reassuring FHR pattern may indicate that the fetus is not currently in distress. Oligohydramnios, decreased amniotic fluid, reduces the cushioning effect of the fluid. As a result, the cord is more likely to become compressed. Cord compression, and consequent shutting off of the blood flow to and from the fetus, will result in a variable FHR deceleration.

The longer the fetal membranes have been ruptured, the greater the risk of **chorioamnionitis**, which is infection of the fetal membranes.

After taking the medical history, performing FHR monitoring, and assessing the labor status, a vaginal examina-

Table 25-3 Findings on Nitrazine Paper

Color	pH	Membranes
Yellow to olive green	5.0–6.0	Probably intact
Blue-green to deep blue	6.5–7.0	Probably ruptured

The pH values of blood, vaginal mucus, and secretions from some vaginal infections also are alkaline. Be aware of the possibility of false readings.

**MECONIUM STAINING**

Presence of meconium in the amniotic fluid can be the result of vagal stimulation from transient umbilical cord compression or can be caused by fetal hypoxia. Fresh meconium staining in the presence of a nonreassuring fetal heart rate (FHR) pattern, such as severe variables or late FHR decelerations, is an ominous sign. The primary care provider should be notified immediately and requested to come to evaluate the client.

tion is performed to ascertain whether there has been cervical dilation, that is, whether the woman is in true labor.

Cervical Status and Fetal Descent

Vaginal examination is performed to determine the degree of cervical effacement and dilation, the fetal presenting part, and station. **Effacement** refers to the taking up of the cervical canal so that the cervix changes from a long thick structure to a paper-thin layer (Cunningham, 1997); effacement is reported as a percentage.

Dilation is the term used to describe the widening of the external os of the uterine cervix from closed to a maximum of 10 cm, at which time the cervix is said to be fully

Box 25-6 Procedure for Fern Test for Presence of Amniotic Fluid

1. Explain the procedure to the woman and her partner.
2. Wash your hands, and put on sterile gloves.
3. Use a sterile cotton-tipped applicator to obtain fluid from the vagina (usually done during a sterile speculum examination).
4. Draw the fluid-soaked applicator over a glass slide, and allow it to dry.
5. Examine the glass slide under a microscope and observe for the presence of a frondlike pattern, which indicates amniotic fluid.
6. Discard the gloves, and wash your hands.
7. Explain your findings and their implications to the client.
8. Document the result, that is, a positive or negative fern test.

MECONIUM STAINING: BREECH PRESENTATION

In a breech presentation, meconium frequently is passed because the fetal abdomen and buttocks are under pressure. This does not necessarily mean that the fetus is in distress.

dilated (Cunningham, 1997). The **presenting part** is the body part of the fetus that is first to enter the birth canal. The most common presentation is cephalic vertex (Cunningham, 1997). **Vertex** refers to the crown of the infant's head, that is, the portion of the fetal head that is born first when the head is well flexed (Cunningham, 1997).

Station refers to the relationship of the presenting part to an imaginary line drawn between the ischial spines of the maternal pelvis (Figure 25-9), which is the narrowest diameter of the pelvis and designated as zero (0) station (Cunningham, 1997). The long axis between the pelvic inlet and the ischial spines can be divided into thirds, as described by Cunningham (1997), and labeled -3, -2, -1 accordingly; the axis between the ischial spines and the perineal outlet similarly can be divided into thirds and labeled +1, +2, and +3. When the presenting part can be seen at the woman's perineum it is said to be at +3 station.

Abdominal palpation for fetal lie and position (see Leopold's maneuvers, Chapter 23), together with a check of fetal heart tones should precede the initial vaginal examination. Situations such as PROM or preterm labor contraindicate a digital vaginal examination, unless birth appears imminent, because of the infection risk. Vaginal examination should never be done by the nurse if the woman has experienced bleeding during the last trimester of pregnancy or if placenta previa is known or suspected.

EFFACEMENT

Effacement is a measurement of cervical thickness and is measured in percentages. The uneffaced cervix is about 1-in thick (0% effaced). A cervix that is 2-in thick is 50% effaced.

Figure 25-9 Stations of the presenting part. A. Front view. B. Lateral view.

Vaginal examination of a woman with placenta previa might cause severe bleeding.

Before vaginal examination the woman should empty her bladder; a full bladder will add to her discomfort. Vaginal examination can begin between contractions but should be continued throughout a contraction for a more accurate assessment. Examination during a contraction gives a much better picture of the fullest extent of dilation, effacement, and descent. Vaginal examination is an uncomfortable and stressful procedure for the woman. Efforts should be made to reduce stress by first giving a full explanation of the procedure and the information to be obtained from it in terms the woman can understand (Box 25-7). An informed woman is more likely to cooperate throughout

Box 25-7 Performing a Vaginal Examination on a Woman in Labor

1. Explain the procedure to the client in terms she can understand. Ensure privacy.
2. Position the client on the examination bed, semi-recumbent, with knees bent and legs apart and draped.
3. Wash your hands, and apply sterile gloves.
4. Apply sterile lubricating jelly to the index and second finger of the examining hand.
5. Inspect the general area of the introitus for presence and amount of bloody show, presence and color of amniotic fluid, malodorous discharge, and presence of blisters or ulcerated areas on the labia.
6. With the hand turned sideways and the thumb pointing upward, insert the first and second fingers of the examining hand gently into the vagina, keeping the fourth and fifth fingers bent inward to the palm of the hand. Insert the fingers the length of the vagina.

Membranes

7. Palpate for a soft, bulging membrane sac through the dilating cervix. Observe for running fluid during the examination, which would indicate that the membranes have ruptured.

Effacement

8. Palpate the thickness of the cervix and estimate the degree (0 to 100%) of thinning.

Dilation

9. Dilation of the cervix is measured in centimeters. One fingerbreadth is approximately 1.5 to 2 cm in width, although this measurement will vary among practitioners. Full cervical dilation is 10 cm in diameter.
10. Palpate for the presenting part.

Station

11. Determine the station by locating the lowest portion of the presenting part, then sweeping the fingers to one side of the pelvis to feel for the ischial spines.
12. Remove the fingers, and discard the gloves.
13. Wash your hands.

Nursing Alert

VAGINAL BLEEDING

If a client presents with bright-red vaginal bleeding, particularly if it is painless, you should suspect **placenta previa**, that is, implantation of the placenta near or over the cervical os.

1. Do *not* perform sterile vaginal examination.
2. Notify the primary care provider immediately.
3. Anticipate ultrasonography to rule out placenta previa.
4. Institute continuous electronic fetal monitoring.

the examination. Privacy must be maintained and modesty respected by closing the door or screening the room or triage area and asking the client whether she would like any family members present to step into the waiting room for a few minutes. Vaginal examination should be performed without delay if the woman complains of a desire to bear down or a perception of perineal pressure (Figure 25-10).

The woman is asked to lie down on the hospital bed, with legs bent and apart. Her legs are draped to avoid unnecessary exposure. If the woman knows a relaxation technique, such as slow deep breathing, she should be asked to use it and to try to relax. If it is not certain whether the membranes have ruptured, sterile lubricating jelly is not used because it can sometimes give a false-positive result on a nitrazine test. There may be sufficient vaginal mucus or bloody show to prevent dryness, or

Figure 25-10 Vaginal examination to determine effacement, dilation, and fetal descent.

HERPES SIMPLEX VIRUS

When no lesions are visible at the onset of labor, vaginal delivery is acceptable. When primary or recurrent lesions are visible near the time of labor or when the membranes are ruptured or when there are prodromal symptoms of a recurrence (i.e., if the woman complains of herpeslike discomfort), cesarean delivery is performed (Roberts et al., 1995).

sterile water can be used instead of lubricating jelly. Presence of a large amount of bloody show indicates that labor is advanced. If raised vesicles or blisters are noted, the nurse should suspect active herpes viral infection. In the presence of active herpes infection, the examination is stopped and the primary care provider notified. Infants infected with the herpes virus during vaginal birth experience high morbidity (Kohl, 1997). Therefore, cesarean section is performed on all women who have herpes lesions at the time of delivery.

Findings of the examination are communicated to the woman and related to her progress in labor. Information about the labor status may be reassuring to the woman and her partner.

Determine the onset of **true labor** (i.e., regular, strong contractions accompanied by cervical change). When doubt exists as to whether the woman is in labor, she may be advised to ambulate for several hours, taking frequent rest periods. Walking often helps to establish a good contraction pattern. The woman should be instructed to return to her room for FHR monitoring at 30- to 40-minute intervals, or to return immediately if any of the following occur:

- Membranes rupture.
- Contractions become more frequent than 5-minutes apart.
- Bloody show increases.
- Nausea or vomiting occurs.
- An urge to push is felt.
- She requires analgesia or finds walking too tiring.

General Systems Assessment

The physical examination of the laboring woman is not as extensive as is that performed at the first prenatal visit. The initial assessment is carried out immediately to identify potential problems. Findings of the initial examination will provide a baseline for evaluation and comparison with future clinical findings. The general appearance of the woman is noted, particularly presence of edema in the face, hands, and feet as well as skin color, speech, manner, mood, state of awareness, gait, and personal hygiene. Initial information usually is recorded in the Admission Record; many facilities now have computer systems into which client information is entered directly from the bedside.

Vital Signs

Temperature, pulse, respirations, and blood pressure are assessed on admission and recorded in the Admission Record and nursing flowchart. Frequency of monitoring will depend on the risk status of the maternal-fetal dyad. Infection or dehydration will cause the client's body temperature to increase. The normal range is 97.4°F to 99.6°F, orally or tympanically. Normal heart rate range is 60 to 90 beats per minute (bpm). When auscultating the heart, the nurse will note that the point of maximal impulse is slightly more to the left than usual owing to displacement of the heart by the enlarged uterus. Increased heart rate may be due to excitement, anxiety, or contraction pain. Other possible causes of increased heart rate are cardiac problems or dehydration. Carefully taking the medical history should reveal preexisting medical problems. Dehydration should be considered as a possible reason for a rapid heart rate, in the absence of other causes, and the primary caregiver may require the administration of a 500-mL bolus of intravenous (IV) lactated Ringer's solution. The respiration rate will vary considerably, depending largely on the amount of pain being experienced. Counting of respirations should be done between contractions when the woman is not practicing a breathing technique.

Blood pressure is taken with the woman in a side-lying position, using the uppermost arm; the findings are

STATION

Imagine a horizontal line from one ischial spine to the other. This line represents 0 station. Estimate how far (in centimeters) the tip of the presenting part is above or below the ischial spine. If the station is judged to be beyond 0, the pelvis probably is adequate for vaginal delivery.

Figure 25-11 Vena caval compression (A) can be avoided by upright positioning (B) or by tilting to the side while lying supine (C).

compared with those on the prenatal record. A measurement showing an elevated systolic but normal diastolic blood pressure may indicate anxiety and should be repeated after the woman has had time to relax. To prevent supine hypotension and fetal distress caused by vena caval compression by the heavy uterus, the woman should be encouraged to lie on her side, or on her back with the uterus tilted to one side (Figure 25-11).

Abdomen

Inspect the abdomen for **striae gravidarum**, which are shiny, reddish lines that appear as a result of stretching of the skin and underlying tissue. An abnormal shape of the abdomen should alert the nurse to a possible transverse lie, which would require cesarean delivery. Transverse fetal lie can be identified using Leopold's maneuvers. Previous abdominal surgery will have been noted when the

PRESENTING PART

If you feel:

- The hard skull with the sagittal suture, it is a cephalic presentation.
- The softer buttock, it is a breech presentation.
- Irregular parts such as facial features, it is a face presentation.

HYPERTENSION

Compare blood pressure readings with those on the prenatal record. The client has hypertension if any of the following is noted:

- Blood pressure value of 140/90 mm Hg or higher.
- A systolic increase of 30 mm Hg or higher.
- A diastolic increase of 15 mm Hg or higher.

medical history was taken, and scarring may be evident. The history of the uterine incision must be obtained. If the uterine scar is classical (not low cervical), the primary care provider should be notified immediately. If a classical incisional scar is seen on the abdomen of a woman in active labor, the primary care provider should be notified immediately because a repeat cesarean delivery will be required and the woman therefore should not be left to labor. Although uterine rupture occurs in only 1 of every 2,000 deliveries (ACOG, 1998), it is more of a risk for women who have had a previous transfundal cesarean delivery and can be catastrophic for both mother and fetus.

Bladder

Gently palpate above the symphysis pubis to determine bladder fullness or suprapubic tenderness. Urinary frequency is common in late pregnancy; however, when the woman also complains of burning on urination, the nurse should suspect urinary infection. The nurse should send a catheter specimen or a clean-catch urine specimen for laboratory analysis.

Lower Extremities

Inspect the legs for varicosities and palpate with both hands for tenderness or areas of particular warmth, which might indicate thrombophlebitis. Other frequent physical findings in deep venous thrombosis are swelling, redness, and a positive Homan's sign (ACOG, March 1997).

Edema

Many women experience some dependent edema of the feet during late pregnancy from constriction of blood vessels by the pressure of the pregnant uterus (Box 25-8). Dependent edema usually is less evident when the woman is in bed. Pretibial edema, however, is an abnormal finding as are edema of the hands and edema around the eyes (periorbital edema), and is one of the signs of PIH. Findings of more than 2+ edema or periorbital edema should be reported to the primary care giver along with blood pressure readings and results of dipstick analysis of urine for albumin. The three cardinal signs of PIH are edema, hypertension, and albuminuria.

Deep Tendon Reflexes

Deep tendon reflexes (DTRs) are assessed by supporting the knee in a slightly flexed and quite relaxed position. The patellar tendon is briskly tapped just below the knee cap; responses are graded as per Table 25-4.

Clonus

When the DTR is 3+ or greater (hyperactive), the nurse should be alert to the possibility of clonus, which is associated with preeclampsia. To test for clonus, the knee is supported in a partially flexed position while the nurse applies sharp dorsiflexion to the foot (Figure 25-12). As the foot is maintained in dorsiflexion it will oscillate rhythmically if clonus is present. An abnormal (positive clonus) is recorded as two or more "beats" clonus and indicates irritability of the central nervous system (CNS). The woman should be questioned about other possible indicators of

POSITIONING

Ask the client to assume a side-tilt or side-lying position. These positions allow the heavy uterus to be displaced off the ascending vena cava and descending aorta, thus preventing a decrease in cardiac output that may lead to a decrease in maternal blood pressure and subsequent fetal bradycardia.

Box 25-8 Procedure for Assessing Edema

Press firmly with the thumb for about 5 seconds over the pretibial area on both legs. Pretibial edema is assessed as follows:

- 1+ Small suggestion of fullness is felt.
- 2+ Sense of fullness.
- 3+ Blanching of the skin and depression seen as the thumb presses down.
- 4+ Indentation made by the pressure of the thumb remains for several seconds and gradually recedes.

Table 25-4 Quantifying Deep Tendon Reflexes

Response	Grading
More than normal (brisk)	3+
Normal	2+
Low or sluggish	1+
No response	0

preeclampsia such as nausea, dizziness, visual disturbances such as “halos” around the lights, epigastric pain, and headache.

Setting Priorities and Making Decisions

Care is prioritized and based on information obtained from the initial prenatal record, physical assessment, and med-

Nursing Alert

C-SECTION INCISIONS

In assessing a woman with a history of C-section, the nurse needs to differentiate between the incision on the skin and the second incision on the uterus. The uterine incision is the determinate for repeat C-sections.

Nursing Alert

HOMAN’S SIGN

Apply dorsiflexion to the client’s foot, and ask her whether this action causes calf pain. Calf pain on dorsiflexion of the foot is a positive Homan’s sign and must be investigated further for deep vein thrombosis.

ical history. Care includes early identification and communication of conditions that might place the client in a high-risk category, educational needs, and discharge needs. A system of care is planned for the achievement of goals that are acceptable to both the client and nurse. A critical pathway of care that might be used is shown in Box 25-9. As labor progresses the plan of care is modified according to the ongoing maternal and fetal assessments as well as labor progress. Those women with critical care or high-risk conditions, or who are likely to give birth to an infant requiring neonatal intensive care, may require consultation with or transportation to a medical center with a neonatal intensive care unit.

Box 25-9 Critical Pathway for a Client During Low-Risk Labor Assessment

Monitor fetal heart rate and contractions as per protocol: Continuous ____ Intermittent ____
 Sterile vaginal examination.
 Blood pressure and pulse every hour.
 Temperature every 4 h; every hour after rupture of membranes. (RDM)
 Laboratory tests: Typing, Rh status, complete blood count (CBC), rapid plasma reagin (RPR), hepatitis B surface antigen (HbsAg) (unless on prenatal record); HIV test is offered.
 Input and output.
 Cord gases: Yes ____ No ____
 Cord blood sent to laboratory if Rh-negative or blood group type O.
 Placenta sent to laboratory: Yes ____ No ____
 Consent form signed.

Interventions

Soapsuds enema as required.
 Oxygen per non-rebreather face mask at 8–10 L/min as required.
 Straight catheter as required if unable to void. If receiving epidural, may insert Foley catheter as required.
 Perineal preparation and stirrups at delivery.

Nutrition

Sips of water and ice chips.
 Intravenous hydration: Lactated Ringer's solution of 1 L at 125 mL/h and as required afterward.

Activity

May ambulate: Yes ____ No ____
 Bathroom privileges (BRP): Yes ____ No ____

Consultation

Notify pediatrician.
 Notify anesthesiologist or Certified Registered Nurse Anesthetist as required.
 Notify neonatologist as required.

Maternal-Family Support and Interactions

A woman is more likely to have positive memories of her childbirth experience when she receives kind sensitive care. Her partner, a significant family member, or friend

Nursing Alert

EPIGASTRIC PAIN

The presence of epigastric or right upper quadrant pain is a serious finding of possible severe preeclampsia. The pain is secondary to obstructed hepatic blood flow caused by fibrin deposits (Queenan & Hobbins, 1996) and the primary caregiver should be called immediately to assess the woman.

should be encouraged to stay at the bedside and support the woman in labor. The support person also will need attention and should be provided with a comfortable chair and offered opportunities to take meal breaks. The nurse can show the family member how to provide comfort to the woman and should include the support person in discussions about the plan of care. Family interaction and the support system are evaluated as labor progresses, always taking cultural beliefs into consideration. When the woman does not have a support person with her, the nurse becomes the support person.

Many women attend childbirth preparation classes and develop expectations in the form of an individualized birth plan. When presented with a birth plan the nurse should consider the safety of the plan, importance of the plan to the client, and feasibility of incorporating some or all of the woman's wishes into the nursing process. It is important for the nurse to be respectful and flexible.

Psychological Considerations During the Latent Phase of Labor

The woman who comes to the hospital in the latent phase of labor often is mildly anxious both about her well-being and that of the baby, and also about how she will react to

Critical Thinking

Prioritize!

A client is rushed to labor and delivery in a wheelchair. She says she feels like pushing.

What would be your initial response?

How would you set your priorities?

the pain of contractions. The hospital is an unfamiliar environment, and the nurse is a stranger to her. The nursing interview and interventions must be performed in a competent and respectful manner that promotes trust and facilitates relaxation. One of the most important nurse behaviors, as perceived by the patient, is that the nursing staff know what they are doing (Manogin, Bechtel, & Rami, 2000). The approach of the nurse should be accepting and supportive of the woman as an individual. Cultural practices related to childbirth also need to be considered.

To provide appropriate teaching to the client, the nurse must first evaluate the amount of preparation for childbirth she has had. Other factors to consider are the stage of labor, maturity of the client previous experience of childbirth, and educational level. During the initial orientation to the labor and delivery or triage room and the primary assessment, the nurse can make inquiries as to any childbirth classes the woman may have attended or books she has read. This also is a good time to ask whether the woman has specific concerns that may be causing anxiety. Family members also should be included in any teaching. Client teaching is an ongoing process, and it is important for the nurse to explain what is happening to the woman during each stage of labor. Examination findings also should be fully explained; some labor rooms have a chart depicting cervical dilation to which the nurse might refer.

The client participates in the plan of care. The rationale for recommended interventions, as well as risks, should be explained fully. Frequent reinforcement usually is necessary. Teaching includes an explanation of the purpose of equipment that is likely to be used, such as the electronic fetal monitor, the correct method of timing contractions, and activity that will be helpful to the woman. Many primary caregivers may allow the woman to have sips of water and ice chips during normal labor. Some women prefer to ambulate during the early phase of labor, returning to the labor and delivery room for intermittent FHR monitoring. The woman and her support person should be shown the correct method of timing contractions.

Explanations are given about the current stage of labor and available options for pain management, when and how they can be administered, and the effect they are likely to have. Although the woman may have received previous instruction about breathing and relaxation techniques, these may need to be reviewed and reinforced. Teaching and the client's response should be recorded in the flowchart.

Documentation and Communication

Admission data are documented in the medical chart and nursing flowchart and communicated to the appropriate

health care team members such as the physician or nurse-midwife, social worker, pediatrician, or neonatologist. Charting of all interventions, medications, and clinical findings is done according to the accepted procedure of the facility and may involve flowcharts or computer-generated charting.

Laboratory Tests

After the initial assessment of the client, the nurse should anticipate the need for laboratory tests according to the hospital protocol.

Urine Specimen Analysis

Urinalysis can be done by the nurse, using a dipstick, to examine for the presence of protein, glucose, blood, and ketones. Urinalysis can be done using a voided specimen, as free as possible from debris. Urinalysis can alert the nurse to possible complications such as PIH (albuminuria), diabetes mellitus (glucose), or inadequate nutrition (ketones). Laboratory urinalysis can provide additional information about hydration status (specific gravity) and infection (presence of leukocytes).

Blood Tests

Blood tests vary with the hospital protocol and risk factors. Information that usually can be obtained from the prenatal record includes results of tests for the following: blood type, Rh factor, atypical antibodies, rubella, syphilis (rapid plasma reagin [RPR], or VDRL test), hepatitis B, glucose levels, and HIV.

Although sufficient information may be available from prenatal records, on hospital admission the hematocrit and hemoglobin levels should be rechecked and an RPR test performed. Many hospitals require a complete blood cell count (CBC), and confirmation of blood type and Rh factor. Blood may be saved in the laboratory for use in cross-matching should the client require a blood transfusion. A screening test for HIV is offered. The role of the nurse is to explain the purpose of drawing blood and often to draw blood and order the tests according to the hospital protocol. Only when all examinations, including laboratory review, are completed can a decision be reached about the normalcy of the pregnancy.

NURSING RESPONSIBILITIES DURING LABOR

Labor progresses through four stages, as outlined in Box 25-10. Nursing responsibilities to the laboring woman and family are tied to the stage of labor and the woman's changing needs.

Box 25-10 Stages and Phases of Labor

First Stage (0–10 cm dilated)

Latent phase: 0–3 cm; contractions are mild every 15–30 min and last for 30 s

Active phase: 4–7 cm; contractions are moderate every 3–5 min and last for 40 s

Transition phase: 8–10 cm; contractions are strong every 2–3 min and last for 60 s

Second Stage (10 cm dilated to birth)

Contractions: Every 2–3 min

Duration of contractions: 60–90 s

Duration of second stage: 5 min–2 h

Third Stage (birth to delivery of placenta)

Duration: 5–45 min

Fourth Stage (recovery)

Duration: 1–4 h

First Stage

The **first stage of labor** begins with the initiation of regular contractions that produce cervical dilation and continues through complete dilation. The first stage is the longest one and is composed of three phases. The latent phase is followed by the active phase and then the transition phase. Nursing assessment of the mother and fetus is ongoing.

Maternal Assessment

Assessment of the woman in the first stage of labor includes evaluation of vital signs, hydration status, and elimination.

Vital Signs

Vital signs of the mother include blood pressure, temperature, pulse, and respiration. Frequency of assessment is determined by the stage of labor and risk status of the maternal-fetal dyad. Monitoring will be more frequent in high-risk situations. Vital signs are monitored between contractions and recorded on the FHR strip and the nursing flowchart.

Blood Pressure is measured between contractions every hour during active labor, if normal. During a uterine contraction approximately 500 mL of blood is shunted into the central circulation, elevating the maternal blood pressure. The normal range of blood pressure is 100 to 120 mm Hg systolic and 60 to 80 mm Hg diastolic. An increase of 30

mm Hg systolic and 15 mm Hg diastolic above the prepregnancy blood pressure level may be indicative of PIH (Cunningham, 1997). Hypertension is defined as a sustained blood pressure of 140 mm Hg systolic or 90 mm Hg diastolic, and the risk of developing PIH is increased in women with preexisting chronic hypertension (ACOG, 1996).

Temperature is an important indicator of hydration and infection and may be slightly elevated throughout labor. Temperature is taken on admission and every 4 hours until the membranes rupture, after which it is recorded every 2 hours. Once the fetal membranes are ruptured, there is an increased risk of ascending infection. For this reason all invasive procedures, such as vaginal examinations, are kept to a minimum. If the membranes are ruptured an elevated temperature could indicate chorioamnionitis, particularly if they have been ruptured for more than 12 hours. A increasing temperature should be reported to the primary caregiver. Foul odor of the amniotic fluid is a late sign of chorioamnionitis.

Meconium may support bacterial growth. For this reason, there is also a potential for chorioamnionitis when there is meconium staining.

Heart rate and respirations vary according to maternal exertion during labor, hydration, infection, and anxiety level. Respirations also are affected by the level of pain and breathing techniques used to cope with labor. **Hyperventilation**, a change in the oxygen-carbon dioxide exchange, is a consequence of breathing too rapidly and too deeply. If the woman complains of tingling sensations in the palms of her hands, she may be hyperventilating and should be urged to slow her breathing. This condition also can be corrected by having the woman rebreathe her exhaled air by breathing into a paper bag.

Hydration and Nutrition

Gastric emptying time is prolonged during active labor, so that ingested food remains in the stomach and may be vomited. Oral fluids usually are well tolerated throughout labor but should be limited to ice chips or sips of water or clear fluids, as tolerated. The various breathing techniques used by laboring women to cope with painful contractions usually result in a dry mouth and craving for sips of water or ice chips.

The woman is asked when she last had something to eat or drink, and the times are noted in the medical record. When general anesthesia is a possibility, the woman receives nothing by mouth to prevent vomiting. Aspiration of acidic gastric contents into the lungs is life-threatening to the woman and fetus. When the primary caregiver requires the woman to be NPO, the nurse provides mouthwashes and applies petroleum jelly to the lips to alleviate dryness.

Intravenous fluids provide calories and prevent dehydration in the laboring woman. Many facilities, particularly

in physician-assisted deliveries, require IV hydration as part of the routine protocol for the laboring woman. Starting an IV may be delayed for the woman in early labor who is ambulating. For hydration, an 18-gauge or 20-gauge cannula is inserted into a vein of the hand or forearm and connected to tubing attached to a 1-L bag of lactated Ringer's solution or dextrose 5% lactated Ringer's solution infusing at 125 mL/h. This constitutes the main IV line and facilitates administration of analgesics or other appropriate medications into one of the access ports. Antibiotics, oxytocics, or tocolytics can be diluted and inserted by piggyback into the main line. An accurate record of fluid intake and output should be maintained.

Elimination

Voiding every 2 hours is encouraged because a full bladder can impede descent of the presenting part. The nurse should palpate the suprapubic region to detect a distended bladder. When the bladder is readily palpated and the woman is unable to void, catheterization is indicated. If the woman wishes to get up to walk to the bathroom the nurse should assist her in doing so by lowering the bed, unplugging the FHR monitoring cables, and moving the IV pole. Urinary output is measured and dipstick testing for glucose, albumin, and ketones performed every shift. The woman who is receiving epidural anesthesia should not be permitted to get out of bed to walk to the bathroom because partial loss of muscle strength in the legs is common. A Foley catheter, attached to bedside drainage, frequently is inserted if the woman is receiving epidural anesthesia because urinary retention is a very frequent side effect of this regional anesthesia.

The use of enemas is infrequent but should be offered to the woman who is in early labor and has not had a recent bowel movement. As the fetal head descends, it exerts pressure on the lower bowel and any stool that is present will be expelled during the second stage of labor. Passage of fecal matter during the birth is embarrassing for the client and also increases the risk for infection. As the

fetal head descends, the woman will experience increased pressure in the rectal area.

Fetal Assessment

The FHR is assessed as per the hospital policy, taking into consideration the phase and stage of labor and maternal and fetal risk factors. Certain abbreviations are commonly used by labor and delivery personnel when documenting baseline, variability, and periodic changes in FHR (Box 25-11).

Baseline Fetal Heart Rate

In order to determine a **baseline fetal heart rate**, that is, the FHR between contractions and accelerations, the FHR must be observed *between* contractions. Because the FHR is an inherently irregular rate, accuracy will be improved by charting it as a *range*, for example, 130 to 140 bpm. The FHR baseline during the third trimester ranges from 110 to 160 bpm, and a FHR strip of at least 10-minutes' duration should be taken before a baseline is established (ACOG, July 1995).

Fetal Heart Rate Variability

Fetal heart rate **variability** (fluctuations in the FHR) has two components: **long-term variability** (the slow rhythmic fluctuations above and below an average baseline rate, producing a wavelike pattern) and **short-term (or beat-to-beat) variability**, which are instantaneous fluctuations in the FHR. The combination of these two types of variability reflects the interaction between parasympathetic (which slows the heart) and sympathetic (which accelerates the heart) branches of the CNS.

The criteria for long-term variability (LTV) does not include accelerations or decelerations. Evaluation of the LTV helps identify changes in the fetal behavioral state

ELIMINATION

If the woman in active labor expresses the need to have a bowel movement, the nurse should perform a vaginal examination to assess cervical dilation and station. Examination may reveal significant descent of the presenting part.

Box 25-11 Common Abbreviations in Fetal Monitoring

bpm	Beats per minute
EFM	Electronic fetal monitoring
FHR	Fetal heart rate
FSE	Fetal scalp electrode
UC	Uterine contraction
IUPC	Intrauterine pressure catheter
LTV	Long-term variability
STV	Short-term variability
TOCO	Tocodynamometer (external)
US	Ultrasonography

FETAL BRADYCARDIA OR MATERNAL HEART RATE?

Always make certain that the rate you are recording using the external fetal heart rate monitor is not the same rate as the woman's radial or apical pulse. When the fetus changes position, the transducer may start picking up the maternal heart rate.

and the response to labor. Absent LTV might also be described as a “flat” FHR. Marked LTV, or **saltatory pattern**, is a term that describes a baseline that is chaotic and jumps up and down multiple times each minute. The presence of two spontaneous accelerations of greater than 15 bpm for at least 15 seconds' duration in 20 minutes is a reassuring sign. When LTV is present, STV also is almost always present.

Short-term variability (STV) or beat-to-beat variability can only be realistically visualized with internal FHR monitoring and is documented as minimal, moderate, or marked. STV variability can be present in the absence of LTV.

CAUSES AND PHYSIOLOGY OF ABSENT LONG-TERM VARIABILITY

- Fetal quiescent state that may last 90 min.
- Medications, for example, central nervous system depressants.
- Hypoxia owing to placental insufficiency.
- Severe fetal anemia, for example, as a result of a fetal viral infection.
- Arrhythmia such as a supraventricular tachycardia or complete heart block.
- Fetal brain death or decerebration.
- Congenital brain anomaly, for example, anencephaly or a heart anomaly or conduction defect.
- Late sign of deterioration of the fetus having intrauterine growth retardation.
- Terminal bradycardia (low baseline and absent LTV, not related to an arrhythmia, suggesting impending intrauterine death).

Periodic and Nonperiodic Fetal Heart Rate Changes

Periodic fetal heart rate changes are transient changes in FHR in association with contractions (Cunningham, 1997). **Nonperiodic fetal heart rate changes** are transient changes in FHR not associated with contractions, although they can occur during contractions. Specific classifications are defined by ACOG (1995) as follows:

1. **Acceleration:** An increase in FHR above the baseline level, with a return to baseline within 10 minutes. An increase in FHR lasting longer than 10 minutes is classified as an increase in FHR baseline.
2. **Deceleration:** A distinct decrease below the baseline, with a return to the baseline within 10 minutes. Decelerations are classified by their shape and timing in relation to uterine contractions as follows:
 - Early—U-shaped deceleration that begins and ends with the contraction. The heart rate reaches its nadir at the peak of the contraction.
 - Variable—May have a V or W shape. May occur during or between contractions, on-set is usually abrupt.
 - Late—Usually has a gradual onset. Nadir of the deceleration usually occurs after the peak of the contraction.

Accelerations

Accelerations are the most common type of FHR change (Figure 25-13). Periodic accelerations are not a sign of fetal distress; they are a reassuring sign that the fetus is able to increase his or her heart rate to compensate for the stress of contractions. Periodic accelerations begin with the onset of the contraction and return to the baseline at the end of

FASTER BASELINE HEART RATE IN THE PREMATURE FETUS

The normal baseline fetal heart rate (FHR) ranges from 110 to 160 beats per minute (bpm). In early fetal life the sympathetic branch of the autonomic nervous system (ANS) establishes and maintains the baseline FHR, which tends to be in the upper range (150 to 160 bpm). As the fetus matures, the parasympathetic branch of the ANS exerts a slowing effect, bringing the baseline into the lower range (110 to 140 bpm) by term.

Figure 25-13 A. Periodic accelerations. B. Nonperiodic accelerations.

the contraction. Nonperiodic accelerations are not associated with contractions. Nonperiodic accelerations most often are seen with fetal activity and during pelvic examination; they are reassuring of fetal well-being. Nonperiodic accelerations have no regular pattern. The presence of spontaneous accelerations of at least 15 bpm lasting at least 15 seconds is almost always an indication of the absence of fetal acidosis (ACOG, July 1995).

Early Onset Decelerations

Early onset decelerations involve a transitory decrease in FHR caused by fetal head compression, which stimulates the vagus nerve to decrease the heart rate. Early decelerations during the second stage of labor, in the presence of adequate descent of the presenting part, usually are benign and reflect compression of the fetal head as it enters the birth canal.

An early deceleration is characterized by a gradual onset at the beginning of a contraction and a slow return to the baseline soon after the contraction ends, like a mirror image of the contraction (Figure 25-14). The slope is gradual and the depth of the deceleration reflects the intensity of the contraction. Early decelerations occur most frequently with vertex presentations in the second stage of labor, during pushing.

No treatment is necessary for early decelerations that occur in the transition phase of the first stage of labor or during pushing in the second stage, provided the vertex is descending and the FHR recovers. If, during the second stage of labor, it becomes difficult to determine the baseline owing to the frequency of early decelerations, the woman should be instructed to stop pushing until the fetus

has recovered and the FHR has returned to baseline. If early decelerations are observed while the presenting part is still above the level of the ischial spines, cephalopelvic disproportion should be ruled out.

Variable Decelerations

Variable decelerations are transitory decreases in FHR caused by umbilical cord compression. Variable decelerations are characterized by rapid onset, rapid return to baseline, and a variable relationship to the contraction (Cunningham, 1997). As long as the baseline rate remains stable

Figure 25-14 Early decelerations.

Critical Thinking

Early Decelerations

Your client has had an epidural and denies feeling pain with contractions. You note that with each contraction the fetal heart rate (FHR) decelerates so that the pattern looks like a mirror image of the contraction. What action should you take?

Perform a sterile vaginal examination to assess dilation of the cervix and descent of the presenting part.

The appearance of early FHR decelerations is an indication that labor may have progressed to the second stage; therefore, the cervix should be assessed.

and the variability is good, variable decelerations are not associated with poor fetal outcome. Variable decelerations have no consistent shape and may appear V-shaped, W-shaped, or U-shaped; they may begin or end at any time in relation to the contraction curve (Figure 25-15).

Variable decelerations occur most frequently after rupture of membranes, when there is less amniotic fluid to provide a protective cushion around the cord. Other circumstances that could result in compression or stretching of the cord causing variable decelerations are the following: loops of the umbilical cord around the fetal neck or shoulder, a true knot in the cord, or prolapsed cord. Variable decelerations are defined according to their depth and duration (Table 25-5). Many variable decelerations are

Table 25-5 Variable Decelerations Defined

Mild	Any depth; duration, <30 s 70–80 bpm; duration, <60 s 80 bpm; duration, any
Moderate	<70 bpm; duration, 30–60 s 70–80 bpm; duration, <60 s
Severe	<70 bpm; duration, >60 s
Prolonged	Isolated deceleration; duration, >60–90 s

so brief that no treatment is necessary. When decelerations last longer than 30 seconds or when the recovery to the baseline is slow, treatment should be given to alleviate the cause of the compression.

Variable decelerations may be preceded or followed by acceleratory phases or shoulders. A **shoulder** is not an acceleration but is an acceleratory phase of a deceleration pattern. It is a compensatory sign of an intact fetal CNS. Appropriate descriptive documentation in the medical record should read as follows: “Variable decelerations with shoulders.”

Occasionally a rebound increase in the FHR occurs after a variable deceleration. This is called an **overshoot** and consists of an increase of 20 or more bpm above the baseline or an increase above the baseline for more than 20 seconds. An overshoot is not an acceleration but is part of a variable deceleration pattern (Murray, 1997). An overshoot is a nonreassuring sign and could indicate significant hypoxemia or hypoxia. The primary caregiver should be notified immediately of such a FHR pattern, particularly if there is absent STV or an increasing baseline (Murray, 1997).

Late Onset Decelerations

Late onset decelerations are transitory decreases in the FHR caused by **uteroplacental insufficiency**, which is compromised blood flow from the placenta to the fetus (ACOG, July 1995). Late decelerations have the following characteristics: uniform shape similar to early onset decelerations, smooth, and U-shaped (Figure 25-16). The late

Figure 25-15 Variable decelerations.

Nursing Alert

LATE DECELERATIONS

Late decelerations are caused by uteroplacental insufficiency (low oxygen delivery) and are nonreassuring. The primary caregiver must be notified without delay of the appearance of late decelerations on the fetal heart rate monitor strip and should come to assess the client immediately.

Figure 25-16 Late decelerations.

deceleration, however, starts at about the time the contraction is at its height and does not return to baseline until after the contraction has ended (ACOG, July 1995). When a pattern of late FHR deceleration occurs, the primary caregiver should be requested to review the FHR strip and assess the client without delay.

Interventions for Nonreassuring Fetal Heart Rate Pattern

Nursing interventions that should be initiated for a nonreassuring FHR pattern depend on the signs and probable cause, and include the following:

1. Change the maternal position from one side to the other side, particularly if umbilical cord compression

is suspected. Changing the maternal position is almost always the first nursing intervention to consider and may be the only intervention necessary.

2. Oxygen therapy by non-rebreather face mask at 8 to 10 L/min. The theory is that oxygen therapy will saturate the mother's blood with oxygen so that when the cord compression is relieved, the fetus will have a good supply of oxygen to use in recovering a normal heart rate.
3. Increase the rate of the main IV fluid line (usually lactated Ringer's solution) to increase perfusion of the placenta, particularly if a decrease in blood pressure has occurred.
4. If moving the client from one side to the other does not relieve the problem, sterile vaginal examination should be performed to rule out prolapsed cord. If prolapsed cord is feared, move the client to the hands and knees position and have her bend her arms until she is resting on her knees and forearms (Figure 25-17). This position helps to shift the weight of the fetus off the cervix and off the umbilical cord.
5. Notify the primary care provider the time of occurrence, duration, severity, and frequency of decelerations and of nursing interventions given. The nurse also should document the rationale behind interventions provided.
6. Anticipate administration of a tocolytic such as terbutaline, 0.25 mg subcutaneously or 0.125 to 0.25 mg IV (ACOG, Dec. 1995), if the woman is experiencing hypertonic contractions, resulting in inadequate resting tone between contractions.
7. Anticipate starting an **amnioinfusion**, which is instillation of an isotonic glucose-free solution (such as

Figure 25-17 Elbows and knees position to relieve pressure on a prolapsed umbilical cord.

normal saline or lactated Ringer's solution) into the uterus to cushion the umbilical cord or to thin out meconium.

8. Chart all information, including the time the primary care giver was notified, the specific information given, and the response. It is acceptable to write, "No new orders received."

When interventions do not improve the FHR pattern, and depending on the seriousness of the deceleration and the stage of labor, the nurse should be prepared to move the client into the operating room for emergency cesarean delivery.

Labor Progress

The nurse assesses the woman throughout labor to establish normal progress during each stage and phase. The primiparous client may be expected to experience a longer labor than would the multiparous woman.

Uterine Assessment

Contraction patterns are monitored carefully, as discussed in the section on Admission Procedures. As the contractions intensify, the nurse continues to assess their frequency, duration, and intensity, and the adequacy of the resting tone. The minimal contractile pattern of 95% of women in spontaneous labor consists of three to five contractions in a 10-minute window. When the woman is having internal uterine monitoring, Montevideo Units, or MVU (a numerical method of calculating adequacy of contraction strength), can be calculated. MVU equals the total strength of contractions, in mm Hg, in a 10-minute window. The equation is as follows:

$$\begin{aligned} &\text{Total strength of all contractions in a 10-minute window} \\ &\quad - \text{Total resting tone of all contractions in a 10-minute window} = \text{MVU} \end{aligned}$$

For example, if the woman has three contractions in 10 minutes of 90, 75, and 85 mm Hg and the resting tone is 20 mm Hg, then the MVU equals 190 mm Hg:

$$\begin{aligned} (90 + 75 + 85 \text{ mm Hg}) - (20 \text{ mm Hg} \times 3) \\ = 250 \text{ mm Hg} - 60 \text{ mm Hg} \\ = 190 \text{ mm Hg} \end{aligned}$$

Most women achieve 200 to 225 MVU, and some achieve 300 MVU. A woman is considered to have arrested labor when she exceeds a rate of 200 MVU for 2 hours without cervical change.

Rupture of Fetal Membranes

If the fetal membranes were still intact when the woman arrived at the hospital, they may rupture spontaneously

Nursing Alert

PROLAPSED CORD

If spontaneous rupture of membranes is accompanied by a decrease in the fetal heart rate, the nurse should suspect umbilical cord prolapse and perform an immediate sterile vaginal examination to confirm or rule out this emergency.

during labor. If the woman states either that she has felt a sudden gush of fluid or has inadvertently urinated in the bed, the nurse should check the bed linen beneath the woman for pooling of amniotic fluid. When membranes rupture spontaneously, the first nursing responsibility is to check the FHR, because the gush of amniotic fluid could possibly cause a segment of umbilical cord to prolapse or become pinched between the fetal head and the cervix. The first indication of such an emergency would be a variable FHR deceleration.

If fetal membranes do not spontaneously rupture, the primary caregiver may perform **amniotomy**, artificial rupture of membranes (AROM). The rationale for AROM is to slightly shorten the length of labor, although there is no research to suggest that this is beneficial to either the mother or fetus.

One benefit of AROM is the earlier detection of meconium staining of amniotic fluid. Once the membranes are ruptured, a FSE can be applied for more accurate monitoring of the FHR. Amniotomy usually is done by the use of an **amnihook**, which is a plastic implement with a blunt hook at the distal end (Figure 25-18). AROM also can be

Figure 25-18 Amnihook.

Research Highlight

Amniotomy for Shortening Spontaneous Labor

Purpose

To study the effects of amniotomy on the rate of cesarean delivery on other indicators of maternal and neonatal morbidity (5-minute Apgar score of less than 7, admission to the neonatal intensive care unit [NICU]). Early amniotomy has been advocated as a component of the active management of labor.

Method

A review of all controlled trials of amniotomy during the first stage of labor. Data were extracted from published reports. Trials were assigned methodologic quality scores based on a standardized rating system. Typical odds ratios (ORs) were calculated using Peto's method.

Findings

Amniotomy was associated with a reduction in labor duration of between 60 and 120 minutes. There was a marked trend toward an increase in the risk for cesarean delivery: OR, 1.26; 95% confidence interval (CI), 0.96–1.66. The likelihood of a 5-minute Apgar score less than 7 was reduced in association with early amniotomy (OR, 0.54; 95% CI, 0.30–0.96). Groups were similar with respect to other indicators of neonatal status (arterial cord pH, NICU admissions). There was a statistically significant association of amniotomy with a decrease in the use of oxytocin: OR, 0.79; 95% CI, 0.67–0.92.

Nursing Implications

Routine early amniotomy is associated with benefits and risks. Benefits include a reduction in labor duration and a possible reduction in low 5-minute Apgar scores. The meta-analysis provides no support for the hypothesis that routine early amniotomy reduces the risk for cesarean delivery. Indeed, there is a trend toward an increased risk for cesarean delivery. An association between early amniotomy and cesarean delivery for fetal distress was noted in one large trial, suggesting that amniotomy should be reserved for women with abnormal labor progress.

Fraser, W. D., Turcot, L., Krauss, I., & Brisson-Carrol, G. (2000). Amniotomy for shortening spontaneous labour (Cochrane Review). In *The Cochrane Library, Issue 1*. Oxford: Updated Software.

effected by applying a FSE directly through the membranes, especially if there is no bulging forebag.

Nursing responsibilities during AROM are to assess the FHR both before and after amniotomy. The client usually is receiving continuous EFM. After AROM, the characteristics of the amniotic fluid are assessed and documented: color—clear, bloody, or meconium stained; odor; and amount—copious or scant. Notify the appropriate health care team members of the rupture of membranes and abnormal findings as per the hospital policy, procedure, and protocol. The primary caregiver should be notified immediately when meconium-stained amniotic fluid is first observed.

Documentation and Communication

Documentation of nursing care is made on a flowchart or entered directly into a bedside computer according to the hospital policy, procedure, and protocol and the client's clinical status communicated to other members of the health care team as appropriate (Figure 25-19). Although physicians and nurse-midwives make the obstetric management decisions, they cannot be in constant attendance at the bedside. It is the intrapartum nurse who alerts the physician or nurse-midwife when a change in the plan of care becomes necessary. Failure of the nurse to correctly interpret assessment findings is below the standard of care. Failure to communicate and document clinical findings are

Research Highlight

Caregiver Support for Women During Childbirth

Purpose

To assess the effects of continuous support during labor (provided by the health care team or laypersons) on mothers and infants. Social support may include advice or information, tangible assistance, and emotional support.

Method

Review of 14 randomized trials involving 5,000 women. Continuous support during labor was compared with intermittent support.

Findings

The continuous presence of a support person reduced the likelihood of medication for pain relief, operative vaginal delivery, cesarean delivery, and a 5-minute Apgar score of less than 7. Continuous support also was associated with a slight reduction in the length of labor. Six trials evaluated the effects of support on mothers' views of their childbirth experiences. Although the trials used different measures (overall satisfaction, failure to cope well during labor, finding labor to be worse than expected, and level of personal control during childbirth), in each trial the results favored the group of women who had received continuous support.

Nursing Implications

Continuous support during labor from caregivers appears to have a number of benefits for mothers and their infants, and there do not appear to be any harmful effects.

Hodnett, E. D. (2000). Caregiver support for women during childbirth (Cochrane Review). In *The Cochrane Library, Issue 1*. Oxford: Updated Software.

two reasons that the intrapartum nurse might be named as a defendant in a malpractice claim. The Board of Nurse Examiners Rules and Regulations, Standards of Professional Practice, require nurses to "accurately and completely report and document" (Rule 217.11 (4)).

Activity

When the woman is in bed, frequent position changes allow for better comfort. During normal labor, however, the woman does not need to be confined to bed, unless analgesics are being used. Many women prefer to walk, accompanied by a support person, and return to the LDR every 30 to 45 minutes for FHR assessment according to ACOG standards (July 1995). A comfortable chair may be beneficial, allowing the woman to maintain a more upright position than being semi-recumbent in bed. Many women use a rocking chair, preferring to rock through each contraction. Continuous EFM can continue with the woman sitting in a chair at the bedside. While in bed, the laboring woman should be allowed to assume the position that af-

fords her the most comfort; additional pillows can be provided to help in positioning. The supine position should be avoided because of the danger of vena caval compression.

Comfort Measures

Anxiety levels and coping mechanisms of the client, partner, and family are assessed continually as labor progresses. Anxiety and fear tend to lower a woman's pain threshold, and the nurse should try to remain with the woman in active labor (client load permitting) to give encouragement and reassurance that normal progress is being made. Ignorance of the process and mechanism of labor can result in anxiety and fear of childbirth. Fear causes catecholamine secretion, which has the effect of decreasing peripheral blood flow. Adrenaline has a terbutaline-like effect in that it can cause labor to be prolonged as uterine contractions become less effective. The biggest factor in management of labor is nursing support and coaching. The value of having a caring skilled professional at the bedside cannot be overestimated.

THE BOARD OF NURSE EXAMINERS

If you are named as a defendant in a malpractice suit, bear in mind that the Board of Nurse Examiners is not there to protect nurses. Its sole concern is to protect the public from incompetent nurses. It does provide the guidelines that set standards of care.

A calm, competent, and gentle manner on the part of the nurse promotes trust and goes a long way toward alleviating client anxiety. Frequent feedback should be given and the findings of each test explained in language the client can understand. It also is important to take care of the woman's partner, and this can be done by providing a comfortable chair and including the person in discussions and explanations. Support for the laboring family is individualized according to the specific needs and expectations of those concerned as well as respectfully taking into account the cultural background.

Pain Management

A common concern of the pregnant woman is whether she will be able to withstand the pain of contractions, or whether she will lose control. There are a variety of measures that will promote relaxation and assist the woman in coping as contractions intensify.

The nurse may need to instruct the woman in breathing techniques or reinforce those already learned. Some women find counterpressure massage of the sacral area helpful during contractions, particularly when contraction pain is being experienced mostly in the lower back. Some childbirth classes advise clients to bring a tennis ball to the hospital to roll in a circular fashion against the woman's lower back, while applying gentle pressure during a contraction. If the fetus is in an occipitoposterior position, the pressure of the fetal occiput on maternal spinal nerves will cause the woman to experience contraction pain mostly in the lower back. Counterpressure is helpful in lifting the occiput off these nerves, to some extent, thus providing pain relief. Changing positions frequently is helpful.

The comforting effects of a warm shower during the first stage of labor should not be underestimated. Some facilities feature a bathtub with whirlpool jets, such as a Jacuzzi, as a comfort measure to decrease muscle tension and promote relaxation (Figure 25-20). Having the client relax in a whirlpool, however, does not relieve the nurse of the responsibility of appropriate fetal assessment.

Figure 25-20 The nurse continues to monitor fetal status while the laboring woman relaxes in a whirlpool.

Bathing during labor is associated with decreased pain and increased speed of cervical dilation (Lowe, 1996).

A **doula** is a woman who is employed by the pregnant woman to assist her through labor by helping her cope with the pain. The doula has no clinical training but is able to reinforce breathing techniques, massage, and sometimes provide ice packs or warm packs. The labor partner or nurse usually is more than able to provide physical and emotional support; however, when the nurse is assigned to more than one client or if the client has no family member with her, the services of a doula are particularly valuable.

The birthing ball is a standard physiotherapy tool used in physical therapy departments worldwide. The ball provides a soft yet firm place to sit while promoting a desirable upright posture and allowing for decreased straining of the muscles. The birthing ball also is used to lie on.

Additional pain relief and pharmacologic measures are discussed in Chapter 24.

Psychologic Considerations

As labor advances, anxiety levels secondary to pain increase in the woman who has not received epidural analgesia. It is important for the nurse to be present with the woman who is in active labor and to continue to offer encouragement and reassurance to the woman and family. As the transition phase approaches, the woman experiences stronger contractions while feeling tired, irritable, and less able to cope after all the hours of labor. She may feel trapped and apprehensive because of the increasing pain and vaginal pressure and will be less interested in her appearance and outside activities. To minimize environmental change, it is advisable for the same nurse, who already has developed a trusting rapport with the laboring woman, to continue care until she gives birth. Emphasis is

on enhancing coping by assuring the client that all is going well, staying with her, and coaching her as necessary with her breathing techniques through each contraction. The client needs constant support during these phases of labor.

Labor Curve

Labor progress may be plotted by use of the labor curve, which was developed by Friedman (1970) as a method of graphically plotting the relationship of time to dilation of the cervix and station of the presenting part. When preparing to plot the labor curve, the number of hours the woman labors are written across the top of the graph, the dilation in centimeters up one vertical side, and the station (in descending order) down the opposite vertical side. The first time interval entered on the graph is the time the woman reported that regular contractions began.

Role of the Support Person

The friend or relative who provides companionship and encouragement to the laboring woman may be male or female; often is the husband or father of the infant who gives emotional support at this time. Some expectant fathers see their role as coach and will actively help the woman focus on breathing through her contractions. Partners who have not attended prepared childbirth classes with their mate, though not familiar with breathing techniques, often are quite willing to give physical comfort such as sips of water and back rubs. The nurse can fill in any knowledge gaps that the support person might have.

Some expectant fathers adopt a more passive role and are content to merely be present and to witness the birth. While being available to guide and encourage the man in taking an active part in the process, the nurse should in no way impose on him any personal philosophy of what his function should be. The laboring woman may be content that her partner is present and may not require him to do more than sit in a chair and read a newspaper while she is in labor. The woman is the one who knows her partner best and probably has a fairly accurate idea of how much he will participate in her birth experience.

Second Stage

The **second stage of labor** begins when the cervix is fully dilated (10 cm) and completely effaced (100%), and ends with delivery of the baby. Inability to feel the cervix during vaginal examination confirms that the second stage has begun (Figure 25-21). When a woman has received epidural analgesia, she may not be aware that the contractions have become stronger. She will feel vaginal pressure with each contraction during the second stage of labor. Premonitory indicators that should alert the nurse that the client may have entered the second stage of labor include the following (Scott et al., 1994):

Nursing Tip

NURSING DIAGNOSES IN THE SECOND STAGE OF LABOR

Nursing diagnoses that apply to a woman during the second stage of labor might include the following:

- Disturbed sleep pattern related to the length of labor.
- Deficient knowledge related to normal labor and delivery as evidenced by client's inexperience and lack of preparation.
- Pain related to uterine contractions.
- Bearing down of her own accord.
- Complaints that her contractions have become stronger and more painful.
- Complaints of pressure on her rectum.
- Increased amount of bloody show.
- Increasing irritability and tearfulness, together with a decreased coping ability.
- Nausea or vomiting.
- Trembling limbs.

The physician or nurse-midwife should be notified when the woman has begun the second stage of labor so that he or she can be available to come to the LDR as soon as birth is imminent. The duration of the second stage varies greatly from woman to woman. A duration of more than 2 hours in a first pregnancy is considered prolonged, unless the woman is receiving epidural or other regional analgesia. In the multiparous woman, a second stage of more than 2 hours might be considered prolonged (ACOG, Dec. 1995). The nurse notifies the appropriate health care provider of progress or lack of progress.

Nursing Tip

PREMATURE PUSHING

If the cervix is not fully dilated, pushing will not only tire the woman unnecessarily but will cause the cervix to become swollen and thus prolong labor. Repeated blowing or panting helps to counteract the tendency to push prematurely.

A.

Figure 25-21 A. Dilation of the cervix is assessed while the woman briefly bears down. B. Many women will want to feel the perineal bulge with their fingers to be assured that labor is progressing. C. Spontaneous urination occurs during a vaginal check. D. The infant's head is clearly visible, meaning that birth is imminent.

B.

C.

D.

During the second stage of labor contractions usually occur every 2 to 3 minutes, with a duration of 60 to 90 seconds, and intensity is strong by palpation or 80 to 100 mm Hg by IUPC. Uterine tone should palpate soft between contractions. Amniotic fluid is assessed for the presence of meconium, and bloody show is monitored for excessive bleeding. The FHR is assessed in accordance with institu-

tional policy. During the second stage of labor the usual protocol requires FHR and uterine activity evaluation every 15 minutes for low-risk clients and every 5 minutes for high-risk clients (ACOG, July 1995).

Refer to the accompanying photo story for a complete account of one couple's birth story.

One Couple's Birth Story

When the couple arrives at the hospital and labor is confirmed, the woman is admitted to Labor and Delivery. Certain admission procedures must be completed including gathering baseline data and lab work.

In the past, women were expected to remain NPO throughout their labor. This policy has been relaxed in most institutions and liquids are encouraged.

Many women find it more comfortable to ambulate or sit in a chair during early labor.

As labor progresses, the woman may want to rest in bed with the exception of trips to the bathroom.

Some women find that a change of position and a backrub assists them in achieving comfort.

Most women try to rest between contractions to conserve energy.

As contractions increase in frequency, duration, and intensity, the woman is less likely to be able to rest.

When the client becomes completely dilated, she feels an urge to push with her contractions. Her significant other is assisting her to assume a position conducive to pushing.

As the fetus descends through the pelvis, the nurse must monitor the fetal heart tones more frequently as well as the station of the presenting part.

As the fetal head crowns, there is much thinning and pressure of the tissue. This pressure also involves the anus.

Finally, the baby's head is delivered between contractions to avoid perineal injury.

The midwife supports the head as external rotation occurs.

The baby's mouth and nose are suctioned immediately so the airway will be clear of amniotic fluid.

As restitution occurs, the midwife makes sure the baby's umbilical cord is not around its neck.

After the next contraction, the remainder of the body is delivered.

The baby is placed on the mother's abdomen while the midwife finishes the delivery.

The infant is covered with a blanket and placed next to the mother's skin to prevent loss of body heat. The nurse suctioned the baby's mouth again to ensure adequate air transport.

The midwife places two clamps on the umbilical cord.

The cord is cut between the two clamps by the baby's father.

Waiting for the placenta to deliver. This usually occurs within a few minutes.

As the placenta separates, there is usually a gush of blood.

When the placenta has been delivered, it is inspected to ascertain that it is intact.

Many times women deliver without an episiotomy but may have small lacerations that need repair.

If the infant is placed at the mother's breast and sucks immediately following the delivery of the placenta, this assists in uterine involution through the release of maternal oxytocin.

The nurse massages the fundus to assist in uterine involution while taking precautions against uterine inversion.

The baby's umbilical cord was intentionally left long at delivery. Now it is time to place a cord clamp and shorten the cord.

The cord is trimmed with sterile scissors.

The baby has a strong, lusty cry.

The nurse completes an assessment of the heart rate.

Matching arm bracelets are placed on the mother and infant for identification.

Infant footprints are obtained as a secondary means of identification.

The happy family begins its life together.

Fetal Descent Assessment

Full dilation of the cervix is a function of descent; therefore, if there is continually a cervical lip, then the baby is not descending. Fetal descent is evaluated by performing a vaginal examination, or visually when the presenting part is at the perineum. When the cervix is fully dilated while the presenting part is still relatively high (0 to +1 station) the woman may wish to defer pushing efforts until after the fetal head has descended further. The second stage can be divided into a passive phase and an active phase. In the passive phase of the second stage, the woman does not yet have any urge to push. Descent does not require pushing. During this phase, the fetal head should be allowed to descend by means of involuntary uterine contractions (primary powers). This action is called *laboring down*, and it helps to prevent stress on the fetus and exhaustion of the mother from extended pushing time. In the active phase of the second stage, pressure on S2 to S4 creates the urge to push; therefore, the woman should begin her expulsive efforts (secondary powers). There are no benefits to pushing before the active phase of the second stage of labor. Visible signs of descent include bulging of the perineum and crowning (Figure 25-22).

Psychological Considerations

The start of the second stage often is a relief for the laboring woman because she can now take a more active part in delivering her baby by augmenting the involuntary primary powers (uterine contractions) with secondary powers (pushing). Instead of panting through each contraction and fighting the almost uncontrollable urge to push, she can concentrate all her energies on pushing out the infant. Being able to push gives the woman a feeling

of having some control over her labor (Box 25-12). The woman's perceptions are narrowed to the extent that she is all absorbed in the effort of pushing with contractions. Between contractions she should be encouraged to close her eyes take a deep cleansing breath and completely relax to conserve her strength for the next expulsive effort. The woman may experience nausea and may perspire with the effort of pushing.

The number of visitors permitted in a hospital room will vary and, as the time of delivery approaches, the nurse should ask the woman whom she would like to attend the delivery. This can best be done when visitors have temporarily stepped out of the room, so that the woman does not feel obliged to allow someone to see the delivery if she really does not want them there. The nurse can be an advocate for the woman by being the gatekeeper and ensuring that the woman's wishes in this regard are met.

Maternal Positioning

The nurse assists with maternal positioning to facilitate fetal descent and promote comfort. Several position options are available during pushing. The most commonly used position in the United States is the semi-Fowler's position in which the head of the bed is elevated about 45 degrees and the woman grasps her flexed knees or ankles. Epidural anesthesia has probably contributed to this semi-recumbent positioning. Women can benefit from pushing in a more upright position, which can be accomplished by leaning forward on a supported bedside table, a squat bar, or a birthing ball. Repeated studies have shown that upright positions, such as walking or standing, benefit both mother and fetus. These positions have a favorable effect on uterine contractility and reduce pain and perineal trauma (Mayberry, 2000). A lateral position also can be used for pushing and delivery. The pushing position used depends on the desires of the client and also requires flexibility on the part of the nurse and physician or nurse-midwife. Arbitrary limits on the second stage of labor should be abandoned if both the mother and fetus are doing well and progress is being made.

To assist with effective breathing and pushing, the nurse can ascertain which techniques the woman has learned in her prenatal classes and reinforce them. The woman is urged to listen to her body and bear down when she feels the urge to do so. The desire to bear down is an involuntary response to the pressure of the presenting part on the stretch receptors of the pelvic muscles. One drawback to this urge-to-push method is that the woman who has received epidural anesthesia may never feel the need to push. If the woman is not aware of contractions because of epidural analgesia, she needs to be coached to push during each contraction. Her partner may help by

Figure 25-22 A bulging perineum is a visible sign of fetal descent.

Box 25-12 Pushing Technique

1. Encourage spontaneous bearing down. Allow the mother to rest until the fetal head has descended low enough in the pelvis to stimulate Ferguson's reflex (a reflex stimulated by stretch receptors in the pelvic floor, which usually occurs at a +1 station that stimulate in the mother an involuntary urge to push).
2. Consider fetal station and position in addition to dilation in determining a woman's readiness for pushing.
3. Discourage prolonged maternal breath-holding (more than 6 seconds) during pushing.
4. Encourage four or more pushes per contraction.
5. Support rather than direct the woman's involuntary pushing efforts, whether they include grunting, groaning, exhaling, or breath-holding for less than 6 seconds (Figure 25-23).
6. Validate the normalcy of sensations and maternal sounds.
7. The woman who has received epidural anesthesia may require more directed support for her expulsive efforts during the second stage.

**A.****B.**

Figure 25-23 A. The perineum is stretched as the infant's head crowns. B. The health care provider supports the woman's efforts by encouraging her to stop pushing between contractions.

supporting the woman's head or shoulders during pushing, wiping her brow with a cool damp cloth, and offering words of encouragement. The nurse and partner need to understand that because of the stress of labor, pain, and exhaustion, it is not uncommon for the woman to say things that she would not otherwise say. The primary provider is kept apprised of progress or lack of progress, as indicated. The woman, her partner, and family are kept informed of her progress, the expected sequence of events, and the delivery routine.

As the fetal head descends, bulging of the perineum occurs and rectal mucosa is exposed. Any stool in the rectum will be expelled. The fetal head passes under the pubic arch, and the vertex is visible as it pushes open the vaginal introitus, which is known as **crowning**.

Other Team Members

Other personnel required to be present during delivery will depend on the needs of the mother and infant as well as the protocol of the facility. If the woman is receiving epidural anesthesia, some facilities require a Certified Registered Nurse Anesthetist (CRNA) to be present during the delivery. The CRNA is there in case a bolus of analgesia is needed and to remove the epidural cannula immediately after the third stage is over and perineal repairs are completed.

If the amniotic fluid is meconium-stained, some facilities require that a neonatologist or a neonatal clinical nurse specialist be at the delivery to provide endotracheal suction to the newborn and ascertain whether meconium was aspirated by the baby. Other personnel that may be required, depending on the particular protocol are a surgi-

cal technician to assist with the instrument table and a nursery nurse to receive the baby. It is the primary nurse's responsibility to ensure that the primary caregiver and other health care team members as appropriate are notified of the impending delivery and are called in time.

Nursing Responsibilities in Preparing for Delivery

The client is never left alone during the second stage of labor; therefore, the nurse must anticipate the need for equipment and supplies. An instrument table is prepared and the individual requirements of the physician or nurse-midwife are considered (Figure 25-24). Other necessary items include a table containing sterile delivery instruments and an antiseptic such as Betadyne, adequate lighting, and oxygen and suction equipment for both mother and newborn. The radiant warmer or incubator should be prewarmed and spread with warmed baby blankets and a knit cap. Identification labels are prepared according to hospital protocol. Four identical identification bracelets usually are used for labeling the baby (two), mother, and partner. Two vials of oxytocin (Pitocin), 10 U, should be on hand for administration to the mother after the placenta has been delivered.

The nurse adjusts the birthing bed, delivery table, or operating table to accommodate the client and health care provider (who also may require a stool). In a physician-assisted delivery the client's legs often are supported in stirrups and the lower section of the delivery bed removed (Figure 25-25). A woman who has received epidural analgesia may have difficulty moving her legs; therefore, the nurse must ensure that the woman's legs are completely secure in the stirrups. It is not advisable for the client's legs to be placed in stirrups until the baby's head is almost crowning and the primary caregiver nurse is present in the

Figure 25-24 Delivery instrument table.

Figure 25-25 This woman is ready to deliver, with her legs supported in stirrups, the perineal area cleansed, and the foot of the bed removed.

delivery room, at which time the woman's legs are secured in the stirrups and the lower part of the delivery bed is removed. In a nurse-midwife-assisted birth, the bed is not broken down and stirrups are not commonly used.

For the birth, the nurse wears a waterproof gown and a mask with an eyeshield. Just before the birth, the nurse dons sterile gloves and cleanses the maternal perineum with prepackaged Betadyne-soaked sponges, using sterile technique as per the hospital policy and procedure (Figure 25-26).

The nurse and client's partner continue to support and encourage the woman in her expulsive efforts, instructing her to modify her breathing and pushing technique as indicated. Xylocaine 1% local anesthetic should be available in case the primary caregiver nurse decides that **episiotomy**, an incision into the perineum, is necessary to shorten the length of the second stage.

Episiotomy and Nuchal Cord

At the time of crowning, when the largest diameter of the fetal head first becomes visible, the perineum is stretched

Figure 25-26 Perineal scrub; clean from the vagina outward, that is, from 1 to 6, moving bacteria away from and not toward the vagina.

extremely thin and may tear, particularly in the case of a nulliparous woman. Episiotomy is performed when a 3- to 4-cm diameter of fetal head is visible, before the perineal floor undergoes excessive stretching (Cunningham, 1997) (Figure 25-27). Local anesthesia can be injected before the episiotomy.

The episiotomy incision is made in the midline downward (median or midline episiotomy), or it begins in the midline and is directed laterally and downward away from the rectum (mediolateral episiotomy) (Figure 25-28). A straight, neat episiotomy incision is easier for the primary caregiver to repair than is a ragged laceration; however, research has shown that liberal use of episiotomy is not associated with a lower frequency of severe perineal tears (Anthony et al., 1994).

After episiotomy has been performed, the fetal head often is delivered with the next contraction. The infant's head is born by extension (see mechanism of labor in Chapter 23) and the primary caregiver feels around the infant's neck for **nuchal cord**, which is umbilical cord that has become wound once or more times around the infant's neck (Figure 25-29). If the cord can be felt around the neck, it often is loose enough to be pulled over the infant's head while the mother is instructed not to push. During the brief pause for restitution of the fetal head to take place, the primary caregiver may suction the mouth and nares of the infant before the infant's first breath. If the amniotic fluid has been stained by meconium, the infant's mouth and nares should be suctioned using a suction catheter to ensure that any meconium in the mouth or nose will not be aspirated (Figure 25-30). If the nuchal cord is tightly wound around the infant's neck the physician or nurse-midwife may need to double clamp and cut the cord to allow the infant to be delivered. Delivery time, date, and sex of the infant are noted on the mother's chart and on the infant labels (Figure 25-31).

Meconium Aspiration

In utero, the fetus has two normal “breathing” patterns by which it moves amniotic fluid into and out of the lungs:

Figure 25-28 Episiotomy.

shallow regular breathing (90% of the time) and deep irregular breathing (10% of the time). In the presence of hypoxia, the fetus may be stimulated to make compensatory gasping respirations. Hypoxia may result in passage of meconium, and the meconium-stained amniotic fluid can be aspirated into the fetal lungs if gasping respirations are stimulated by asphyxia.

When there is thick meconium in the amniotic fluid, the primary caregiver may order **amnioinfusion**, introduction of warm normal saline or lactated Ringer's solution into the uterus by way of an IUPC, in an attempt to thin out the meconium and prevent meconium aspiration by the fetus.

Figure 25-29 Birth of the fetal head with nuchal cord.

Figure 25-30 This infant was born so rapidly that there was no time to suction the mouth and nares until after the delivery was completed.

At delivery, the neonatology personnel should be present to provide prompt resuscitation and oxygenation as necessary. As the fetal head appears, the woman should be asked to refrain from pushing so that the primary caregiver can clear the airway, using a DeLee suction catheter, before the infant takes its first breath. The neonatology

Figure 25-31 The nurse documents the delivery date, time, and the infant's gender on the mother's chart.

personnel may need to intubate the infant to clear the airway of meconium by way of an endotracheal tube.

Third Stage

The **third stage of labor** begins with delivery of the infant and ends with delivery of the placenta. This process may take up to 20 minutes. The nurse's attention at this time is directed toward newborn care.

Newborn Care

The time of birth is noted in the delivery record and the newborn's chart. When indicated, oral, pharyngeal, or endotracheal suctioning is performed according to the hospital policy, procedure, and protocol. Ideally, the infant is laid on the mother's abdomen and quickly covered with warm blankets to prevent heat loss by evaporation. The primary caregiver hands the infant directly to the nurse, who (wearing waterproof gown, mask, and sterile gloves), receives the infant into a sterile baby blanket. The nurse places the infant either into an incubator or beneath a radiant heater to prevent loss of body heat by evaporation while the infant is being dried. When necessary, the mouth and nares are again cleared by use of a suction bulb. In the neutral thermal environment of the incubator or infant warmer, the infant is dried thoroughly and a cap placed on the infant's head for extra warmth. As the nurse dries the infant, respiratory effort, color, and muscle tone can be observed. The action of drying the infant with warm baby blankets acts to stimulate the baby to breathe deeply and cry. Lightly flicking the soles of an infant's feet also will stimulate an infant to cry.

While drying the infant the nurse notices any rib, sternal retractions, "grunting" sounds or nasal flaring, which indicate respiratory compromise. Heart rate is checked by

Nursing Tip

CHECKING NEWBORN HEART RATE

Place a finger and thumb at the base of the umbilical cord. Count the pulsations for 6 seconds and multiply by 10 to calculate the infant's heart rate.

placing the thumb and two fingers over the base of the umbilical cord and counting the pulsations, which should be within the range of 110 to 160 bpm. Skin temperature should be 97.8°F (36.5°C). While assessing respirations and heart rate, the nurse conducts a gross physical examination (Table 25-6). The infant should be crying and becoming pink. The infant's hands and feet usually are still slightly blue. This condition is known as **acrocyanosis** and may persist for 7 to 10 days. Respiratory support is initiated, if required, according to the hospital policy, procedure, and protocol. Respiratory support includes administration of oxygen or ventilation by bag or mask. Obvious abnormalities, such as spina bifida, cleft palate, and extra digits, are documented. The number of vessels in the umbilical cord also are noted; the umbilical cord should have two arteries and one vein.

The **Apgar score**, a numerical expression of the newborn's well-being, is assigned at 1, 5, and 15 minutes after birth as the neonate's immediate adaptation to extrauterine life is monitored (Table 25-7). The newborn is given a score of 0 to 2 in each of the following five categories: respiratory effort, heart rate, muscle tone, reflex irritability, and skin color.

Newborn laboratory studies vary according to the hospital protocol but might include cord blood samples if the mother is Rh-negative or has type O blood group. Cord blood for neonatal blood type and Rh factor is obtained by

Nursing Alert

"FLOPPY" INFANT, NOT BREATHING

When receiving an infant from the delivering primary caregiver: if the infant is "floppy" (lacking muscle tone) and is making no respiratory effort, it is wise to assume that the infant is already experiencing secondary apnea and therefore will be unresponsive to stimulation. Artificial ventilation with positive-pressure oxygen must be initiated at once. The nurse should not waste time by trying to stimulate the infant to cry but should call immediately for the neonatologist and nursing assistance, while administering bag and mask ventilation with 100% oxygen.

Table 25-6 Newborn Evaluation at Delivery

Assess	Normal Findings
Respirations	Rate 30–60 breaths per minute, irregular No retractions No grunting
Apical pulse	Rate 120–160 beats per minute
Temperature	97.5°F (36.5°C)
Skin color	Body pink, with bluish extremities
Umbilical cord	Two arteries and one vein
Gestational age	Should be >37 weeks to remain with the parents for an extended time

Table 25-7 Apgar Scoring System

Sign	Score		
	0	1	2
Respiratory effort	Absent	Slow, irregular	Good crying
Heart rate	Absent	Slow, below 100 beats per minute	Above 100 beats per minute
Muscle tone	Flaccid	Some flexion of extremities	Active motion
Reflex irritability	None	Grimace	Vigorous cry
Color	Pale blue	Body pink, blue extremities	Completely pink

the birth attendant while awaiting placental separation (Box 25-13). Cord blood gas analysis to evaluate biochemical status may be requested if the infant has a low Apgar score (Figure 25-32).

If the Apgar is less than 9 at 5 minutes, the infant should be stabilized rather than remaining with the mother in the LDR. Other situations that would require stabilization by the neonatal personnel include the following: “Grunting” respirations or rib retractions, nasal flaring, heart rate below 120 bpm or above 160 bpm, pallor, serious congenital anomalies such as spina bifida, a mother who is insulin-dependent, less than 38 weeks’ gestational age, or small for gestational age appearance.

After the Apgar evaluation, identification procedures are completed according to the hospital policy, procedure, and protocol (Figure 25-33). Usual identification includes taking the footprints of the infant and a fingerprint or thumbprint of the mother, and labeling. A common

Box 25-13 Procedure for Collection of Umbilical Cord Blood for Blood Gases

1. Before delivery, request that a 6- to 8-in segment of umbilical cord be clamped, cut, and passed off the surgical field as soon as possible after delivery.
2. One person is needed to attend the delivery and care for the neonate; another is needed to collect the blood samples.
3. Prepare a cup or Ziplock® bag of crushed ice, two 1-mL insulin syringes with 23-gauge needles and rubber stoppers, two laboratory slips, and two specimen labels.
4. Don gloves and goggles.
5. Using a bevel-down approach, aspirate 1 mL of blood from one of the umbilical arteries first.
6. Remove air bubbles: Air contamination has no effect on pH, partial pressure of carbon dioxide, or bicarbonate but may increase the partial pressure of oxygen (Gaskins & Goldkrand, 1994).
7. Remove the needle from the syringe with a hemostat, and cap the syringe with the rubber stopper.
8. Repeat the process with the umbilical vein (Figure 25-32). Compare the color of the blood in the syringes. The pinker blood is venous, and the darker blood is arterial.
9. Label each syringe with name, identification number, source, and time; place both syringes in the bag of ice.
10. Expedite delivery of the blood samples to the laboratory for blood gas analysis.

Critical Thinking

What is This Infant's Apgar Score?

The infant has just been delivered, and the physician hands the infant to you. You immediately lay the infant beneath the radiant heat lamp and begin your initial assessment as you dry the infant. The infant is breathing but not crying and the hands and feet are blue. The heart rate is 120 beats per minute, and the respirations are 30 breaths per minute and irregular. The infant's arms and legs are floppy. When you suction the mouth, the infant begins to cry more vigorously.

What is the 1-minute Apgar score that you will assign to this baby?

Answer: 6 (respiratory effort, 1; heart rate, 2; muscle tone, 0; reflex irritability, 2; skin color, 1).

Figure 25-32 Aspiration of umbilical cord blood.

labeling protocol involves preparation of a set of four identically numbered waterproof bracelets with the mother's name, sex of the baby, physician or nurse-midwife of record, and the date and time of delivery. The baby wears two bands and the mother and her partner wear the others.

Delivery of the Placenta

The third stage of labor begins after the birth of the newborn and ends with delivery of the placenta. The priority at this time is the complete separation and expulsion of the placenta and prevention of hemorrhage from **uterine atony**, which is inability of the uterus to contract. After the baby is born, the height of the fundus is ascertained by palpating the abdomen. As long as the uterus remains contracted and there is no bleeding, the policy is one of watchful waiting for signs of placental separation. Separation of the placenta may take as long as 20 minutes but more often takes place within 1 to 10 minutes of the birth. During the waiting time the physician or nurse-midwife may examine the cervix and vagina and perform any necessary perineal repairs; however, repairs usually are undertaken after the third stage is complete. Contractions during the third stage of labor are of much less intensity than are those experienced during the second stage.

The placenta is attached to the endometrium by numerous fibrous villi, which break when uterine contractions cause the placental site to shrink. If the uterus remains flaccid, the placental site does not contract and thus the placenta cannot detach from the endometrium. Attempts to deliver the placenta, before it detaches from the uterus, by using cord traction or fundal pressure can result in tearing of the cord or membranes or inversion of the uterus. **Inversion of the uterus**, turning the uterus inside out, results in serious hemorrhage and shock. Indications that the placenta has separated from the uterine endometrium are the following (Cunningham, 1997):

- A firmly contracting fundus.
- Globular shape of the uterus as the separated placenta descends into the lower uterine segment.
- A small spurt of blood from the vagina.
- Apparent lengthening of the umbilical cord at the introitus as the placenta descends into the lower uterine segment.

When signs of placental separation are evident, the mother should be asked to bear down for the final time (Figure 25-34). Whether the shiny fetal surface of the placenta appears first (Schultze mechanism) or the dark roughened maternal surface shows first (Duncan mechanism) is of no consequence (Cunningham, 1997) (Figure 25-35). Perineal

repairs for laceration (tear in the perineum, vagina, or cervix caused by childbirth) and episiotomy are then performed (Figure 25-36).

Oxytocin Administration

Oxytocin is given at the end of the third stage of labor, according to the hospital policy and procedure. The purpose of oxytocin administration is to prevent postpartum hemorrhage by stimulating the uterus to contract (Table 25-8). If the woman has an IV line, a frequent protocol is to add of oxytocin (Pitocin), 20 U, to 1 L lactated Ringers solution and infuse over 40 to 60 minutes. A second liter of oxytocin (Pitocin), 20 U, in 1 L lactated Ringers solution or 5% dextrose lactated Ringers solution is sometimes given at a rate of 125 mL/h.

The placenta and membranes are examined by the primary caregiver for completeness, and the placenta may be sent for pathological examination. Cultures or tissue

specimens are obtained as per the request of the primary caregiver and according to the hospital protocol.

The time of delivery of the placenta, its condition, and any abnormal characteristics are recorded in the Delivery Record. The amount of blood loss during delivery is estimated by the physician or nurse-midwife and noted in the Delivery Record by the nurse. The average blood loss at vaginal delivery is up to 500 mL (ACOG, 1998). The mother's perineum is cleansed gently and a sterile peripad applied. The degree and type of episiotomy or laceration is recorded in the Delivery Record (Table 25-9). An ice pack should be applied to the perineum to prevent swelling and pain, particularly if there are lacerations or an episiotomy. The lower portion of the delivery bed is replaced, and the woman's legs are carefully and slowly removed from the stirrups and placed back on the bed. If the woman has received epidural analgesia, it is discontinued and the cannula removed by the CRNSA. Warm blankets can be provided for comfort. All care is documented in the delivery record (Figure 25-37).

Table 25-8 Oxytocin Administration After Delivery of Placenta

Oxytocin (Pitocin)	Polypeptide hormone.
Action	Increases myometrial contraction by increasing the availability of intracellular calcium. Binds to oxytocin receptors in the decidua and myometrium.
Indication	Delivery of the placenta.
Dosage and route	Oxytocin, 20 U, in 1 L lactated Ringer's solution or dextrose 5% lactated Ringer's solution. Administer the first liter at a rapid rate. When a second liter of solution is ordered, administer at 125 mL/h. Oxytocin for control of postpartum bleeding may be diluted and administered by IV, or 10–20 U IM.
Adverse effects	With too rapid an infusion, tachycardia may occur; hypotension or hypertension also may occur. The antidiuretic effect may cause oliguria, fluid overload, arrhythmia, water intoxication, nausea, vomiting, or headache.
Nursing considerations	Assess the fundus for contraction. Assess the amount of lochia. Monitor vital signs, record intake and output, and assess the bladder.

Fourth Stage (Recovery)

The recovery phase immediately after delivery of the placenta often is referred to as the fourth stage of labor. This is a misnomer because labor and delivery are completed with the expulsion of the placenta. The fourth stage is the critical time that begins after delivery of the placenta and ends when the mother's systems have stabilized, usually 1 to 4 hours later.

Newborn-Family Attachment

The recovery period is a time of relative peace after the exertion and activity of labor and delivery. It also is a time of becoming acquainted with the newborn and for initial bonding to take place. Newborn-family attachment is promoted by encouraging touch and eye contact as soon as possible after delivery and by giving the family time to hold and admire the baby. Maternal bonding behaviors include smiling and talking softly to the baby, holding it up to her face and making eye contact, and breast-feeding. If the mother displays a negative behavior toward the baby, such

as refusing to hold it or look at it, further exploration and supportive follow-up are warranted as are documentation and communication with the other nurses caring for the family.

Nursing Tip

NURSING DIAGNOSES, POSTPARTUM

Appropriate nursing diagnoses during this stage are the following:

- Deficient fluid volume related to hemorrhage as evidenced by blood loss secondary to uterine atony or perineal trauma.
- Impaired skin integrity secondary to median episiotomy.
- Interrupted family process related to addition of a new member.
- Grieving related to the birth experience not being as was expected, or the newborn not being the desired sex, as evidenced by the mother refusing to hold the newborn.
- Risk of uterine and perineal infection related to bacterial invasion secondary to trauma during labor and delivery, episiotomy, and extended time with ruptured membranes.
- Health-seeking behaviors related to newborn care, self-care, normal postpartum physiologic occurrences as evidenced by the client asking questions.

Table 25-9 Lacerations of the Birth Canal

Degree	Involvement
First	Fourchette, perineal skin, and vaginal mucous membrane
Second	Fourchette, perineal skin, vaginal mucous membrane, and fascia and muscles of the perineal body
Third	A second-degree tear involving the anal sphincter
Fourth	A third-degree tear extending through the rectal mucosa to expose the lumen of the rectum

Figure 25-37 (continued)

Some women wish to breast-feed immediately after the baby is born. At this time, the newborn usually is quite alert and amenable to breast-feeding. Suckling the baby as soon as possible after the birth is desirable from the mother's viewpoint because it stimulates the release of oxytocin, which helps the uterus to contract and thereby prevents hemorrhage. Refer to Chapter 30 for a complete discussion of breast-feeding.

After the excitement and stress of labor and delivery, the recovery time is an appropriate time to review events with the parents and give positive reinforcement. The nurse encourages verbalization of the birth experience and provides explanations so that the client and family can better incorporate these events into their life experience. During this time it is not unusual for the mother to apologize to the nurse for making "too much" noise or for being irritable during labor. The nurse can promote positive recall of the birth experience by commending the woman for her efforts and reassuring her that she fulfilled her part well. The objective is for the woman to remember her childbirth experience as an empowering and satisfying event.

Maternal Status

As the mother's organs begin the task of readjusting to the nonpregnant state, careful observations are recorded by the nurse. The priority of care during the recovery period is prevention of hemorrhage from the placental site.

In LDR settings, the woman remains in the labor and delivery area for 1 to 2 hours of intense observation. Findings during these first 2 hours are charted in the Obstetric Recovery Record according to the hospital protocol (Figure 25-38). Handwashing precedes assessment. Nonsterile latex gloves are worn when the perineum is inspected or when there is a possibility of contact with mucous membranes, skin that is not intact, blood, or other body fluids. Hands are washed again after removal of gloves.

Uterus

The uterus is assessed every 15 minutes for the first hour. The woman is positioned with knees flexed and head flat. The nurse uses one hand to stabilize the uterus just above the symphysis pubis and the outer edge of the other hand to locate the fundus. Position of the fundus is noted in relation to the umbilicus and recorded as centimeters above or below the umbilicus. During the fourth stage, the fundal height usually is at the level of the umbilicus. Placement of the uterus also is noted in relation to midline. Consistency is noted: If the uterus is not firm, it is referred to as *boggy*, and the fundus is massaged gently in a circular motion until the uterus contracts and becomes firm (Figure 25-39).

Clots are expelled at this time by the nurse placing both hands on the mother as if for measuring fundal

height and applying gentle but firm pressure downward with the upper hand while observing the perineum for amount and size of expelled clots. Once the fundus is palpated firm, the nurse should not continue to massage because overmassaging is unnecessary and painful for the woman. A full bladder should be suspected when the uterus requires repeated massage to contract, remaining at the level of the umbilicus or above and being displaced to one side.

Lochia

Lochia is monitored every 15 minutes for the first hour, and the findings are recorded. The nurse notes the amount, color, and presence of clots. The red lochia encountered during this stage is known as lochia *rubra*. A standardized method for estimating the amount of lochia after delivery was devised by Jacobson (1985):

- ✿ Scant: Blood on tissue only when wiped or less than a 2-in stain.
- ✿ Light: Less than a 4-in stain on the peripad.
- ✿ Moderate: Less than a 6-in stain on the peripad.
- ✿ Heavy: A saturated peripad within 1 hour.

A perineal pad that is completely soaked with blood contains about 68 to 80 mL of blood (Lugenbiehl et al., 1990). When lochia is heavy, pads and linens should be saved for inspection by the physician or nurse-midwife. Continuous bleeding in the presence of a well-contracted uterus indicates soft tissue damage or retained products of conception such as placental tissue or membranes.

Prevention of Hemorrhage

Hemorrhage from the placental site is controlled by contraction of the uterus. Anything that impedes contraction of the uterus may result in postpartum hemorrhage. Assessments are designed to identify events that presage postpartum hemorrhage. The loss of at least 500 mL of blood is considered postpartum hemorrhage. The uterus is palpated at 15-minute intervals to ensure it is firm. A well-contracted uterus will not fill with blood. The peripad is

Nursing Alert

CHECKING FOR HEMORRHAGE

When assessing a newly delivered woman for bleeding, always look beneath her buttocks. Sometimes the perineal pad is barely soiled because blood is running down and pooling beneath the mother. The client may be completely unaware that she is hemorrhaging.

Figure 25-38 Recovery Flow Record. Courtesy of Hollister Incorporated.

Figure 25-39 Recovery assessment of the fundus.

checked every 15 minutes to monitor lochia. The fundus normally is firm or can become firm after gentle massage and expulsion of any clots that have accumulated within the uterus. Certain factors are associated with postpartum uterine atony:

- Rapid labor.
- Prolonged first and second stages of labor.
- Forceps or vacuum extraction.
- Overdistention of the uterus (owing to hydramnios, multiple gestation, or large fetus).
- Previous postpartum hemorrhage.
- Advanced maternal age.
- Parity of four or more.
- Abruptio placentae or placenta previa.
- Induced labor.
- Preeclampsia and eclampsia.

Perineum

The perineum is observed every 15 minutes for the first hour to assess the episiotomy site or laceration repair to ensure it is intact and for edema, bleeding, and hematoma. Ice packs provide comfort and prevent swelling.

Bladder

The woman may have difficulty voiding spontaneously owing to bruising of the meatus or the effects of epidural anesthesia. The nurse should palpate the bladder for filling every 15 minutes during the first hour. When the mother's

MAKE SURE THE BLADDER IS EMPTY

When your client is to be transferred after the recovery hour from an LDR room to a busy postpartum unit (with a higher nurse-client ratio), it is prudent to have the woman empty her bladder before she is transferred. A client who has not voided after delivery is at risk for hemorrhage secondary to uterine displacement by a full bladder.

vital signs are stable and she is not suffering the effects of sedation or anesthesia, she may be assisted to the bathroom to void. Alternatively, a bedpan may be offered. Urine is measured and the time of voiding recorded. A full bladder usually causes the uterus to become boggy and be displaced to the right, and may lead to increased bleeding. When the woman is unable to void even though the bladder is palpable, or the uterus is displaced, catheterization is necessary.

Blood Pressure

Recording of blood pressure provides a database for possible diagnosis of complications such as hypertension. Under normal circumstances, few alterations in blood pressure are seen and pressure readings should return to prelabor levels within the first hour of vaginal delivery. Blood pressure is monitored every 15 minutes for the first hour, or more frequently if the client's condition warrants (AAP & ACOG, 1997).

Heart Rate

Pulse readings are recorded every 15 minutes for the first hour, and rhythm and regularity are assessed. The pulse usually returns to the prelabor rate within the first hour after vaginal delivery. If the nurse detects tachycardia, dehydration or infection should be ruled out.

Temperature

A temperature reading is taken during the first hour. It is not unusual for the woman's temperature to increase to at least 100.4°F (38°C) owing to the dehydrating effects of labor; however a higher temperature than this should be reported to the primary caregiver.

Psychosocial Status

The mother may be emotionally and physically exhausted but at the same time elated. She may be talkative and

eager to phone friends and relatives with news of the newborn. Women often feel hungry immediately after delivery; however, food usually is withheld until after the recovery hour.

Pain

The mother may experience abdominal cramping commonly referred to as afterpains as the uterus contracts. Oxytocin administration after delivery of the placenta also will stimulate uterine contractions, and the nurse can explain to the woman the rationale for oxytocin administration and how this may cause some cramping. Analgesics should be administered according to the hospital policy, procedure, and protocol.

Maternal Teaching

The mother should be instructed in palpating her own uterus and how to massage it when necessary. The nurse can guide the woman's hand so that she can feel the firm contracted uterus (about the size of a grapefruit). It often is less uncomfortable for the mother to massage her own fundus than for this to be done by the nurse; however, teaching the mother in no way relieves the nurse of the responsibility of checking the fundus for firmness every 15 minutes during the recovery hour. It should be stressed that neither the woman nor the nurse should massage the fundus if it already is firm. Before she gets out of bed for the first time, the woman should be cautioned to call for a nurse to assist her.

Transfer to the Postpartum Unit

In some hospitals the mother remains in the same room for labor, delivery, recovery, and the postpartum period and the same nurse may care for the mother and infant. At other institutions the care may be handed over to a postpartum nurse. Many hospitals take the newborn to a nursery for 4-hours' transition time, during which the infant is observed closely. If the baby is to go to the nursery, the LDR nurse should encourage the partner to accompany it. When the father goes with the infant to the nursery, the mother may feel more at ease because she knows a family member is in attendance.

Recovery from Anesthesia

If the woman is to be transferred from the LDR to the postpartum unit, she should not be discharged from the LDR until her vital signs are stable. If she received epidural analgesia, she should be sufficiently recovered from its effects to be able to move both legs and raise her hips in order to move from the delivery bed to a gurney. Effects of an epidural may take several hours to completely dissipate; therefore, the mother should be instructed to call for

nursing assistance before getting out of bed the first time. A complete verbal report is given to the nurse coming on duty.

PRECIPITOUS DELIVERY

Occasionally, labor progresses so rapidly that the infant is delivered before the primary caregiver can attend, and therefore, the labor and delivery nurse assists the woman in giving birth. This is referred to as a **precipitous delivery**. The two most important concepts that the nurse must bear in mind when assisting a woman in the absence of the primary caregiver, is to support the fetal head as it descends, preventing it from popping out quickly, and to ensure that the newborn has a patent airway.

Nursing Alert

NURSING INTERVENTIONS DURING PRECIPITOUS DELIVERY

1. Instruct the woman to pant with contractions if the fetal head is crowning.
2. With a gloved hand, apply gentle pressure against the fetal head to maintain flexion and prevent it from popping out quickly. Support the perineum with the other hand.
3. When the fetal head is born, instruct the woman to pant and not to push. Suction the fetal nares and mouth with a bulb syringe.
4. Insert two fingers along the back of the fetal neck to check for a nuchal cord. If present, pull it over the infant's head. If the cord is too tight to pull over the infant's head, clamp it twice and cut between the clamps. Unwind the cord from around the neck.
5. While requesting the woman to push gently, exert gentle downward pressure on the head and neck to assist in the birth of the anterior shoulder. Then exert gentle upward pressure to assist with the posterior shoulder. Support the rest of the infant's body as it is born.
6. Place the newborn on the maternal abdomen, and dry the infant with warm blankets. Keep the newborn covered.
7. Check the firmness of the fundus and observe for bleeding.
8. Watch for signs of placental separation.

DELIVERY IN A NONHOSPITAL SETTING

Childbirth that occurs too rapidly for the mother to get to the hospital is referred to as **emergency childbirth**. Because there may be a certain amount of panic on the part of the mother and those with her, it is important that the person helping the mother remain calm and reassuring. Someone should call 911 as soon as possible so that help will be on the way. Most infants born under such nonconventional circumstances do very well, although they are at risk for cold stress. If there are other persons willing to give assistance, here are some main points to keep in mind.

1. Someone must be designated to take notes as the events unfold. The primary helper can dictate as the events unfold so that times will be accurate. Important information to record during emergency birth includes:
 - a. Time the membranes ruptured, color of the amniotic fluid, and any unusual odor.
 - b. Fetal position and presentation.
 - c. Time of delivery.
 - d. Presence or absence of the nuchal cord and the number of loops.
 - e. Apgar scores at 1 and 5 minutes after birth.
 - f. Resuscitation efforts, if needed.
 - g. Condition of the infant.
 - h. Sex of the newborn.
 - i. Time of delivery of the placenta and its appearance.
 - j. Amount of bleeding.
 - k. Woman's condition: interventions to control bleeding and condition of the perineum.
2. Try to ensure some privacy.
3. If the mother is lying on the floor, put something beneath her such as towels, a blanket, or layers of newspaper.
4. Help her to remove her clothing as necessary.
5. If you have a few minutes and the head of the infant is presenting, it is best to have the mother push between contractions rather than at the height of the contraction. This will help to prevent tearing. Positioning the mother on her side also will lessen the intensity of the contractions and lessen the pressure, which, in turn, will help prevent the infant's head from popping out precipitously. A lateral position and pushing between contractions also will lessen the risk for perineal tearing.
6. Place your hand against the infant's head to provide support and to prevent it from popping out precipitously.
7. Check whether the amniotic sac is intact. If it is, then try to tear the sac so the newborn will not breathe in amniotic fluid with the first breath. Sometimes the fetal membranes are covering the infant's face and are too slippery to be grasped. If this is the case, break the membranes when the head is out by inserting a finger into the infant's mouth.
8. When the infant's head is out, have the mother relax and stop pushing while external restitution takes place. Watch as the infant's face turns toward the mother's inner thigh.
9. While restitution is taking place, feel around the infant's neck for a possible nuchal cord. If you feel the cord, and it is loose, slip it over the infant's head.
10. After restitution there is no need for manipulation of the shoulders unless more than 3 or 4 minutes has passed since the birth of the head. Placing your hands on each side of the infant's head, covering the ears, and pushing gently down on the head toward the floor may help free the anterior shoulder, and then lifting up the infant may facilitate birth of the lower shoulder.
11. The infant must be supported as it emerges. Hold the newborn at the level of the uterus to facilitate blood flow through the umbilical cord. Bring the infant up onto the mother's abdomen and cover it with whatever is available, preferably a clean cloth or towel. Wipe the infant's nose and mouth with a cloth or towel.
12. It is essential to keep the infant warm at all times. The best way to do this is to lay the infant skin to skin on the mother and cover them both. While the mother is holding the infant close to her body, stimulate the infant to cry by gently drying the skin with the cloth. Assign an Apgar score without exposing the infant to cold air. There is no need to tie or cut the umbilical cord. It will stop pulsating within a few minutes.
13. If the infant is showing no signs of spontaneous respiration, rescue breathing must begin (adult mouth over infant's nose and mouth).
14. To facilitate separation of the placenta and membranes, by contraction of the uterus, the mother should be encouraged to put the infant to her breast at this time. Suckling of the infant stimulates uterine contractions through release of oxytocin from the pituitary gland.
15. Watch for signs of placental separation. When the placenta has separated, have the woman give one slow steady push and catch the placenta in your hands. Gently twist the placenta so that the trailing membranes will twist to form a rope as they slowly separate from the uterus. Try not to let the membranes tear away from the placenta.

Case Study/Care Plan

THE CLIENT WITH PAIN DURING A VAGINAL DELIVERY

Maria Brown, a 26-year-old gravida 3, para 2, is admitted to the labor and delivery unit at 41 weeks' gestation. Maria says that she thinks her "bag of waters" has broken. The nurse orientates Ms. Brown and her boyfriend to the labor, delivery, and recovery room (LDR). After Ms. Brown has undressed and put on a hospital gown, external fetal heart rate (FHR) monitoring is begun. The FHR has a baseline of 140 beats per minute (bpm) and good variability.

The nurse has Maria sign a consent form and proceeds with the interview and assessment. No risk factors are identified from the prenatal record and the nursing assessment. A vaginal examination indicates Maria's cervix is 80% effaced and 3 cm dilated. The presenting part is vertex at -1 station. No amniotic sac is palpated, and there is clear fluid draining from the vagina and pooling in the bed. Nitrazine paper, when touched to the wet bed linen, turns deep blue, indicating the presence of amniotic fluid. When asked the time the membranes ruptured, Maria indicates that they have been ruptured for 2 hours. The nurse-midwife is notified and states that she is en route to the hospital.

Maria's labor continues uneventfully. Blood is drawn for routine laboratory tests. Maria's temperature is taken every 2 hours. Various measures are employed to ensure her comfort during the first few hours. She ambulates up and down the hall with her boyfriend, and he brings her back to the LDR every 30 minutes for intermittent fetal monitoring. After 3 hours of labor, Maria says that she would like to rest in bed. The nurse and Maria's boyfriend help her into a comfortable lateral position and support her with extra pillows.

At 5 cm dilation, Maria becomes increasingly uncomfortable and requests epidural anesthesia. The nurse starts IV lactated Ringer's solution, 1 L, to infuse over the next 30 minutes. The anesthesiologist briefly interviews Maria as the nurse positions her to receive the epidural anesthesia. The boyfriend helps to support Maria in the required position.

Thirty minutes after the epidural is placed and Maria is feeling comfortable once more, vaginal examination reveals the cervix to be 8 cm dilated, 100% effaced, and the vertex at 0 station. At this time, the FHR decelerates from the 140 bpm baseline to 90 bpm, and then to 60 bpm. Maria's blood pressure is 94/44 mm Hg. The nurse quickly turns Maria on her side and opens the IV to give a rapid bolus of fluid. Oxygen is started by way of a non-rebreather mask, at 10 L/min. After 2 minutes, Maria's blood pressure is 100/54 mm Hg, and the FHR has returned to baseline. After a 500-mL bolus of IV fluid has been infused, the nurse slows the rate to 125 mL/h. Vaginal examination reveals the cervix still 8 cm dilated, 100% effaced, but the vertex is at $+1$ station. A fetal scalp electrode is placed for internal FHR monitoring. The amniotic fluid remains clear, and Maria is afebrile. A Foley catheter is inserted and attached to bedside drainage. Intake and output are recorded carefully.

Labor continues uneventfully for the next 3 hours, when Maria is fully dilated and the presenting part is at $+2$. Because of the effects of the epidural, Maria does not have an urge to push. The nurse instructs Maria how to support her knees, and to push when there is a contraction. After 1 hour of pushing, a viable male is delivered and placed skin to skin on the mother's abdomen. Maria's boyfriend, the baby's father, is able to cut the umbilical cord. The Apgar scores are 8/9/9. The placenta and membranes are delivered complete 5 minutes later. Total blood loss is 250 mL; the perineum is intact although swollen. An ice pack is applied. Maria and her boyfriend are jubilant as she prepares to breast-feed their new son.

Assessment

MB is 26 years old and in labor with her third baby. External fetal monitoring is in progress and the FHR shows average variability, with a baseline of 140 bpm. Vaginal examination reveals MB's cervix is 3 cm dilated, 80% effaced, and vertex presentation at -1 station. Membranes are ruptured, and the amniotic fluid is clear. Contractions are moderate in intensity. MB is gasping with each contraction and sometimes verbalizing pain.

(continued)

Nursing Diagnosis

Pain related to uterine contractions and cervical dilation as evidenced by MB's facial contortion and gasping when uterine contractions occur and her statement: "I am really hurting now."

Expected Outcome Maria will verbalize decreased discomfort with uterine contractions and experience a degree of relaxation.

Planning The nurse must take into account the length of time Maria's labor is likely to endure (she is only 3 cm dilated), and structure care to help Maria cope with labor progress.

Nursing Interventions	Rationales
1. Assess the MB's preparation for labor.	1. Patients who have attended childbirth preparation classes often use psychoprophylactic methods to reduce pain.
2. Teach MB breathing techniques during early labor.	2. Controlled thought and focused breathing will increase relaxation. Patients are more receptive to teaching during early labor.
3. Encourage MB's boyfriend in methods that may help to reduce her discomfort: offering fluids, ice chips as ordered, back rubs, assist MB into comfortable position, give praise.	3. Measures are often more effective when effective when delivered by a familiar person. Studies have shown that a support person helps to reduce the length of labor.
4. Provide comfort measures.	4. Ambulation, back rubs, change of position, extra pillows, warm shower, and other comfort measures help to reduce the discomfort of labor.
5. Explain what analgesics and anesthesia are available for use during labor and mode of administration.	5. Explanation of pharmacological methods of pain control will provide knowledge to help MB make decisions about analgesia and anesthesia.
6. Assist in the placement of an epidural catheter, if ordered.	6. Regional anesthesia provides analgesia and anesthesia during labor and delivery.
7. Keep MB aware of her progress and review the process of labor.	7. Knowledge that she is making expected progress will allay anxiety and increase coping.
8. Encourage regular voiding to decrease the chance of distention.	8. Bladder distention can increase discomfort during contractions and impede the progress of labor.
9. Encourage conscious relaxation between contractions.	9. Fatigue contributes to increased pain perception and inability to cope with pain.

Evaluation

MB verbalizes decreased discomfort with her contractions during early labor with the assistance of her boyfriend and the nurse, who supplied back rubs, extra pillows, encouragement, information, assistance in positioning, and ambulation. As labor progressed, and after receiving information about analgesia and anesthesia, MB made the decision to have epidural analgesia. After the epidural was placed, MB was able to rest peacefully and stated: "I can no longer feel any pain with my contractions."

16. Wrap the placenta and place it together with the infant; it will provide some warmth.
17. Check the firmness of the uterus. The fundus may be massaged to stimulate contractions and decrease bleeding.
18. Clean the area under the mother, and inspect the perineum for lacerations. Bleeding from lacerations may be controlled by pressing a clean peripad against the perineum and instructing the woman to keep her thighs together.

Web Activities

- What information can you find on the Doulas website?
- Outline client teaching tips drawn from the Lamaze internet offerings.

Key Concepts

- Nursing care of the laboring woman is very complex because the nurse must ensure the well-being of the mother and fetus throughout the labor process.
- Although labor and delivery are normal physiologic events, there is a great potential for negative outcomes.
- In many birthing units, the nurse is the sole health care provider with which the client interacts throughout labor.
- The nurse who provides intrapartum care must have a thorough understanding of the labor process as

well as signs of fetal status to identify actual or potential labor complications.

- Initial and ongoing assessment for risks and changes in condition are of paramount importance.
- Every woman deserves to have the most positive birth experience possible considering her condition.
- Interventions that provide relaxation and comfort to the laboring woman facilitate the birth process.
- Every woman deserves to know her birth experience was special.

Review Questions and Activities

1. What should the nurse ask first about the amniotic sac?
 - a. Presence of bloody show
 - b. Time the membranes ruptured
 - c. Frequency of contractions
 - d. Appearance of the fluid

The correct answer is d.

2. Estelle is encouraged to change positions to promote comfort. Which position should not be used during labor?
 - a. Lateral position
 - b. Squatting position
 - c. Standing position
 - d. Supine position

The correct answer is d.

3. Which of the following structures are involved when an episiotomy is performed?
 - a. Glans clitoris
 - b. Labia minora
 - c. Levator ani muscle
 - d. Labia majora

The correct answer is c.

4. Which of the following is an expected characteristic of amniotic fluid?
 - a. Deep yellow color
 - b. Clear, with small white particles
 - c. Nitrazine test shows acidic result
 - d. absence of ferning

The correct answer is b.

5. When planning care for a woman whose membranes have ruptured, the nurse recognizes that the woman is at increased risk for:
 - a. hemorrhage
 - b. precipitous labor
 - c. supine hypotension
 - d. intrauterine infection

The correct answer is d.

6. When assessing a woman in the first stage of labor, the nurse recognizes that the most conclusive sign that uterine contractions are effective would be:
 - a. dilatation of the cervix
 - b. presence of caput succedaneum on the vertex
 - c. rupture of amniotic membranes
 - d. increase in bloody show

The correct answer is a.

7. The nurse who performs vaginal examinations to assess a woman's progress in labor should:
- perform an examination at least once every hour during the active phase
 - perform the examination more frequently if vaginal bleeding is present
 - wear two clean gloves for each examination
 - discuss the findings with the woman and her labor partner

The correct answer is d.

8. The nurse knows that the second stage of labor has begun when the:
- Amniotic membranes rupture
 - Cervix cannot be felt during a vaginal examination
 - Woman experiences a strong urge to bear down
 - Presenting part is below the ischial spines

The correct answer is c.

9. The most critical nursing action when caring for the newborn immediately after birth is:
- Keeping the newborn's airway clear
 - Fostering parent-newborn attachment
 - Drying and wrapping the newborn in a blanket
 - Recording the time of birth and Apgar score

The correct answer is a.

10. The nurse prepares to administer oxytocin to a woman, after expulsion of the placenta, to:
- Relieve pain
 - Stimulate uterine contraction
 - Prevent infection
 - Facilitate rest and relaxation

The correct answer is b.

High-Risk Births and Obstetric Emergencies

Complications arise suddenly and often quite dramatically in obstetrics. Complications can transform a routine antepartum or intrapartum experience into an emergent situation, with both maternal and fetal well-being at stake. Because of the ever-present potential for complications to arise, the obstetric nurse should possess strong critical thinking skills coupled with anticipatory preparations that allow immediate intervention. The nurse must incorporate these skills and preparations without compromising the birthing environment in which the client and her family are seeking to participate. Balancing the goals of positive birth experiences with acute and intensive support of maternal and fetal status can be quite a challenge for the professional nurse. As you review the following questions, reflect on your own personal views, experiences, and coping mechanisms:

- ❖ *How do I feel about being responsible for the fetus whose status may be difficult to assess because of limited available assessment data?*
- ❖ *How do I react in emergency situations?*
- ❖ *Have I ever been present during a cesarean section? How did I feel?*
- ❖ *Have I ever been present at a delivery where complications occurred? How did I respond?*
- ❖ *Have I or has anyone close to me experienced a perinatal loss, had a baby born with a birth defect, or had an infant injured at birth? How do I feel about that experience now?*
- ❖ *How do I feel about comforting a client who will have or has had a baby requiring intensive care, or who has had an infant who will not or did not survive?*

Key Terms

Abruptio placentae	Face presentation	Malposition	Shoulder presentation
Amniotic fluid embolism	Fetal distress	Malpresentation	Transverse lie
Amniotomy	Hydrocephalus	Multiple gestation	Turtle sign
Anencephaly	Hypertonic labor	Oligohydramnios	Umbilical cord
Breech presentation	Hypotonic labor	Placenta percreta	compression
Brow presentation	Intrauterine pressure	Placenta previa	Umbilical cord prolapse
Cephalopelvic	catheter (IUPC)	Polyhydramnios	Undulating variability
disproportion (CPD)	Kleihauer-Betke test	Precipitate labor	Uterine rupture
Contracted maternal	Labor augmentation	Short-term variability	Vasa previa
pelvis	Long-term variability	(STV)	Velamentous insertion of
External cephalic version	(LTV)	Shoulder dystocia	the cord

Competencies

Upon completion of this chapter, the reader should be able to:

1. Identify selected dysfunctional labor patterns and the nursing interventions to enhance maternal and fetal well-being.
2. Identify and differentiate the common fetal malpositions and malpresentations. Discuss the assessment data relative to confirming the fetal position. Explain the delivery concerns for each of the malpositions and malpresentations.
3. When fetal distress occurs, integrate the nursing process by focusing on assessment, diagnoses, and implementation of appropriate interventions to achieve the desired outcomes. Describe the evaluation parameters that will verify successful implementation.
4. Discuss the assessment data found in clients who have experienced uterine rupture and the plan for implementing care and evaluation of outcomes.
5. Compare and contrast the assessment parameters found with placenta previa and abruptio placentae. Differentiate the plans of care and evaluations of outcomes.
6. Discuss the assessment findings that indicate a prolapsed umbilical cord and the emergent implementation of required interventions.
7. Identify the hemorrhagic conditions that predispose obstetric clients to coagulopathies, such as disseminated intravascular coagulation, or DIC.
8. Discuss the maternal and fetal implications when a diagnosis of oligohydramnios or polyhydramnios has been confirmed. Identify the contributing causes of both of these abnormal volumes of amniotic fluid.
9. Describe the assessment data indicative of amniotic fluid embolism and two critical factors impeding maternal survival.

Pregnant clients at risk for or who incur obstetric emergencies are dependent on the entire health care system to support their needs during pregnancy, labor, and delivery. Because of the constant interaction with the professional nurse during the labor and delivery process, clients and their support persons anticipate and trust that the nurse will be

ready to identify problems that develop and intervene immediately. The goal is clear: a positive outcome for both mother and child. That goal, however, is not always easily achieved.

Integration of the nursing process into the high-risk obstetric setting can be challenging. Assessment of clients includes reviewing historical and prenatal data; complet-

ing a maternal physical assessment; assessing fetal status; and obtaining pertinent emotional, cultural, developmental, and educational data. The development of outcomes or goals must be done with regard to the current plan of medical management. Nursing plans and interventions may combine one-on-one interactions, such as massaging and positioning clients, with highly technical skills, such as maternal-fetal monitoring and management of multiple medications to augment labor. Evaluation of the process depends on the confirmation of assessment data, success of the nursing interventions, and comparison of the actual with the desired maternal-fetal outcomes.

The obstetric nurse working in labor and delivery often provides care in an atmosphere of a relaxed home environment. The nurse's initial interactions with the client and her significant others include acknowledging their hopes and dreams for their expected baby. The expectations of the client and her support persons for the pregnancy, labor, and delivery are affected by various factors: family structure; cultural aspects, including language barriers; educational levels; and religious beliefs. The relationship that develops between the nurse and client often is a personal one that may last throughout the labor and delivery experience. The nurse must take the time to establish rapport and trust with the client. Rapport may enable the nurse to accomplish necessary interventions quickly and efficiently, while minimizing the client's fear and anxiety (Manogin, Bechtel, & Rami, 2000). The nurse also must be able to recognize the many feelings that the woman may experience as an obstetric patient at high risk. These feelings vary with the person and the chronicity of the problem but may include a sense of entrapment or being held prisoner, boredom, loss of control, reversal of the role of caregiver to one of being cared for, and frustration with the limitations imposed by bed rest and hospitalization. The nurse is challenged to incorporate interventions that minimize negative feelings and support optimal coping (Gupton, Heaman, & Ashcroft, 1997). Establishing a strong relationship between the nurse and client, and the client's support persons, confirms the nurse's role as a client advocate during the course of care.

Assessment of maternal-fetal status is critical. The total clinical picture should incorporate data from both the mother and fetus that offer reassurances of maternal stability and fetal well-being. The assessment process is very dynamic in the intrapartum period because changes that compromise the maternal-fetal status may occur in minutes. Interventions also are completed quickly and often have results requiring immediate evaluation. Quick interventions, however, should not be the result of an incomplete assessment. Complete assessment of critical information best enables the nurse to formulate diagnoses, intervene appropriately, and achieve successful and timely outcomes.

REFLECTIONS FROM A NURSE

"The miracle of birth is an awesome experience. To participate and support a client throughout the course of her labor and delivery is rewarding. Encountering and overcoming the challenges of high-risk situations, complications, and obstetric emergencies to achieve a positive birth outcome truly result in a victory for the obstetric health care team! Regardless of the outcome, providing professional, supportive, and compassionate care is equally challenging."

The intensity and speed of the labor and delivery process may at times produce a feeling of being overwhelmed in clients, support persons, and even the nurse. These feelings become more intense as high-risk situations, complications, or emergent situations arise. It is important for the nurse to remain calm, use critical thinking skills, communicate clearly, and intervene appropriately. To help increase the efficiency of interventions during an emergent situation, the nurse should anticipate client needs; ready equipment and other personnel; and put in place well-established lines of communication with the physician or Certified Nurse Midwife (CNM), nursery, anesthesia services, and additional team members.

Several conditions make the intrapartum period one of high risk. Conditions that will be addressed in this chapter include dysfunctional labor patterns, fetal malpresentation, maternal and fetal structural anomalies, multiple gestation, fetal distress, uterine rupture, placental anomalies, umbilical cord anomalies, and amniotic fluid anomalies. Each condition requires astute nursing care to ensure positive maternal and fetal outcomes.

DYSFUNCTIONAL LABOR PATTERN

A **dysfunctional labor pattern** is a labor processes that does not proceed normally. Normal labor is characterized by uterine activity that causes cervical change in effacement and dilation and fetal descent, resulting in a vaginal delivery (Cunningham et al., 1997). Dysfunctional labor patterns often are medically classified as labor dystocias (Bashore, 1992). Labor dystocias are ranked as the leading cause of primary cesarean sections at approximately 43%

(Cunningham et al., 1997). Labor dystocias during the first stage of labor occur in 8% to 11% of vertex presentations. They occur at approximately the same rate during the second stage of labor (Wiznitzer, 1995). Hypertonic labor, hypotonic labor, and precipitate labor are three types of dysfunctional labor patterns, or dystocias, attributed to uterine dysfunction.

Hypertonic Labor

Hypertonic labor is classified as an “abnormality of the expulsive forces” of the uterus in *Williams Obstetrics* (1997). The pattern of uterine activity includes uterine irritability, poor resting tone, and contractions occurring at a frequency of closer than every two minutes. Whereas this pattern of uterine activity is painful to the pregnant client, it usually is not effective in causing the cervical changes necessary for labor to progress and the fetus to descend. Maternal and fetal factors that contribute to hypertonic labor include primiparous labor, fetal presentation other than cephalic, persistent occipitoposterior position (Joshi & Bharadwaj, 2000), flexion of the fetal head, and increased fetal size. Up to 50% of the time however no attributable cause for the dysfunction can be clearly identified (Cunningham et al., 1997).

The consequences of a hypertonic uterine pattern may include maternal exhaustion and inadequate pain relief from prolonged uterine activity, a prolonged latent or active phase of labor, increased risk for maternal or fetal infection when the membranes have ruptured, and increased risk for maternal or fetal injury.

Medical management of hypertonic labor patterns may be approached in more than one way. The physician or CNM may choose to allow the client to rest using hydration and sedation, which also will reduce uterine irritability and allow reevaluation of uterine activity (Cunningham et al., 1993). When the membranes have already ruptured, resting the client is not an option. The physician or CNM also may choose to use oxytocin to stimulate a more effective contraction pattern (Bashore, 1992). When oxytocin is used to enhance ineffective uterine activity, the procedure is called **labor augmentation** (Payton & Brucker, 1999).

The nursing process begins with thorough maternal and fetal assessments. Data that will assist in confirming a hypertonic uterine pattern focus first on assessment of uterine activity. Manual palpation of uterine activity and the uterine activity recording found on the external fetal monitor tracing provide valuable information to the nurse. Contraction activity may occur closer than every two minutes, with poor uterine relaxation between contractions. The contractions usually will not feel firm even at peak intensity, although the client may voice variable levels of discomfort. The pelvic examination should include assessment of cervical dilation and effacement and fetal station,

Critical Thinking

Oxytocin and Propanolol

A 1996 study reported the comparison of oxytocin augmentation alone with oxytocin augmentation accompanied by the additional administration of intravenous (IV) push doses of propanolol in the treatment of dysfunctional labor. The study results were favorable, with the group receiving both oxytocin and IV propanolol having fewer cesarean sections. In addition, no increase in poor maternal or fetal delivery outcomes were reported. The outcomes of this study will change the management of dysfunctional labor patterns. What is your opinion of the value of the oxytocin-propanolol combination?

Sanchez-Ramos, L., Quillen, M. J., & Kaunitz, A. (1996). Randomized trial of oxytocin alone and with propanolol in the management of dysfunctional labor. *Obstetrics and Gynecology*, 88, (4), 517–520.

presentation, and position. Failure to observe changes in the cervix or fetal descent in the presence of irritable uterine activity indicates an ineffective pattern of labor. Membrane status must be assessed. When the membranes have ruptured, the risk for infection becomes a consideration in the client's medical management. Augmentation is the primary medical management of a hypertonic pattern of labor when the membranes have ruptured.

Fetal tolerance to the contraction pattern also must be assessed (Box 26-1). Assessment is accomplished through auscultation or, better, intermittent or continuous external fetal monitoring. When fetal monitoring is employed, data used to make the assessment include fetal heart rate baseline, the presence of heart rate variability, the presence and type of periodic changes, and any nonperiodic changes (Feinstein & McCartney, 1997). Maternal vital signs, including temperature and input and output status, may offer information about her physical tolerance of the labor pattern. The assessment also should indicate the client's level of knowledge, particularly of the labor experience, and the cultural and religious considerations that may affect her response to the labor process.

Nursing diagnoses for a client experiencing a hypertonic labor pattern may include the following:

1. Risk for infection (maternal or fetal) related to prolonged latent labor process, as evidenced by maternal fever of 100.4°F, maternal tachycardia, fetal tachycardia, or a combination of these (Feinstein & McCartney, 1997).

Box 26-1 Fetal Monitoring Terms and Parameters**Baseline Data**

Rate: Maintained for a minimum of 10 minutes.

Normal: 120–160

Tachycardia: >160

Bradycardia: <110

Fetal Heart Rate Variability: The heart rate changes from beat to beat or over an extended period of time measured in one-minute intervals that indicate central nervous system status.

Short-term variability (STV): Measured in beat-to-beat changes in the baseline as either present or absent. Only measurable with internal mode of fetal monitoring.

Long-term variability (LTV): Measured in minute intervals from the baseline and rated as follows: decreased, 0–5 bpm; average, 6–25 bpm; or marked, >25 bpm (on a 3-point scale).

Undulating variability: Waveform variation that is repetitive and almost uniform in appearance, including sinusoidal and pseudosinusoidal patterns.

Rhythm**Regular****Irregular**

Periodic Changes: Heart rate changes in response and relation to the occurrence of uterine activity.

Accelerations*: Variations upward from baseline. Presence, frequency, peak, and duration of accelerations are assessed.

Decelerations*: Variations downward from baseline. Presence, frequency, shape, type classification, depth, and durations are assessed.

Variable: Frequency and timing in relation to contractions, shape, and duration vary.

Early: Shape and occurrence are more uniform before or with contractions; “mirroring.”

Late: Shape and occurrence also are uniform but begin during or after contractions.

Prolonged: >2 minutes but <10 minutes in duration.

*Accelerations and decelerations also may occur without a defined relationship to the contraction and are then termed nonperiodic or spontaneous in occurrence.

Adapted From Feinstein, N., & McCartney, P. (1997). *AWHONN: Fetal heart monitoring principles and practices*, 2nd ed. Dubuque, IA: Kendall/Hunt.

2. Acute pain (maternal) related to uterine irritability and prolonged labor, as evidenced by frequent or persistent maternal requests for pain relief, frequent uterine contractions, poor uterine resting tone, and failure of the cervix to dilate 1- to 2-cm/h on cervical assessment.
3. Deficient knowledge of labor processes and variations related to inexperience and unfamiliarity with intervention options, as evidenced by client questions and an inability to cooperate with requested interventions.
4. Fatigue (maternal) related to a prolonged labor process, as evidenced by an inability to rest between contractions, inadequate pain relief, client statements of exhaustion, and client inability to cooperate with requested interventions.
5. Impaired gas exchange (fetoplacental) related to hyperstimulation of the uterus with oxytocin augmentation, as evidenced by nonreassuring fetal tracing inclusive of severe variable decelerations; late decelerations; bradycardia; or loss of long-term or short-term variability, or both. Inadequate fetoplacental oxygenation as a result of uterine hyperstimulation can adversely affect the fetus (Feinstein & McCartney, 1997).
6. Anxiety related to unfamiliar experiences, surroundings, and unexpected medical nursing interventions, as evidenced by client verbal and nonverbal behaviors.

Desired outcomes are based on the nursing diagnoses developed for the client. Prevention of risks for problems

or resolution of actual problems are addressed in the following outcome statements:

1. Client and fetus will not experience infection related to a prolonged labor process.
2. Client will verbalize effective pain relief without demonstrating adverse maternal or fetal response to the selected interventions.
3. Client and support persons will verbalize an understanding of the uterine pattern; plan of care to address it; and expected outcomes, including the projected mode of delivery. The client also will be able to participate in and cooperate with requests from the nurse.
4. Client will not experience exhaustion related to prolonged fatigue during a hypertonic labor pattern.
5. Fetus will not exhibit **fetal distress**, a nonreassuring fetal heart rate response to the intrauterine environment as a result of the hypertonic labor pattern or oxytocin augmentation of labor.
6. Client will demonstrate effective coping behaviors in response to heightened anxiety.

Achieving the above outcomes requires ongoing assessment and support of the client by the professional nurse. The nurse must assess maternal-fetal status and relay the pertinent information to the attending physician or CNM. Critical elements include monitoring of uterine activity, results of the pelvic examination (changes in cervical dilation or fetal descent), maternal vital signs, and fetal heart rate data. Changes in maternal-fetal status may alter the current medical plan of management. For instance, if the initial medical plan was to rest the patient and on reassessment the fetal heart rate data are of concern, the physician or CNM may decide to augment the labor pattern and move toward delivery.

Assessment data should include ongoing monitoring for signs of infection. The fetal heart rate and the maternal temperature, heart rate, and respirations may increase with the onset of infection. Fetal tachycardia is most frequently the result of maternal fever or maternal or fetal infection (Feinstein & McCartney, 1997). Monitoring maternal input and output reduces the likelihood of dehydration being a cause of maternal fever and maternal or fetal tachycardia. Monitoring of the input and output also is critical when oxytocin is administered because of its antidiuretic effect and the potential for water intoxication (Payton & Brucker, 1999; Cunningham et al., 1997). Ongoing maternal-fetal assessments become even more imperative once the membranes rupture and this barrier of defense is no longer intact.

Anxiety can increase catecholamine secretion and thus lead to a dysfunctional labor process (Feinstein & McCartney, 1997). Aside from the physiologic effects, anxiety im-

pacts the client's perception of the birth experience and can further impact the resolution or successful integration of the events into her adaptation from pregnancy to parenthood. Lack of knowledge can increase the anxiety levels of both the client and her support persons. Thus, all interventions should be explained in a manner best understood by the client and questions should be encouraged and answered. Initially establishing rapport with the client and her support persons is fundamental in developing trust. In turn, trust can allay fears and reduce anxiety. A trusting relationship also makes it easier for the client to follow instructions and better participate in the labor process. When the client and her support persons feel the nurse is aware and respectful of their level of knowledge and any cultural or religious considerations, they are more likely to cooperate and actively participate in the plan of care. Finally, when they believe the nurse is knowledgeable and capable of managing the client's care, the labor experience is more likely to be perceived as being positive, regardless of the need for technical intervention (Manogin, Bechtel, & Rami, 2000).

The nurse can help provide pain relief by using physical comfort measures such as position changes, lower back rubs, counterpressure at the lower back during a contraction (pressing the fist firmly into the identified pressure point low on the back), and administration of analgesic medications. The physical presence of the nurse along with sincere encouragement may further alleviate anxiety that may enhance pain perception (Manogin, Bechtel, & Rami, 2000). An explanation about the medications and the likely responses after administration may further reassure the client regarding pain relief. Ensuring that the environment is conducive to rest by reducing external stimuli (e.g., lowering lighting levels, reducing the volume on noise-producing equipment, and turning off televisions) is another intervention the nurse can use. Although the nurse does not insert or administer epidural anesthesia, assisting with adequate hydration, assessing baseline vital signs, positioning the client, and evaluating maternal-fetal responses to the effects of the epidural anesthesia are all within the nursing role. Finally, the nurse can help the client achieve adequate pain relief and reduce fatigue by evaluating her responses to the medications, regional anesthesia, and physical comfort measures taken, and by promoting rest opportunities between contractions.

When the physician orders oxytocin to augment labor, the nurse should ensure that the orders and protocols for administration are observed. Adding the correct amount of oxytocin to the IV solution and administering it to the client by IV pump through a piggyback approach to the main IV line are all important steps in this process. Monitoring the maternal-fetal responses to the augmentation process is critical because the increase in dosage is titrated to these responses. Some protocols require dosage in-

creases of a set amount of milliunits every 15 to 30 minutes until an effective labor pattern is achieved. The parameters may be established by the individual physician after a low-dosage regimen or may follow a high-dosage regimen. The administration rate of a low-dosage regimen is 0.5 to 2 mU/min and is increased by the nurse every 15 to 40 minutes, with a maximum dosage limit between 20 and 40 mU/min. When a high-dosage protocol is ordered, the starting rate may be 6 mU/minute, with increases every 20 to 40 minutes and a maximum dosage of 40 mU/min (Payton & Brucker, 1999). Regardless of the protocol, the nurse should try to ensure the occurrence of regular contractions of moderate to firm intensity that last 30 to 60 seconds every 2 to 5 minutes, without causing maternal or fetal compromise.

Once an effective labor pattern is established and cervical change occurs, the physician may choose to perform an **amniotomy**, which is artificial rupture of the membranes to further augment the labor process (Figure 26-1). When assisting with the amniotomy, the nurse should ensure that the fetal heart tracing remains stable and note the color, amount, particulate matter in, and odor of the fluid. At that time, fetal monitoring options may include internal monitoring modes to increase the accuracy of uterine activity assessment (intrauterine pressure catheter [IUPC]), fetal heart rate assessment (fetal spiral electrode [FSE]), or both. Having the amniotomy hook, internal monitoring devices, sterile gloves, appropriate monitor cables, towels, and fresh hip pads readily available will enhance the efficiency of the procedure. Although the modes of data attainment may have changed, the nurse is still responsible

for ongoing maternal-fetal assessments as the client progresses through labor.

Evaluation of maternal-fetal status ensures that the interventions employed have been effective. Medical management and nursing interventions may need to be altered or continued based on the findings of the evaluation.

1. Are signs of infection present? Are maternal and fetal vital signs stable? Is the fetal heart rate tracing reassuring, with long-term variability and accelerations present?
2. Is the client's pain relieved? Does she state there is less pain? Does she appear less distressed? Is there less uterine irritability, or is there better uterine relaxation between contractions? Are the contractions less frequent? If an epidural is in place, is it intact? Has the client stated she has adequate pain relief from the epidural without demonstrating hypotensive responses, fetal bradycardia, or prolonged decelerations?
3. Does the client understand what is happening? Does she ask appropriate questions? Is she cooperative? Does she verbalize understanding? Do her support persons verbalize an understanding of the process? Do they express confidence in the management of care?
4. Does the client rest between contractions? Does she verbalize resting between contractions? Does she participate in her care?
5. Does the client's labor pattern become effective? Is there cervical change? Is there fetal descent? Are the maternal-fetal responses to the augmentation of labor reassuring or stable?
6. Has the client and her support persons coped with the process of labor and the associated interventions effectively? Has she verbalized relief or reduction of anxiety?

A hypertonic uterine pattern of labor may evolve into a normal labor pattern, and the client eventually will deliver vaginally. In contrast, an ineffective pattern of labor may continue, necessitating a cesarean section either as a result of arrested labor or because the maternal or fetal status shows evidence of compromise. The professional nurse must continuously assess maternal-fetal status and communicate this information to all health care providers to optimize outcomes. Readiness to initiate alternative interventions in the event the desired outcomes are not achieved is essential. The physician or CNM, anesthesia services, nursery, and all health care personnel required at the delivery should be kept abreast of the client's changing status. Finally, the nurse is responsible for recording the following: assessment data, interventions employed, maternal-fetal responses, and evaluations of outcomes.

Figure 26-1 A. Disposable amnihook to rupture membranes. B. Technique for amniotomy.

Hypotonic Labor

Hypotonic labor refers to uterine contractions that are inadequate in terms of frequency, intensity, or duration. Hypotonic labor tends to occur during the latent or active phase of labor. The client experiences contractions that are ineffective in causing cervical dilation or effacement, or fetal descent. Risk factors that contribute to the occurrence of a hypotonic labor pattern include large fetal size, fetal malpresentation, and early or repeated maternal sedation in labor. Recent concerns have been voiced regarding epidural administration as a contributing cause of hypotonic labor patterns. Current studies do not support the claim that epidural anesthesia negatively impacts labor, although it is frequently used for pain management in clients with ineffective labor patterns because of increased need for adequate pain relief (Thompson, et al., 1998). In another study, Clark, et al., (1998) further found that epidural anesthesia did not increase the rate of cesarean sections in women with dystocia managed actively with oxytocin. Similar findings were the result of a study by Bofill et al., (1997). The significance of these studies impacts the nurse in two ways. Epidural anesthesia is a viable pain relief intervention that is monitored throughout its duration of action by the nurse. In addition, each study acknowledges the need for strict active management of the labor method that employs the high-dosage oxytocin protocol. This method requires the nurse to intensively monitor maternal-fetal responses and oxytocin titration based on uterine activity. The results of a hypotonic labor include prolonged latent labor, prolonged active labor, or both; increased risk for maternal or fetal infection; increased risk for fetal compromise from insufficient reserve; maternal fatigue and exhaustion; and the need for additional medical, technical, and nursing interventions, including altering the client's desired birth plan.

Medical management of the hypotonic labor pattern is similar to that used for the hypertonic labor pattern. The physician or CNM may choose to allow the client to rest by administering hydration and sedation and then reevaluate her later for cervical changes, fetal descent, and improved uterine contraction activity. The other management option is to augment the labor with IV piggyback administration of oxytocin, amniotomy, or both.

Nursing considerations for the client with hypotonic labor include assessment information obtained from the monitoring of uterine activity and the pelvic examination. Maternal vital signs and fetal status must be assessed and monitored closely for changes that may indicate either complications or progression of labor. The nursing assessment should explore the client's level of formal or experiential knowledge, cultural and religious considerations, influence of support persons, and her perceived fear and anxiety level.

As with the hypertonic labor pattern, the nursing diagnoses for hypotonic labor address the risk for maternal and fetal infection. Prolonged labor processes related to hypotonic labor patterns also can impair fetoplacental gas exchange relative to the sheer duration of the labor process and the lack of further fetal reserve (Feinstein & McCartney, 1997). Maternal pain and fatigue and knowledge deficit of the client and her support persons also are risk factors in hypotonic labor. The client may incur heightened anxiety, particularly when it seems as if little to no progress is being made. The desired outcomes for these diagnoses also will be similar to those for hypertonic contraction patterns. The ultimate outcome is for the client to deliver vaginally, without evidence of maternal or fetal compromise.

The nursing plan and interventions employed also are similar to those used for hypertonic labor patterns. Continuous monitoring for signs of maternal or fetal infection and fetal intolerance to oxytocin augmentation is imperative. Implementation of client comfort measures, use of labor pain relief methods, emotional support of the client and her support persons, and ongoing client teaching are instrumental throughout the labor process. The nurse must always anticipate alternative outcomes that require rapid intervention. Communication and documentation of assessment data, interventions, and evaluations also are necessary. Communication and documentation cannot be overstressed in an area where dramatic changes may occur very rapidly.

In evaluating outcomes the nurse should ask pertinent questions of the situation.

- Have the outcomes been achieved or are further interventions required?
- Is the medical management of the client changing?
- Will the nursing interventions need to change to support the medical management?
- Is the maternal-fetal status stable?
- Is the client coping effectively?
- Are her support persons able to support her and participate in her care?
- What is the delivery outcome?
- Is the neonate stabilized easily at birth?
- Is the mother able to initiate bonding interactions with her newborn?

Precipitate Labor

Precipitate labor refers to a labor pattern that progresses rapidly and ends with delivery occurring less than three hours after the onset of uterine activity. Maternal and fetal contributory factors for precipitate labor include maternal

Research Highlight

Prediction of Difficult Birth

Purpose

A total of 1,692 clients were evaluated in early labor, and predictions were made for easy labor-vaginal birth, difficult labor-vaginal birth, or improbable vaginal birth-cesarean section.

Method

The prediction was based on clinical evaluation of pelvic dimensions, and fetal measurements by sonography at term.

Findings

The combined prediction that a client would have either a difficult labor-vaginal birth or cesarean section was very accurate (362 out of 370, or 97.8%). However, the separate prediction of difficult labor-vaginal birth and a cesarean section was less accurate, although still significant (73.4% and 90.2%, respectively).

Nursing Implications

Careful evaluation of a client in early labor could help to recognize the dystocic labor-delivery and early indication for cesarean sections. This would avoid unnecessary and prolonged labor without necessarily increasing the cesarean section rate.

Abitbol, M. M., Bowen-Ericksen, M., Castillo, I., & Pushchin, A. (1999). Prediction of difficult vaginal birth and of cesarean section cephalopelvic disproportion in early labor. *Journal of Maternal Fetal Medicine* 8 (2): 51–6.

multiparous status, small fetus, relaxed pelvic and vaginal musculature, and a history of rapid labors with previous deliveries. Maternal and fetal risks include a delivery out of asepsis, maternal soft tissue injuries, and fetal injuries from rapid expulsion at delivery. Medical diagnosis and management include a readiness on the part of the entire health team for the delivery, particularly when the client has a history of rapid labor. The American College of Obstetricians and Gynecologists (ACOG) acknowledges that a history of rapid or precipitous labors is a reason for medical induction to ensure a hospital delivery and increase the likelihood for a controlled delivery that minimizes the potential for maternal and fetal injuries.

The nursing assessment of the client should include a thorough history of gravidity, length of previous labors, and delivery outcomes. Uterine activity should be assessed by palpation, fetal monitoring, or both. Precipitate delivery may occur as a result of pelvic relaxation; however, intense and frequent contractions may contribute to rapid progression of labor. When uterine relaxation is inadequate, fetoplacental gas exchange may be compromised. Assessment of fetal position using Leopold's maneuvers, review of ultrasonography information for position, and estimation of fetal weight may provide information regard-

ing the likelihood of rapid delivery. The pelvic examination will reveal information on cervical status, fetal station, and adequacy of pelvic outlet. Subsequent examinations will denote changes, and a rapid or significant change may be a predictor of a short labor process. Assessment of patient responses, such as intensity of behavior, bearing down, and increased anxiety, may reveal a need for the nurse to reevaluate the progression of labor. Fetal tolerance to labor should be assessed continuously. Maternal vital signs are significant for baseline information because women who experience particularly intense, precipitous labor and deliveries are at a higher risk for amniotic fluid embolism and uterine atony after delivery than are women who do not (Cunningham et al., 1997).

Nursing diagnoses for the client experiencing precipitous labor and delivery include a recognition of risks for the following: maternal or fetal soft tissue injury related to rapid descent and expulsion, maternal or fetal infection if delivery occurs outside of aseptic surroundings, and maternal hemorrhage if atony results after delivery. The nurse also must consider maternal pain and anxiety. The goals of these client outcomes are to avoid the risks of soft tissue injury, infection, and hemorrhage, while reinforcing maternal comfort and attempting to reduce or limit anxiety.

Nursing care involves vigilant attendance, preparations for delivery in advance, client comfort measures, and education and emotional support for the client and her support persons. The onset of rapid labor can be frightening and overwhelming. When uterine relaxation is minimal, little reprieve between contractions is provided. Thus, the opportunity of resting, refocusing, and preparing for the next contraction is limited. Communication with the physician or CNM and all other team members anticipated at delivery must be clear, concise, and timely to avoid the lack of critical support personnel during delivery.

The nursing plan of care and interventions should include continuous reassessment of maternal-fetal status. Any change in status, maternal or fetal tolerance, or sign of impending problems must be communicated in a timely manner to the physician or CNM and all other required health care providers. The nurse should inform the client of any change in the plan of care. As changes are made, the nurse should explain all procedures and offer reassurance to the client of the readiness of the health care team for delivery. Visually seeing the nurse set up for the anticipated delivery may reassure the client and her support persons that the nurse trusts their concerns and is responding by preparing for the birth of their baby. Teaching or reinforcing relaxation techniques may assist the client in optimizing rest periods between contractions. Rapid labor may prevent the client from obtaining regional anesthesia; however, small IV dosages of pain medication may be ordered when cervical dilation has not progressed to the second stage of labor or immediately preceding this stage. When medication is administered, maternal responses and vital signs and fetal heart rate responses should be evaluated. The nurse also should anticipate successful relaxation and a resulting rapid delivery when providing pharmacologic interventions. When labor progresses too rapidly for even small amounts of pain medication, the nurse can support the client by staying with her and encouraging and assisting her into a comfortable position. After delivery, monitoring maternal vital signs, assessing the uterine fundus for uterine atony, and observation for signs of soft tissue hematoma or increased vaginal bleeding that may indicate a hidden laceration should be done at frequent intervals (every 15 minutes, if stable; more frequently, if there are concerns). The nurse should assess the neonate for soft tissue injuries and monitor vital signs to ensure stability after delivery.

Evaluation of client outcomes involves answering the questions that recognize the success of the established outcomes.

- Did the neonate have bruising, swelling, or signs of injury after delivery?
- Is the mother demonstrating signs of hematoma, lacerations, or increased bleeding?

- If lacerations were present, are the repairs intact with heavy bleeding evident?
- Are maternal vital signs stable?
- Is the mother or neonate demonstrating signs of infection?
- Did the delivery occur in an appropriate setting?
- Are temperatures and respiratory efforts within normal limits?
- Are there signs of maternal hemorrhage after delivery?
- Is the fundus firm and at the umbilicus?
- Is excessive fundal massage required to increase fundal tone?
- Did the client demonstrate reduced anxiety with the nursing support interventions?
- Did the client verbalize enhanced relaxation or reassurance with the nursing interventions?
- Did the client verbalize or demonstrate reduced pain?
- Were pharmacologic interventions helpful?
- Were the maternal-fetal responses reassuring, without evidence of vital sign or fetal heart rate compromise?
- Were nonpharmacologic comfort interventions helpful to the client?

FETAL MALPRESENTATION AND MALPOSITION

Fetal malpresentation and malposition may interfere with the progression of labor and fetal descent. **Malpresentation** refers to a fetal presenting part other than the vertex and includes breech, transverse, compound, shoulder, face, and brow presentations. Malpresentations may be identified late in pregnancy or may not be discovered until the initial assessment during labor. Fetal **malposition** refers to a position other than an occipitoanterior position. Malpositions include occipitotransverse, occipitoposterior, and oblique, or acynclitic, positions of the fetal head in relation to the maternal pelvis. Fetal malpositions are assessed during labor. Fetal malpresentation or malposition may pose risks to maternal-fetal well-being and may necessitate operative vaginal delivery, cesarean section, or other interventions to accomplish delivery.

Breech Presentation

Breech presentation occurs when the fetal buttocks, legs, feet, or a combinations of these parts present first into the maternal pelvis. Classifications of breech presenta-

Figure 26-2 Breech presentations. A. Complete. B. Frank. C. Footling.

tion include complete, frank, and footling (double or single) (Figure 26-2). The complete breech presentation is best described as when the thighs are flexed on the abdomen and the legs are upon the thighs. In the frank breech presentation the fetus appears as if it is folded in half, with its feet in its face and the buttocks presenting. The fetal legs are extended in the frank breech presentation, unlike the crossed legs found in the complete breech presentation. The fetus in the footling breech presentation has one or both feet presenting first in the maternal pelvis followed by the buttocks. Breech presentation is frequently found in pregnancies of 28 weeks' gestation and less; however, it is documented in approximately 3% to 4% of term pregnancies (Toth & Jothivijayrani, 1999; Acien, 1995; Albrechtsen, Rasmussen, Dalaker, & Irgens, 1998). Of breech presentations, 65% are frank, 25% are footling, and the remaining 10% are complete breech presentations.

The most common contributing factors to malpresentation and malposition include prematurity; fetal anomalies, such as **hydrocephalus** (increased circulating cerebrospinal fluid, resulting in an increase in the size of the fetal head) and **anencephaly** (failure of the fetal brain, skull, and head to fully develop; this condition is incompatible with life); multiple gestation; placental placement abnormalities; maternal uterine or pelvic abnormalities; and **polyhydramnios**, a condition in which the amount

of amniotic fluid in the uterus is increased to two or more liters within the third trimester (Toth & Jothivijayrani, 1999). Advanced maternal age also has been associated with an increased incidence of breech birth (Acien, 1995; Rayl, Gibson & Hickok, 1996).

Maternal risks from breech labor and delivery include prolonged difficult labor, potential for soft tissue injury, lacerations, and need for cesarean section. Fetal risks from breech delivery exceed maternal risks for injury. Even without fetal anomalies present that can be exacerbated by a vaginal delivery, risks to the fetus include umbilical cord prolapse, with compression and resultant hypoxia; brachial plexus injuries; and fetal head and neck injuries from entrapment.

Medical management of the client with a suspected breech presentation includes plans to confirm the fetal presentation. Sonography also is used to screen for apparent anomalies and obtain an estimate of the fetal weight. The physician or CNM will find these data to be instrumental in determining the best plan of care for the client. The physician or CNM will determine whether a vaginal trial of labor or cesarean section is in the best interests of both the mother and fetus. In some cases, there is an attempt to perform **external cephalic version**, which is a procedure by which the physician manipulates the fetus externally through the maternal abdomen to turn the fetus from the abnormal presentation to a cephalic presentation. Most breech presentations are delivered by cesarean section due to the dwindling number of skilled physicians able to safely deliver breech babies (Cunningham et al., 1997). Cesarean delivery is commonly used in the following circumstances: (1) a large fetus; (2) any unfavorable shape of the maternal pelvis; (3) a hyperextended fetal head; (4) maternal indications for delivery including pregnancy-induced hypertension (PIH) or ruptured membranes for 12 hours or more without labor; (5) uterine dysfunction; (6) footling presentation; (7) a healthy, viable preterm fetus of 25 to 26 weeks or more with the mother in active labor or in need of delivery; (8) severe fetal growth restriction; (9) previous perinatal death or children suffering from birth trauma; and (10) a request for sterilization (Cunningham et al., 1997). Trial of labor may be attempted when estimated fetal weight is equal to or less than previous delivery weights (2,500 to 3,800 g), pelvic assessment reveals adequacy of the outlet, the position is frank breech, the fetal head is flexed, and the gestational age of the fetus is 36 weeks' or more (Toth & Jothivijayrani, 1999).

During the initial assessment the nurse should take into account the gestational age of the fetus, keeping in mind that breech presentations are more frequently found in premature gestations. The nurse should review the client's prenatal history and enquire if a breech presentation has already been suspected or diagnosed, if there is a

multiple gestation, or if there has been a prenatal diagnosis of fetal or maternal anomalies. Initial assessment of the gravid abdomen with Leopold's maneuvers may reveal a suspicion of breech presentation. Auscultation of the fetal heart rate at or above the umbilicus may increase this suspicion of a noncephalic presentation. Finally, pelvic assessment may further increase or confirm a breech presentation by palpation of feet, buttocks, or genitalia. Confirmation of presentation with a limited sonographic scan may be permitted as an institutional protocol. Suspicion of breech presentation during the initial maternal assessment should be relayed to the physician or CNM. Care should be taken to avoid rupturing the membranes because there is an increased risk of prolapsed umbilical cord with a noncephalic presentation.

Nursing diagnoses in the management of breech presentation include the risk for fetal injury related to hypoxia from cord prolapse and injury to the fetal head, neck, soft tissue, and nerves related to traumatic delivery. Potential maternal problems include the risk for hemorrhage and infection related to soft tissue injury or lacerations from operative vaginal or cesarean delivery. Maternal pain, anxiety, and knowledge level are actual diagnoses routinely addressed in all laboring patients.

Maternal and fetal outcomes evolve from both medical and nursing management. The medical plan of care and nursing interventions strive to prevent fetal hypoxia, fetal injury, and maternal hemorrhage and infection. These critical interventions are provided concurrently while promoting physical comfort, ensuring adequate pain management, and offering both emotional and educational support for each obstetric client at high risk.

In order to achieve these outcomes, the professional nurse must continuously monitor and update the maternal-fetal assessment and relay the information to the physician. To prevent injury from cord compression related to prolapse and avoid artificially rupturing the membranes, pelvic examinations should be conducted with care. The nurse also should instruct the client to report suspicion of her membranes rupturing. When membranes rupture spontaneously, the nurse should assess for the presence of the umbilical cord in the vaginal vault. The fetal heart rate should also be assessed to ensure it is stable and within normal range. When the medical plan includes a cesarean section, all health team members required at the surgery should be notified. When a vaginal trial of labor is the plan, the nurse should have a double delivery setup available. A double setup consists of a vaginal delivery table setup and a cesarean section instrument table ready to be opened in the surgical suite. Special instruments such as Piper forceps should be in the room, if not open on the instrument table. The nursery personnel should be made aware of any complicating factors, such as prematurity or fetal anomalies.

Pain interventions should be implemented according to the client's assessed needs. Position changes, back massage, IV medication per physician orders, and regional anesthesia may be used to relieve maternal pain during labor. Labor support, reassurance, client education, and validation of client response to the comfort interventions are all interventions the nurse may employ for pain relief. For cesarean section, regional anesthesia is used when possible to minimize fetal anesthetic effects that could occur with a general anesthetic. The nurse's role may include assisting with client positioning for insertion of the regional anesthetic. Although the client is monitored by the anesthesiologist throughout the cesarean section, monitoring during recovery is within the scope of the nurse's role.

Client anxiety may be heightened by the discomfort of the labor and threat of the unknown. Assessment of baseline knowledge, feelings, and perceptions helps the nurse reassure and educate the client to reduce anxiety. Validating information with the client provides appropriate feedback to promote her emotional and physical support during breech labor or a cesarean section. Manogin, Bechtel, and Rami (2000) reported that providing the laboring client with information about her status and the plan of care for delivery enables her to incorporate the information into her experience and develop a healthier, positive perception of the delivery process.

The nurse caring for the client with breech presentation may be required to function in the role of a circulating nurse during the cesarean section. This role includes preparing the client for the operative procedure (shaving when ordered, insertion of a Foley catheter, and preanesthesia fluid loading) and transporting her, as necessary. The circulating nurse supports the needs of the anesthesiologist and obstetrician during the delivery, records sponge and instrument counts, documents occurrences during the procedure, and ensures both equipment and team readiness to receive the neonate. A cesarean section performed for breech presentation may require additional supplies. Obtaining verification of special requests for supplies from the obstetrician promotes readiness. These supplies may be present in the operative suite unopened, unless needed. After the case is completed, the nurse also may be required to monitor the client during the recovery period.

When a client undergoes a trial of labor for vaginal breech delivery, similar preparations should be anticipated. The physician may request additional personnel to assist with delivery or additional supplies. The labor process may be prolonged related to lack of a firm presenting part to enhance dilatory processes. Augmentation may be required to avoid dystocia, which can result in heightened discomfort and anxiety. The nurse's meticulous attention to client responses to labor discomfort will

not only promote client support and better meet pain needs but also should reduce anxiety. At delivery, the physician may request administration of amyl nitrite or nitroglycerin to obtain rapid uterine relaxation should head entrapment become apparent. Having the requested medication readily available reduces delays at a critical time in the delivery.

After delivery, vaginal or operative, rapid feedback to the mother regarding the status of the neonate offers reassurance and reduces additional anxiety. Neonatal assessment for soft tissue injuries, swelling, lack of mobility, and lack of flexion of the extremities is critical once respiratory support and thermoregulation are established. Any deviation from normal neonatal assessment should be reported to the nursery or neonatal staff receiving the infant.

Evaluations of the maternal-fetal outcomes answer several questions.

- Did the fetal heart monitoring provide reassuring rates, accelerations, and variability?
- Did the client experience frank or occult prolapse and compression of the umbilical cord?
- Did the neonate demonstrate effective respirations or require minimal support at delivery?
- Did the neonate experience injury at delivery?
- Was assessment rapid, and were interventions initiated immediately?
- Did the client express adequate pain relief verbally or nonverbally?
- Did maternal-fetal status remain stable throughout pharmacologic interventions?
- Did the client express comfort with the plan of care?
- Were questions by the client asked and answered?
- Did the client verbalize reduced anxiety?
- Did maternal vital signs remain stable?
- Did fluid balance remain stable?
- Did the client experience hemorrhage?
- Did the client experience laceration or hematoma?
- Was aseptic technique observed?
- Did the client or fetus demonstrate signs of infection?

Shoulder Presentation

Transverse lie involves the fetus assuming a more horizontal position in the uterus. This type of lie results in a **shoulder presentation** in which the presenting part of the fetus is the shoulder or combination of shoulder, arm, and hand (Figure 26-3). When the fetal back faces the maternal abdomen, it is referred to as an acromiodorsoanterior position. When the fetal back faces the maternal back, it is referred to as an acromiodorsoposterior position. Cunning-

Figure 26-3 Shoulder presentation.

ham et al. (1997) has identified the incidence of transverse lie with shoulder presentation as 1 in 420 singleton deliveries. Common contributing factors for transverse lie and shoulder malpresentation include grand multiparity (as a result of relaxed abdominal musculature), prematurity, multiple gestation, placenta previa, polyhydramnios, and abnormalities of the maternal pelvic structure. When this presentation is identified antenatally, external cephalic version may be attempted to reposition the fetus into cephalic or even breech presentation. Risks to the client include uterine rupture, a high probability of cesarean section, and sepsis if the fetal arm prolapses after membrane rupture and returns through the uterus during cesarean section. Fetal risks include umbilical cord prolapse and fetal injury from attempted and failed version. Medical management is aimed at confirming the transverse lie and shoulder presentation. The usual plan of care is cesarean section once the malpresentation is confirmed.

The nursing assessment is instrumental as a first indicator of malpresentation. A review of maternal prenatal history may promote identification of risk factors. Initial abdominal assessment with Leopold's maneuvers often will identify the transverse or oblique lie. Pelvic assessment may reveal a very high presenting part or no presenting part at all. Care should be exercised to prevent accidental rupture of membranes because this malpresentation also carries a high risk of umbilical cord prolapse. Fetal heart rate assessment should be performed, and the nurse may locate the fetal heart rate at the umbilicus or laterally to it.

From the data obtained in the nursing assessment, the nursing diagnoses should address the risk for the following: fetal injury related to hypoxia from prolapsed umbilical cord or uterine rupture; maternal injury related to hemorrhage from uterine rupture; infection from prolonged labor, with eventual chorioamnionitis; and postoperative infection.

Once malpresentation has been confirmed the nursing plan of care is based on the medical plan of management. Preparation for cesarean section must be completed before the physician attempts external version because the potential for injury exists. Otherwise, the nurse will repeat the interventions for the breech malpresentation in preparing, accompanying, assisting, and monitoring the operative recovery of the client.

Outcome evaluation validates the following: neonatal physical stability at delivery, maternal physical stability during and after cesarean section, maternal coping with and understanding of procedure, and the absence of signs of infections postoperatively.

Face Presentation

Face presentation occurs when the fetal head is hyperextended and the fetal face descends into the pelvis, as opposed to the flexed position, resulting in fetal vertex presentation. **Brow presentation** occurs when the area between the anterior fontanelle and the fetal eyes descends first (Figure 26-4). *Williams Obstetrics* (1997) reports the incidence of face presentation as 1 in 600, or 0.17%. Brow presentation is described as occurring less frequently than does face presentation at a rate of 0.02%, or 1 in 4,470 births. Contributing causes are less clearly defined for face and brow presentations but do include maternal multiparity, fetal macrosomia, fetal anencephaly, and abnormalities of the maternal pelvis. Brow presentation is presumed rare because of its expected conversion

to face or occiput presentation to allow vaginal delivery. Unless the maternal pelvis is generously adequate or the fetus is small, persistent brow presentation is not a viable presentation for vaginal birth (Cunningham et al., 1997). This fact may increase the likelihood of prolonged or difficult labor, and failed vaginal delivery, and increases the potential for surgical delivery. Fetal risks for both of these presentations include significant facial edema and bruising and the potential for aggressive interventions at the time of vaginal delivery.

Medical management is expectant in nature, meaning that the client is allowed to labor and her progress is evaluated (Shields & Medearis, 1992a). As stated previously, the brow presentation usually will convert to face or vertex presentation so the fetus can pass through the pelvis. Oxytocin augmentation may be employed for dystocia. When arrested dilation or descent occurs, medical management may then be operative delivery. Aggressive interventions involving midpelvic manipulation are not currently recommended because they increase fetal morbidity and mortality (Shields & Medearis, 1992).

The nursing assessment should include client history, including perinatal diagnosis of any anomalies or multiple gestation. Estimated gestational age should be documented and verified. Auscultation or fetal monitoring indicates fetal well-being. The pelvic assessment is the one most likely to reveal a nonvertex presentation by palpation of the soft facial features or anterior fontanelle to brow. Sonography may be performed to confirm position, flexion, hyperextension, and fetal size.

The nursing diagnoses for the face or brow presentation are similar for all cephalic labors, plus the risk for fetal injury related to the difficult delivery and the potential for infection should operative vaginal or cesarean delivery become necessary. The outcome for the client based on the first additional diagnosis is that the fetus will not incur permanent injury. Realistically, little can be done to avoid the facial edema associated with a face delivery. The other specific diagnosis addresses maternal well-being and absence of postdelivery infection.

The nursing plan should address both vaginal and cesarean delivery potentials. The nurse must continuously monitor maternal labor progress, fetal well-being, and maternal pain and coping behaviors. Ongoing labor assessment allows early identification of abnormal labor processes so that the physician or CNM may intervene with orders for augmentation when deemed appropriate. When augmentation is ordered, nursing actions include careful IV medication administration and monitoring of uterine activity to prevent hyperstimulation, while promoting an effective labor pattern. The nurse also must continuously reassess the fetal response through fetal heart rate monitoring. Communication with the physician or CNM by the nurse is instrumental to being a client advocate. The

Figure 26-4 A. Brow presentation. B. Face presentation.

nurse must assess client pain responses, offer comfort interventions, administer pain medications as ordered, assist with regional anesthesia, and monitor the client after administration of anesthesia. In order to educate and reduce anxiety, the nurse may offer explanations to the client and support persons regarding the plan of care; reason for augmentation; and expectations regarding face or brow presentation, particularly fetal appearance. Offering reassurance and maintaining a vigilant presence also will help reduce anxiety in the client and her support persons. Preparation in advance for operative vaginal delivery with any additional instruments, such as forceps or vacuum suction devices, ensures readiness and reduces potential delays if complications were to arise. In addition, communication with the other health team members promotes ready availability of support for the neonate once delivered. When cesarean section is required the nurse must prepare quickly and efficiently, while monitoring maternal-fetal status. As before, the nurse probably will assume the role of circulating nurse during the cesarean section or operative vaginal delivery, and possibly will assume the role of recovery nurse after the procedure. The continuity of the nurse's attendance should reassure the client and limit anxiety throughout the delivery process.

Evaluation of the outcomes unique to face and brow presentations addresses the neonate's stability and presence or absence of injury. Evaluation of maternal pain management and anxiety requires obtaining feedback verbally and observing behavioral responses. Periodic evaluation throughout labor and delivery allows for revision or reinforcement of the nursing interventions to better meet the emotional and educational needs as well as the physical care of the client and her fetus.

Malpositions

Malpositions include persistent occipitoposterior and persistent occipitotransverse positions, which result from fetal rotation as the fetus descends through the pelvis. When the extension process is incomplete, the rotational process also may be incomplete. Fetal and maternal contributing factors include macrosomia and pelvic abnormalities, respectively. A malposition may result in increased discomfort during labor, particularly back pain; prolonged, abnormal labor; soft tissue injury; lacerations; or an extensive episiotomy incision. The fetus in a malposition may experience extensive caput and molding from the sustained occipitotransverse or occipitoposterior position. Caput succedaneum is swelling of a portion of the fetal head most commonly occurring when the head is in the lower portion of the birth canal after the resistance of a rigid vaginal outlet is encountered (Cunningham et al., 1997).

Molding refers to the movement of the bones in the skull of the neonate to fit through the maternal pelvis.

Figure 26-5 Shoulder dystocia.

The degree to which the neonate's head is capable of molding may make the difference between successful vaginal delivery and cesarean section (Cunningham et al., 1997). When the fetus has macrosomia, the potential exists for shoulder dystocia. Shoulder dystocia is a condition in which the fetal shoulders are large and cannot be delivered spontaneously by the maternal pelvis (Figure 26-5). Most cases of malposition resolve spontaneously, and less than 10% fail to resolve (Cunningham et al., 1997). Those cases that do not resolve may be managed with operative vaginal delivery, including outlet forceps to assist delivery in the occipitoposterior position, forceps rotation of the fetal head to an occipitoanterior position, and manual rotation of the fetal head for subsequent delivery (Thompson, 1995; Hankins & Rowe, 1996). When arrest of descent occurs and macrosomia or abnormal pelvic outlet is suspected, the physician may choose delivery by cesarean section.

The nursing assessment should include the historical, physical, emotional, and educational information necessary to plan for the holistic support of the client, her fetus, and her support persons. The history should include information that may indicate macrosomia, such as maternal diabetes, excessive weight gain, results from sonography showing large for gestational age status, and a history of an infant with macrosomia. A history that includes prolonged labor or operative vaginal delivery also may indicate the potential for a malposition to occur. The experienced obstetric nurse may be able to assess malposition during the pelvic examination by denoting fetal suture line and fontanelle position in relation to the maternal pelvis. However, assessment becomes much more difficult once significant caput is present. Fetal heart rate monitoring for well-being and labor tolerance should be performed. Uterine activity assessment is necessary to ensure adequacy of

Case Study/Care Plan

CLIENT WITH FETAL MALPRESENTATION

Linda is a 29-year-old gravida 2, para 1001 at 39 5/7 weeks' estimated gestational age. She arrives in labor and delivery with her partner, Tim. She states that she is having contractions every 5 minutes and denies that her membranes have ruptured. Her first baby weighed 6 pounds, 7 ounces and was born after 14 hours of labor. Her physician has voiced concern that this baby appears much bigger than that based on ultrasonography, Leopold's maneuvers, and fundal height measurements. After orientation to her room and the unit, Linda is assessed for labor status. External fetal monitoring is applied. Fetal heart tones are located at the maternal umbilicus and are in the 130s. Accelerations are present. Maternal vital signs are the following: temperature, 98°F, pulse, 88; respirations, 18; and blood pressure, 120/72. Pelvic examination reveals cervical dilation of 4 cm, 80% effaced, and -2 station with palpable intact membranes. The presenting part feels softer than a vertex (fetal skull), raising the suspicion of a breech presentation.

The nurse finds that critical elements of the assessment are suspicions of a larger baby than the first, who weighed 6 pounds, 7 ounces. In addition, fetal heart tones are located around the maternal umbilicus. Finally, the presenting part seems more like a breech presentation, which is a malpresentation. The cervical dilation of 4 cm may play a role in the face of spontaneous rupture of membranes. In such a case, if the breech presentation is not well applied to the cervix, prolapse of the umbilical cord could occur.

Assessment

- 39⁵/₇ weeks
- P 88
- BP 120/72
- T 98°F
- R 18
- 4 cm dilated

Nursing Diagnosis

Risk for injury (fetal) related to possible umbilical cord prolapse with spontaneous rupture of membranes, soft tissue injury, or nerve compression from macrosomia or a complex delivery owing to malpresentation, as evidenced by signs of acute fetal cord compression or fetal trauma after operative or cesarean birth.

Expected Outcome Fetus will not incur injury from cord prolapse or complex delivery maneuvers.

Planning Alert care team to potential risks and prepare for emergency procedures.

Nursing Interventions

Rationales

- | | |
|--|---|
| <ol style="list-style-type: none"> 1. Report to the physician or CNM suspicion of malpresentation. Supplemental confirmation of large baby is also important because a vaginal breech delivery is probably not the option of choice for this client due to large fetal size. 2. Order and report ultrasonography results to the physician or CNM. 3. Monitor maternal vital signs and fetal tolerance to labor. 4. Instruct the client to report any sensation of ruptured membranes and to be alert for potential prolapse of the umbilical cord. | <ol style="list-style-type: none"> 1. Medical management is necessary to carefully assess fetal presentation, fetal size, maternal pelvic size, and mode of delivery. 2. Information about presentation and fetal weight is critical to determining course of action. 3. Constant monitoring of maternal and fetal well-being is most important in fetal malpresentation. 4. With a breech presentation, a significant fetal risk includes umbilical cord prolapse. |
|--|---|

(continued)

Evaluation Fetal vital signs are stable and cord did not prolapse before delivery. Fetal tracing showed no cord compression. No fetal injuries, bruising, brachial nerve compression, or hip problems were noted.

Nursing Diagnosis

Risk for infection (maternal) and injury related to operative procedure, as evidenced by postoperative infection, hemorrhage, or hematuria.

Expected Outcome Client will not experience postoperative infection or injury from operative delivery.

Planning Prepare client for post-delivery care procedures so that she may anticipate and accept nursing care measures.

Nursing Interventions

Rationales

- | | |
|--|--|
| 1. Preoperative procedures to minimize the risk for infection and operative injury may include abdominal shaving and preparation and insertion of an in-dwelling Foley catheter. | 1. These steps will reduce the risk of infection. |
| 2. Give Tim appropriate scrubs and position for procedure to support Linda without contaminating surgical setup. | 2. Partner participation in the birth process must be in line with the need to maintain a sterile environment. |
| 3. After surgery, carefully monitor the client according to postanesthesia unit standards to minimize the risk of postoperative complications. | 3. Febrile morbidity is rather frequent after cesarean deliveries because of postpartum infection. |

Evaluation Maternal vital signs are stable and there is no maternal fever or signs of infection, hemorrhage, or shock.

Nursing Diagnosis

Anxiety (maternal and family) related to altered plans for childbirth experience and unfamiliarity with the management of breech presentation, as evidenced by client verbalization and nonverbal behaviors.

Expected Outcome Client and support persons will verbalize concerns regarding birth plans, alterations, and possible management, while demonstrating effective mechanisms for coping with the stress of the labor and delivery process.

Planning Work with client and partner so they understand and accept the delivery options that are now likely.

Nursing Interventions

Rationales

- | | |
|---|---|
| 1. Remain in the room with the client while the attending physician or CNM visits with the client and family, and listen to the plan of care and how it is presented. | 1. This enables the nurse to reinforce the plan of care with the client and family. |
| 2. Answer client questions regarding the attendance of her partner, Tim, at the scheduled cesarean section and access to infant after delivery. | 2. Client education and support reduces anxiety and stress. |

Evaluation Client and family verbalized and demonstrated effective coping with the altered plan of a cesarean section.

(continued)

Nursing Diagnosis

Acute pain (maternal) related to an active labor pattern, as evidenced by verbalization and nonverbal behaviors.

Expected Outcome Client will verbalize effective pain relief from pharmacologic and nonpharmacologic interventions.

Planning Help client to mentally prepare for the impending labor and delivery.

Nursing Interventions	Rationales
1. Use positional comfort interventions along with lower back counterpressure to assist the client.	1. Comfort measures including frequent position changes, low back counterpressure, and appropriate pain control are all nursing support measures aimed at reducing client anxiety and facilitating labor progression.
2. Consult the anesthesia service for consideration of regional anesthesia and analgesia for vaginal or cesarean delivery.	2. Imminent cesarean delivery will require appropriate preparation.
3. Administer pharmacologic agents as ordered after informed consent is obtained for both treatment and anesthesia.	3. Pharmacologic and nonpharmacologic measures combined will provide the greatest measure of client relief.

Evaluation Client verbalizes effective pain relief.

contractions and early identification of signs of abnormal labor. Client complaints of pain may be focused on her back when the fetal position is occipitoposterior. Assessing the location of pain allows better intervention and provides indications of fetal position. Client level of knowledge, fear, and anxiety also should be assessed.

The nursing diagnoses address fetal injury, maternal injury, maternal pain, anxiety, and knowledge deficits. The outcomes seek prevention and resolution of these potential or actual problems. Nursing interventions include ongoing assessment of maternal-fetal status and the progression of labor. Particularly useful in converting malpositions in labor are maternal position change laterally or onto her hands and knees in the form of a knee-chest position (Smith, Ou, Chen, & Su, 1997). In addition, nursing support for pain management, containment or reduction of anxiety, and client education are essential interventions. Because of the likelihood and intensity of back labor, nursing support should include a variety of comfort measures, including position changes; low back counterpressure during contractions; and the use of, if permitted and requested, epidural anesthesia. IV anesthesia also is helpful but should not be used late in labor to avoid fetal sedation and fetal respiratory depression at delivery. Additional

needs for vaginal delivery, such as forceps or vacuum suction devices, should be anticipated and equipment made available. Evaluations should obtain the objective and subjective feedback necessary to determine whether interventions have been successful or require revision. Interventions are successful when no fetal or maternal trauma occurs, pain is adequately managed, and the clients anxiety and educational needs are met.

MATERNAL AND FETAL STRUCTURAL ABNORMALITIES

Variations in maternal and fetal structural proportions that may result in high-risk deliveries include cephalopelvic disproportion and macrosomia.

Cephalopelvic Disproportion

Cephalopelvic disproportion (CPD) exists when the maternal pelvis cannot accommodate the fetal head as it descends. A contracted maternal pelvis and fetal macrosomia contribute to CPD (Bashore, 1992). A **contracted ma-**

ternal pelvis refers to abnormalities in measurements that fall short of those required for an average delivery. Congenital or acquired (from trauma) pelvic deviations may exist. Relative CPD is said to exist when the fetus is larger than the maternal pelvic inlet-outlet or when the fetal position places the head at an angle that is larger than the size the pelvis can facilitate. Relative CPD is particularly important when considering the mode of delivery for subsequent pregnancies. A 1998 study that reviewed cesarean deliveries for CPD showed that 68% of the women successfully delivered their subsequent neonate vaginally and 47% had larger babies (Impey & O'Herlihy, 1998). This data should encourage practitioners, including nurses, not to predetermine the mode of delivery for clients attempting trial of labor who have a history of cesarean section for CPD. Contracted maternal pelvic outlets are reported in less than 1% of the delivering population. The reported incidence of macrosomia using 4,000 g as the weight index is 5.1%. Using 4,500 g as the weight index, the incidence is 0.4% (Cunningham et al., 1997).

Contributing factors for CPD include congenital non-gynecoid pelvic (flattened, narrow, or irregular) shape or post-traumatic contractures as a result of a crushed or fractured pelvis. The risks to the laboring client are a prolonged and painful labor and failure of the cervix to dilate or the fetus to descend, with resultant need for operative delivery. The potential also exists for maternal uterine rupture from prolonged thinning of the lower uterine segment during a nonprogressive but active labor process. Fetal risks include extensive caput and molding from the prolonged labor; fetal intolerance, with resultant hypoxia from the prolonged labor; and the potential for birth injury related to a difficult and traumatic delivery.

Medical management will carefully assess pelvic and fetal sizes. Sonography may be beneficial, although estimates of fetal weight with very large fetuses are not very reliable. X-ray pelvimetry measures were more commonly used several years ago but offer true pelvic measures. The management of labor may be expectant when labor activity is adequate, or augmentation may be attempted when the contraction pattern is not regular or firm. At the point of delivery in CPD, the physician may attempt outlet forceps delivery or vacuum suction to assist in delivering the fetus vaginally. When measurements or these interventions are not satisfactory, or the fetal heart rate demonstrates intolerance of the delivery process, the physician may order preparations for cesarean delivery.

The nursing assessment history may help identify a pelvic adequacy problem. Risk factors are maternal diabetes, previous prolonged labor, previous fetal or maternal trauma at delivery, previous need for operative vaginal delivery (extensive episiotomy, use of forceps or vacuum extraction), and previous cesarean delivery. Leopold's maneuvers may reveal a fetus that is not well descended into

the maternal pelvis. Pelvic examination that identifies caput or molding, particularly while the fetus remains at station 0 or higher, may indicate a problem. Pelvic examination by the nurse that fails to reveal cervical change hourly despite regular contractions that are moderate to firm in intensity also may be significant in identifying CPD. These assessment variables help to indicate potential CPD; however, they do not preclude the initial thorough and complete assessment of maternal-fetal status or the dynamic elements that are reassessed every 5, 15, 30, or 60 minutes, depending on the stage of labor, client risk status, and fetal tolerance (Feinstein & McCartney, 1997).

Nursing diagnoses address the risks for maternal and fetal injury and infection and the concerns for maternal pain, anxiety, and lack of knowledge during labor and delivery. Desired outcomes designate that no fetal or maternal injury or infection will occur, and adequate pain and anxiety management and appropriate education will be achieved.

While the nursing interventions to meet the above outcomes may seem routine, the dynamics of the potential problem require the nurse to be alert for changes that are either reassuring or nonreassuring in nature. The individualization of the emotional and educational support as well as the unique interaction between the nurse and each client prevent the experience from being routine or less than challenging. The client experiencing CPD or relative CPD may experience a prolonged labor process and require extensive medical intervention for an operative vaginal delivery, or she may need to undergo a cesarean section. The nurse does not control the medical management of labor and eventual delivery; however, assisting the client to achieve optimal delivery outcomes with a minimum of negative occurrences is a nursing role. Evaluation of successful or less than successful outcomes provides the nurse with feedback from which new interventions or further support can be applied.

Macrosomia

Macrosomia is a cause of relative cephalopelvic disproportion. The increased size of the fetus can make passage through an adequate-sized pelvis difficult or impossible. As stated previously, macrosomia is more common than are contracted maternal pelvic disorders, with a 5.1% incidence (Cunningham et al., 1997). When the fetus does descend, the passage may be further complicated by delivery of the fetal head but then halted abruptly because of shoulder dystocia. Shoulder dystocia occurs when the fetal shoulder width is so large that it is not deliverable beneath the maternal symphysis pubis without additional delivery intervention or fetal injury. Shoulder dystocia occurs when the anterior shoulder of the fetus is aligned with the anteroposterior line of the pelvis and becomes lodged behind

REFLECTIONS FROM A MOTHER

"I was feeling very alone as I neared my due date. I had friends, but the father of my baby was not involved. My parents tried to be supportive. However, they were not pleased with my status as a single pregnant woman. When I arrived in labor and delivery in active labor, I was scared and hurting terribly from my contractions. When the nurses saw the heart beat on the monitor everything began to happen very fast. I had three people working on me at the same time. I had an oxygen mask on my face, and the smell of plastic was awful. My parents' faces had looks of concern and fear. They stood away from me while everyone was busy working on me. I was so scared!

Then I saw Marta. She is a nurse who was called into my room when the other nurses saw my baby's heart beat recording. She calmed everyone down, and they worked fast without panic. She explained what was happening and why. She assured me my doctor was aware of what was happening and was coming immediately. She asked

me if I had questions, and then she asked my parents. She brought my mother to one side and let her hold my hand. Up until then, my mother and I had said little to each other because of her disappointment in me. Now, however, we just held hands and prayed my baby would be okay.

Marta seemed to calm everyone. When my baby did not respond to the oxygen, IV fluids, and all the different positions they had me move to, she appeared concerned but did not panic. My doctor came in and confirmed her expectations for a cesarean section. Even though everything happened very fast, I trusted Marta. She stayed with me and encouraged me throughout my surgery. She showed me my baby as soon as he was ok. She explained to me the things that were around me. I wasn't scared with everyone working around me, because she told me they would help my baby adjust to being outside. I have a healthy son, Aaron, because the labor and delivery team worked so hard and fast. I have a good memory of my experience because of Marta."

the symphysis pubis, the alignment is appropriate but the size of the shoulders prevents anterior shoulder progression toward delivery, or the posterior shoulder becomes lodged behind the sacral promontory (Hall, 1997). The delivery of the shoulders can be extremely difficult for the mother to experience, and fetal injury may be impossible to prevent regardless of the skill and experience of the physician or CNM. Shoulder dystocia is considered an obstetric emergency (Hall, 1997; Wagner, Nielsen, & Gonik, 1999). The reported incidence of shoulder dystocia varies from 0.2% to 2% because of variable definitions of true shoulder dystocia. Within this range, the low percentages are attributable to those cases requiring classic delivery maneuvers and the high percentages are based on fetal weights with documentation of shoulder dystocia (Cunningham et al., 1997; Hall, 1997).

The literature shows that the most frequent risk factor leading to shoulder dystocia is macrosomia (Cunningham

et al., 1997; Hall, 1997; Lewis et al., 1998; Wagner, Nielsen, & Gonik, 1999). Other risk factors include concurrent maternal diabetes, a history of a previous large infant, prolonged second stage of labor, and excessive weight gain during pregnancy (Toohey et al., 1995; Lewis et al., 1998). Less clear as risks but still frequently believed to be contributory are advanced maternal age, previous history of gestational diabetes, multiparity, short maternal stature, and maternal obesity (Hall, 1997; Lewis et al., 1998). Two acronyms summarize the risk factors that should be assessed routinely: Diabetes Obesity Postterm Excessive (DOPE) fetal or maternal weight gain, and Age + DOPE (ADOPE) (Cunningham et al., 1997; Hall, 1997).

Risks to the client that are related to shoulder dystocia include soft tissue injury; bladder injury; cervical, vaginal, or perineal lacerations; separation of the symphysis pubis; uterine rupture; postpartum hemorrhage; and cesarean section (Hall, 1997). Risks to the fetus include fractures of

the clavicle and humerus and nerve damage, resulting in Erb's or Klumpke's palsy. Erb's palsy affects mobility of the upper arm; Klumpke's palsy affects mobility of the lower arm and hand and tone. The fetus also may experience increased intracranial pressure, hypoxia, acidosis, and asphyxia (Cunningham et al., 1997).

Medical management is determined by early identification of risk factors and consideration of delivery options. Both early elective induction and scheduled cesarean section have been evaluated for delivery of infants with macrosomia whose mothers have diabetes, with variable results (Gonen et al., 1998; Conway & Langer, 1998; Wagner, Nielsen, & Gonik, 1999). These measures are anticipatory in nature. Many times, however, shoulder dystocia must be dealt with at the time of occurrence.

Nursing considerations are significant in the recognition of and intervention for shoulder dystocia. The nurse's initial and ongoing assessments during labor may be the first data indicating shoulder dystocia. Labor delays, particularly with fetal descent, should be communicated to the physician or CNM. Pronounced caput or molding even at a relatively high station (above zero) may also be indicative of impending shoulder dystocia. Observation during maternal pushing may allow recognition of the turtle sign. The **turtle sign** occurs when the fetal head pulls back instead of completing the external rotation process and progressing forward into the maternal perineum. The appearance is as if the head is retracting back into the shell of the pelvis. Once the head is delivered, the inability to deliver the anterior shoulder beneath the symphysis pubis with gentle traction is diagnostic of shoulder dystocia (Hall, 1997; Cunningham et al., 1997).

The nurse should remain with the physician or CNM and call from the room for assistance. Once shoulder dystocia is recognized, constant monitoring of fetal status at one-minute intervals is essential. Fetal acidosis can begin after five minutes. The fetus may experience low Apgar scores or signs of asphyxia after only 7 to 10 minutes (Hall, 1997). Several maneuvers may be used by the physician or CNM to complete the delivery process. It is essential that the nurse remain calm to assist in delivery, reduce the client's anxiety, and facilitate client cooperation while these maneuvers are being attempted (Hall, 1997; Simpson, 1999).

The McRoberts maneuver requires maternal position changes in which the client's legs are bent at the knees and hyperflexed against her abdomen to straighten the sacrum and alter the angle, allowing for the anterior shoulder to be dislodged (Figure 26-6). Preferably two nurses assist the mother, with one nurse supporting each leg in the hyperflexed position while the physician or CNM attempts to complete the delivery. When reviewed as a first procedure used for reducing shoulder dystocia, the McRoberts maneuver was successful in 47% of cases. The

Figure 26-6 In the McRoberts maneuver, the client's legs are bent at the knees and hyperflexed against her abdomen. The result is straightening of the sacrum and altering of the angle, allowing the shoulder to dislodge.

remaining deliveries reviewed required additional interventions (Gherman et al., 1997).

Suprapubic pressure is another procedure used that the nurse may be requested to perform. By applying suprapubic pressure either in an oblique or lateral approach (Rubin technique) or posteriorly and laterally (Mazzanti technique), the anterior shoulder may be compressed and slip beneath the symphysis pubis (Figure 26-7). These techniques may be combined with maternal pushing, or the client may be requested not to push and

Figure 26-7 Suprapubic pressure may release shoulder dystocia.

rely only on the traction of the physician or CNM. The client's bladder should be empty to prevent trauma. The nurse may have already emptied the bladder before delivery, or the physician or CNM may do so before performing these maneuvers.

The other maneuvers employed for shoulder dystocia are more invasive in nature. They include the Woods corkscrew maneuver in which the physician or CNM places his or her fingers within the vagina against the anterior chest wall of the fetus to push the posterior shoulder back and rotate it 180 degrees. Either shoulder may deliver as a result of this maneuver. The physician may request that the nurse apply suprapubic pressure to keep the anterior shoulder in an adducted position. The Rubin maneuver requires the physician or CNM to place his or her fingers within the vagina against the scapula of the anterior shoulder and rotate it forward 180 degrees. This maneuver also may be used to rotate the posterior shoulder anteriorly. Once again, the nurse may be requested to provide suprapubic pressure. When the rotational maneuvers are unsuccessful in dislodging the shoulders and delivering the fetus, the physician may then attempt to deliver the posterior arm. In this procedure, a hand is inserted into the vagina to the posterior arm and traces the path to the elbow, allowing flexion, retrieval, and delivery of the arm. This procedure allows for room to dislodge the anterior shoulder. This maneuver may result in fracture of the fetal humerus. When these maneuvers fail, the fetal head may be rotated to direct occipitoanterior position and pressure applied to replace the head within the pelvis for retrieval through emergent cesarean section. The person supporting the head will remain in that position until the cesarean is complete and the fetus delivered. The morbidity is much higher with this procedure; however, the alternative may be stillbirth when the shoulders cannot be delivered vaginally (Hall, 1997; Cunningham et al., 1997).

Nursing diagnoses include risks of fetal injury and fetal hypoxia, risks of maternal injury and infection, as well as the usual nursing diagnoses. The outcomes seek to prevent negative outcomes from occurring. Interventions during the labor process focus on the ongoing assessment that indicates possible shoulder dystocia, communicating concerns effectively, remaining with the physician or CNM, calling for help, remaining calm, offering reassurance and information to the client and support persons, assisting with maneuvers, notifying nursery personnel, and documenting the events that transpired as accurately and systematically as possible (Hall, 1997; Simpson, 1999).

MULTIPLE GESTATION

Multiple gestation refers to the carrying of more than one fetus during the same pregnancy (Figure 26-8). With the in-

Figure 26-8 Twin fetuses can assume any number of presentations.

crease in infertility management and assisted reproductive technology, such as in vitro and gamete transfer technology, the incidence of twins, triplets, and higher-order gestations (quadruplets, quintuplets, and so on) has increased significantly. Bowers (1998) reviewed the 1995 U.S. statistics and found there were 96,736 neonates born alive as twins, 4,551 as triplets, 365 as quadruplets, and 57 as quintuplets or higher-order multiple births. In 1990, the reported incidence of twins was 1 in 43 live births and that of triplets was 1 in 1,341 live births. Ovulation induction and assisted reproductive technology are identified as the causes of 83% of triplet pregnancies and 95% of quadruplet pregnancies (Eganhouse & Petersen, 1998). Higher-order pregnancies, inclusive of triplets, have increased rapidly at approximately 11% a year since 1997 (Bowers, 1998).

Multiple fetus pregnancies are evaluated for separate amnions and chorions. Shared amnion and chorions allow for shared placental circulations and physical entanglement issues. Shared placentas, amnions, and chorions are the result of monozygotic splitting. *Williams Obstetrics* reports that *monozygotic twinning*, (when twins occur from a single ovum and may share a single placenta, amnion, and chorion) occurs in approximately 1 in 250 births (Cunningham et al., 1997). Most triplet pregnancies are reported as trizygotic (separate chorions and amnions); however, assisted reproductive interventions have increased the likelihood of monozygotic triplets (Eganhouse & Petersen, 1998).

The increase in the number of multifetus pregnancies is attributed to advanced maternal age as the result of delaying pregnancies and infertility requiring ovulatory stimulation medications and assisted reproductive technologies (Bowers, 1998). With additional fetuses come additional risks, which increase with each additional fetus in the pregnancy. The major risks in all multiple gestations are prematurity and low birth weight. Bowers (1998) reported that 47.9% of twin gestations and 87.8% of all higher-order gestations end before the 37th week, unlike singleton pregnancies. Other problems are also increased, with twin gestations experiencing an overall complication rate at least twice that of singleton pregnancies. Triplets and higher-order multiples experience much higher complication rates than do twins. Over 92% of higher-order multiples fall into the low-birth-weight category, and 35% are reported as having very low birth weights (Bowers, 1998). In addition, the infant death rate for higher-order multiples exceeds that of singleton gestations by 12 times.

Among the fetal risks are *conjoining abnormalities* (when twins have incomplete separation and demonstrate a common organ or portion of the body), placental abnormalities, twin-to-twin transfusions, and discordant fetal growth (when the growth of one twin exceeds that of the other(s) by at least 25%). Cerebral palsy and other neurologic impairments, stillbirth, glucose instability at birth, and birth injuries also occur more frequently (Cunningham et al., 1997). Fetal mortality ranges from 9.8% to 13.6% (Eganhouse & Petersen, 1998). Perinatal mortality is described as being five times higher for twin gestations than for singleton pregnancies (Ellings, Newman, & Bowers, 1998).

Maternal complications of multiple gestations also increase with the number of fetuses carried. All of the physiologic changes that occur to the client carrying a singleton gestation are increased to the extreme with multiple gestations. These include cardiac output, diastolic blood pressure, plasma volume, and venous distention. In contrast, maternal cardiac reserve, pulmonary residual volumes, and even gastrointestinal tone and motility are decreased (Bowers, 1998). Problems that can occur with pregnancy, such as anemia, pyelonephritis, cholelithiasis and cholesta-

sis, peripartum cardiomyopathy, and fatty liver disease, are more likely to occur in women with multiple gestations; and preexisting chronic problems affecting any organ system are likely to be exacerbated (Bowers, 1998). Maternal challenges also include increased nutritional demands, increased discomforts and compromises from uterine distention, and the risk for preterm labor. The complications that result from treating these problems also are challenges for the client. Preeclampsia, uterine atony after delivery, and postpartum hemorrhage are also risks the client with multiple gestation faces (Shields & Medearis, 1992b; Ellings, Newman, & Bowers, 1998). Psychosocial risks for the client and support persons include the incorporation of the multiple fetuses into the client's and the family's pregnancy plan and adaptation; acceptance as a high-risk obstetric patient; altered activities, including prolonged hospitalizations; financial concerns related to the loss of income and hospital costs; and the overriding fear of potential fetal loss (Bowers, 1998; Sather & Zwelling, 1998). The potential for anxiety and depression related to all of the concerns listed is well documented in families of multiple gestations (Leonard, 1998).

Medical management of the multiple gestation surrounds early diagnosis, monitoring of maternal and fetal well-being, and interventions as indicated in the face of complications. Medical surveillance may rely on laboratory values (for anemia), sonogram data (to assess fetal growth, chorionicity, and complications such as entanglement of cords) (Aisenbrey, 1995), fetal viability and cervical assessment (for stable labor status). Intrapartum management of multiple gestations may consider vaginal delivery for twins; however, many twins and all higher-order gestations are delivered by cesarean section.

Nursing considerations for the client and her support persons experiencing a multiple gestation are numerous. Whether the client is receiving nursing care in a high-risk antepartum hospitalization, is trying to halt the threat of preterm labor, or is in labor and delivery for her high-risk delivery, the nurse will be an integral part of a multidisciplinary team. The focus of care is to minimize or prevent antepartal and intrapartum complications (Bowers, 1998). The need for emotional support also is tremendous (Sather & Zwelling, 1998). The thoroughness of the nursing assessment is critical to identify even subtle concerns or changes in maternal-fetal status. The assessment should focus on maternal stability, fetal well-being with serial nonstress testing, and the absence or presence of uterine activity recorded on the fetal monitor. Psychosocial assessment should address the client's adaptation to the multiple pregnancy, the current situation, anticipatory grief processes, basic knowledge, coping skills, the ability to cooperate with the plan of care, and her support system (Bowers, 1998; Sather & Zwelling, 1998). An awareness of the potential for peripartum depression is particularly

important. The nurse may facilitate the client in seeking additional support that may reduce the likelihood of impaired maternal-infant attachment or even neglect or abuse (Leonard, 1998). The nurse may become the hub of the team by communicating needs, problems, plans, and readiness to other team members, such as the physician, the neonatal nursery team, social services, pastoral care, lactation support persons, and postpartum caregivers. An additional benefit to the client is provided through the nurse's consistent presence in an organized and calm environment (Bowers, 1998). Readiness for delivery and the necessary fetal and neonatal support are essential to prevent delay in resuscitative efforts or stabilization of all neonates. Perioperative procedures should be strictly observed to reduce the potential for infection. Provision of information and answering of questions should be done to meet the client's and support person's educational needs and reduce anxiety.

Evaluations of outcomes for the client and her neonates in a multiple gestation require review of the events.

- ❖ Was preterm labor halted long enough to achieve fetal viability, growth, and optimal survival?
- ❖ Did the delivery result in minimal problems for the fetuses and mother?
- ❖ Were the emotional needs of the client and her family met?
- ❖ Were resources consulted to assist with social and economic challenges?
- ❖ Were spiritual needs, inclusive of grief, addressed and supported?

The challenge of providing care for the client with multiple gestation is becoming more frequent and requires that the nurse provide highly technical care coupled with careful attention to the emotional well-being of the whole family.

FETAL DISTRESS

Nonreassuring fetal status, inclusive of the term **fetal distress**, refers to the response of the fetus to the antepartum or intrapartum uterine environment. Distress refers to the lack of fetal reserve or presence of fetal hypoxia, acidosis, or asphyxia. The fetal monitor tracing may demonstrate repetitive late decelerations; loss of variability; increasing baseline; or deep prolonged decelerations, with failure to return to baseline. A low scalp pH may indicate distress. A poor biophysical profile score also may indicate fetal compromise.

Any pregnant client may demonstrate a nonreassuring fetal status. It is safe to assume however that obstetric clients with high-risk conditions, such as prematurity, post-

maturity, infectious processes, hemorrhagic conditions, and preeclampsia, are more likely to experience problems. Fetal risk factors include permanent injury or death as a result of sustained hypoxia, with resultant acidosis and asphyxia. Maternal risks include the potential for operative vaginal or cesarean section, once the condition is diagnosed, and the resultant complications.

Concurrent medical management depends on whether the client is antepartal or intrapartal and the extent of the nonreassuring data. For example, when a client who is antepartal undergoes a fetal nonstress test that is nonreactive, despite adequate maternal hydration and various fetal stimulation interventions, the physician or CNM may

FETAL SURVEILLANCE KEY

Nonstress Test

A noninvasive test using an external fetal monitor to note fetal response, oxygenation, and autonomic functioning. A reactive nonstress test exists when two fetal heart rate accelerations of 15 bpm lasting for 15 seconds occur in a 20-minute period. Accelerations may occur spontaneously after fetal movement or other stimulation methods. A nonreactive test fails to demonstrate these accelerations and may indicate a need for further testing (Halle, 1993).

Contraction Stress Test

Use of the external fetal monitor to evaluate the fetal response to the stress of contractions. The challenge is to achieve three moderate-intensity contractions lasting 40 to 60 seconds in 10 minutes and note the fetal response. The contractions are achieved by client nipple stimulation or IV administration of an oxytocin piggyback drip. The desired response is referred to as a negative test. The occurrence of repetitive late decelerations is referred to as a positive test and indicates the need for intervention, usually delivery (Halle, 1993).

Biophysical Profile

Combines a nonstress test with ultrasound evaluation of fetal movement, breathing, tone, and amniotic fluid measures, with a scoring system from 0 to 2.

Halle, J. (1993) Diagnostic evaluation of high risk pregnancies. In S. Mattson & J. Smith (Eds.) (Chapt. 11). *NAACOG: Core curriculum for maternal newborn nursing*. Philadelphia, PA: W. B. Saunders.

AMNIOINFUSION

Amnioinfusion may be ordered to be performed at a bolus rate (up to 800 mL at one instillation); continuous flow rate (3 mL/min); or combination of an initial bolus (600 to 800 mL at 10 to 15 mL/min followed by continuation at 3 mL/min), with a subsequent continuous flow rate. Amnioinfusion requires ruptured membranes and an intact intrauterine pressure catheter (IUPC), preferably a double-lumen one. You must:

1. Check the functioning of the IUPC.
2. Connect the primed tubing by way of the controller pump to the instillation port of the IUPC. Set the rate for bolus or continuous flow.
3. Use warmed solution, which is standard practice; some policies require a warmer to maintain temperature.
4. Monitor the maternal abdomen for tension, the perineum for outflow of fluid on the hip pad, and the fetal tracing for symptomatic relief of cord compression.
5. Discontinue as per orders or if complications arise (e.g., no fluid return and fetal intolerance).
6. Document preinfusion data, amount, maternal fetal response, and tolerance to amnioinfusion.

Adapted from a protocol in Schmidt, J. (1997). Fluid check: Making the case for intrapartum amnioinfusion. *AWHONN: Lifelines*, 1, (7); 47–51.

choose to obtain a biophysical profile or other evaluation of the fetus. In contrast, when a client who is antepartal demonstrates **oligohydramnios** (less than 5 cm total of four quadrant measurements) on a biophysical profile along with a nonreactive stress test, the physician or CNM may choose to deliver. A client who is intrapartal and demonstrates deep variables in labor may respond to interventions and continue without additional problems. In contrast, the client who is intrapartal and demonstrates deep variables, decreasing variability, lack of accelerations, and delayed return to the baseline may require immediate delivery.

Nursing assessment of fetal status is critical. Fetal heart rate baseline, variability, the presence of periodic or non-periodic accelerations, the presence of periodic or nonperiodic decelerations, depth, and duration should all be assessed in detail. Maternal status that can affect fetal response, including position, maternal infection, hydra-

tion, uterine activity, blood pressure and medication, also must be assessed. Psychosocial elements, such as anxiety, pain, and lack of knowledge, also may affect maternal tolerance and thus fetal oxygenation.

The nursing plan is based on the initial and ongoing maternal-fetal assessment. Nursing interventions specifically used to increase fetal oxygenation may include use of maternal position changes to either side or even a modified knee-chest position to relieve pressure on the umbilical cord in utero. The nurse may apply supplemental oxygen by face mask at 8 to 10 L/min to enhance maternal-fetal oxygenation; increase IV fluid hydration to correct dehydration or dilute oxytocin stimulatory effects; and reduce or discontinue oxytocin uterine stimulation, particularly in the face of hyperstimulation. The nurse may be able to increase the accuracy of fetal monitoring by applying an internal fetal electrode for direct electrocardiogram monitoring or inserting an intrauterine pressure catheter (IUPC) to accurately assess intrauterine pressure during contractions and at rest. Application of these devices may be done by individual order, standing order, or critical pathway orders. Application should be done by the physician, CNM, or a nurse with additional expertise and experience. Each institution has policy parameters for performing these procedures based on the nursing practice act of the state and community norms. The nurse may be requested to start, maintain, and monitor an *amnioinfusion*, which is an invasive procedure that instills warm fluid into the uterine cavity by infusion pump to increase fluid volume and relieve pressure on the umbilical cord. This procedure also serves to dilute thick meconium and therefore may reduce the likelihood of meconium aspiration syndrome (Schmidt, 1997). Finally, in the face of non-reassuring responses, the nurse needs to make preparations for an emergent delivery.

Although not specific for fetal distress, the nurse also must incorporate general nursing monitoring and support interventions for client well-being. It is critical that the nurse maintain excellent channels of communication with the physician or CNM to discuss maternal-fetal status, interventions, and results. The intervention process should be calmly explained to reassure the client and support persons, convey concern and confidence in the interventions, and help reduce the overall level of anxiety. Finally, communication with the neonatal team is also important so that the members can prepare for any neonatal resuscitative efforts.

UTERINE RUPTURE

Uterine rupture involves a separation of the uterine wall that may allow protrusion of fetal parts into the maternal abdomen. A longitudinal rupture, sometimes referred to as

a classic rupture, occurs over the body of the uterus and is an acute emergent situation. Maternal shock and fetal distress may quickly become apparent to the nurse providing care. Uterine rupture of a low transverse segment over a scar from a previous low transverse cesarean section may have less acute symptoms; however, all ruptures place the mother and fetus at risk. Ruptures are classified as complete and incomplete. A complete rupture extends into the peritoneal cavity; an incomplete rupture maintains peritoneal integrity. Dehiscence refers to the separation of the old scar line and does not result in protrusion of fetal parts into the peritoneal cavity (Cunningham et al., 1997).

The rate of uterine rupture varies by institution, with reported incidences ranging from 1 in 1,280 to 1 in 3,000 deliveries (Cunningham et al., 1997). One 10-year review from Singapore has revealed an incidence of 1 in 6,331 deliveries, with a ratio of three previous cesarean scarred uteri to one unscarred uterus (Chen, Tan, & Yeo, 1995). The incidence of rupture in an unscarred uterus is even less common, and has been reported in one study as 1 in 16,849 deliveries (Miller, Goodwin, Gherman, & Paul, 1997). Contributing factors to uterine rupture include a previous cesarean scar, major surgery involving the uterus, such as a myomectomy; congenital abnormality of the uterus; grand multiparity; and use of oxytocin or prostaglandins (Al Sakka, Dauleh, & Al Hassani, 1999; Caughey et al., 1999; Kirkendall, Jauregui, Kim, & Phelan, 2000; Cunningham et al., 1997; Miller, Goodwin, Gherman, & Paul, 1997). Rupture also has been reported when forceps were used (Miller, Goodwin, Gherman, & Paul, 1997). Blunt trauma also has been associated with spontaneous uterine rupture (Cunningham et al., 1997). There have been reports, although rare, of spontaneous rupture of the unscarred primigravid uterus in the absence of uterine trauma or an infectious process. The second such case ever recorded was associated with an abnormally implanted placenta (**placenta percreta**; abnormal placental attachment that completely penetrates the uterine myometrium) in the second trimester and occurred as a spontaneous acute event (Imseis, Murtha, Alexander, & Barnett, 1998).

Maternal consequences of rupture include hypovolemic shock, bladder injury, anemia, emergent hysterectomy, anemia, transfusion, bowel injury, and death; fetal and neonatal outcomes include low Apgar scores, brain damage, intrapartum death, and neonatal or infant death (Kirkendall, Jauregui, Kim, & Phelan, 2000). Admissions to the neonatal intensive care unit and increased neonatal acidosis at delivery also have been associated with uterine rupture (Menihan, 1998).

Medical management of uterine rupture includes identification of risk factors, such as the client being a candidate for vaginal birth after cesarean section; careful management of all intrapartum patients; and surgical intervention and repair, as indicated. Clients who have had

previous cesarean sections are evaluated carefully, including previous scar documentation, before undergoing a trial of labor after cesarean (TOLAC) section. Clients with longitudinal uterine scars usually are not considered candidates for TOLAC. Clients with low transverse uterine scars, an adequate pelvis, and an appropriate-sized fetus without indication of malposition or malpresentation may be considered candidates for TOLAC. Management of prostaglandins and oxytocin should follow accepted medical standards of care. Many institutions require the ready availability of the physician or CNM when oxytocin is being administered during labor. Medical awareness of signs and indications of possible uterine rupture and ready availability for surgical intervention are necessary to ensure optimal maternal-fetal outcomes. Finally, repair of any sustained injuries and possible hysterectomy coupled with appropriate volume and blood replacement are part of the medical management of the client experiencing uterine rupture.

Nursing considerations for providing care for the client with potential uterine rupture is to identify risk factors with a thorough nursing assessment. Maternal history should be reviewed for previous cesarean section and type of uterine scar (longitudinal or low transverse), previous uterine surgery (such as a myomectomy in which uterine fibroids were removed), and trauma. Nursing assessment should focus on maternal uterine activity, especially contraction frequency, intensity, duration, and resting phases. When oxytocin is being administered, care should be taken to avoid hyperstimulation of the uterus. The client's abdomen also should be assessed for signs of abdominal trauma, bruising, tenderness, pain, and rigidity. Maternal vital signs may indicate shock with an elevated pulse, shallow respirations, and decreasing blood pressure. Maternal complaints of acute pain without interruption or evidence of fetal distress may support suspicion of uterine rupture.

Nursing diagnoses specific for uterine rupture identify the risks for injury to both mother and fetus from hemorrhage, shock, sustained hypoxia, hypovolemia, and acidosis. Nursing diagnoses also should address the emotional and educational needs of the client and family. Grief challenges should be included among the nursing diagnoses.

Nursing interventions center around prevention of uterine rupture induced by aggressive use of oxytocin, immediate recognition and stabilization of the client experiencing this obstetric emergency, and notification of the physician or CNM (and team members) to perform an emergency cesarean and possibly a hysterectomy. During this urgent situation the nurse should remain calm, offering explanations and reassurances to the client and informing the family of the status of the mother and fetus. Specific interventions to stabilize the client include monitoring maternal vital signs, ensuring IV access with fluid volume replacement, discontinuation of oxytocin, place-

ment of an oxygen face mask at 10 L/min, and monitoring fetal status. Immediate laboratory tests should include, at minimum, a complete blood count (CBC), platelet count, typing, and crossmatching. Operative preparations, including insertion of a Foley catheter, are managed urgently. The nurse also may need to assist in obtaining and administering blood products as ordered.

PLACENTAL ABNORMALITIES

Placental abnormalities also may contribute to a high-risk delivery or obstetric emergency. Placental abnormalities may be related to the implantation depth or site in the uterus; early separation from the uterine wall; or developmental problems, such as poor attachment of the cord, veins, or arteries to the body of the placenta. All of these placental abnormalities place the client and fetus at risk for hemorrhage, hypoxia, and even death. The incidence of hemorrhage related to placental abnormalities varies related to differing definitions but ranges somewhere between 3% and 7% (Cunningham et al., 1997).

Placenta Previa

Placenta previa is a condition in which the placenta implants low in the uterus (Figure 26-9). It is referred to as a *complete placenta previa* when the cervical os is completely covered by the placenta. When the cervical os is only partially covered, it is called a *partial previa*. When the placenta borders on the edge of the cervical os, it is referred to as a *marginal previa*. A placenta that implants

very close to the edge is called a *low-lying placenta* (Cunningham et al., 1997; Schmidt, 1993). The incidence of placenta previa is reported to be between 0.33% and 0.5% (Crane et al., 1999; Cunningham et al., 1997). The problem with such low implantation is that as the uterus contracts or the cervix dilates, the placenta is separated from the cervix and bleeding occurs. Acute or chronic bleeding may adversely affect the mother and fetus. Acute, dramatic bleeding places the mother and fetus at risk for hypovolemia, shock, and diminished perfusion. Chronic bleeding over the second and third trimester may result in impaired fetal perfusion and growth. Ultrasonography may identify placenta previa in the second trimester before the first episode of antepartum or intrapartum bleeding. As the gestation advances, however, as many as 90% of marginal and low-lying placentas resolve (Ricci, 1992). Placenta previa demonstrates a higher rate of abnormal implantation in the uterus. *Placenta accreta* refers to abnormal implantation to the myometrium. *Placenta increta* extends into the myometrium. *Placenta percreta* implants through the myometrium. These conditions further increase the risk for hemorrhage, uterine injury, and infection (Cunningham et al., 1997). With the exception of low-lying placentas and some marginal presentations, cesarean section is the mode of delivery for clients with placenta previa.

Contributing factors to placenta previa include previous placenta previa, advanced maternal age, multiple gestations, multiparity, uterine scars from previous cesarean sections, abortions, and endometriosis (Cunningham et al., 1997). Smoking also has been associated with increased risk for placenta previa (Cunningham et al., 1997; Andres, 1996). Consequences for the pregnant client include acute or chronic hemorrhage accompanied by resultant anemia

Figure 26-9 Placenta previa. A. Low implantation (marginal). B. Partial placenta previa. C. Total placenta previa.

and coagulopathies, including disseminated intravascular coagulopathy (DIC). Additional maternal risks include the potential that the previa has abnormally implanted as a placenta accreta, increta, or percreta. These conditions not only necessitate emergent cesarean delivery but require hysterectomy (Cunningham et al., 1997; Lin, et al., 1998). Fetal risks include impaired placental perfusion that may inhibit growth and survival. Complications reported by Crane et al. (1999) include preterm delivery, respiratory compromise, anemia, and a higher rate of congenital defects.

Medical management strives to identify placenta previa before the onset of bleeding; however, this is not always successful. Even when placenta previa is identified, the onset of bleeding is not always predictable. Acute bleeding episodes may be managed initially in the hospital; after bleeding cessation, if maternal-fetal status is deemed stable, home management may be attempted (Love & Wallace, 1996). Close monitoring of maternal-fetal status with blood tests to evaluate hemodynamic stability is necessary for maternal and fetal well-being, regardless of whether the client is hospitalized or is managed on an outpatient basis. Outpatient management requires frequent office visits and concurrent home health care. When maternal-fetal status is nonreassuring or the client is approaching term, cesarean delivery is performed.

Nursing considerations when managing an obstetric client who is bleeding include identification of the source or cause of the hemorrhage and stabilization of the client and fetus until cesarean section can be performed. Assessment data should include review of prenatal history, predisposing risk factors to suggest previa, other antepartum bleeding events, maternal Rh-factor status, and whether Rh₀(D) immune globulin (RhoGAM) was received if indicated. The current assessment should include when the bleeding began, the amount, the duration, whether or not the bleeding was associated with pain, and the presence or absence of fetal movement. Vaginal bleeding should be assessed for color, amount, and presence of clots. The assessing nurse should not perform a vaginal examination in the presence of bleeding. Fetal monitoring should be performed to assess for signs of fetal well-being or nonreassuring fetal status. Blood for initial laboratory testing should be drawn to evaluate hemodynamic stability. The nurse may anticipate orders for a complete blood count, typing, and crossmatching. Clotting studies, such as prothrombin time (PT), partial thromboplastin time (PTT), fibrinogen, fibrin split products and fibrin degradation products also may be performed. A **Kleihauer-Betke test** may be performed to denote evidence of fetal cells in the maternal circulation, which is significant for clients who are Rh negative. The nurse should be aware of the acute onset of abdominal or referred pain that may indicate a placental abruption co-existing with or instead of placenta previa.

Unit-based ultrasonography may allow confirmation of the placental abnormality and provide better information with which to plan care.

Nursing interventions include ongoing maternal-fetal assessment, establishment of IV access with a large-bore cannula in anticipation of transfusions, continuous monitoring of maternal vital signs, maternal pulse oximetry, oxygen supplied by face mask at 10 L/min, and insertion of an in-dwelling Foley catheter for strict intake and output measures. Assessment of bleeding can be obtained by weighing the hip pads before and after use and by counting the total number of saturated pads. As a rule, 1 g is equivalent to 1 mL. Positioning the client laterally to increase good circulatory return is useful. The nurse should perform these interventions while explaining the reasons for them and offering information about the procedures as they occur. The nurse may offer reassurance to the client and family by giving feedback about the fetus.

If the client stabilizes and stops bleeding, she may remain in the hospital or eventually return home on strict bed rest, with home health nursing support. Maintaining a client on bed rest for an extended period of time causes challenges for client mobility, strength, loss of control, coping mechanisms, and heightened anxiety. When the client with placenta previa is near term or continues to bleed, preparations for cesarean delivery and the associated communications, setup, and preparations are carried out while informing and involving the client and family as much as possible. The client with known placenta previa who has been bleeding chronically may actually be quite relieved with the aspect of impending delivery; the client with newly diagnosed placenta previa who has acute bleeding may be highly anxious and frightened. These differences should be assessed by the nurse to individualize client and family support. Finally, nursing considerations should include spiritual and grief support, as indicated, keeping in mind that uncontrolled acute hemorrhage may result in maternal or fetal illness, permanent injury, and even death.

Abruptio Placentae

Abruptio placentae is a condition in which the placenta separates prematurely from the uterine wall (Figure 26-10). Partial abruption involves a portion of the placenta and may be very small or nearly completely separate. In complete abruption, the entire placenta separates from the uterus. When complete placental separation occurs, fetal demise is certain and maternal morbidity is high. Hemorrhage is the chief characteristic of placental abruption. The bleeding may be frank, bright red, and associated with abdominal tenderness, as in a classic abruption. The abruption may be hidden beneath the placenta and concealed, without apparent vaginal bleeding. Pregnancies can con-

Figure 26-10 Abruptio placentae A. Central abruption, concealed hemorrhage. B. Marginal abruption, external hemorrhage. C. Complete abruption, external hemorrhage (could also be concealed).

continue with partial concealed abruptions that do not exceed 50% of the placental surface. When abruption of more than 50% of the placenta occurs, fetal perfusion usually is very severely compromised and the fetus will die in utero (Anath, Berkowitz, Savitz, & Lapinski, 1999). The incidence of abruption ranges from approximately 1 in 100 to 1 in 200 deliveries (Anath, Berkowitz, Savitz, & Lapinski, 1999; Cunningham et al., 1997). Abruptio recurs in subsequent pregnancies up to 16% of the time (Schmidt, 1993). Misra and Ananth (1999) has reported that initial abruption rates average 1.7%, whereas rates in second pregnancies average 2.2%.

Factors that contribute to the development of abruption include advanced maternal age and advanced parity. Abruptio also occurs more frequently in African American women than it does in Caucasian or Hispanic women. The most significant contributing factor, however, is maternal hypertension (Cunningham et al., 1997; Schmidt, 1993). There seems to be no difference in potential for abruption based on whether maternal hypertension is chronic and preexisting or acute, as in preeclampsia. Other risk factors for abruption include smoking, preterm premature rupture of membranes, external trauma from motor vehicle accidents, internal trauma from insertion of an IUPC, maternal cocaine use, uterine leiomyomas beneath placental implantation, and a short umbilical cord (Andres, 1996; Misra & Anath, 1999; Reis, Sander, & Pearlman, 2000; Handwerker & Selick, 1995; Cunningham et al., 1997; Schmidt, 1993). Maternal risks include shock, severe anemia related to hemorrhage, hypovolemia, risk for DIC, risk for embolism during the placental separation process, and death. Fetal risks include fetal growth impairment when the abruption is small and chronic; prematurity; severe hypoxic insults resulting in permanent neurologic damage; and intrauterine fetal demise (Anath, Berkowitz, Savitz, & Lapinski, 1999).

Medical management centers around the earliest possible identification of abruption, emergent cesarean delivery when the fetus is still alive, and maternal hemodynamic stabilization. When the abruption is minimal and maternal-fetal status is stable, an attempt at expectant management to allow fetal maturing may be considered cautiously, with emergent cesarean delivery an ever-present probability (Cunningham et al., 1997). Tocolysis may be provided to control uterine irritability and contractility that may increase the process of placental separation (Cunningham et al., 1997; Towers, Pircon, & Heppard, 1999). When the fetus is no longer alive in utero, vaginal delivery may be attempted with regard to maternal coagulopathy (DIC) that predisposes her to significant hemorrhage (Corbett & Fonteyn, 1995). Hypovolemia is treated with IV fluids and blood product replacement (cryoprecipitate, packed erythrocytes, and platelets), as indicated.

Nursing considerations in the care of the client experiencing an abruption depend on a thorough but efficient nursing assessment, keying in on risk factors that may signal this potential emergency. The nurse should also explore habits and events leading up to the point of maternal symptoms, such as abdominal trauma, cocaine use, or a history of heavy smoking. During the physical assessment the nurse should pay special attention to maternal vital signs, especially in the face of hypertension or shock indices (hypotension, tachycardia, and tachypnea); vaginal bleeding; and uterine tenderness, rigidity, or hypertonic response. Noting an increase in abdominal girth may alert the nurse that the client is bleeding into the uterine muscle, resulting in a Couvelaire uterine hematoma. Vaginal bleeding should be assessed with a hip pad count, with before and after weights of the pads being documented. Monitoring the fetal status is critical to establishing fetal well-being or identifying fetal distress as close as feasible to the onset of compromise. Particular attention should be paid to the presence of tachycardia, bradycardia, late decelerations, sinusoidal pattern, and loss of variability. IV access with a large-bore catheter is essential for delivery of lactated Ringer's solution and blood products. Necessary laboratory tests include a CBC, a platelet count, clotting studies, typing, crossmatching, baseline electrolyte and chemistry studies, and liver and renal functions studies. An in-dwelling Foley catheter should be inserted, with strict measurement of intake and output. Pulse oximetry monitoring should be used, if available, and supplemental oxygen delivered by face mask. When the maternal hemodynamic status is not stable or oliguria is not corrected with administered fluids and blood products, the client may require hemodynamic monitoring with a central venous line or pulmonary catheter. The mode of delivery depends on maternal-fetal status and maternal clotting status. If the fetus is alive, the nurse may anticipate an emergent cesarean. If the fetus is not alive, a vaginal delivery may be

in order, with oxytocin stimulation required. When oxytocin is ordered, careful titration must be observed to prevent further uterine trauma (Cunningham et al., 1997). In the midst of rapid medical and nursing interventions employed to stabilize the client and her fetus, the nurse must also provide the vital information necessary to quickly educate and reassure the client and her family. In the event of fetal demise, grief and spiritual support also must be considered. This aspect of care is particularly challenging because the family may have numerous unanswered questions as they try to cope with overwhelming grief related to the loss of their baby and uncertainty regarding maternal survival.

Other Placental Anomalies

Other placental abnormalities may contribute to poor fetal outcome, because maternal hemorrhage may go undetected until it is discovered at or after delivery. These abnormalities may be developmental or the result of superimposed trauma, such as from hypertensive episodes. Hypertension, either chronic or pregnancy-induced, may cause placental injuries called *infarcts*. These areas of tissue injury are no longer able to facilitate placental circulation. When these areas of damaged placental tissue are large or numerous, perfusion to the fetus may be compromised. Fetal growth may be affected over an extended period of time. Fetal heart tracings on the monitor may be nonreassuring, particularly during the stress of labor. Such fetal intolerance may result in fetal distress and necessitate cesarean section.

UMBILICAL CORD ANOMALIES

Developmental errors may occur as the umbilical cord joins into the placenta. **Velamentous insertion of the cord** refers to the junction of the cord at the edge of the placenta. The vessels separate into the membranes before reaching the insertion site. This abnormality can result in chronic altered fetal perfusion. More significantly, this abnormality can undergo trauma and compression during labor and delivery, resulting in rupture and hemorrhage. **Vasa previa** involves the cord vessels crossing the cervical os and results in significant compression and possible rupture from the pressure of the fetal head during descent. Fetal compromise may include hypoxic injury, hemorrhage, hypovolemia, and death. Before the ability to diagnose vasa previa in the antepartum period, the mortality rate was 33% to 100% (Oyelese et al., 1998). Both velamentous insertion and vasa previa tend to accompany other placental abnormalities, such as placenta previa and bilobed or irregularly developed placentas. These abnor-

malities also occur more frequently in multiple pregnancies and pregnancies that result from in vitro fertilization. With the advent of more detailed ultrasonography, vasa previa and cord abnormalities may now be detected before labor, allowing for an alternative form of delivery in highly suspicious cases (Oyelese et al., 1998; Lee et al., 2000).

Umbilical cord events and abnormalities may occur that result in a high-risk pregnancy or emergent status. Problems may be developmental, as in an umbilical cord having only two vessels instead of three. The absence of one of the umbilical cord arteries occurs in 0.72% to 0.85% of delivered infants, and it occurs more frequently in Caucasian women and even more frequently in women who have diabetes (Cunningham et al., 1997). Labor and delivery may proceed without any indication of problems until the neonate's cord stump is assessed at delivery and found to have only two vessels. Antenatally, sonography currently can screen for the presence of a three-vessel cord at the anatomic scan performed during the second trimester. Although this abnormality is not a problem during labor and delivery, neonates with only two vessels in the cord have been found to have a higher incidence of multisystem abnormalities (spinal, gastrointestinal, renal, and cardiac). Other cord problems may become evident during labor, such as cord length. Whereas *Williams Obstetrics* (Cunningham et al., 1997) identifies the average cord length as 55 cm, the variances range from 0 to 300 cm. Higher risks of rupture, abruption, and inversion of the uterus are associated with a short umbilical cord. An exceptionally long umbilical cord may result in fetal entanglement, with an intrauterine fetal demise being the result. **Umbilical cord compression** involves pressure applied to the umbilical cord. Compression can occur as the presenting part presses against the cord on descent or from entanglement or looping around a body part, such as the neck or shoulder, or from the existence of a true knot. Fetal perfusion is interrupted as cord compression increases or persists. Cord compression has been associated with nonreassuring fetal tracings, low Apgar scores, meconium-stained fluid, emergent cesarean section or operative vaginal delivery, neonatal resuscitation, and admission to the neonatal intensive care unit (Jauniaux, Ramsay, Peel-laerts, & Scholler, 1995; Larson, Rayburn, Crosby, & Thurnau, 1995). Longer cords also may incur a true knot (occurring in 1.1% of cords) or prolapse during labor once the membranes rupture. **Umbilical cord prolapse** occurs when the cord precedes the presenting part into the birth canal (Figure 26-11). Fetal position, multiple fetuses, artificial rupture of the membranes, and fetal activity may contribute to the likelihood of a prolapsed cord. Maternal risks include hemorrhage, uterine inversion accompanied by profound shock, and trauma from emergent interventions. Fetal risks include decreased or obliterated perfu-

Figure 26-11 Prolapsed cord. A. Occult (hidden, cannot be seen or felt). B. Complete (cannot be seen but may be felt). C. Visible (can be seen protruding from vagina).

sion, hypoxic injury, and death. The incidence of umbilical cord prolapse has been reported to be as frequent as 1 in 426 births or 0.4% to 0.5% (Murphy & MacKenzie, 1995; Cunningham et al., 1997). The prolapse may be either frank, with obvious fetal response and the umbilical cord found in the vagina or protruding from the introitus vaginae, or the prolapse may be occult, compressed between the presenting part and the cervix and not discovered until the time of delivery. Time is essential once a prolapse is suspected or confirmed. Delays in intervention for a prolapsed cord can result in fetal injury or death. Prabulos and Philipson (1998) reported that in a review of 26,545 cases of cord prolapse, a significant percentage of negative fetal outcomes still occurred despite diagnosis-to-delivery times averaging 11 minutes, 9 minutes less than the average vaginal delivery time of 20 minutes from diagnosis of cord prolapse to delivery of the baby. This study emphasized the need to deliver emergently once a diagnosis of prolapse has been made and also raised questions about the possibility of other variables contributing to negative neonatal outcomes.

Medical management of cord compression and prolapse involves early recognition, intervention, and delivery to avoid fetal compromise or death. Medical management of prolapse is an obstetric emergency. Umbilical cord compression can be managed conservatively as long as the fetal tracing is reassuring. When fetal intolerance becomes evident, alternative medical management may become necessary, including emergent cesarean section.

Nursing considerations focus on assessment of risk factors and evidence to support concerns about fetal perfusion. Most significant will be the fetal response recorded on the monitor tracing. Cord compression may be accompanied by variable decelerations that become deeper, wider, or return slowly to the baseline. Loss of variability or increasing baseline may signify loss of fetal reserve and indicate fetal compromise. In a frank cord prolapse, an acute and sustained bradycardia, decreasing fetal baseline,

or prolonged deceleration may be observed on the tracing. The pelvic examination also may assist the nurse to identify risk factors. When the presenting part is not well applied to the cervix or when a malposition or malpresentation (e.g., in breech and transverse lie presentations) is present, the client is at high risk for prolapse of the umbilical cord. Cord compression may be more apparent in the client with oligohydramnios, a condition in which the amniotic fluid volume equals 5 cm or less of the estimated total volume at or near term. A client with ruptured membranes also may experience more frequent compression because limited fluid is available to prevent pressure on the cord in utero. When the nurse suspects a prolapse, a pelvic examination should be performed. When the umbilical cord is palpated, the nurse can attempt to gently lift the presenting part away from it, thus permitting cord perfusion to resume. Once this is done, the examiner should not remove the examining hand. Fetal monitoring should continue, and the client either may be positioned with her head slightly downward or assume a modified knee-chest position to further remove the presenting part off of the cord. The nurse should call for assistance while remaining with the client. It is important to explain to the client what is happening and why the interventions are being performed. Supplemental oxygen with a face mask should be added to enhance placental fetal perfusion. Frank cord prolapse is an emergent condition. An emergent cesarean section is needed to deliver the fetus before significant circulation is interrupted and fetal hypoxia and acidosis occur.

Vaginal deliveries sometimes occur when the prolapse is occult, or hidden. In these cases, deep, broad variables may be observed on the fetal tracing. Maternal position changes and supplemental oxygenation with a face mask may provide some relief of the cord compression and enhance circulating oxygen until delivery occurs. If the fetal tracing becomes nonreassuring or demonstrates loss of fetal well-being, the physician may choose to perform

operative vaginal delivery with low outlet forceps or vacuum suction if delivery is imminent. A cesarean section may be necessary if labor is early. Having supplies available for these options is a part of the anticipatory preparations the nurse can make once the fetal monitor tracing becomes suspicious for problems.

The nurse providing care for the client experiencing cord compression may employ similar interventions, with maternal position changes from side to side or even a modified knee-chest position. The client may benefit from oxygen supplementation by face mask. The nurse may be asked to start and maintain an amnioinfusion to instill fluid within the uterus to replace the cushioning effect of amniotic fluid and relieve cord compression. The nurse should carefully monitor labor progression. When labor is progressing rapidly, the fetus may better tolerate the effects of cord compression. When cord compression is significant in early labor or during a sluggish labor, the fetal tracing may become nonreassuring before vaginal delivery is feasible. It is particularly important that the nurse complete preparations for delivery, including notifying the nursery personnel and having resuscitation supplies available in the event the fetus has respiratory depression from chronic cord compression. Emotional support and educational information are helpful to reduce or alleviate patient anxiety that accompanies high-risk situations.

AMNIOTIC FLUID ABNORMALITIES

Problems with amniotic fluid also can make a pregnancy and delivery high risk. Amniotic fluid amounts that deviate from normal can result in complications for the client and her developing fetus. Abnormal amounts of amniotic fluid are referred to as polyhydramnios (or hydramnios) and oligohydramnios. Amniotic fluid embolism is a critical event with an unclear cause. These three amniotic fluid aberrations can result in significant maternal and fetal complications.

Polyhydramnios

Polyhydramnios refers to an increased amount of amniotic fluid within the uterus. An amount of 2 L at term is considered to be polyhydramnios (Cunningham et al., 1997). This measurement is often based on clinical assessment of uterine size and perceived amount of fluid using Leopold's maneuvers. Another way of measuring polyhydramnios is to calculate the amniotic fluid index, which measures a pocket of amniotic fluid in each of the four quadrants using sonography. If the sum of the measures in the four quadrants exceeds 24 cm, the client is diagnosed

with polyhydramnios. The advent of routine sonography has offered a more objective way to evaluate amniotic fluid volume. The reported incidence of occurrence is approximately 0.9%, with most cases identified as mild hydramnios (Cunningham et al., 1997).

The occurrence of polyhydramnios has been associated with maternal diabetes; multiple gestations; and maternal isoimmunization, with resultant fetal hydrops (Kellogg, 1993). Polyhydramnios is also found in the fetus with neural tube malformations such as spina bifida or anencephaly, with increased fluid loss through meningeal membranes, gastrointestinal problems that interfere with the normal swallowing and absorption of amniotic fluid (Cunningham et al., 1997). Maternal effects of polyhydramnios include general discomfort from overexpansion of the uterus, respiratory compromise, uterine irritability from overdistention, premature labor, and uterine rupture. Fetal risks include premature delivery, cord prolapse, malpresentation, macrosomia, and cesarean delivery (Kellogg, 1993; Panting-Kemp et al., 1999). A 1998 study that evaluated the incidence of complications and hydramnios found a higher number of antepartum and postpartum deaths, abruptio placentae, fetal distress, meconium-stained fluid, low Apgar scores, and chorioamnionitis, as well as the problems listed previously (Maymon et al., 1998). An earlier study had concluded similar findings in hydramnios when the condition was persistent throughout the second and third trimesters. When hydramnios resolved in the third trimester, the incidence of negative outcomes decreased significantly (Golan et al., 1994b).

Medical management of the client with polyhydramnios is related both to an identified cause and symptomatic complaints. When hydramnios is severe, amniocentesis to remove fluid is performed. The procedure is carried out with ultrasound guidance, and the amount of fluid is measured and recorded. Otherwise, medical management addresses the client and fetus at the time of labor (i.e., prematurity, maternal diabetes, fetal anomalies, and so on).

Nursing considerations also depend on the contributing causes and maternal symptoms. For instance, when the client is admitted in preterm labor, the nursing care focuses on tocolysis, fetal and maternal monitoring, and prevention of therapy side effects. In addition to the cause of hydramnios, if known, client comfort is a particularly important nursing issue. Maternal comfort in late pregnancy is always challenging, and the addition of more amniotic fluid that causes further uterine distention and dyspnea is even more so. Elevation of the head of bed, pulse oximetry, and humidified oxygen supplementation by nasal cannula may be beneficial in late antepartal care. Oxygen by face mask is still preferred in labor. Fetal monitoring may be difficult related to the additional uterine expansion and bulk. Leopold's maneuvers also may be more difficult because of the taut abdominal skin and the large volume of

fluid to try and “feel through.” Once delivery is inevitable, the neonatal team should be notified of the premature labor and anticipated fetal anomalies. The client experiencing hydramnios has the additional challenges of coping with increased physical discomforts; causative factors, such as diabetes; and the overriding concern for the well-being of the infant. The chronicity of the condition may be extremely fatiguing and become comparable to the client on extended bed rest for multiple gestation or preterm labor. Diligent client education, emotional support, and encouragement are nursing interventions that may assist the client to better cope with her situation.

Oligohydramnios

Oligohydramnios refers to the amniotic fluid being significantly less than expected for pregnancy. The volume measurement is 500 mL or less between 32 and 36 weeks’ gestation, or an amniotic fluid index of 5 cm or less (Kellogg, 1993; Cunningham et al., 1993). Sonography has allowed early identification of oligohydramnios along with follow-up surveillance of the client with persistent oligohydramnios. Oligohydramnios identified early in the pregnancy has a more negative prognosis relative to the cause and chronicity of the condition (Cunningham et al., 1997). The incidence varies with the associated cause; however, a 1994 study found a rate of 0.58% in a review of 25,000 obstetric clients (Golan, 1994b). A more recent study of 6,423 pregnancies found an occurrence rate of 2.3% (Casey et al., 2000).

Contributing causes toward the development of oligohydramnios include fetal anomalies, especially of the renal system. Fetal anomalies were attributed as being the cause in over 50% of cases of oligohydramnios in the second trimester of pregnancy and almost 25% of cases in the third trimester (Shipp et al., 1996). Fetal renal agenesis (known as Potter’s syndrome), or the failure of the fetal kidneys to develop, is associated with severe chronic oligohydramnios. The renal agenesis is accompanied by pulmonary hypoplasia. The fetal renal and pulmonary systems are significant in maintaining and rebuilding amniotic fluid volumes (Cunningham et al., 1997). Without their existence or development, the fetus is compressed within the uterus. Renal agenesis is an anomalous condition that is incompatible with life outside the uterus. Other fetal problems that contribute to oligohydramnios include renal system obstruction and polycystic kidneys. Maternal factors that contribute to oligohydramnios are hypertension; leaking or premature rupture of membranes; and most frequently, gestations that continue beyond 41 weeks (Cunningham et al., 1997).

Perinatal outcomes reported in a study examining the various complications included increased rate and need for labor induction, increased stillbirths, nonreassuring

fetal heart rate tracings, neonatal intensive care unit admissions, meconium aspiration, and neonatal death (Casey et al., 2000). Cesarean section and an Apgar score of less than 7 at 5 minutes were found more frequently in clients with oligohydramnios (Chauhan et al., 1999). Increased rates of maternal hypertension, second trimester bleeding, fetal intrauterine growth retardation, fetal skeletal and renal system anomalies, and perinatal mortality were reported in a 1994 study (Golan et al., 1994a). Even borderline amniotic fluid levels ranging between 5 and 10 cm on the amniotic fluid index have been associated with increased intrauterine growth problems and perinatal complications (Banks & Miller, 1999). *Idiopathic* (meaning unknown cause) oligohydramnios without associated fetal growth problems as followed on surveillance sonography did not demonstrate a higher incidence of fetal complications other than premature delivery in a 1997 study reported by Garmel et al. (1997).

Medical management of the client with oligohydramnios includes early diagnosis with anatomy surveillance for anomalies. When maternal conditions such as hypertension and postdate gestation are contributory, evaluation for delivery must be considered. Use of the biophysical profile may augment the practitioner’s plan of care by providing feedback on fetal well-being. When oligohydramnios results from premature leaking or rupture of membranes, medical care may be expectant. That is, maternal-fetal status is monitored for stability and infection while the opportunity is provided for amniotic fluid to accumulate. When signs of infection are apparent, delivery plans replace expectant management to minimize the risk of sepsis. When oligohydramnios is severe or associated with fetal anomalies, the client and family must be informed and prepared for the likely outcomes.

Nursing considerations in the care of the client with oligohydramnios are determined by assessment data related to the cause of the oligohydramnios and the medical plan of care. When expectant management is the plan, nursing considerations include thorough maternal-fetal assessment, with the fetal tracing providing critical information on fetal status. Monitoring for signs of infection in the event the membranes are leaking or ruptured also is a nursing concern. The client with hypertension may be on strict bed rest and required to undergo repeated surveillance sonograms and nonstress tests. Anticipatory grief support may be the most important support offered to the client with a fetus that has significant anomalies. When delivery is planned, the nurse can anticipate orders for an amnioinfusion to relieve cord and fetal compression and thus reduce overall stress during labor. Ongoing fetal monitoring may reveal deep variables and prolonged decelerations related to severe umbilical cord compression. Maternal position changes may be futile relative to the uterine compression of the fetus in severe cases of oligohydramnios

Critical Thinking

Cardiopulmonary Resuscitation in Labor and Delivery

- Are you currently credentialed in cardiopulmonary resuscitation?
- Have you recently reviewed the unit policies?
- Do you know where your cart or supplies are?
- Remember the ABCs? They are the same.

Airway: How do you insert an oral airway? Can you obtain a seal and secure a chin lift position?

Breathing: How do you use a self-inflating resuscitation bag? How many ventilations should be done?

Circulation: What are the landmarks to be assessed to ensure proper hand placement on the patient's chest wall? What is the proper position for a pregnant patient receiving CPR? How many compressions should be done each minute for an adult?

but should be attempted to achieve optimal fetal response. Supplemental oxygenation may benefit fetal perfusion and can be administered by face mask. IV hydration should be maintained to avoid perfusion complications that increase fetal stress. As in all high-risk delivery settings, the neonatal team should be ready in the event neonatal resuscitation is required.

Promoting parental grief and acceptance of their loss in the event the fetus or neonate does not survive is a critical nursing concern. The nurse should assess the parental needs and readiness for grieving and provide adequate time for the parents to see, hold, and bond with their infant with privacy, respect, and any requested spiritual support. Many facilities have protocols for perinatal loss support that include photographs, time together, burial layettes, and memory books with a lock of hair and handprints and footprints of their baby. Recognizing that all persons grieve differently should provide insight into how to implement and observe such a protocol without offending or upsetting the mother and family if they are not ready or are unable to participate in such a personal farewell. In some cases, the memorabilia is collected and saved in a labeled envelope in case the parents desire it at a later time.

Amniotic Fluid Embolism

Amniotic fluid embolism is a very rare but life-threatening condition. Amniotic fluid embolism involves the presence of an embolus composed of amniotic fluid along with

particulate matter (such as vernix caseosa, lanugo, meconium, and other fetal cells) that enters the maternal circulation and causes acute respiratory distress, cardiovascular collapse, severe coagulopathy, shock, and death (Austin, 1993). The reported occurrence is 1 in 65,000 deliveries, and the maternal mortality rate is up to 80%. A 1995 review of national registry records reported a maternal mortality rate of 61% (Clark et al., 1995). A more recent study in 1999 reviewed approximately 1.1 million deliveries and identified an incidence of 1 per 20,646 deliveries and an associated maternal mortality rate of 26.4% (Gilbert & Danielsen, 1999). Half of all maternal survivors of amniotic fluid embolism have significant neurologic sequelae (Locksmith, 1999). The embolic event occurs during or immediately after delivery when the placenta separates from the uterine wall and maternal veins are open for transport of the embolus. Intrauterine pressures are favorable for transport of the embolus, especially when there is aggressive uterine stimulation; tumultuous, hypertonic labor; or placental abruption. Amniotic fluid embolism is more common when the labor has been precipitous or strong; when premature placental separation makes maternal access available sooner; and when more particulate matter, such as meconium, is available to compose the embolus (Cunningham et al., 1997). Studies repeatedly have reported classic responses of maternal respiratory distress, cardiovascular collapse, shock, and coagulopathy; however, the similarities between amniotic fluid embolism and anaphylaxis or septic shock are identified as possible potentiators that increase the mortality rate (Clark et al., 1995; Locksmith, 1999; Weiwen, Ningyu, Lanxiang, & Yu, 2000).

Clinical presentation of an amniotic fluid embolism is abrupt and spontaneous and includes complaints of respiratory difficulty and pain, cyanosis, and chest pain, with rapid onset of shock and cardiovascular collapse (Weiwen, Ningyu, Lanxiang, & Yu, 2000). In the previously cited study, the time of onset of symptoms to the time of death was reviewed. Thirty-nine percent of mothers died within one hour of onset of symptoms, and one-third died within the first 30 minutes. Women who survive are at significant risk of neurologic impairment from severe hypoxemia. If delivery has not been completed, the fetus is at the same risk of hypoxemia and subsequent damage or death.

Medical management depends on recognition of the clinical symptoms and is supportive in nature because there is no known curative protocol (Locksmith, 1999). Rapid intervention involves immediate and aggressive resuscitation to maintain oxygenation; volume replacement; monitoring of cardiac output and vital signs; and transfusions of cryoprecipitate, fresh frozen plasma, and packed erythrocytes and platelets to control the coagulopathy (Cunningham et al., 1997). When delivery has not occurred, it must be performed surgically and immediately if the fetus is to survive.

Nursing considerations include astute assessment of maternal-fetal status throughout the third and fourth stages of delivery. Attention should be focused on vital sign stability and any maternal complaints of shortness of breath, chest pain, heightened anxiety, and sensation of impending doom. Other assessment data include listening to breath sounds, observing for increased bleeding from the perineum or incision, and monitoring the level of maternal consciousness. The nurse should never leave an unstable or deteriorating patient. Calling for assistance and emergency supplies such as the crash cart should be done immediately on identification of maternal problems. The first interventions are based on the classic ABCs of resuscitation: **a**irway, **b**reathing, and **c**irculation. Maintaining or reestablishing an airway is first and foremost, and may be as simple as initially applying an oxygen face mask at a rate of 10 L/min. However, maintaining the client's airway may progress rapidly from oxygen supplementation to manual ventilation with a self-inflating resuscitation bag, and finally to assisting with intubation and support by ventilator. Circulation and

perfusion are maintained with IV fluids, chest compressions if cardiac arrest occurs, and assisting with defibrillation as necessary. Multiple pressor drugs may be ordered to help maintain blood pressure and promote adequate perfusion. Continuous monitoring of maternal vital signs is critical. Pulse oximetry should be used until a pulmonary catheter and an adjunctive arterial line are put in place for accurate cardiac output assessment and monitoring of blood gases. The nurse can anticipate orders for various laboratory tests, including CBC, platelet count, typing, crossmatching, a clotting panel (PT, PTT, fibrinogen, fibrinogen split products, and fibrin degradation products), and chemistry panels to assess electrolyte stability and renal function. An indwelling Foley should be inserted, with strict intake and output monitored hourly. Receiving and following through with orders for the various blood products and strict compliance with administration procedures also are nursing responsibilities. Monitoring ongoing blood loss and recording of amounts are important factors in estimating replacement needs.

REFLECTIONS FROM A NURSE

"Labor and delivery was my passion! I had just attained a level of clinical comfort as an experienced labor and delivery nurse. I had participated in numerous high-risk deliveries, started IVs in almost nonexistent veins, protected seizing patients from self-injury, managed Pitocin and magnesium sulfate, transfused blood, and raced my patients to the OR like lightning in an emergent situation. I prided myself on bonding with the clients, their families, and even their newborns.

Then entered our newest admission. Kate was 31 and in labor with her first child. She and her husband, Scott, were so excited about their baby. They worked together in labor, and her labor was tough. Strong contractions were exhausting but she coped well with minimal pharmacologic intervention. She pushed hard to deliver a strong, loud, healthy boy weighing in at 9 pounds. They were oblivious to the repair as it was in progress. Within

10 minutes of the placental delivery, she began complaining of chest pain and acting so anxious. Her color paled and she became diaphoretic. We had to initiate resuscitation in another few minutes. Minutes felt like hours. The ABCs of CPR rang in my ears. The response of everyone was admirable and quick, but futile. Later as I would clean and prepare Kate for her return to her horrified husband, I reviewed the process and wondered what else could have been done. I hugged him, cried with him, and told him how sorry I was.

Still later as I reviewed my chart and followed the process for closing a chart that would undergo immediate risk review, I tried to retrace the events to explore one more time what could have been done. Nothing. How humbling that thought. We are but human. We did all that could be done. Alone, on my way home, I cried for us all; Kate, Scott, their newborn son, my colleagues, and myself."

The resuscitative process can be overwhelming to the health care team. The process certainly will be a terrifying experience for the family and support persons who witness a cardiovascular arrest, significant hemorrhage, and the incredibly aggressive response. Because such events are unexpected, the scene can appear chaotic as supplies and team members are rapidly assembled and participate in the resuscitative efforts. Quick explanations about the situation to the family and support persons should be provided. They may be asked to move to an area in the room where they can remain close or to wait outside the room. Available space in the room or hospital policies may determine where the family and support persons will be asked to stay. Whenever possible, a social worker or spiritual counselor should remain with the family to provide support while resuscitative efforts continue. If the client is stabilized and placed on ventilatory support, the family should be allowed to see her before she is transferred to the intensive care unit. If the client does not survive, the family should receive grief support and be allowed to spend time saying farewell. If the fetus does not survive, the family's grief will be further increased. If the neonate survives, support will be needed to enable a healthy adaptation with the surviving family.

Most of the time, obstetrics is a happy nursing specialty area. In the event of maternal or fetal death, the

health care team must deal with their own personal feelings of loss and possibly failure. It may be helpful for a grief or spiritual counselor to meet with the team that was involved to assist them with coping, both personally and professionally. Review of all resuscitations can be expected as a part of risk management and quality improvement requirements. Careful review of the chart documentation, including entering of any late entries, should also be done after a resuscitation.

Web Activities

- Visit ACOG's and AWHONN's websites. Do they include information specific to some of the dysfunctional labor patterns discussed in this chapter? Compare information regarding the nurse's role v. the physician's role.
- Search the internet for information for parents of multiples. Are there chat rooms? Support groups? Toll-free numbers? Resource materials, such as books and videos?

Key Concepts

- Dysfunctional labor patterns include hypertonic, hypotonic, and precipitate labor patterns. Oxytocin may be used to regulate and normalize a dysfunctional labor pattern.
- Malpositions include occipitotransverse and occipitoposterior. Malpresentations include breech, acromion, face, brow, and transverse presentations. Persistent malpositions and malpresentations place mother and fetus at risk for cesarean section or operative vaginal delivery.
- Fetal distress indicates fetal intolerance to the intrauterine environment, labor, or both. When left untreated, the fetus can experience hypoxic injury, acidosis, and death. Nursing interventions focus on increasing fetal oxygenation and perfusion.
- Uterine rupture is more likely to occur in a scarred uterus and may result in fetal death and maternal shock and hemorrhage. Uterine hyperstimulation may contribute to rupture.
- Placenta previa and abruptio placentae are hemorrhagic conditions of pregnancy. Placenta previa frequently presents as silent, nonpainful bleeding that

may initially occur in the second and third trimesters. Abruptio placentae is more frequently acute and associated with abdominal pain. Complete placenta previa necessitates cesarean section, as does acute abruption. Abruption of over 50% is incompatible with fetal survival. Two consequences of abruption include DIC and a higher risk of amniotic fluid embolism.

- Prolapsed umbilical cord is an obstetric emergency. When unrelieved, the cord compression may result in fetal death.
- Abruption, uterine rupture, and amniotic fluid embolism predispose the obstetric client to DIC.
- Oligohydramnios refers to less than normal amniotic fluid volume in the second and third trimesters. Fetal cord compression, intolerance to labor, and negative fetal outcomes are increased in clients with oligohydramnios. This abnormality is frequently found in pregnancies with fetal anomalies. Maternal factors include hypertension and postdatism.
- Polyhydramnios refers to a greater than normal amniotic fluid volume and can result in maternal respi-

ratory compromise, fetal malpresentation, and cord prolapse. Polyhydramnios is frequently found in pregnancies with maternal diabetes, multiple gestation, and isoimmunization.

- Amniotic fluid embolism is a rare event with a high maternal mortality rate as a result of obstetric shock from cardiopulmonary collapse and hemorrhagic coagulopathy. The physiologic response is comparable to anaphylactic and septic shock.

Review Questions and Activities

1. Ms. J. is an obstetric patient who is in observation status in labor and delivery. Her contractions are occurring irregularly every 2 to 10 minutes. She states that she has had contractions like these for 9 hours. She is afebrile, and her vital signs are stable: pulse, 90; respirations, 18, and blood pressure, 114/72. The fetal heart rate is in the 140s, the baseline tracing demonstrates several accelerations, and no decelerations are noted. What other assessment information should you gather to assist in formulating diagnoses and a plan of care for Ms. J?
2. Ms. P. is a 32-year-old gravida, para 2002. She arrives in labor and delivery breathing, panting, and holding her abdomen near the suprapubic region. She tells you her membranes ruptured 10 minutes ago and that she now feels the urge to push. As you take her to a bed, you continue to gather additional information and discover she had her last baby en route to the hospital after a 30-minute labor. Without a pelvic examination performed, what action might you take?
3. Ms. R. is a gravida 2, para 1001. She has been completely dilated and at +1 station for 2 hours. She had an epidural and was unable to push well with contractions. She has begun to feel the pressure sensation and believes she can push better now. The fetal heart rate is in the 130s with long-term variability present, no decelerations noted, and an occasional acceleration observed. Ms. R.'s vital signs are stable. What interventions might you try to enhance her pushing efforts? What signs might you observe that may indicate a problem with fetal descent?
4. Ms. B. is a gravida 3, para 1011. She is 36 5/7 estimated gestational age with a twin gestation and presents with contractions that are 3 minutes apart, lasting 45 seconds, and moderate to firm in intensity. The twins' heart rates are identified at the right lower quadrant and left upper quadrant and range in the 130s and 150s, respectively. Discuss the assessment information you require for a safe labor and delivery process for this client. What factors may affect her mode of delivery and outcomes?
5. Ms. K. is a gravida 2, para 1001, and is attempting a trial of labor after having a cesarean section. Her original cesarean was 4 years ago for arrested descent. She complains of intense burning pain over the parapubic region. What other assessment parameters must you evaluate to identify a uterine rupture? What preparations have you already completed knowing this client has had a previous cesarean section and is undergoing trial of labor?
6. Ms. T. arrives in the labor and delivery unit by stretcher from an ambulance. Her vital signs follow: pulse, 120; respirations, 24 and shallow; blood pressure, 84/50 and faint. She complains of acute abdominal pain that began abruptly 1.5 hours ago. She has a very scant amount of bright red bleeding. Fetal heart tones are auscultated in the 90s. What do you suspect has occurred? Formulate a priority-based plan to ensure the best outcome for Ms. T. and her fetus.
7. As you begin your shift you receive a report on Ms. A. She is a gravida 4, para 0030, at 37 2/7 estimated gestational age, with a history of late pregnancy losses for unknown reasons. She is currently in a low Fowler's position, on continuous fetal monitoring, and having contractions of moderate intensity that are 4 minutes apart and last for 45 seconds. While you review her fetal monitor tracing, you note that the baseline is in the 120s. You do not note any accelerations and, in fact, notice late decelerations occurring after each contraction for the last 15 minutes. Identify interventions to attempt to alleviate this non-reassuring pattern. Are there other tests to reinforce your concerns or establish a sense of well-being in the client?
8. Ms. F. presents to labor and delivery in active labor. Examination finds that she is 4 cm dilated, has 80% effacement with bulging membranes, and the presenting part is at -3 station. Fetal heart tones are reactive in the 130s to 140s, with accelerations present. As you enter laboratory requisitions at the desk, you note on the central monitor that the fetal heart rate is now in the 90s. You return to find Ms. F. saying she just was going to call you because her membranes have ruptured. What are your next actions in a prioritized order?

9. Ms. Y. is a 26-year-old gravida 3, para 3003, who just delivered 15 minutes ago. You are assessing her vital signs and talking with her about her baby while the physician repairs her perineal laceration when she suddenly looks worried and tells you she cannot breathe well. You note that she has become pale and clammy in this few moments. Her vital signs are re-

flecting changes with a pulse that is increasing and at 106, a blood pressure that is decreasing and at 88/56, and respirations that are shallow and rapid at 28. She is gasping and looks panicky. What do you suspect is occurring? Discuss the prioritized interventions and complications that may arise secondary to her immediate diagnosis.

Birth and the Family

Working with childbearing families is one of the most rewarding challenges in nursing practice. During this time, the nurse has an opportunity to assist clients and families in developing coping strategies that will help them reach their full potential as individuals and a family unit (Maushart, 1999; von Klitzing, Amsler, Schleske, Simoni, & Bergin, 1996). Families are more open, receptive to education, and willing to make changes in their lives during the childbearing years than during any other time in their lives (Maushart, 1999; von Klitzing et al., 1996; Hawkins & Gorvine, 1985). This is also a time when the nurse discusses important issues about reproductive health. While assisting a family during labor, birth, and the immediate postpartum period, the nurse has an opportunity to examine the client's personal views, choices, and experiences. The most effective maternal-newborn nurses integrate a sensitivity to their own response to birth with the skills they need to assist families in moving through their particular experience.

Consider the following questions as you examine your personal feelings regarding birth.

- *What are my personal experiences with birth?*
- *If I have given birth, or if I have been present at the birth of a child, were there professionals who were helpful to me in having the birth experience I desired?*
- *What were the qualities of these professionals?*

Situational crisis

Competencies

Upon completion of this chapter, the reader should be able to:

1. Discuss the effect of an uncomplicated birth experience on mothers and fathers.
2. Compare the effect of an uncomplicated birth experience for primiparous and multiparous families.
3. Describe the potential effect of a new birth on siblings.
4. Discuss the effect of birth within a multigenerational family.
5. Explain how to identify the needs of a family that is experiencing a complication of birth.
6. Discuss the relevance of assessing the family's response to birth when identifying infants at risk for child abuse and neglect.
7. Apply the nursing process in the assessment of the family's response to birth, the identification of adaptive and maladaptive processes, the development of a plan of care that supports positive responses or assists the family in developing appropriate responses, and the evaluation of the care provided.
8. List community resources available to postpartal families that can assist in coming to terms with the birth experience.

The moment of birth is a transition point, a line of demarcation between life before the baby and life with the baby. No matter how well prepared a woman or her family believes they are for this transition, the reality of the experience of birth is impossible to predict. Each birth is unique, each infant unlike any other. The congruence of the quality of the labor and the specific qualities of the birth and the infant with the expectations of the participants determines the response of family members to the birth (Maushart, 1999). One important family experience during the birth process is fear for the life or health of the mother and the infant.

The location of birth can affect the family's response. The family that is invested in a noninterventional style or unconventional place of birth, such as the home setting, may experience anxiety and stress if the birth occurs in a hospital. A sudden change in birth venue, whether from home to hospital, birth center to hospital, or hospital birthing room to operating room generates disequilibrium in the family as it struggles to come to terms with expectations that are not mirrored by reality.

The responsiveness of the birth site to the needs of the family influences their experience. "Ownership" of the birth experience is perceived differently in different set-

tings. The home environment is under the control of the family and parents; the birth center environment is usually constructed to allow the family to control events to a certain extent; and hospital sites are governed by administrative rules that tend to remove the locus of control from clients and families. Depending on the philosophy of the institution, families can be limited not only in choices about how to birth but about who may be present. Table 27-1 offers insight into some of these philosophies. Some institutions and some professionals are more restrictive than others. Reasons for these variations may be based in theory or on the personal experience and perspective of the professionals involved (DeVries, Wrede, Teijlingen, & Benoit, 2001).

Assessment of the family member's immediate response to the birth experience sets the stage for nursing interventions during the postpartum period. By using the nursing process and thoroughly understanding the diverse aspects of nursing, obstetric, psychological, sociologic, educational, and political theory that intersect during the time of birthing, the nurse can choose culturally competent interventions that assist the family in moving through their birth experience (Cross, Bazron, Dennis, & Isaacs, 1989).

Table 27-1 Potential Effects of Birth Site Philosophy on Family Birth Experience

Birth Site	Philosophy	Effect on Family Birth Experience
Home	This is the family's personal space. The family owns and operates the space.	The family controls who is present in the space where the birth occurs. The family assumes responsibility and contracts with the birth attendant. The family controls issues such as clothing worn during labor, fluid, nutrition, and ambient music. Supportive people are present at the family's request.
Birth Center	The center owns and operates the space. When beginning prenatal care the family contracts with the center for services. Self-care and participation in decision making are expectations of the relationship.	The family has control over the experience in collaboration with the center staff and policies. Responsibility is shared. The family controls issues such as clothing worn during labor, fluid, nutrition, and ambient music. Supportive people are present at the family's request.
Hospital	Corporately owned with strict visitation policies dictated by nursing and administration. Governed by infection-control policies.	Institutional policy governs where the birth occurs, who and how many people may be present; who those persons may be; how long they may stay; available food and fluids; clothing worn, and how the family can use music or other support strategies. Obstetrical medical policy dictates whether oral nutrition is available and if technology is used routinely. The family has as much control as they are willing to exercise within the boundaries of the institutional policies.

HISTORICAL ASPECTS OF BIRTH AND THE FAMILY

The history of birthing is an interesting one. Cultural and family practices and beliefs around childbearing have been passed from generation to generation. In the United States, the 20th century, the location for birth moved from the home to medical institutions. There were many contributing factors, including the development of medicine as a science, the trend away from using midwives to using doctors to care for women during pregnancy and birth, the development of medications and anesthetics, the redefinition of hospitals as places of healing where services were available that could not be provided in the home, the growth of hospital beds, the advent of hospitalization insurance, and the redefinition of birth as an illness requiring specialized care. By the 1950s, most women gave birth in the hospital with the latest technologies, including twilight sleep (a combination of sedation and anesthesia for the birth itself). Rural and non-Caucasian women continued to birth at home during this time, probably because of lack of proximity to hospitals and the segregation of many facilities (DeVries et al., 2001).

In the 1960s, the natural childbirth movement grew, partially from the women's movement and partially as a result of some women's desire to reclaim control over their childbearing experiences. During the next 20 years, changes were made in who could accompany a woman in labor (fathers and the infant's siblings), where the birth could take place (in a labor or birth room as opposed to a traditional delivery room), and how long the hospital stay

would be. In the 1970s, the Birth Center Movement began as families asked for a place of birth that was home-like but had some medical technology available. And during that time, the number of practicing nurse-midwives began to grow (DeVries et al., 2001; Simkin, 1996).

Family centered maternity care developed in the 1970s and 1980s as hospitals and obstetric professionals responded to the growing demands of families to participate in birth and to the growing amount of research that supported the positive outcomes for families when their personal and cultural needs were met (Simkin, 1996).

The history of birth in the United States has substantial implications for maternity nursing practice. In each of the following sections of this chapter, consideration is given to the historical changes that have affected family participation in the birth process.

CULTURAL CONSIDERATIONS IN A FAMILY'S RESPONSE TO BIRTH

Worldwide, pregnancy and birth are perceived from either a wellness or an illness viewpoint. Racial, religious, ethnic, political, economic, and technologic advancement all influence perspectives of childbirth. Over time, culturally specific practices have developed that enable family members to deal with this time of vulnerability for the mother and her child and of change for the family and community. The way a family experiences birth is influenced by the values of the culture than they are born in to and the con-

gruence of that orientation with the culture in which they birth (Esposito, 1999).

Birth sites and those individuals who staff them have their own orientation to childbearing, which is influenced by the same factors. Given the mobility available to individuals and families today, it is quite likely that a family from one culture gives birth in a place unlike their homeland and is cared for by attendants who come from still other environments. Based on the interactions of the individuals in these multicultural situations, the potential exists for powerful, positive, growth-enhancing outcomes for the family and the practitioners and also for negative, personally destructive outcomes.

A **cultural competence continuum** is a progressive description of the ability of an individual or institution to respond to the individual, culturally specific needs of people. Table 27-2 illustrates the layers of a cultural competence continuum from cultural incapacity through cultural competence (Cross et al., 1989). Individuals or agencies can fall anywhere on this continuum and therefore have a positive or destructive interaction with a family during the birth experience. Nursing professionals have a responsibility to assess where they fall on the cultural competence

continuum and seek opportunities to move forward toward cultural competence.

THEORETICAL APPROACHES TO THE STUDY OF THE FAMILY

A family’s adaptation and response to a birth can be viewed through different frameworks. Systems theory, developmental theory, and crisis theory each provide a context for understanding a family’s growth and change.

Systems Theory

Systems theory describes the relationship of the individual and the multiple forces with which the individual interacts throughout life. Each person is a part of multiple larger groups and contributes to the totality of those groups. The family is the primary group. As a system the family is influenced by its individual members and responds to the feedback from other systems and the social network in which it is maintained. As both the individual member and

Table 27-2 A Cultural Competence Continuum

Cultural destructiveness	Attitudes, policies, and practices, including person interactions that are destructive to cultures and consequently, to the individuals within the culture. For instance, belittling ritual practices and denying access to culturally acceptable healers.
Cultural incapacity	Attitudes, policies, and practices, including personal interactions that are not intentionally destructive but which reflect a lack of ability or capacity to help clients of other cultures. For instance, restricting a laboring woman to only one “helper” or stereotyping women based on their behavioral response to labor pains.
Cultural blindness	Functioning with the belief that skin color and culture make no difference at all and that all people are the same. Usually characterized by the belief that the helping approaches used by the dominant culture are universally applicable. This approach ignores the cultural strengths of a family, encourages assimilation, and blames the family for not “fitting in.”
Cultural pre-competence	Individuals and agencies recognize their weaknesses in providing services to families of other cultures and seek to develop approaches to meet some of the needs of some of the families. Characterized by the ability to ask, “How can I help?” This level is indicative of beginning the process of becoming culturally competent but shows a lack of information and clear knowledge of how to proceed.
Cultural competence	Individuals and agencies that accept and respect the differences of the varied families they serve. They see the differences between cultures and within cultural subgroups, each distinct from each other and having important strengths. Such individuals are able to engage in self-assessment regarding culture, pay careful attention to the dynamics of difference between their cultural orientation and that of their clients, and are continually expanding their cultural knowledge and resources.
Cultural proficiency	Advanced cultural competence. Every culture is held in high esteem. Individuals and agencies conduct research and develop new therapeutic approaches based on culture. They advocate for cultural competence and improve relations in their own agencies and communities. For instance, the development of a culturally specific doula program would address the individual needs of families giving birth.

Adapted from Cross, T., Bazron, B., Dennis, K., & Isaacs, M. (1989). Towards a culturally competent system of care: Vol. 1. National Technical Assistance Center for Children’s Mental Health, Georgetown University, Washington, DC.

the group interact with other organizations and individuals in the environment, adaptive changes occur. In this way, the family system responds and contributes to its environment. By balancing the needs of the individual and the collective group, the family dynamically progresses through life (Cox & Paley, 1997).

Individual systems have boundaries that define their identity and maintain their integrity. Those boundaries change as members are added or removed (Figure 27-1). As the number of persons in this system changes the relationships among the remaining members change. For instance, when a couple has a child, they move from a dyadic system to a triadic one. This alters lines of communication, the number of members for which the system is responsible, and the amount of input the system receives from its members.

The family is the first social context to which an individual belongs. However, the interactions of the family do not occur in isolation from other social interactions that present opportunities and risks for the development and well-being of the family and its members (Patterson, 1999). By envisioning the family as a microsystem within the context of the larger environment of community, culture, religion, socioeconomic class, and geographic group, a family can be seen as central to its **ecologic environment** (the total of the macrosystems within which a family resides) (Cox & Paley, 1997; Patterson, 1999).

Family systems have four central functions, which affect their members and the society of which the family is part. These functions are: (1) family formation, which provides a sense of belonging, direction for life, and identity for its members; (2) economic provision for the basic needs of food, clothing, shelter, and other resources for its members; (3) nurturance, education, and socialization, which provide physical, psychological, social, and spiritual

development and instills social values and norms; and (4) protection, which provides care for young and vulnerable members (Patterson, 1999). The ability of the family to fulfill these responsibilities for its members and for society depends to a large extent on its relationship with the macrosystem.

Birth represents a change in the family system—in its constellation and its internal communications—and challenges the family's ability to provide the basic necessities and protection for its members. This is a time when the family system interacts with the medical care system and other institutional systems and a time when the relationships with employment systems may change. At the time of birth, the nurse is in a unique position to facilitate the dynamic changes the family is going through by being sensitive to the cultural, economic, and physiologic issues confronting the family members; by assisting them in navigating the medical system; and by supporting them in making choices that improve their level of functioning.

Developmental Theory

Families, like individuals, go through developmental stages. Family structure changes with the addition of members during the childbearing cycle or through adoption, and when family members leave, such as a young adult leaving home or the death of a family member. Family functions change and family roles are negotiated as members move from dependency to contribution and then become more independent (Patterson, 1999). At birth, the family is in the process of moving from one developmental stage to another. For instance, at this time a two-person family must move from the stage of independence to a stage of nurturance, with the addition of a totally dependent new member. This transition to parenthood disrupts the balance the family has achieved and requires learning new roles and strategies for coping. While working with families during labor and birth, the nurse has the opportunity to provide anticipatory guidance that will assist the family during this transition (Patterson, 1999; Belsky & Kelly, 1994).

Crisis Theory

A **crisis** can be defined as a situation in which a family or individual's balance is disrupted, requiring development of new coping strategies. Erikson first used the term **developmental crisis** in describing the adjustment of the individual to new stages of development (Erikson, 1963). In his work, Erikson describes the work involved in of each developmental crisis, or turning point, as the individual moves from birth to death. The key to successfully resolving the crisis is reduction in the anxiety level generated by the person's move from homeostasis to disequilibrium and back to equilibrium, once the turning point is

Figure 27-1 The birth of a child presents the extended family with new opportunities for growth and bonding.

successfully negotiated (Maushart, 1999; Erickson, 1963; Elkind, 1994).

In moving chronologically from one stage to the next, the individual either completes the work of the developmental stage, which provides the foundation from which to do the work of the next stage, or the individual remains stagnant at that stage, interfering with progress to the next stage. The result of not negotiating the crisis point in the life cycle is that the state of disequilibrium continues. This state of disequilibrium, or constant anxiety, is what prevents the person from functioning optimally and moving on developmentally to the next stage (Maushart, 1999; Hawkins & Gorvine, 1985). Pregnancy, birth, and parenting, viewed from this theoretical framework, are developmental crises, or turning points, in human growth and development (Mercer, 1995).

These same events can be viewed as situational crises in the life cycle. A **situational crisis** is an event or situation that occurs in a person or a family's life, which requires the adaptation or acquisition of new coping mechanisms. Using Erickson's theoretical framework, the adaptations that a 16-year-old needs to make in life to accommodate pregnancy and parenting are added to the adaptations necessary to work through the developmental stage of adolescence (Erickson, 1963).

Families, whatever their configurations, can be viewed as systems that move through the same kinds of crisis as individuals (Maushart, 1999). As individuals come together to form family groups, they move through developmental stages in much the same way that individuals do. At each turning point, the family seeks to develop strategies with which to cope with its life in a way that maintains the homeostasis or equilibrium of the family. The family group experiences the same movement from equilibrium to anxiety and back to equilibrium as the individual does. The family's success or failure in developing higher levels of coping is dependent on the success of its members in achieving equilibrium and is influenced by culture, environment, and family history (Maushart, 1999; Belsky & Kelly, 1994).

Birth represents a crisis or turning point for the family. The family brings to the birth room all its baggage, hopes, expectations for the experience of birth, expectations for the baby, and projections for the future. As the birth unfolds, there is congruence or lack of congruence with family member's expectations (Cross, et al., 1989; Esposito, 1999; Mercer, 1995). Perhaps the labor is longer than expected and the time commitment of the family is an issue, or perhaps there is more pain or noise than family members expected or can tolerate.

NURSING IMPLICATIONS

The nursing process is a valuable framework for working with families. Using the nursing process, the nurse gathers

data and assesses the response of the family unit to birth and of individual family members. Based on these observations, decisions can be made about the level of positive or negative response and a specific plan can be developed in collaboration with the family to identify the goals of the individual members and of the family as a system. With an understanding of the needs and goals of the family, the nurse can choose appropriate interventions, which may include referrals to other health care professionals, and design a strategy for evaluating the progress of the family as they journey toward meeting their goals.

At the time of birth, the nurse must assess each family member's response to the experience. This is a time of heightened awareness, when potential risks to mother, infant, and family system can be identified, and a time when positive responses can be reinforced.

In promoting a positive response to the birth, the nurse must validate the family's experience. Listening is the first step. Secondly, the nurse must understand that, because most families have limited experience with the birth process and medical procedures, their own perceptions of the events are reality for them. Reinforcing positive responses to the birth, the infant, and the support of the family is an important strategy in helping a woman integrate the events that have occurred. Assisting the woman and her family in identifying those events that were consistent with their expectations and helping them to find honest adaptations to those events that were inconsistent with their expectations helps to promote a positive response to the birth.

Because the current trend in postpartum stays for women who give birth in a hospital or birth center facility have significantly shortened, with the range from 24–48 hours in an uncomplicated vaginal birth to 72 hours for an uncomplicated cesarean birth, the evaluation of the outcome of interventions may require follow-up with outpatient services or home visiting (Wallace, Green, Jacos, Paine, & Story, 1999). This is an important collaborative piece of the plan. Use of the nursing process is highlighted in each of the following sections that describe the family response to birth.

EFFECT OF BIRTH ON THE FAMILY

Each member of the birthing family experiences a period of adaptation after the birth of a new member. An individual's response is shaped by personal experience, history, cultural background, and developmental stage.

Maternal Adaptation

Labor and birth encompass a proportionately short period in a woman's life. However, no other experience has the

intensity of physical and emotional feelings or represents such a profound life change (Simkin, 1996; Rubin, 1984). A woman's self-concept is affected by the congruence of her birth experience and her expectations. Ego strength is enhanced by a birth, which leaves the woman with a sense of accomplishment, some sense of control, and positive reinforcement from family. In contrast, an experience that does not meet expectations or that leaves the woman with a sense of loss of control may foster feelings of frustration, disappointment, or shame (Mercer, 1995; Katz-Rothman, 1996).

The maternal response to an uncomplicated birth experience is colored by her previous birth experiences and her expectations for this birth. During a comparatively short period, the woman has an intense physical experience that is totally outside of her control. Her body acts on its own in ways she might not have anticipated. Choices in dress, food, and activity may be dictated by the stage of labor, institutional policy, and provider preference. The amount of control that a woman perceives that she has during the birth process and the degree of pain she feels both have direct relationships to her feelings about that experience and to her self-concept (Mercer, 1995). Data obtained from focus groups with postpartum women indicate that when labor and birth go well, the mother and baby had no problems and the woman felt supported and involved in care. They felt emotions ranging from happy to delighted and indicated that the commonly used term "satisfied" was in no way descriptive enough regarding how they perceived the care they received. On the other hand, when things did not go well, the woman felt unsupported and uninvolved and when the outcomes were less than expected, feelings ranged from disappointed to devastated (Proctor, 1998).

The timing of the birth, whether at term or postterm, affects the mother's response to birth. A woman who has given birth to an infant at term may be happy, tired, and interactive with her baby and family. In contrast, a woman experiencing the birth of an infant during the 2 weeks past her due date may be fearful, unwilling to touch or interact with her baby, and disappointed with herself and her body's inability to perform correctly and on time (Mercer, 1995). The fact that delivery within 42 weeks' gestation is within the realm of normal may not be reassuring enough for a woman who has been looking to the estimated date of delivery (EDD) as the marking point of the end of pregnancy.

The duration of labor has an effect on the woman's response to the experience. It may be obvious that a long labor can leave a woman exhausted and depleted of resources at the birth. However, a precipitous birth experience is physically tumultuous and may be frightening in its intensity.

The difficulty of the delivery is another variable that influences the mother's response (Figure 27-2). A normal

Figure 27-2 The difficulty of the delivery may influence a couple's response to the birth process.

vaginal birth can be perceived to be difficult. Women who are unprepared for the feeling of extreme perineal pressure as the head crowns may be frightened. Women, who have received regional anesthesia for labor and whose practitioner has allowed the anesthesia to wear off to allow the natural pushing reflex to return, may perceive the birth as difficult. A situation that requires manipulation by the birth attendant, for example, shoulder dystocia, may cause the mother to experience fear for herself, her baby, and her birth. Immediately after such an experience, the woman may feel relief that all is well, disappointment that this was not the birth experience she expected, or anger that she or her infant could have been hurt.

Theories of Maternal Adaptation

Rubin, Lederman, Mercer, and others have described the developmental tasks of pregnancy and have discussed how the completion or noncompletion of these tasks affects a woman's labor, birth, and parenting experience. While many of these tasks are nonsequential, there appear to be three that must be accomplished in a certain order. Building one upon the other, the woman first accepts the reality of her pregnancy during the first trimester; second, develops a relationship with the unborn child during the second trimester; and third, prepares for the unknown experience of giving up the fetus and meeting her newborn. Women who do not complete these tasks before delivery may not be fully psychologically equipped to move into their role as mother (Mercer, 1995; Rubin, 1984; Lederman, 1984).

Rubin (1984) discusses the immediate response of the mother to her infant. After months of fantasizing, the woman meets her newborn at the moment of birth (Rubin, 1984). The congruence of that real infant with her fantasy affects her response and her incorporation of the child into her reality. From observation and client inter-

REFLECTIONS FROM A MOTHER

"Becoming a mother is the most life-altering and wonderful experience a woman can have. It becomes who you are, and everything you do in life becomes secondary to that, requiring extraordinary ability to balance it all. While pregnant or awaiting the arrival of a child through adoption, you can read and read about how your relationship with your spouse will change and how you need to maintain that relationship with your spouse. What I'd never read about and wish I'd known more about is that your spouse changes, too, from becoming a parent. And that in a sense, you will fall in love again with this new person, who is now a father and showing tenderness toward the child you carried for 9 months.

A pleasant surprise is how all of your relationships change as you evolve into a mother. Suddenly, to everyone in your life, you are someone's mother, with the expectations of that role in their eyes (and that's different for so many people). And then you are the other things around that—daughter, daughter-in-law, professional, friend, sister, brother. All of the continuous emotional growth in my life that stems from being a mother has, in most cases, helped me be a more empathetic daughter, daughter-in-law, professional, friend, and sister, and to realize the powerful effect a mother's nurturing has on the entire world—in a way only a mother can do it."

views, Rubin describes the stages of attachment between mother and child that the mother experiences. These stages are: "taking-in" describing the early postpartum period; "taking-hold" during the later postpartum period around a week after birth; and "letting go" the final incorporation of the maternal role. Moving from touching the

infant with her fingertips to using finger pads and then palmar surfaces to encircle the infant, the woman brings the baby close to her body again. The "en face" position, where the mother places the infant on the bed at her eye level and turns face to face with the baby, was found to occur in women who had a positive self-image (Mercer, 1995).

A woman may also feel a sensation of loss, once the infant is delivered and outside of her body. Rubin observed women positioning infants on their abdomen immediately after birth and continuing to hold the baby in this manner when lying down for some weeks thereafter. She hypothesized that holding the baby this way might be a compensation for a sense of loss of the internal feeling of the fetus in the uterus, which these women continued to describe feeling for several months (Rubin, 1984).

Rubin describes labor as a period when time and space lose congruence with reality. Contractions, their length and frequency, measure time. Perception of space narrows almost to the woman's body boundaries. How she incorporates those around her into her experience is influenced by her cultural background and style of coping with life. Some women want to be surrounded and touched, others want to be left alone. Her perception of safety and the intensity of the experience influence who and what else she can attend to and allow into her "space" (Rubin, 1984).

In her research describing women's birth experience, Simkin (1996) found that women remember their labor and birth with unusual clarity for up to 20 years after the event. The benefits of continuous labor support have been documented by several authors (Scott, Klaus, & Klaus, 1999; Fowles, 1998). Women who feel they were surrounded by supportive people in labor have been shown to have more positive feelings about their experience, use less pain medication, and be more likely to choose to breastfeed their baby and to breastfeed for a longer period of time. During the later postpartum period, these women are less likely to experience depression and more likely to exhibit higher levels of self-esteem and demonstrate increased sensitivity to the needs of their infants (Scott et al., 1999; Scott, Berkowitz, & Klaus, 1999; Hodnett, 1994).

Nursing Process

Hawkins and Gorvine (1985) used the "crisis model" to develop a useful framework for maternal-newborn nurses to use in assessing family responses to birth and in planning appropriate interventions for postpartum women and their families. They discuss the risks to the postpartum woman in negotiating this time of crisis and how to develop the coping strategies required to enter the role of parent. Those women who meet this challenge experience a reduction in anxiety as they achieve equilibrium in the resolution of the pregnancy and birth. Those women unable to achieve equi-

Client Education

Self Care for Postpartum Families

Recent work by Jeanne Watson-Driscoll and Deborah Sichel (1999) describes the effects of birth on brain chemistry and the ability of the woman to adapt to the new family relationships postpartum. To enable women to address the emotional challenges of this period, these researchers have developed a self-care program that can maximize the woman's ability to develop effective coping strategies during the postpartum period. The program is called NURSE and provides the following guidelines to use in developing a plan with the woman:

- **N—Nourishment:** Maintain basic nutrition, using the food pyramid as a guide, to provide the brain with appropriate vitamins and basic nutrients. Discuss a multivitamin supplement with your midwife or physician. Be sure to include adequate amounts of alpha-3 omega fatty acids, such as those found in fish proteins, because they are important for nerve cell functioning and, through modulating chemical nerve transmission, may have mood-stabilizing effects.
- **U—Understanding:** Work with the new mother and family to develop strategies that provide support in the form of listening, validating feelings and nurturing each other. Identify family resources for backup, such as the phone numbers of counseling services and community support groups.
- **R—Rest and relaxation:** Adequate rest and sleep are essential for the brain to restore itself biochemically. New parents may become sleep-deprived if they do not actively plan rest periods and sleep when the infant sleeps. Planning for rest periods and for taking turns at getting up with the infant may be important strategies to protect against sleep deprivation.
- **S—Spirituality:** Each woman and family has experiences and activities that nourish their souls. Planning to include such activities, which can be as simple as buying fresh cut flowers to place in a living space or listening to soulful music, addresses this need.
- **E—Exercise:** It is well-documented that physical exercise causes the release of endorphins, which cause a feeling of well-being. A daily exercise regimen can be as simple as taking the newborn out together for a walk.

librium experience a continuing level of anxiety, which interferes with achieving the role of mother and the development of successful parenting skills (Hawkins & Gorvine).

Nursing interventions in this model are designed to enable postpartum women and their families to develop successful coping strategies for this new dimension of their lives by using what they bring to the experience with them as well as resources available through their extended family and community. Examples of resources that a woman brings to the childbirth experience may include: previous coping mechanisms, nutritional status (which influences her physiologic ability to adapt to birth), and belief system. Examples of external resources include family and friends, community support groups, social services, and religious organizations (Hawkins & Gorvine, 1985).

Assessment

Relevant clinical, demographic, and social data can be gathered from the medical record or the client herself, including:

- ✿ Cultural background
- ✿ Gravidity and parity
- ✿ Prenatal course (complications or lack thereof)
- ✿ Social situation, including housing, income, presence of partner, gender of partner, and extended family
- ✿ Work situation, type, and job title
- ✿ Recorded plans for infant feeding and postpartum care

While interacting with the woman during labor and birth, the nurse should gather data, such as the following:

- ✿ Conduct and length of labor
- ✿ Type of birth, vaginal or operative
- ✿ If the mother holds the infant immediately after birth
- ✿ What the mother says to the infant, e.g., “I am so glad to see you” or “you nearly killed me”
- ✿ If the mother looks at the infant

Research Highlight

Labor Concerns of Mothers 2 Months After Delivery

Purpose

The majority of the research about family adjustment to birth is found in the social, behavioral, and family therapy disciplines. Reva Rubin's descriptive studies of women's immediate response to birth remain the hallmark of qualitative observations in the research of maternal role attainment (Rubin, 1984). Subsequent studies have built on Rubin's observations and have shown how changes in society, medicine, and the family affect adaptation to motherhood.

Methods

As part of a larger study that examined the development of maternal role identity, Eileen Fowles (1998) described the contribution of the experience of labor and birth to a woman's self-esteem in maturing into the maternal role. In this qualitative study, the researcher asked women at 9-weeks postpartum to respond to the following open-ended question: "Is there anything about your labor and delivery that is still bothering you?"

From September 1992 through June 1993, a convenience sample of women was obtained from the prenatal classes held in three hospitals in the Midwest for the larger study. The institutions were distributed throughout the area. Women included in the sample were ages 18 to 35, primiparous, in the last 3 months of pregnancy without any complications, living with the father of the baby, and English-speaking. One hundred fifty-seven women (93% of the women who were given a prenatal questionnaire), remitted a completed postnatal questionnaire, and 77 of these women completed the open-ended question. The analysis of the 77 completed open-ended responses is the data for the study.

Analysis of the Data

Qualitative research methods provide insight into the areas of emotional, social, and experiential phenomena in health care. Qualitative research questions explore what happened and how and why, and in so doing, often generate theories and hypotheses and show relationships and patterns that may result in conceptual frameworks for looking at observed phenomena.

Through qualitative analysis, themes and concepts were identified from the questionnaire responses and divided into major or minor categories. Relationships between categories and subcategories and among subcategories were examined.

(continued)

- How the mother touches the infant (e.g., does she progress from fingertips to encircling the infant, or turn away or hold the infant away from her body?)
- How the mother interacts with her support network

Nursing Diagnosis

Nursing diagnoses represent the nurse's decision about the data gathered. Diagnoses commonly seen include impaired parenting related to inability to bond with newborn, and anxiety about feelings of loss.

Outcome Identification

Outcomes can be described in terms of short- and long-term goals. For example:

- The mother demonstrates positive interaction with her newborn.
- The client discusses the difference between postpartum "baby blues" and the symptoms of depression.
- The client and her partner identify childcare options within their extended family and community for babysitting.

Research Highlight (continued)

Findings

Two major themes, positive experiences and frustrations, were identified from the women's responses, and within each major theme, several subcategories were identified, which helped to explain and support the major theme.

The theme of "positive experiences" was expressed by 12 of the women and related to who helped the women in labor and to specific actions by birth attendants that were supportive and professional.

A theme of "frustrations" was expressed by 42 of the women and was related to pain, lack of control, lack of knowledge (feeling uninformed), and negative perceptions of caregivers.

Nursing Implications

The results of this study are consistent with those of Simkin (1996), who found that women remember and are influenced by their birth experiences long after the event. Actions by health care professionals identified in this study that contributed to a positive feeling and were most helpful were those that promoted self-confidence and that made the women feel cared for and respected. Women who reported feelings of frustration felt that health care professionals did not help them feel in control of events, did not provide adequate information, and were not helpful in decreasing pain.

Generalization of the results of this study is limited for two important reasons. First, the sample was a convenience sample, not randomized, and limited to one area of the country, and second, the phrasing of the question focusing on things "still bothering you" may have elicited excess negative responses, as reflected in the distribution of 12 responses focused on positive aspects and 42 focused on negative aspects.

However, the message for nurses remains clear. Women remember the behaviors of their primary caregivers, and these behaviors greatly influence women's ultimate perception of their birth experience. Nursing actions that promote self-confidence, communicate sensitivity and caring, and provide information about what is happening and why are pivotal in helping women perceive the birth experience positively, regardless of the method of delivery. The concept of family-centered maternity care was developed to help professionals and institutions meet the individualized needs of families. Birth is an experience that either fosters growth and coping or has negative effects on the mother and other family members. This study highlights the effects that the birth experience has on women and the important role that the nurse's choice of behavior plays in influencing women's memories.

Fowles, E. (1998). Labor concerns of women two months after delivery. *Birth*, 25(4): 235–240.

Planning

With the client, the nurse identifies those strategies that will assist the client in meeting short- and long-term goals. Strategies range from bedside education and reading materials to referral to a visiting nurse service or social services.

Interventions

Nursing interventions can assist the mother in developing a realistic interpretation of her birth experience and may include:

- Encouraging the mother to talk about what she experienced
- Describing the birth of the baby, if she was not able to see it in a mirror
- Helping the mother distinguish between what she thought happened and what actually occurred
- Assisting the woman to inspect the infant
- Encouraging the mother to hold her baby

Evaluation

The ability of the nurse to evaluate the success of the interventions varies, depending on the length of interaction with the family. Observations of behaviors that meet stated goals may be possible. Additionally, referral to collaborative agencies or providers may be necessary to evaluate the progress toward long-term goals.

Paternal Adaptation

The history of the participation of men in birth experiences has been affected by sex role definitions, cultural mores, economic status, politics, and social expectations. Some cultures have prescribed activities for fathers during pregnancy and childbirth. However, to a great extent throughout most of history, men have been excluded from participation in the childbearing process (Jordan, 1990; Heggenhougen, 1980).

In earliest history, men waited outside the tent or the cabin or the bedroom, while the women labored and were delivered by female attendants. In the 19th and 20th centuries, men waited outside the house or in hospital waiting rooms to be told “what their wife had had.” Before the 1970s, little, if any, exploration was done of expectant or new fatherhood as a developmental process. All attention was focused on the maternal experience (Jordan, 1990a).

As the attendants at birth moved from the female midwife at home to the physician in a hospital, the presence of men in the birth room became more acceptable, at least for those male physicians performing their duties. Heggenhougen (1980) looked at the role of fathers in childbirth from an anthropologic perspective. He described the research of leading anthropologists about the cultural role of men in childbirth. **Couvade** is a term used to describe the physiologic responses a man has to his partner’s pregnancy and those ritual actions that men perform during pregnancy and childbirth (Heggenhougen, 1980). In some traditional cultures, male behaviors range from weight gain, particularly in the abdomen, to nausea and vomiting and specific acts during labor and birth, such as acting out of contractions or holding the birthing woman as she pushes. The behavior enacted during labor may be an effort to divert the pain of childbirth from the woman to help her deliver with less effort (Nichols & Humenick, 2000; Pryia, 1992).

In industrialized societies, there is a common notion that, because conception is a shared experience, birth should be no less so. This perspective was influenced by the growth of the women’s movement and the changing view of men’s role in the family. Fathers were provided with specific tasks for labor by the prepared-childbirth movement. This ability to take an active part in birth is viewed by families and health professionals as an impor-

tant step in consolidating the family unit (Nichols & Humenick, 2000; Pryia, 1992).

To better understand the father’s response to pregnancy and parenting, Jordan (1990a) reviewed related literature from other helping disciplines and found that pregnancy is a developmental experience for men that parallels that of women during the reproductive and parenting cycles. Essential tasks for the father in each trimester include integrating the physical and emotional changes in his mate, reworking his own relationship with parent figures, and the reality of fatherhood at the time of introduction to his baby. Specific issues for men develop from their perspective of the outsider or the one who is not physically involved with the growing pregnancy. Fathers may be anxious about loss of income when the woman stops working in a two-income family and his ability to provide for a new family constellation. He may have feelings of inadequacy in childcare activities because of lack of exposure and concern about the change in status he may experience in the relationship as he anticipates sharing his partner with the new family member (Jordan, 1990b). The level of anxiety for a father and his feelings of helplessness may be increased when the pregnancy is unplanned and he feels as though he was unable to plan for these significant events (Clinton & Keiber, 1993; Hall, 1995).

The decision to share the birth experience is one that fathers do not take lightly. This is one subject about which men have traditionally been deprived of information. Fear of the unknown, discomfort with “female” bodily processes, and inability to cope with his partner’s pain all influence the man’s decision to attend the birth. In some areas of Western society today, this trend is to almost demand the father’s participation in labor and birth whether he is comfortable with it or not. Palkovitz (1987) explored the motives for fathers attending birth in 37 primiparous couples. She identified a variety of motives that developed from the father’s beliefs about their roles as partners, their social reference points, and their expectations for the experience (Palkovitz, 1987).

Paternal Role Attainment

While the fetus becomes real to the mother as she feels it move, the father does not perceive the reality of the child until after the birth, when his perception moves from secondhand, or vicarious, to face-to-face, seeing and holding the baby after birth. According to Jordan, “Seeing the infant emerge from his mate’s body through vaginal or cesarean birth was a powerful experience for each father. Birth proved that this infant had been the growth within the mother’s abdomen. Fathers then sought physical similarities to validate [that] the child was theirs” (Jordan, 1990b). The father’s progressive touching behaviors, be-

REFLECTIONS FROM A FATHER

"Becoming a father is the greatest thing that ever happened to me. Children are an absolute blessing. It struck me, however, on the birth of my second daughter, how different the experience was from the birth of my first daughter. When Madeline was born (after 20 hours of labor, my wife would want pointed out), I couldn't stop crying. I was incredibly happy and relieved that everything went well, but I was simply overwhelmed with raw emotion. By contrast, when my second daughter was born (9 hours of labor), my wife and I couldn't stop laughing. We were both thrilled, relieved, and emotional, but this time we expressed it through laughter. It was so bad that, when my wife went into hard labor, she got the giggles. That has always struck me as an odd contrast."

ginning with the fingertips, progressing to full palmar touch and enfolding in the arms, which mimics the behavior of the mother, were identified by Tomlinson, Rothenberg, and Carver (1991). These behaviors demonstrate the incorporation of the child, from first touch, into the body space of the father as he validates the reality of the child (Figure 27-3).

There is agreement in the literature that pregnancy and birth represent a turning point or crisis for the father in ways that are both similar and dissimilar to the mother (Elkind, 1994; Jordan, 1990a, 1990b; Teichman & Lahan, 1987; Hall, 1995; Deimer, 1997; Duncan, 1995). Like his partner, the father's coping mechanisms are challenged. He loses his equilibrium as the life he has come to know is altered by the experience of this pregnancy and birth, and he struggles individually and in concert with his partner to develop new strategies of coping that bring equilibrium back to his world (Hawkins & Gorvine, 1985). The length of the labor, the level of pain endured by his partner, the mechanism of birth, and the location of birth all affect the reaction a father has to the birth experience.

The experience of the father at birth may be a different one from that of the mother (Nolan, 1996). He must be a participant and an observer of the changes experienced

Figure 27-3 Immediately after his wife's cesarean delivery, this father begins to bond with his newborn son.

by his partner. The early relationship of the father and his child and the father as parent with his partner in this new family constellation is significantly influenced by the emotional experience of birth (von Klitzing et al., 1996).

The experience of fathers is also influenced by attitudes of the health care providers who interact with him during the birth experience. Jordan (1990b) found that fathers predominantly felt treated as peripheral to the mother by health care professionals. Their needs were addressed only as they related to the woman. In this way, the man felt excluded from active participation in the birth. Inclusion of the father as an active participant in the support system and provision of care to the laboring woman significantly increased the father's investment in the labor and birth. Nurses working closely with the laboring couple have an unparalleled opportunity to assist the father in having a positive birth experience, which can bolster his self-concept and help him lay the foundation for effective coping as a parent.

Nursing Implications

When working with families, it is important for the nurse to understand the father/partner's role, which may be evidenced by his participation in the prenatal course and previous birth experiences. While interacting with the father, the nurse should observe his physical relationship to his partner (does he physically soothe her, massage her back, or sit by the bed without touching her?) and listen to his interaction with the laboring woman (does he coach her, encourage her, and share her experience?). His coping strategies and desire to hold or touch his newborn may also be indicative of his view of his new parental role. Positive adaptations may be seen in the father's identifying ways in addition to feeding that he can participate in the care of his newborn, and the father's participation in identifying childcare options.

Nursing interventions that can assist the father in developing a realistic interpretation of his birth experience might include: including the father in discussions about the decisions being made with the laboring woman, providing the father with explanations about what is happening, encouraging the father to cut the umbilical cord, and encouraging the father to hold the baby with the mother, to enfold both of them in his arms (Figure 27-4)

Sibling Adaptation

The participation of siblings in birth has a history similar to that of fathers. The acceptance of children in the birth setting has been influenced by social attitudes regarding children, economics, cultural beliefs, and the politics of birthing institutions.

In cultures in which extended families live in close proximity and pregnancy is an accepted developmental rite of passage, children are more likely to be a part of the group experience of birth. The presence of alternative caretakers, such as older children or other family members, and geography has dictated whether children were sent away from the home when birth occurred.

Developmental Issues

Children's perceptions of birth are limited by their developmental stage. Erickson's work describes the cognitive ability of children, which progresses from self-centeredness to other-centeredness and from fantasy to concrete thought and expression. At each of these stages of development, the child is increasingly able to focus on the events going on around him or her and to understand what is happening (Erickson, 1963).

Preschool children may not be attentive to the activities of the adults around them. In the birth setting, they may be focused on their dolls or toys, ignoring the adults

Figure 27-4 This father welcomes his daughter to the world by enfolding the mother and baby in his arms.

around them. School-aged children may be bothered by the noise of a birth setting. They may perceive their mothers' pain and, in some way, take responsibility for not being able to assuage it. Adolescents may be able to be supportive or may identify with the bodily functions inherent in the birth process and personalize the events (Erickson, 1963).

A mother's relationship with each child is different, changing with the addition of another child. The older children must alter their current relationship with mother and with each other to accommodate the new baby (Mercer, 1995). Therefore, children may perceive the birth as threatening and as invading their space and interfering with their relationships within the family. Alternatively, the new baby may be perceived as a welcome playmate. The child may not immediately understand the dependence of a newborn and may be excited to have a new friend.

The participation or attendance at birth of older children is determined on the basis of the dynamics of the individual family and institutional and provider policy. In families where the cultural norm is that children are peripheral to the adults until they become old enough to be

Nursing Alert

CHILDREN ATTENDING A BIRTH

If children are present during labor and delivery, one adult (other than professional staff) must be present for each child to provide safe and adequate supervision.

treated as adults, there may not be an issue: the children will not have the option to attend the birth. In families where the cultural norm is to include children in the dynamics of change, they may have been incorporated into the family experience of pregnancy and may be present for all or part of the birth. In some families, the adults want the children to be active participants; however, the children may be uninterested (Nolan, 1996).

The birth site has a major effect on the presence of siblings at birth and the level of their participation. At home in a familiar environment, children may move in and out of the birth room, interspersing normal activities with looking in on what is happening. Depending on the length of labor and the time of delivery, children may even sleep through the birth. In a birth center environment, children are usually accommodated as space allows and should be accompanied by an adult who is not involved with supporting the birthing woman. It is not possible to predict children's reactions to labor and birth, so it is essential that a responsible adult be available to meet their needs or even to remove them from the setting, if necessary.

In more traditional hospital birth settings, the children's presence is dictated by institutional and infection control policy. Most hospitals require some preparation for children who will attend a birth. This may take the form of a puppet show, a hospital tour, viewing a video, or attending a series of classes with parents. Parents are told of the need to be alert to health concerns, such as viral illnesses, that would prevent the older children's participation, and some institutions may require proof of health screening and up-to-date vaccination status of children who wish to attend.

Sometimes the opinion of the birth attendants or other professional staff dictates whether children can be present. Individual professionals may have personal feelings about children viewing birth. These feelings or opinions may or may not be theoretically supported. To address the effect that self-interest has in the politics of birth, health care providers must distinguish their own needs and opinions from those of the birthing family. This enables them to implement a plan of care that safely meets the needs of families and their children (Kuhn & Kopcinski, 1984; Brown, 1996).

Nursing Tip

NURSING INTERVENTIONS THAT CAN ASSIST SIBLINGS AT BIRTH

- Providing simple factual explanations of events at the level of the child's understanding
- Answering questions posed by the children as simply and honestly as possible
- Orienting the children to the birth environment as early as possible before the intensity of the experience clouds their vision
- Allowing the children to move in and out of the birth environment at will
- Assuring that there is a competent adult present, other than the staff, whose only responsibility is to meet the needs of the children
- Encouraging the parents to interact with the children as much as possible so that the children see that the parents are safe
- Interacting with the child or children as much as possible
- Providing simple explanations to the children about procedures that they see their mother undergoing
- Creating a space for the child or children (perhaps at the head of the bed rather than at the foot of the bed) that allows them to interact with their mother but preserves her modesty
- Providing positive reinforcement for the decisions the child makes relative to his or her participation in the labor and birth and his or her response to the newborn

Grandparent and Extended Family Adaptation

Adults view pregnancy, birth, and childrearing from the perspective of their own experience. "Birth baggage" refers to the feelings one has about one's own child birth experience. Included in this "baggage" are all the feelings about needs that were met or unmet. The expectations of birth held by grandparents are colored by the experiences they had during childbirth experiences. Many women were not afforded the opportunity to process their feelings about what happened during their own labor and delivery, for example, the pain they had or how helpless they may have felt (Figure 27-5). These unresolved feelings affect

Figure 27-5 To help his daughter through her labor and delivery, this father, soon to be a grandfather, needed to be open-minded to the changes in practice that have occurred since his children were born.

the amount of energy available and the kind of support grandparents, siblings, aunts, and uncles can give to the birthing woman and her family (Simkin, 1996). A woman who was not given a choice about the use of medication may not understand her daughter's desire for an unmedicated delivery. A man who waited in the waiting room during the birth of his children may not understand the desire of his son to be present at delivery. Alternatively, extended family members who were not able to birth as they would have liked or who may, for example, have had emergency operative deliveries may be strongly supportive of the choices made by the birthing family.

Grandparents who have successfully negotiated the life stages preceding having children will be ready to view the birth as an addition to their own lives. Grandparents who have not completed the appropriate developmental tasks may not be ready to see themselves as “old enough to be grandparents.” By the same token, aunts and uncles who are comfortable with their developmental stage in life will have a different response to the birth of a new generation than those who have not completed their own developmental work. “I’ll be a great aunt but I am not a Great Aunt!” may be the response of a woman, present at the birth of her niece’s child, who is not ready to view herself as a member of an older generation (Erickson, 1963).

Family members may be so overwhelmed by the experience of birth that they may have strong emotional reactions. The family’s response to birth and their ability to provide positive reinforcement to the birthing woman is dependent on their usual coping styles (Figure 27-6). Birth provides an opportunity for families to develop more effective coping mechanisms (Hawkins & Gorvine, 1985).

The birthing woman, her partner, and the baby are the first responsibility of the nurse. The response of the family

Figure 27-6 Birth: three generations.

to birth is a complex, multifaceted issue. “Birth baggage” or other experiences of individual family members may prevent them from bringing positive energy to the birth environment. While it is the mother who defines the family and dictates who is present at the birth, family members who are unable to be supportive or who are interfering with the mother’s ability to cope with labor should be politely escorted to a waiting area.

Prolonged Labor and Assisted Delivery

Birth, by its very nature, is an unpredictable experience. Any deviation from expectations can leave the woman and her family feeling unfulfilled or detract from their feelings of confidence and wholeness. For the birthing woman, a prolonged labor may indicate to her that her body won’t work correctly. A delivery assisted by forceps, vacuum, or episiotomy may place her in a position of loss of confidence in her body, loss of integrity of her body boundaries, or a sense of unfulfillment or of ineptitude (Hawkins & Gorvine, 1985).

For a partner, a prolonged labor and difficult delivery may challenge his or her self-concept as a protector. The persistent feeling of helplessness in the face of the events of birth can influence the partner’s response to the newborn. A partner who feels guilty about not protecting the woman from the difficulties of the birth may experience anger or frustration. The nurse is in a pivotal position to help partners come to terms with their feelings of disappointment and frustration and to avoid displacing these feelings on each other. By using communication skills to engage partners in a discussion about the experience and validating their frustrations and fears, the nurse can guide

Critical Thinking

A New Mother

J.L. is a 21-year-old primipara single woman who has just given birth to an 8-lb baby boy. Her pregnancy was obstetrically uncomplicated. However, her social situation was not stable during the last trimester. Her partner, the baby's father, moved to another state and refused to communicate with her; she moved in with her parents, who have been supportive of the pregnancy and her decision to continue as a single parent. Her parents accompanied her in labor; her mother was her primary support person. Because she had an uncomplicated labor and birth, J.L. will be discharged from the hospital after 48 hours.

Discuss appropriate nursing assessments that will indicate the level of risk that J.L. has for difficulty in adjusting to her role as a mother.

What are the strengths of this situation that will ultimately assist J.L. in adjusting to her role as a new mother?

How can you assess the response of the grandparents to the birth of their grandson?

What are two immediate and two long-term interventions that you can implement to assist this family?

the partners to an understanding of their response and channel that energy in to positive activities to assist the new mother, such as breastfeeding support.

Cesarean Delivery

Cesarean delivery may be perceived as the ultimate inability of the woman's body to perform the normal function of giving birth. Not only did her body fail to deliver normally, but she also loses the integrity of other body systems for varying lengths of time. A cesarean birth means that the woman's motor system is temporarily impaired; her mobility is affected by anesthesia, pain, and the presence of intravenous lines or drains; her systems of elimination are altered as she recovers from Foley catheterization and decreased bowel motility; and the pain of the childbirth experience continues for a longer period of time than anticipated, as incisional pain and the discomforts of postoperative exercises (Hawkins & Gorvine, 1985).

DiMatteo, Morton, Lepper, Damush, Carney, Person, & Kahn (1996) reviewed research describing early and long-term sequelae of the cesarean birth experience for women. Women delivered by cesarean section held their

babies later after delivery than those who delivered vaginally; however, they held them for a longer period of time. Women delivering by cesarean felt less satisfied with their birth experience than those delivered vaginally, and initially, cesarean-birth mothers viewed their babies in a less positive light.

Response of the At-Risk Family

DeMeir, Hynan, Harris, and Manniello (1996) evaluated the incidence of posttraumatic stress disorder (PTSD) in mothers who experienced a high-risk birth. Using six measures of perinatal stressors, which included (1) gestational age of the baby, (2) birth weight, (3) length of hospital stay for the baby, (4) a postnatal complication rating for the infant, and (5) and (6) Apgar scores at 1 and 5 minutes, they predicted the occurrence of PTSD. The authors found that mothers of premature and term infants who required neonatal intensive care reported significantly more symptoms of PTSD than mothers of term infants who were born without stress factors present. The researchers found that the difficult birth experience left scars within the woman's, psyche, which affected them and their coping abilities for many years (DiMatteo et al., 1996). This profound affect on the mother's life is consistent with long-term memory of birth experiences that Simkin perceived in her interviews with women (Simkin, 1996).

Older children in a family that has experienced a difficult birth may blame themselves for interfering or causing the problem. How a child perceives the events surrounding a difficult birth depends on age and developmental stage (Erickson, 1963). Feelings may range from exclusion if they planned to participate and could not, to fear for the life of their mother as they observed her in pain and the reactions of other adults around her.

The extended family fears for the safety of both the mother and the baby. Maternal grandparents fear for their daughter and her infant. They may feel guilt for nonsupport or the level of support they gave their child. The experience may seem to confirm their fears that their child isn't normal and that there is some undiagnosed reason that she is not able to birth normally, for which they are responsible. They may feel they did not do enough. Alternatively, they may be angry with the partner or obstetric professionals for not protecting their daughter from harm or illness.

The family reaction to a difficult birth experience also has implications for the relationship each member has with the new infant. In a family where the infant is blamed for the pain or the type of delivery, the infant is potentially at risk for neglect or abuse, such an infant is termed a "vulnerable infant." DeMier and colleagues (1996) found parental hypervigilance to be sequelae, both in the immediate postnatal

Case Study/Care Plan

A GROWING FAMILY

G.P. is gravida 3, para 3 (G3, P3), a Native American woman who has delivered at the New Market Birth Center and is now 2 hours postpartum.

After a 15-hour labor and without the use of medications, Dahlia Louise was born over an intact perineum, weighing 8 pounds, with an Apgar score of 9 at 1 and 5 minutes. The baby breathed spontaneously and was delivered onto the mother's abdomen. M.P., the father, was present, providing labor support throughout, and cut the umbilical cord. During the labor and birth, specially recorded taped music was played; the family explained to the nurse that the pieces were special spiritual songs that promoted peacefulness and inner strength.

Also present during labor and for the birth were both sets of grandparents; Marc, the couple's 8-year-old son; and Jean, the couple's 4-year-old daughter.

During the labor and birth, Jean slept, colored, and roamed around the center, appearing unconcerned with the events in the birth room. Marc was actively involved, giving his mother ice chips and timing contractions, while his father provided physical support. The grandparents alternated sitting in the family room, visiting and observing activities in the birth room, and going out for provisions. Much of their conversation was about the changes in birth practices and worries about the safety of out-of-hospital birth. After the birth, they gathered in the birth room, cooing over the baby and praising G.P. and M.P. for their accomplishment.

Postpartum assessments have been within normal limits. The midwife has done a newborn examination that yielded results that were within normal limits. The mother has been to the bathroom and eaten. The baby has had a stool and passed urine.

The family plans to leave the birth center at 12 hours postpartum to return home. They live in a single-family dwelling with two flights of stairs. M.P. has to return to work in 2 days. G.P. plans to exclusively breastfeed her baby, as she did her first two children, and has already put the baby to breast, establishing a good latch-on. G.P. plans to return to work in 6 weeks and to place the infant in daycare with her 4-year-old daughter.

Assessment

- No contributory medical or surgical history
- Pregnancy at term without complications
- Postpartum recovery without complication
- Newborn examination (within normal limits), baby has passed urine and meconium
- Multiparous family, apparently prepared for the birth experience and comfortable with participation from all members, each member having a proscribed role
- Family does not have a plan for support after discharge

Nursing Diagnosis

Interrupted family processes related to the birth experience

(continued)

period and on a continuing basis as a parenting style on the part of women who experienced a high-risk birth. Some families may become overprotective of the infant in an attempt to shield them from further trauma.

Identification of negative responses to the mother or child in the birth setting may be the first sign of risk to the infant for neglect or abuse. In families in which the mother is not the primary caretaker, for example, if the mother

is a single adolescent, the nurse must include the grandmother, or other identified primary caretaker, in the birth experience. This provides an opportunity for the person to bond with the infant and for the nurse to observe the response and interaction of the birth mother, infant, and primary caretaker. If inappropriate behavior is identified, early referral and intervention can be accomplished, reducing the risk to the infant.

Expected Outcomes

1. The client and family will validate their experiences during labor and birth.
2. The family will develop support strategies, using community and family support systems.
3. Before leaving the birth center, G.P. will discuss specific strategies that she can employ to help her organize life at home to reduce stress.
4. The client and family will discuss the warning signs of postpartum depression.
5. At 3 days and 1 week postpartum, the family will not exhibit signs of dysfunction related to the birth experience.

Planning

The nurse can include the family and siblings in planning care that will reflect the needs of the family as a whole.

Nursing Interventions**Rationales**

- | | |
|---|--|
| 1. The nurse will encourage the individual members of the family to talk about how they felt during the labor and birth. | 1. At this time, the nurse will validate feelings and provide accurate information about events. |
| 2. The nurse will provide referrals to home visiting nursing services for intervals at 24 hours postdischarge and 3 days postpartum to assess the mother, newborn, and family adjustment. The nurse will also provide a pediatric referral to the pediatrician of the mother's choice of 48 hours postpartum for newborn assessment and relevant testing. | 2. This assists the family in identifying community resources, such as church, to enlist in providing postpartum support services. |
| 3. The nurse will discuss specific options, such as the NURSE program, to help the client manage stress. | 3. These strategies offer resources to the client to learn how to manage stress. |
| 4. The nurse will discuss the specifics of the signs of postpartum depression. | 4. This helps the client become independent and assists the family in recognizing symptoms that should be addressed. |
| 5. The nurse will make follow-up phone calls to the client at 3 days and 1 week postpartum and document the success of the care plan for this family or identify problems needing resolution. | 5. To assess family adjustment and offer assistance if needed. |

Evaluation Family adjustment is facilitated by actions of the nurse that foster maternal self-confidence and family support. By beginning with validation of the birth experience, the nurse can identify feelings of satisfaction or dissatisfaction and congruence or dissonance with actual events. Helping the family put the experience in perspective before they leave the birth site is a preventive measure. Assisting the family to identify and develop support systems after discharge is preventive and supportive. Evaluating the family at proscribed intervals allows the nurse to address developing issues before they lead to dysfunction.

RESPONSE TO LOSS AT BIRTH

Loss of an infant at birth can be viewed from several perspectives. One is the incongruity of the experience with the expectations of the parents: the loss, so to speak, of the perfect baby. The stillbirth of a fetus is another type of loss, which is discussed in detail in chapter 37. Finally, the

birth of an infant that is to be relinquished, either to adoption or because the woman cannot keep the child (for example, an incarcerated mother) is a different type of loss.

Any type of loss engenders a process of grieving in the parents and family. The value placed on the pregnancy and the newborn influences the depth and intensity of the emotions. The intensity of loss felt in the family who has labored through the process of infertility treatment may be

stronger and more prolonged because they are forced to deal with the emotional rollercoaster of assisted fertility (Woods & Esposito-Woods, 1997).

Kübler-Ross (1969) identified stages of grieving, through which individuals move, as they try to come to terms with death and loss. These include denial that the event has occurred; anger directed at anyone deemed responsible, including self, God, the midwife or doctor; the hospital, other family members; bargaining by trying to find alternatives to accepting the reality of the event; resolution to the facts; and, finally, acceptance. In the birth setting, the most likely stages that the nurse sees and assists the family with are anger, denial, and bargaining. The entire process can take days, months, years, or, for some families, remain forever unresolved.

Birth mothers and fathers fantasize about what their baby will look like and how it will act. This is a way of rehearsing for parenthood (Rubin, 1984; Lederman, 1984). The newborn they meet at birth, while not an imperfect baby, will not look like the baby of their fantasies. It is necessary for the parents to give up and grieve for the imagined perfect baby and move into acceptance of the real baby, wrinkled and covered with vernix. This happens quite quickly. So quickly, in fact, that the nurse may miss the cues that may be present during transition of labor or the second stage, such as the mother saying that she cannot push or holding her legs tightly together. Once she is able to hold the infant, validating the number of fingers and toes and the resemblance to her partner or to other family members are ways of coming to accept the newborn.

Even after an uncomplicated birth experience, a woman may grieve the loss of the fetus as a part of her body. For 9 months, the fetus was a part of her body space. She may grieve the loss of that sensation similarly to the loss of an appendage, even as she is joyful in embracing her newborn (Rubin, 1984).

Loss Through Adoption

In some instances of open adoption, adoptive parents develop a relationship with the birth mother or parents. In these cases, the birth experience may be shared with the adoptive parents. Even in a normal, uncomplicated birth, the nurse is working with two families in flux, one experiencing the joy of expansion, the other perhaps a combination of relief and grief. Assessment of each family and their coping mechanisms is a challenge for the nurse. Immediate strategies to incorporate both sets of parents in the birth room may include bringing the adoptive mother to the bedside of the birth mother and encouraging them to initially hold the baby together and gradually encouraging the birth mother to move the infant into the arms of the adoptive mother. Allowing the birth mother to express her

feelings, perhaps by crying, with acceptance and support may occur simultaneously with the adoptive mother's joyful tears.

One area that has not been written about in great detail is the loss felt by parents who relinquish their birth child. Fathers in particular are left out of the literature. Deykin, Patti, and Ryan (1988) interviewed 125 birth fathers about their feelings about relinquishing the child to adoptive parents. Loss of the child continued to be an unresolved issue of grieving for the fathers many years later. Menard (1997) looked at the role of the birth father who is relinquishing his child in a perinatal setting from the perspective of the social services. There is a delicate balance that must be kept to address the needs of the father in this situation, along with the needs and rights of the mother, the child, and the adoptive family. Nurses as care providers in the birth setting are in a pivotal position to help birth fathers and mothers own the decisions they have made and develop coping strategies. Additional investigation should be done in this area to enable nurses in the birth setting to develop appropriate interventions for families that are relinquishing their newborns.

Loss Through Special Circumstances

An unusual situation for the nurse to encounter is one in which the birth mother is relinquishing her child to another family or foster care because she is incarcerated. A woman who is pregnant when arrested for committing a crime or who is pregnant when sentenced will not, in most instances, be able to stay with her newborn after birth. In a few prisons, such as Bedford Hills Correctional Facility in Bedford Hills, New York, programs have been developed for pregnant and parenting prisoners (Felter-Wernsdorfer, Nass, & Weingrad-Smith, 2000). However, for the majority of incarcerated women, within days or hours after birth, they will have to relinquish their baby to someone else's care and be separated from their newborn for extended periods of time. Whatever their crime, a woman relinquishing her child right after birth will grieve and exhibit behaviors related to sadness and loss (Wismont, 2000).

Response of Health Care Professionals

The professional and institutional response to loss at birth has changed dramatically over the years. Historically, in an effort to "spare" the mother and parents, women were anesthetized for delivery and stillborn babies were whisked out of sight. Infants slated for adoption were removed from the delivery room quickly to protect the

mother from seeing or hearing the child and feeling the sadness of her decision. Today most institutions have perinatal grief teams, which are specially developed teams of nurses, social workers, and others who are available to assist families and staff with the issues of grieving. Rather than trying to brush the experience away, we know today that it is necessary for families to come to closure with the loss of the baby to develop effective coping strategies for continuing their lives.

Web Activities

- Visit the websites listed in the Resources. What information is offered on assisting new families through the adaptation process when a new member is born?
- Locate Internet sources designed for families who are losing a child to adoption or because of incarceration of the parent.

Key Concepts

- Nursing care of the birthing woman and her family is based on an understanding of the theoretical framework of the family's response to birth.
- Appreciating the history and development of family participation in birth helps the nurse assess and plan for individual needs of families.
- A family's response to birth reflects their culture, belief system, and style of coping with changing life circumstances.
- Birth is a crisis, or turning point, in life that challenges the family to adapt their lifestyle coping mechanisms. This is an unprecedented time, during

which the nurse has the opportunity to assist the family in moving into a new stage.

- Appropriate nursing interventions may be developed only after careful assessment of the individual family member's developmental stage and coping ability.
- An understanding and acceptance of the nurse's personal experience and response to both the birth experience, and the loss of an infant at birth help assure that these issues do not interfere with the nurse's ability to meet the needs of the client and family.

Review Questions and Activities

1. Describe Reva Rubin's theory of maternal response to birth.
2. Define birth as a "crisis," or turning point, for families.
3. Discuss the impact of birth on the father, siblings, and grandparents.
4. Go to a hospital that has a "grief team." Describe the organization of the team and the roles of the different members. What role do nurses play? What are the specific activities the team engages in that assist the woman and her family? What follow-up is provided by the team to the families?
5. Discuss how personal unresolved feelings that a nurse may have about birth can interfere with his or her ability to assist the family in reaching their goals for birth.
6. List three specific areas for nursing research regarding a family's immediate response to birth.
7. What are the potential implications for a female infant if the parents were invested in the sex of their child being male?
8. In what specific ways can a normal, uncomplicated birth be an empowering experience for the woman, her partner, and her family?
9. Discuss the implications of the birth experience for older children. List nursing interventions that can assist children in appreciating the experience.
10. Define "couvade" and discuss modern rituals that fathers may go through during the birth experience.

UNIT VII

Postpartum Health and Nursing Care

Normal Postpartum Nursing Care

In today's society, many women place great importance on body image and thinness. Immediately after delivery, the postpartum woman may be shocked and discouraged when she discovers her body appears "as if she were still pregnant." Use the following questions to assist the new mother in sorting through her personal feelings:

- ❖ *How do you feel about your delivery?*
- ❖ *How does your body feel?*
- ❖ *How do you feel about the shape of your abdomen?*
- ❖ *What do you think about still fitting into the clothing you wore during pregnancy?*
- ❖ *Are you interested in learning about postpartum exercises?*
- ❖ *What are your plans to get back to your prepregnancy figure?*

Competencies

Upon completion of this chapter, the reader should be able to:

1. Define the key terms.
2. Determine a systematic, logical approach to postpartum assessment.
3. Identify the expected values and clinical assessments to be evaluated in the care of the woman postpartally.
4. Summarize the systemic physiologic changes women experience after childbirth.
5. Identify and describe appropriate nursing interventions for the woman postpartally.

The **puerperium**, or the postpartum period (fourth trimester), lasts from delivery of the placenta to approximately 6 weeks afterward. During the postpartum period, the woman is referred to as the **puerpera**. The immediate postpartum period consists of the first 24 hours after delivery. The early postpartum period lasts from the second day after birth to the end of the first week. The postpartum period continues until 6 weeks postpartum.

The obstetric nurse will see the pregnant client experience various physiologic and psychosocial changes when she makes the transition from a pregnant woman to a mother on delivery. Postpartum nursing care often is considered routine; however, it encompasses a wide range of nursing care that includes psychological and physiologic assessment and intervention and provision of infant care.

The needs of the client and her family in the postpartum period can best be met through coordinated multidisciplinary care. Physicians, midwives, nurses, social workers, lactation consultants, and others must ensure that clients receive the services they need. The responsibilities of the obstetric nurse in caring for the client postpartally include being able to make relevant assessments, plan and implement a family-centered plan of care, and evaluate the effectiveness of her care. The nurse also has the potential to significantly affect the client's postpartum health by presenting self-care and infant care education, preparing for hospital discharge, and providing follow-up for the mother and infant.

POSTPARTUM CARE

The birth of a child most often is a joyous occasion for the family. Unless complications occur the father or significant other and other supportive family members and friends should be encouraged to remain with the mother and infant after birth. Interaction between the family and infant should be facilitated by encouraging members to hold the infant and point out special physical characteristics. If the mother is not breast-feeding, the father or other siblings may provide infant feedings. The bonding or family-infant interaction provides an initial introduction to each other.

Mother-Baby Nursing

The postpartum nurse may need to be prepared to care for both the mother and her infant. Some hospitals continue to offer a traditional postpartum unit and separate nursery. In this type of setting the postpartum nurse is responsible for caring for the mother, whereas another nurse cares for the infant. Many facilities (i.e., birth centers) have now transitioned to family-centered maternity care (FCMC) in which the nursing philosophy is based on the concept of mother-baby nursing or couplet care (Phillips, 1997). The approach to care in this nursing strategy is based on the family being the primary caregivers. The mother's well-being is interdependent with that of her newborn as they adjust to multiple physical, cognitive, and psychosocial changes during the postpartum period (Box 28-1). One team of health care providers (e.g., a nurse and technician

Box 28-1 Practicing Mother-Baby Nursing

The benefits of mother-baby nursing for the family and newborn include the following:

- Facilitating earlier establishment of biologic rhythms with flexible feeding and sleeping cycles.
- Fostering breast-feeding.
- Decreasing the incidence of cross-infection.
- Providing individualized, one-on-one care.
- Promoting the mother's role and attachment.
- Increasing educational opportunities.
- Fostering continuity of care and reduction of confusion of messages between caregivers.
- Promoting the mother's learning about her newborn and self-care capabilities.
- Increasing maternal self-confidence in caring for her newborn.
- Eliminating anxiety about whether the newborn is properly cared for.

The benefits of mother-baby nursing for the nursing staff include the following:

- Streamlining responsibilities of care and teaching.
- Increasing nursing involvement and responsibility for patient care and learning.
- Increasing accountability.
- Improving communication between the family and caregivers.
- Replacing fragmented care with continuity of care.
- Eliminating duplication of services.
- Facilitating discharge planning.
- Increasing efficiency and productivity.
- Improving teamwork and interdisciplinary communication.
- Increasing job satisfaction through the provision of individualized care, a more stimulating work environment, and positive feedback from families.

or aide) cares for both the mother and her newborn as a unit, viewing them as an interdependent couplet.

A gradual shift has occurred from the nurse providing all the newborn care while the mother watches, to the mother independently caring for her newborn. Education about self-care and newborn care is integrated during the nurse's daily physical care for the couplet. The expanded

Figure 28-1 The practice of rooming-in allows mother and baby to be together throughout the day.

role of the “mother-baby nurse” involves early parent-infant interaction, demand feeding, flexible care schedules, personalized parenting education, and family visitation.

In addition to mother-baby nursing, there is a separate concept of rooming-in, whereby the infant remaining in the mother's room at her bedside is permitted and encouraged (Figure 28-1). The infant rooms in with the mother unless medically contraindicated or the mother is unable to care for her infant owing to medical problems or emotional difficulties.

Infant Security

An important aspect of postpartum care is infant security. Cases of infant abduction have directed hospitals to institute infant safety and security systems. The nursing staff must be alert and educate mothers and families about proper security and identification processes (Figure 28-2). The nurse should always check the identification bands on both the mother and infant when providing care.

Hospital Length of Stay

The usual hospital length of stay for mothers having normal vaginal delivery is 24 to 48 hours. Some hospitals, along with third-party insurance companies, previously dictated early discharge without consideration of the mother's needs. Today, the mother and newborn are protected in regard to the length of hospital stay after childbirth based on the Newborns' and Mothers' Health Protection Act of 1996. Under this federal law, third-party insurance companies cannot restrict benefits for hospital stays in connection with childbirth to less than 48 hours after a vaginal delivery and 96 hours after a cesarean delivery. The attending provider is permitted to discharge the

Figure 28-2 Security measures in the postpartum unit and nursery always are in force.

client earlier if the client agrees. The 48-hour period begins at the time of delivery. If the mother delivers outside the hospital and is later admitted, the period begins at the time of admission. The newborn's 48-hour length of stay is independent of the mother's hospital stay.

Thus, the Health Protection Act impacts the way health care is delivered. Compared with years ago, mothers now have less time to recover from the birth process while under professional supervision. Nurses, in turn, have less time to ensure that new mothers are physiologically stable, able to safely provide care for themselves and their new infants, and able to assume the responsibilities of motherhood. Because the purposes of hospitalization after birth are to (1) identify maternal and neonatal complications and (2) provide professional assistance at a time when the mother is likely to need supportive care (American Academy of Pediatrics [AAP] & American College of Obstetricians and Gynecologists [ACOG], 1997), it is essential that the postpartum nurse effectively completes the nursing process to successfully attain an optimal outcome.

Critical Thinking

Practicing Family-Centered Maternity Care

Progressive new hospitals have transitioned obstetric services to offering family-centered maternity care (FCMC) (Phillips, 1997). This style of care philosophizes that health includes not only physical dimensions but social, spiritual, psychological, and economic dimensions as well (in comparison with the more traditional model in which the health care professional has a paternalistic attitude about what families need and want).

The elements of FCMC are based on principles designed to promote greater family self-determination, decision-making capabilities, and control. The families are empowered to be responsible for their own care. The family is recognized as a whole unit and care is not necessarily limited to the nuclear family.

- How can you collaborate with families while providing appropriate care and education in respect to their structure, cultural background, and racial and ethnic group?
- How can you be flexible, accessible, and responsive to the needs of families while also respecting their privacy?

CLINICAL ASSESSMENT

Before providing care for the postpartum client, the nurse should review the medical record for the antepartum and intrapartum histories. A nursing report from the labor and delivery nurse should communicate pertinent information regarding the intrapartum course. Information such as length of labor, estimated blood loss, and the presence of episiotomy will alert the postpartum nurse to potential complications.

The nurse should be prepared to provide physical and psychosocial nursing care. The new mother may want to discuss the events of her child's birth in the immediate postpartum period. Retelling what happened during birth validates the events for her and gives the nurse an idea of the mother's state of mind. Active listening by the nurse may elicit potential problems that may occur later in the postpartum period, (e.g., "I pushed for 3 hours. I am so tired, and now my bottom really hurts.")

During the entire hospital stay, the nurse must incorporate client teaching in all aspects of nursing care. Although the new mother may be emotionally and physically overwhelmed after birth, she must be provided information and educated. The sensitive nurse will instruct the mother

with each step and will explain the reasoning for doing it. (For example, the nurse might say, “I am checking your lochia. It should normally be bright red for the first 3 days.”) Client education after birth is important and should be provided at the same time the nursing care is being performed. Ensuring privacy before examining the client will convey respect and may help ease the new mother’s fears.

Nursing Approach to Cultural Sensitivity

The nurse also should remember to approach the client with sensitivity, taking cultural and religious practices into consideration. For example, some clients may have deep beliefs regarding personal hygiene and modesty or foods to eat (i.e., hot versus cold). The nurse should consult a reference guide, such as *Cultural Assessment* by Geissler (1998), that addresses cultural considerations for the type of patient population she serves in her community. This guide annotates health care beliefs, predominant sick care practices, health team relationships, food practices and intolerances, birth and death rites, infant feeding practices, and child rearing practices for many nationalities.

In addition to cultural differences, the nurse may find herself unable to communicate to her client if the woman speaks a different language. A family member or professional interpreter may assist in relaying important information to the client.

Vital Signs

The recovery period normally lasts for the first few hours after delivery and until the client is stable. Depending on the protocol of the particular unit, the nurse should measure vital signs every 15 minutes for the first hour, every 30 minutes for the second hour, at the third and fourth hour, and then every 8 hours thereafter (Association of Women’s Health, Obstetric and Neonatal Nurses [AWHONN], 1996). Close monitoring assists in identifying potential complications, such as hemorrhage and infection. Clients who received some type of conductive anesthesia (e.g., an epidural or spinal) should be monitored during recovery by trained staff in an area with appropriate resuscitative equipment.

Blood Pressure

The client’s blood pressure may demonstrate negligible if any changes in the postpartum period. Within the first 6 hours the blood pressure should stabilize to or remain consistent with the client’s baseline before delivery. Blood pressure may be lowered owing to the effects of analgesia or anesthesia. Hypotension may result from administration of epidural anesthesia or hemorrhage. Signs of orthostatic hypotension may include dizziness or faintness immedi-

Critical Thinking

Cultural Differences in Postpartum Care

Soon after childbirth, American women are encouraged to get out of bed, ambulate, and care for themselves. Other cultures treat new mothers differently.

A new mother on the Japanese island of Goto Archipelago will stay in bed for 1 month after delivering her baby (Epstein, 2000). It is normal in this culture to have an extended postpartum recovery period. Female relatives, such as grandmothers, aunts, and others, take turns “mothering” the mother and her infant until she feels ready to care for her baby herself.

Based on anthropologic research, historical tribes also mothered new mothers for the first year postpartum (Griffin, 2000). They treated the mothers with massage to help them relax and to restore normal circulation. Massage also was thought to facilitate musculoskeletal healing. Some mothers were treated to a daily full-body massage for the first 3 months after birth.

The balance of hot and cold is part of a belief system in many cultural groups, such as Chinese, Filipinos, and Hispanics. They believe there are natural external factors that must be kept in balance to maintain health. To restore a disrupted balance, for example, the treatment is to apply the use of opposites. To treat a so-called hot condition, such as a fever, the person should eat cold foods, such as fresh vegetables, dairy products, and meats. To treat a so-called cold condition, such as a headache, the person should eat hot foods, such as eggs, cheese, chocolate, and aromatic beverages.

How would you incorporate these beliefs and practices into your nursing care to ensure that your practice embodied cultural sensitivity?

ately after sitting or standing. Hemorrhage in the postpartum client may be difficult to identify because the blood pressure may be within normal limits. Blood volume increases 30% during pregnancy, and therefore, time is needed for it to return to prepregnancy volumes. The postpartal client may be in moderate shock before blood pressure changes occur; thus, a decrease in blood pressure may be a late sign of hemorrhage.

Blood pressure elevation may be related to oxytocin administration or excessive use of medications (AWHONN, 1996). Hypertension may be the result of pregnancy-induced hypertension (PIH), anxiety, or essential hypertension. When a client has PIH, her blood pressure values may remain elevated 5% above the norm until 4 days postpar-

Figure 28-3 The nurse assesses the apical pulse of the postpartum mother.

tum (AWHONN, 1996). Clients with PIH should be monitored more frequently, measuring blood pressure every 4 hours for the next 48 hours because the risk for seizures may continue into the postpartum period.

Pulse

Owing to increased blood volume during pregnancy, normal findings for pulse rate may be slightly bradycardic (50 to 60 beats per minute [bpm]) immediately after birth owing to increased blood volume (AWHONN, 1996). A heart rate greater than 100 bpm may indicate pain, fever, anxiety, dehydration, infection, or hypovolemia (Figure 28-3).

Respiratory Rate

Without the presence of respiratory disease or medications, such as an epidural narcotic, the normal respiratory rate should be 16 to 24 breaths per minute. Epidural narcotics include fentanyl and morphine, both of which depress the respiratory rate to less than 12 breaths per minute. The nurse

POSTPARTUM SHIVERS

Shivering immediately after delivery may be caused by chills or an infection. Many women experience tremors or shaking, sometimes uncontrollably. Changes in hormones, adrenaline, and the physiology of the body cause shivering. You should assess the client's vital signs and risk factors for infection. Once infection has been ruled out, reassure the client that the tremors are normal and soon will pass. Placing a warm blanket over her can reduce the shivering.

should carefully monitor the respiratory rate and have a narcotic antagonist (e.g., naloxone [Narcan]) readily available.

Temperature

The client's oral temperature should range from 36.2°C to 38°C (98°F to 100°F). A temperature greater than 100.4°F in the first 24 hours after delivery may indicate dehydration (Figure 28-4). A temperature greater than 38°C (100.4°F) 6 hours apart after the first 24 hours after delivery for 2 consecutive days may indicate a postpartum infection (AWHONN, 1996). Unless proved otherwise, fever in the postpartum period suggests the presence of an in-

Figure 28-4 The nurse should assess the new mother's temperature regularly in the early postpartum period because fever may suggest an infectious process.

VITAL SIGNS

Despite a stable blood pressure, the presence of both tachycardia and tachypnea may suggest hypovolemia secondary to early hemorrhage. In a client with hypertension, it may be difficult to determine hemorrhage because blood pressure may appear normal when she actually may have hypovolemia.

fectious process, usually somewhere in the genitourinary tract (Williams & Cooper, 1993).

Physical Assessment

The nurse should follow an organized method when examining the postpartum client. This manner provides a consistent, quality approach to nursing care. The acronym BUBBLE-HE can serve as a helpful reminder of the elements in a postpartum assessment. BUBBLE-HE stands for:

- Breasts
- Uterus
- Bladder
- Bowel
- Lochia
- Episiotomy
- Homan's sign
- Emotional status

The nurse should assess these elements every 8 hours, along with vital signs (AWHONN, 1996).

Breasts

After delivery, on palpation breasts usually are enlarged, soft, and warm and contain only a small amount of colostrum, the precursor of milk. The nipples should be intact without redness, tenderness, cracks, or blisters. Colostrum may be expressed. If the mother is not breast-feeding, the breast changes as a result of pregnancy regress after 1 to 2 weeks postpartum.

The mother may experience breast **engorgement** (enlargement and filling of the breasts with milk), which may begin as a tingling sensation in her breasts, 2 to 4 days after delivery. In the presence of prolactin hormone, the breasts begin to fill with milk or become engorged. Engorged breasts are secondary to increased vascularity and lymph and venous stasis. The breasts feel very full, tender, and uncomfortable until the milk is either released through infant sucking, manual expression, or pumping. The discomfort from engorged breasts normally subsides once stimulation to produce milk is decreased. The nursing mother's breasts should be inspected and palpated for the presence of inverted nipples, cracks, blisters, fissures, and tenderness (Figure 28-5).

When a client chooses to bottle-feed her infant, the nurse should teach the client about lactation suppression. Suppression can be achieved through a variety of methods: decreasing stimulation to the breasts (e.g., securely binding the breasts with a snug support bra and with an ace bandage if more support is needed), avoiding warmth (e.g., hot shower water) on the breasts, and applying ice packs to the breasts. The mother can take acetaminophen

Client Education

Breast Care in Nonlactating Women

For the nonlactating client to successfully care for her breasts, you should teach her the following:

- Do not manually express milk from the breasts.
- Do not stimulate the nipples.
- Wear a tight-fitting bra.
- Use ice packs to constrict the superficial blood vessels.
- Take analgesics to minimize discomfort.
- Do not take medications (e.g., bromocriptine [Parlodel]) to suppress lactation because they may cause adverse side effects.

(Tylenol) for breast discomfort. These methods can be used until milk production stops.

Uterus

Immediately after delivery the uterus begins the process of **involution** or reduction in size. It generally takes 6 weeks for complete physiologic involution and for the reproductive system to be restored to its nonpregnant state, except for the nursing mother's breasts. **Subinvolution**, or the failure of the uterus to return to a nonpregnant state, occurs when the process of involution is prolonged or stopped as a result of hemorrhage, infection, or retained placental parts.

Uterine involution involves the return of the uterus to a nonpregnant condition—diminishing in size and weight—and anatomic location back into the pelvis (Figure 28-6). The endometrial decidua is shed, as noted by the lochial vaginal bleeding. By the end of the 3 weeks postpartum, the endometrial lining and site of the placental attachment should have returned to a nonpregnant state. The placental site usually is completely healed without scarring by the 6 weeks postpartum.

Immediately after delivery, the uterus weighs about 1,000 g (2 lb, 4 oz), measuring 14 by 12 by 8–10 cm, which is two to three times the nonpregnant size (Table 28-1). At the end of 6 weeks postpartum, the uterus weighs 50 to 100 g (AWHONN, 1996). Breast-feeding or breast stimulation assists in hastening the speed of uterine involution. There generally is no difference between primiparas and multiparas regarding healing time. Multiparas may have less abdominal muscle tone, however, and the cervix does not completely return to its closed nonpregnant appearance. The parous cervix is easily distensible and appears as a slit.

Figure 28-5 Postpartum breast assessment. A. The nurse palpates the breast for tenderness and lumps, which may indicate a plugged milk duct. B. The nipples are assessed for inversion, cracks, blisters, and tenderness; colostrum may be expressed during compression of the areola. C. Showing the new mother how to assess her breasts is an important element of postpartum teaching. D. After assessing the first breast, the nurse examines the second breast.

Assessment of the Fundus

When assessing the location and firmness of the uterine **fundus**, the top portion of the uterus, the nurse should place the client in a supine position with the bed flat. Using a two-handed approach, the nurse places one hand beneath the uterus to support it, while using the other hand to cup the fundus (Figure 28-7).

Immediately after delivery, the fundus usually can be located midline at the level of or one to two fingerbreadths below the umbilicus. Immediately after birth, the fundus should be at or below the level of the umbilicus. The fundus is approximately 1 cm below the umbilicus at 12 hours after delivery. After the first postpartum day the fundus descends or involutes 1 to 2 cm (0.4 to 0.8 in) each day. Finally, the fundus is nonpalpable as it gradually descends into the true pelvis on or about 9 days postpartum.

Assessments may be documented using the abbreviations ML (midline) at “U + 2, U + 1, @U, U-1, U-2” from the umbilicus. There may be individual variations in the as-

essment of the fundal location from one examiner to the next owing to differences in fingerwidths (Figure 28-8).

The fundus should be massaged for firmness (Box 28-2). Fundal massage provides the opportunity to maintain contraction of the uterine blood vessels where the placenta was once attached, preventing potential hemorrhage and expelling placental fragments and blood clots (Figure 28-9). If it is not firm or palpable, the fundus may feel soft or **boggy**. A boggy uterus may be related to an overdistended uterus or structural anomalies (e.g., fibroids). A fundus that remains boggy is a warning sign of uterine atony and potential postpartal hemorrhage.

The position of the fundus also should be noted if it is midline or displaced to the left or right of the umbilicus. If the bladder is full, the fundus may be displaced higher and to the right of the umbilicus. Because the broad and round ligaments were greatly stretched during pregnancy and become very lax after the loss of the enlarged uterus after delivery, the uterus is easily displaced by an overfilled blad-

der. Women who have had several pregnancies or large babies may have a large uterus that is palpated higher than is normally expected.

Management of Bleeding

After delivery of the placenta, 20 to 40 U of oxytocin (Pitocin) often are added to the mainline intravenous (IV) solution if an IV is in place. Oxytocin is prescribed to hasten uterine contractility and control bleeding (Spratto

and Woods, 2001). When IV access is not present, other options include administering oxytocin (10 U) intramuscularly (IM), initiating early breast-feeding, or performing nipple stimulation (Table 28-2).

When the uterus remains boggy despite fundal massage and oxytocin administration, other reasons for bleeding

Time	Size (g)
After delivery	1000
End of first week	300–350
End of second week	100
End of sixth week	50

ASSESSING BLEEDING

Postpartum hemorrhage should be considered if a pad is saturated with blood within 15 minutes or two pads within 30 minutes (AWHONN, 1996). A slow, steady seepage of blood also may lead to postpartum hemorrhage.

must be determined. When bleeding continues, a second pharmacologic agent, such as an ergot preparation, should be considered. Methylergonovine (Methergine), 0.2 mg, may be given IM to clients who do not have a current history of high blood pressure (Table 28-3).

Another medication useful in controlling bleeding is a prostaglandin called carboprost tromethamine (Hemabate) (Table 28-4). Hemabate often is used when fundal massage and second-line medications such as methylergonovine do not stop the hemorrhage.

Assessment of Uterine Pain

Abdominal cramping or **afterpains** are caused by uterine tonic contractions, which are the efforts of the uterus to expel blood clots and placental fragments. The contractions are enhanced with oxytocin. A history of multiple gesta-

Nursing Alert

PRECAUTIONS FOR METHYLERGONOVINE

Methylergonovine should only be given to clients who *do not* have high blood pressure. Take a blood pressure reading before administering the medication. If the patient with hypertension or risk of hypertension has a blood pressure greater than normal parameters, do not give the medication.

Box 28-2 General Approach to Fundal Massage

- Ensure that your hands are warm and clean.
- Inform the client what you are going to do.
- Determine if the client needs to empty her bladder. A full bladder impedes uterine involution.
- Put the client in a supine position with her legs slightly flexed.
- Gently touch the client's abdomen to decrease tension on it.
- Tell the client you are going to place (cup) one hand on top of the symphysis pubis to support and hold the lower part of the uterus.
- Place (cup) the other free hand on the fundus.
- Gently palpate the fundus and massage with a downward, steady pressure. If you cannot locate the fundus, move your hand higher or lower as needed. The fingers should lay flat on top of the abdomen while massaging. Do not massage for more than a few minutes because overstimulation of the fundus may cause muscle fatigue and continued agony.
- Note the consistency of the fundus that is, whether it is soft and boggy or firm. The firm fundus will feel hard like a softball.
- If the fundus is soft, massage it until it contracts and becomes firm.
- Teach the client how to massage the fundus.
- Note the location of the fundus. When the fundus is greater than the level of the umbilicus, the nurse should assess for the possibility of uterine filling with blood or blood clots and uterine displacement by a distended bladder.
- It is best to observe the perineum at the same time you palpate the fundus to note the amount and color of lochia or clots that may be discharged during massage. The bleeding may increase during massage.
- Replace the old peripad, as needed.
- Cover the client and reposition her in the bed, as needed.
- Document findings in the client's medical record.

tion, multiparity, or uterine overdistention usually is associated with afterpains.

The uterus of the primipara woman tends to remain in a better or more prolonged state of contraction compared

Figure 28-9 Fundal massage helps the uterus return more quickly to its prepregnancy state; massage also helps prevent hemorrhage and expel placental fragments and blood clots.

Table 28-2 Pharmacology in the Postpartum Period: Oxytocin (Pitocin)

Therapeutic Class	Oxytocic agent
How Supplied	10 μ /mL ampule or vial
Indications for Use	Induces or stimulates labor, controls postpartum bleeding, induces completion of an incomplete or inevitable abortion
Chemical Effect	Causes selective potent stimulation of the smooth muscles of the uterus and mammary glands
Therapeutic Effect	Induces labor; reduces postpartum bleeding
Dosage	When used postpartum: IV, 10 to 40 μ , are added to 1,000 mL of D ₅ W, D ₅ LR, lactated Ringer's solution, or 0.9% normal saline at a rate of 20–40 m μ /min or a rate necessary to control bleeding; IM, 10 μ
Side Effects	Anaphylaxis, fatal a fibrinogenemia, hypertension, increased heart rate, arrhythmias hypersensitivity, nausea and vomiting, water intoxication from prolonged IV infusion
Nursing Considerations	Monitor for fluid overload, coma, or seizures; monitor intake and output; note amount and color of lochia; do not give as an IV bolus; no effects on breast-feeding infant

Data from Spratto, G. R., & Woods, A. L. (2001). *PDR nurse's drug handbook*. Albany, NY: Delmar Thomson Learning.

Table 28-3 Pharmacology in the Postpartum Period: Methylergonovine (Methergine)

Therapeutic Class	Oxytocic agent
How Supplied	IM or IV, 0.2 mg/mL; PO, 0.2 mg
Indications for Use	Manages and prevents postpartum hemorrhage by producing firm uterine contractions
Chemical Effect	Stimulates rate, tone, and amplitude of uterine contractions
Therapeutic Effect	Stops postpartum hemorrhage
Dosage	IM, 0.2 mg, every 2 to 4 h; IV, 0.2 mg, slow IV push over 1 min; PO, 0.2 mg three to four times a day 2 to 7 d
Side Effects	Dizziness, headache, seizures, hypertension, palpitations, thrombophlebitis, dyspnea, diaphoresis, nausea and vomiting, uterine tetany
Nursing Considerations	Monitor blood pressure and other vital signs for evidence of shock or hypertension while administering IV; abdominal cramps may continue for 3 h after administration; may dilute IV dose up to 5 mL of normal saline; not recommended for use in lactating women

Data from Spratto, G. R., & Woods, A. L. (2001). *PDR nurse's drug handbook*. Albany, NY: Delmar Thomson Learning.

with that of a multipara woman. Thus, the multipara woman's afterpains will seem more intense, contracting vigorously at regular intervals. Afterpains usually become milder after 3 days. When abdominal pain becomes significantly more intense or the uterus is tender to palpation, the nurse should assess for further indications of problems, such as **endometritis**, an infection of the uterine lining. Severe pain that is not relieved by medications should be reported to the health care provider.

If the third stage of labor is mismanaged by pulling on the cord before readiness of the placenta to detach from the uterine wall, uterine inversion or prolapse may occur. Although rare, this is a life-threatening occurrence that requires emergency measures and immediate notification of the physician. The client may go into shock. The uterus must be reinserted immediately by returning it to a normal position in the pelvis, a procedure that must be performed by a physician.

Bladder

In the immediate postpartum period, the bladder is congested, edematous, and hypotonic from the effects of

Table 28-4 Pharmacology in the Postpartum Period: Carboprost Tromethamine (Hemabate)

Therapeutic Class	Oxytocic; uterine stimulant
How Supplied	IM, 250 µg/mL
Indications for Use	Prevents and treats postpartum hemorrhage not managed by conventional methods
Chemical Effect	Produces immediate strong uterine contractions
Therapeutic Effect	Stops postpartum hemorrhage
Dosage	IM, 250 µg/mL, deep IM every 1.5 to 3.5 h, may increase to 500 µg if bleeding is not controlled; total dosage should not exceed 12 mg
Side Effects	Nausea, vomiting, diarrhea, fever, chills
Nursing Considerations	Monitor drug's effectiveness by evaluating uterine contractions and cessation of bleeding; may prophylactically administer an antidiarrheal drug, such as diphenoxylate and atropine (Lomotil)

labor. Unless a urinary tract infection is present, these effects should resolve within 24 hours of delivery. Considerable diuresis—up to 3,000 mL—may follow for several days after delivery, decreasing by 3 days postpartum (AWHONN, 1996). The diuresis results from the decreasing production of aldosterone hormone (sodium retention decreases and urine production increases) and the body's method of removing excess fluid. The renal pelvis and ureters, stretched and dilated during pregnancy, return to normal by the end of 4 weeks postpartum.

In the immediate postpartum period, urinary distention, incomplete emptying, and residual urine are complications that result in a full bladder. These complications are related to an edematous perineum, pain, reflex spasms, and bladder desensitization. A full bladder interferes with uterine contractions and increases the risk for hemorrhage.

Risk factors for these problems include: episiotomy (surgical incision to enlarge the vaginal opening for delivery of the infant's head), perineal edema or tenderness, long labor, assisted vaginal delivery (forceps or trauma may cause neural blockage), lacerations, previous catheterization (secondary to pain and swelling associated with an episiotomy), and anesthesia (bladder tone may be temporarily lost, resulting in urinary retention and diminished perception of bladder fullness).

The newly delivered mother requires ample fluids. Nursing responsibilities include teaching her to empty the bladder often after birth to assist in controlling pain and bleeding. Immediately after delivery, the client should be assisted to the bathroom the first two or three times to protect against falls; the nurse must monitor her for dizziness and faintness (Figure 28-10). Early ambulation and comfort facilitate urination. After delivery the client should be able to urinate within 4 hours, at least 150 mL, with complete emptying of the bladder (AWHONN, 1996). The nurse should note complaints of urinary frequency, dysuria, and retention. The primary provider should be notified if the woman has not voided 6 to 8 hours after delivery.

The nurse should closely observe for bladder distention and adequate emptying after urinary efforts. After urination, the fundus should be repalpated for location to ensure appropriate emptying of the bladder. The bladder normally should be nonpalpable. If the bladder remains distended, the client may be retaining residual urine. **Residual urine** is defined as urine remaining in the bladder after elimination. Residual urine can result in urinary tract infection.

The nurse may need to perform a straight catheterization when the client cannot urinate, the bladder remains distended, and the client is uncomfortable. The judgment to perform a straight catheterization depends on the client's

Figure 28-10 The nurse should assist the new mother the first few times she attempts to ambulate after delivery.

URINATION AFTER DELIVERY

The newly delivered client may need assistance in urinating. Actions, such as mental relaxation, taking an analgesic before voiding, drinking fluids, running the tap water, blowing bubbles through a straw in a glass, pouring water over the perineum, concentrating on relaxing part of the perineum using pelvic tightening exercises (Kegel's), or standing in the shower, may aid in stimulating urination. A few drops of peppermint oil in the toilet water also is helpful in stimulating the urge to urinate.

circumstances: the degree of bladder distention, location of the displaced uterus, amount of bleeding, amount of fluid or IV intake since the last voiding, and the techniques used to encourage voiding. When all of these parameters are not extreme or have not been met, catheterization should be delayed an hour or so until further assessment.

An indwelling catheter should be inserted when the client cannot empty her bladder completely. An increased incidence of bacteriuria exists with an indwelling catheter. An indwelling catheter inserted before cesarean delivery generally is kept in place for 24 hours.

Bowels

The client's appetite typically will return to normal immediately after delivery, with the new mother usually becoming hungry 1 to 2 hours after delivery. If there are no complications from anesthesia, diet habits with regular food may be resumed. The client who had vomited during labor

DETECTING A DISTENDED BLADDER

When the bladder is full and distended, on palpation it will feel like a ballotable cystic mass or rounded bulge. The mound may fluctuate as does a water-filled balloon. Dull percussion may be heard over the symphysis pubis. A full bladder tends to displace the uterus up and to the right. Lochia may be more than normal because the uterus is unable to contract effectively. A distended bladder takes longer to regain its original tone because muscle tone may have been lost as a result of stretching.

Critical Thinking

Voiding after Delivery

Marissa, your newly delivered 30-year-old gravida 2, para 2, mother, is unable to void 5 hours after delivery. She received an epidural when she was 5 cm dilated, and a Foley catheter was inserted after the epidural when she was unable to void. She quickly progressed through labor, delivering a 9 lb, 7 oz baby boy.

- Which methods would you use in assisting your client to urinate?
- Which nursing intervention must be performed if the client is unable to void spontaneously?
- Which other assessments should you monitor if the client has a distended bladder?

may not have an appetite. The nurse should encourage her to increase her fluid intake and choose foods high in potassium and protein. Especially after a long and difficult labor, the new mother needs nourishment with food and fluids to regain her strength.

A woman's nutrition continues to be important throughout the postpartum period, regardless of choice of infant feeding methods. The physical stresses of labor and delivery and the psychological demands of being a new mother take a toll on her body. The client may need a diet high in protein and iron if she has experienced postpartum hemorrhage. Adequate dietary protein and iron facilitates tissue healing and restore iron levels from the normal hemoglobin hemodilution of pregnancy.

The client's bowel pattern should remain unchanged after a vaginal delivery, with a bowel movement normally occurring by 2 or 3 days postpartum. Often, a woman may defecate while pushing during the second stage of labor. When gastric motility does not return by 2 or 3 days after delivery, constipation may occur. The nurse should assess the client's abdomen for nondistention, softness, and bowel sounds.

Constipation in the early postpartum period may occur owing to decreased bowel motility during labor, postpartum fluid loss, prelabor diarrhea, the side effects of medication and anesthesia, and the self-restraint or hesitancy to defecate owing to perineal or rectal discomfort. For women who have had an episiotomy, fear of tearing the stitches may lead to or exacerbate the occurrence of constipation.

The client's possible inhibition must be assessed because it may lead to fecal impaction. The nurse should ex-

USE OF ENEMAS AND SUPPOSITORIES AFTER DELIVERY

Do not administer enemas or suppositories to women who have experienced a fourth-degree laceration.

plain that the stitches are inserted in layers and assure the client that the normal effort of bearing down with rectal pressure will not affect the episiotomy. The client should be encouraged to drink six to eight 8-oz glasses of fluids daily and eat a high-fiber diet (e.g., whole grains, legumes, vegetables, and fruits). Warm sitz baths, topical anesthetics (e.g., chloroprocaine [Nesacaine]), and stopping medications that cause constipation (e.g., Tylenol with Codeine) are helpful interventions to lower the chances of constipation.

When constipation is severe, administering an analgesic and a stool softener (e.g., docusate [Colace]) before ambulation may assist in facilitating a bowel movement. Many health care providers order a mild prophylactic laxative, such as magnesium hydroxide (Milk of Magnesia), 30 mL/day, for women who have had a fourth-degree laceration. If the client has not yet had a bowel movement by 2 to 3 days postpartum, mineral oil, bisacodyl suppository (Dulcolax), or Fleet enema may be prescribed to stimulate intestinal activity.

Hemorrhoids

Examination of the bowels includes assessment for the presence of hemorrhoids. Hemorrhoids present during pregnancy may enlarge during labor. If the hemorrhoids are too large, they may cause pain if they become thrombosed and may subsequently cause constipation. Treatments with witch hazel or a topical anesthetic spray may relieve discomfort.

Lochia

The usual uterine discharge of blood, mucus, and tissue after childbirth is called **lochia**. Lochia contains the sloughing of decidual tissues, including erythrocytes, epithelial cells, and bacteria. Lochia is assessed according to its amount, color, and change with activity and time. The duration of lochia is not affected by breast-feeding or the use of oral contraceptives (Bowes, 1996).

The descriptive name of lochia changes concomitantly with the changes in color. *Lochia rubra* is the term given for the discharge in the first 3 days after delivery. Lochia rubra is small to moderate in amount and having a bright-

red color, secondary mainly to decidual tissue and bloody content. The color becomes progressively paler. Small clots may be present.

Lochia serosa, which occurs 4 to 10 days after delivery, is a watery, pink, or brown-tinged color, which is lighter in amount than is lochia rubra. Lochia serosa primarily contains serous fluid, leukocytes, erythrocytes, and decidual tissue.

The lochia transitions into *lochia alba*, a whitish-yellow creamy discharge on days 10 to 17. Many women may have minimal discharge by day 14; however, it is not uncommon for lochia alba to last until 6 weeks postpartum (Bowes, 1996). Lochia alba consists of a mixture of leukocytes, decidual tissue, and decreasing fluid content. The nurse should inform the client that there likely will be an episode of heavy vaginal bleeding between days 7 to 14 when the placental eschar sloughs off (Bowes, 1996).

The flow of lochia rubra is evaluated by examining the blood saturation on a peripad that occurs in 1 hour or less. The nurse should document her assessment of lochia using the descriptive term and the amount of blood saturation. Descriptions of lochia can be scant (less than 2.5 cm, or 1 in), light/small (less than 10 cm, or 4 in), moderate (less than 15 cm, or 6 in), or heavy/large (one pad saturated within 15 to 30 min) (Figure 28-11).

Determining the exact amount of blood on a peripad can be a challenge. Health care providers often mistakenly underestimate blood loss. Quantifying blood loss is a learned skill that should be practiced to accurately assess blood loss. Factors influencing objectivity and consistency in reporting include education of personnel and type of pad used.

Saturation of a pad within 15 to 30 minutes may indicate hemorrhage. When the client is bleeding heavily, the nurse needs to ensure that the blood is not coming from another source, such as a cervical or vaginal laceration. Lacerations are more highly suspected when heavy bleeding continues despite a firm uterus. The nurse also should check under the woman's buttocks for bleeding on the underpad and bed sheets.

The peripad, along with the Chux or pads used, may be weighed (1 g = 1 mL fluid). Blood tests can be used as an indicator of blood loss. A complete blood count (CBC) may indicate a 1.0 to 1.5 g/dL decrease in hemoglobin and a 3% to 4% decrease in hematocrit, which is consistent with a loss of 500 mL of blood (AWHONN, 1996).

The amount of lochia varies with position changes but should continually decrease throughout the first 4 to 6 weeks postpartum. The blood pools in the vaginal vault when the client is recumbent and drains when standing up. Clot formation occurs as a result of the pooling in the uterus or vagina. An increase in bright-red bleeding and the passage of clots also may occur during physical activity or breast-feeding. Lochia with a reddish color that

A.

B.

C.

D.

Figure 28-11 Assessment of lochia is based on the amount of blood saturation on a peripad. A. Scant. B. Light/small. C. Moderate. D. Heavy/large.

persists after 2 weeks of delivery may indicate subinvolution of the placental site or retained placental parts; this finding must be reported to the physician (Bowes, 1996).

The client should be instructed to notify the nurse if blood clots larger than 1 cm or roughly the size of a silver dollar are passed. Nursing actions include assessing the fundus for firmness and amount of lochia (Figure 28-12). When clots persist the nurse should notify the health care provider because an examination may be required to evaluate for other sources of continued bleeding.

Lochia has a characteristic menstrual-like musky or fleshy smell. A foul-smelling discharge, along with other indicators, such as fever and uterine tenderness, may suggest an infection, such as endometritis. Lochia serosa emits

the strongest odor, which increases if mixed with perspiration. Because lochia is an excellent medium for bacterial growth, clients should be taught to change the peripad at every urination.

The first menstrual period usually begins within an average of 8 weeks after delivery for most nonlactating women. The timing may be delayed from 2 to 18 months in breast-feeding mothers; however, ovulation may occur without the onset of the first menstrual period (AWHONN, 1996). Thus, it is possible for a woman to become pregnant before the return of menses. Consistent, continuous breast-feeding increases prolactin levels, thus postponing the resumption of ovulation. Once breast stimulation decreases, prolactin levels decrease and FSH and LH hormone levels increase, inducing ovulation.

Client education includes teaching the client to report signs and symptoms of problems, such as foul-smelling lochia, heavy flow or change in normal flow, presence of large clots, and lochia rubra that continues past 4 days postpartum or that returns after initial cessation.

Figure 28-12 The nurse places a hand on the fundus while assessing the amount of lochia.

Episiotomy

An **episiotomy** is the surgical incision made to enlarge the vaginal opening for delivery of the baby's head. Depending on client preference, situation, and provider preference and judgment, some women experience delivery with an episiotomy. The episiotomy is incised midline down the center of the perineum, rather than mediolaterally, which extends in a diagonal angle to either the left or right side. With or without an episiotomy, the perineum also may suffer from lacerations during childbirth. Lacerations are classified as first, second, third, or fourth degrees (Table 28-5).

Table 28-5 Classification of Perineal Lacerations

Classification	Description
First degree	Involves only the skin and superficial structures above the muscle
Second degree	Extends into the perineal muscles
Third degree	Reaches into the anal sphincter muscles
Fourth degree	Continues into the anterior rectal wall

To assess an episiotomy and the condition of the perineum, it is best to have the client lie on her side, flexing her upper leg toward her hip. The nurse can then lift the buttocks to expose the perineum. Using a good light source, such as a gooseneck lamp or flashlight, facilitates visualization of the incision and repair (Figure 28-13). The REEDA (redness, edema, ecchymosis, discharge, and approximation) scoring scale can be used when assessing the episiotomy. At the client's request, the nurse can provide a mirror to show her the episiotomy to help dispel fears and misconceptions about healing of the perineum. (See Postpartum Complication for assessment and care of a perineal hematoma.)

Care of the vulva includes applying ice packs to the perineum for the first 24 hours to help decrease edema and pain. Ice packs also assist in constricting blood vessels, minimize the risk of hematoma formation, and decrease muscle irritability and spasm (Bowes, 1996). Ice packs should not be applied directly to the skin; they should be wrapped with an absorbent disposable type of covering.

After the first 24 hours after delivery, a sitz bath with warm water or moist heat may be used to reduce the local discomfort caused by perineal trauma and an episiotomy.

Figure 28-13 The nurse inspects the episiotomy site with the client lying on her side.

REEDA SCALE

Use the REEDA acronym as a nursing tool when evaluating an episiotomy (Davidson, 1974). REEDA stands for redness, edema, ecchymosis (purplish patch of blood flow), discharge, and approximation (closeness of the skin edges).

This tool used to assess healing is based on a 3-point scale; a score of 3 signifies an assessment of very poor wound healing. On the first postpartum day, the score may range from 0 to 3; by the second week postpartum, the score should be 0 to 1.

The change from cold to warm therapy enhances vascular circulation and healing. The sitz bath may be used until the episiotomy heals. Use of a heat lamp two or three times a day also will assist in the healing process (Box 28-3).

The client should be taught perineal hygiene, including daily washing with warm water and mild soap. The perineum should be cleansed after each voiding and bowel movement. A squeeze-bottle filled with warm tap water may be used to clean the perineum. The water should be comfortably warm on the wrist (approximately 38°C, or 100°F). The nozzle should be directed toward the perineum. The perineum should be wiped from the anterior to the posterior, or in a front-to-back motion, to avoid contamination from the anal region. Practices such as changing the peripad frequently (after each voiding and bowel movement or at least four times a day, removing the pad from front to back, and hand washing will help decrease the risk for infection and promote wound healing for episiotomy and repaired lacerations. Soiled pads should be placed in an appropriate disposal container.

USING ICE PACKS

Many commercially prepared ice packs are available; however, an inexpensive way to make an ice pack is right on your unit. A condom or latex glove filled with crushed ice and wrapped with a disposable paper towel can be used as an ice pack. Fresh ice will easily mold on the woman's body; however, frozen packs will last longer before they begin to melt.

Box 28-3 Nursing Care of the Episiotomy: Sitz Bath and Heat Lamp

Sitz Bath

- Inform the client about the rationale and process of using a sitz bath.
- Remove the contents from the package.
- Clamp the tubing.
- Fill the enclosed bag with warm water.
- Hang the bag on a hook by the toilet.
- Fill the container half-way with warm water.
- Lift the toilet seat.
- Place the container on the toilet with the overflow opening facing toward the back.
- Attach the tube into the opening in the container.
- Instruct the client to sit atop the container for 15 to 20 min.
- Adjust the water level and temperature of the water by opening the clamp and releasing more water into the container.
- Instruct the client to dry the perineum and apply a clean peripad when finished.
- Empty the container.
- Clean the container and allow to dry.

- Assess the perineum.
- Document the use of a sitz bath and assessment of the episiotomy site.

Heat Lamp

- Obtain a lamp with a 40-W bulb.
- Inform the client about the rationale and process of using a heat lamp.
- Instruct the client to empty the bladder, cleanse the perineum with a squeeze-bottle, and apply a clean peripad.
- Prepare the client on the bed in a lithotomy or side-lying position, with appropriate drapes as needed.
- Cover the lamp with a towel.
- Position the lamp 50 cm (20 in) away from the perineum.
- Tell the client to use the lamp for a 20-min period three times a day.
- Instruct the client to apply a clean peripad when finished.
- Assess the episiotomy site when treatment is completed.
- Document use of the heat lamp and assessment of the episiotomy site.

Immediately after delivery, the vagina appears edematous, bruised, stretchable, and may gape at the introitus. By weeks 4, the vaginal rugae return. Always remaining slightly larger than in the prepregnant state, the vagina returns to its prepregnant state by 6 to 8 weeks postpartum. The nurse should teach the client how to perform perineal exercises, such as Kegel's exercises, to assist in restoring vaginal and perineal tone and elasticity and to help reduce urinary incontinence. (See Exercise for instructions on performing Kegel's exercises.)

Homan's Sign

Assessment of the extremities should include examination of varicosities, deep tendon reflexes (DTRs), tenderness, and presence of edema or nodular areas on the legs. DTRs should be no greater than +1 to +2. Brisk DTRs (+3 to +4) may present hyperactive reflexes suggestive of PIH. Pretibial or pedal edema may be present, especially in the client with PIH.

Preconditions of blood hypercoagulability, severe anemia, traumatic delivery, and obesity are risk factors for de-

veloping superficial or deep vein thrombosis. Pain, erythema, or local swelling on the legs, especially the calves, may signify thrombophlebitis. The nurse should assess for Homan's sign as a positive indicator of thrombophlebitis (Figure 28-14). Early ambulation in current practice reduces the incidence of developing thrombophlebitis.

In addition, the client's legs should be assessed for sensation and mobility when epidural or spinal anesthesia has been administered. After delivery, the epidural infusion should be discontinued and the epidural catheter removed by the anesthesiologist or certified nurse anesthetist. (The catheter may be left in if the client will be undergoing a postpartum tubal ligation after delivery.) The nurse should assess for continuing abatement in the effects of the epidural or spinal anesthetic by determining the level at which the client feels sensation. The nurse may place a needle or sharp object on the client's torso to determine the level of tactile sensation, which should begin to approach T-11 or T-12 within the first hour of delivery. With appropriate return of mobility, the client should be able to move her toes and lift her buttocks off the bed within 2 to 4 hours after the discontinuation of the anesthesia.

Figure 28-14 The nurse assesses for Homan's sign by checking for calf pain when the foot is flexed.

Emotional Status

Many times the client experiences a sense of elation immediately after the birth of her baby. She is excited and relieved that labor is finally over. The mother may want to relive the experience by talking about the labor. If she went through a particularly long and painful labor and delivery, however, she also may be exhausted and need sleep and rest to restore her body to health. In this “taking-in phase,” the mother wishes to meet her own rest and nutritional needs before focusing her energy on her newborn. Chapter 29 provides a more in-depth description of the psychosocial phases the woman usually experiences after childbirth.

ASSESSING HOMAN'S SIGN

Homan's sign is assessed by straightening the client's leg flat on the bed. Place one hand on the knee, applying gentle pressure to keep the leg straight. Place the other hand on her foot, gently flexing the foot toward the body. The leg may be more easily examined when the woman slightly bends her knees and places the foot flat on the bed. The feeling of calf pain on flexion in either foot is a positive sign of thrombophlebitis. Use both hands on either side of the leg to palpate the calf for warmth and tenderness. Examine the calves for redness, hardness, or nodules along a vein. In addition, check the ankle and pretibial areas for edema.

PREVENTION OF THROMBOPHLEBITIS

Clients who remain in bed up to 8 hours should perform leg exercises to prevent formation of clots (thrombus) in the legs, which can develop into thrombophlebitis or thromboembolism. Deep vein thrombosis (DVT) is a severe condition in that a clot formed in the deep pelvis leg veins may fragment from the original clotted site and lodge into the lungs as pulmonary embolus. Superficial thrombophlebitis is noted as a hard, painful, warm, and red vein. Unlike DVT, there is little potential for pulmonary embolism with superficial thrombophlebitis.

Teach clients to flex and extend both feet and legs alternately while in bed. In a rhythmic motion, press then relax the backs of the knees into the mattress. Clients should also be taught other ways to prevent thrombus formation, such as keeping the legs uncrossed while seated, not flexing the legs at the groin, resting the legs without putting pressure on the back of the knees, wearing support hose or antiembolism stockings when varicosities are present, and padding pressure points during lithotomy positions.

Assess the client for signs of pulmonary embolism: dyspnea, coughing, and chest pain.

OTHER ASSESSMENTS

In addition to the basic postpartum assessments addressed in the approach using the acronym BUBBLE-HE, other important body systems need to be examined.

REFLECTIONS FROM A FAMILY

“The recovery period was difficult for me. I waited 9 months to be able to hold my baby for the first time, but I didn't get the chance to do it. I was bleeding a lot after the delivery so the doctor was rubbing real hard on my belly. I just couldn't deal with holding my baby when I was bleeding.”

Hemodynamic Status

A CBC may show marked leukocytosis, predominantly neutrophils, both during and after labor. The leukocyte count may increase during labor up to $25,000/\text{mm}^3$, increase to as high as $30,000/\text{mm}^3$ during a prolonged labor, and remain elevated for the first 2 days postpartum (AWHONN, 1996). The average leukocyte count is 14,000 to $16,000/\text{mm}^3$. A possible infectious process should be ruled out in the presence of such increased counts or an increase of more than 30% from baseline during the first 6 hours after delivery.

Hemoglobin, hematocrit, and erythrocyte levels may fluctuate during the first postpartum days. When considerable blood loss occurs, the levels may decrease below those measured before labor. Immediately after delivery the hematocrit begins to rise increase owing to hemodilution, increase in plasma volume, and dehydration. By 4 to 5 weeks, the hematocrit returns to normal values of 37% to 47% (AWHONN, 1996).

Blood coagulation normalizes a few days after delivery; profiles secondary to PIH remain elevated. Findings may include uterine clot formation at the placental attachment site or pooled blood in the uterine cavity. It takes 3 to 4 weeks for the blood volume to return to prepregnant levels, depending on the amount of blood lost during delivery. Cardiac output remains increased for at least 48 hours after delivery.

Integumentary System

The newly delivered client may wonder if the stretch marks or **striae** on her breasts, thighs, and abdomen will ever go away. The striae eventually fade to a pale color but may never completely disappear, especially in dark-skinned women (Figure 28-15). Massaging lotion, such as

aloe vera, may assist in lightening the color. Skin discolorations that appeared during pregnancy (e.g., chloasma) usually disappear toward the end of pregnancy. However, hyperpigmentation of the areolae and linea nigra may be permanent (Cashion, 1997).

After giving birth, the mother may complain of profuse perspiration, especially at night, which is normal during the first week as the body rids itself of excess fluid from pregnancy. The nurse should try to keep the mother warm and dry.

Some women may note an eruption of mild acne from hormonal changes (AWHONN, 1996). Women who suffered from pruritic urticarial papules and plaques of pregnancy, or PUPPP, will note a rapid regression of this uncommon pregnancy rash within 1 to 2 weeks after delivery (Gordon & Landon, 1996). Topical steroids is the standard treatment for controlling the intense pruritus.

Other changes include hair loss for the first 2 months after delivery. The mother may become concerned with the large amount of hair found at the bottom of the tub or shower; the nurse should reassure her that this is normal owing to hormonal changes. The increase in fine hair usually disappears; however, coarse or bristly hair may remain (Cashion, 1997). The rapid decrease in estrogen also induces the regression of vascular abnormalities, such as palmar erythema and spider angiomas.

Musculoskeletal System

Because the abdomen stretches during pregnancy, the mother's abdominal walls relax or become flaccid after delivery. When visually assessing and palpating the abdomen and fundus, the nurse may notice some degree of muscle separation, called **diastasis recti**, along the center of the abdomen. This separation is due to pressure from an enlarging uterus and may increase with each subsequent

Research Highlight

Differences between Primigravida and Multigravida Mothers in Sleep Disturbances, Fatigue, and Functional Status

Purpose

To determine whether differences occur in levels of functioning in primigravida compared with multigravida mothers.

Methods

A secondary analysis of a descriptive longitudinal study was done using an available sample of 31 pregnant women (primigravida, 12; multigravida 19). The mothers were tested during the third trimester and the first month postpartum for their level of functioning in the household, sleep efficiency, and fatigue and vitality.

The level of functioning was determined by the Inventory of Functional Status tool, an 11-item, Likert-type instrument by which the subjects rate their ability to perform certain activities of daily living. On a four-point scale, subjects described their ability to perform activities, such as cooking and shopping, from “not at all” to “fully.”

Measurements of sleep disturbance were conducted using a sleep efficiency index taken from an electroencephalogram (EEG) machine during two consecutive nights during the two time periods in the study.

Fatigue and vitality were measured by a self-reporting tool called the VAS Fatigue scale, consisting of 18 items along a 100-mm visual analogue line. Subjects rated 13 items relating to fatigue and 5 items related to vitality.

Findings

Primiparas experienced increased fatigue, less vitality, and decreased sleep efficiency over time compared with multiparas. Multigravidas, indeed, experienced increased levels of household functioning compared with primigravidas.

Nursing Implications

It is important for nurses to provide anticipatory teaching to first-time mothers to help them transition into motherhood. Integrating the new role as mother may be more difficult for the primipara than expanding the already acquired role of mother may be for the multipara woman.

Water, M. A., & Lee, K. A. (1996). Differences between primigravidae and multigravidae mothers in sleep disturbances, fatigue, and functional status. *Journal of Nurse-Midwifery*, 41, (5), 364–367.

pregnancy. The severity depends on the client's general physical condition, muscle tone, timing between pregnancies, parity, and other circumstances that distend the uterus and abdomen. Multiple gestation, macrosomia, and hydramnios also distend the uterus to a larger than average size, making it difficult for the client to regain her pre-pregnant muscle tone.

Many mothers complain of fatigue after childbirth. They require time to recuperate and recover from the effects of labor and delivery. Primiparas and multiparas often have different physical and emotional needs. (See the accompanying Research Highlights.)

Activity

Once the puerpera is stable, the nurse should encourage her to ambulate often. The advantages of early ambulation are well established (Box 28-4). Women who deliver vaginally often are able to ambulate to the restroom within a few hours of delivery.

Although the nurse must be ready to assist a patient out of bed, the client should be offered the use of a wheelchair, when necessary. Before rising from the bed, the client should be assessed for dizziness and motor weakness from weak knees or legs. Ask the client how she feels

Box 28-4 Advantages of Early Ambulation

In general, the client will feel better and stronger if she begins to ambulate early after delivery. The following are the specific medical advantages of early ambulation:

- Fewer bladder infections.
- Less frequent constipation.
- Decreased incidence of deep vein thrombosis.
- Decreased incidence of pulmonary embolism.

when she rises from a recumbent position and if she is able to stand straight without assistance. When the mother is very tired or has received an epidural or analgesics that may cause drowsiness, she may not have the ability to stand and walk independently. When assisting the client in getting up from bed for the first time, the nurse should accompany her because she may experience orthostatic hypotension and be at risk of falling.

The client should be encouraged to return to normal activities of daily living as soon as possible. She should be able to provide independent self-care before going home. Once home, depending on the physician's instructions, she may perform light household chores. Family members or friends should take on the primary responsibility for major household chores, however, such as meal preparation. The client should be cautioned against driving for 10 to 14 days, especially if she received anesthesia or is taking analgesics that cause drowsiness. When episiotomy has been performed, the client should shower instead of using a tub until the incision has healed and the flow of lochia has diminished.

Exercise

Although vigorous exercise should be delayed until the client feels well-recovered, a woman who has had an uncomplicated vaginal delivery can begin moderate exercise soon afterward. The client may perform mild stretching and flexing of muscles, especially abdominal muscles, which may relieve tension and muscle strain (Figure 28-16). Care should be emphasized because joints do not stabilize until 6 to 8 weeks postpartum. Other safe exercises include Kegel's exercises, deep breathing, and pelvic tilts. Exercising too much and too soon may result in an increase in bright-red vaginal blood flow. The client must not lift anything heavier than her baby for the first 2 weeks after childbirth. She should avoid climbing stairs for about 2 to 3 weeks.

A safe healthy exercise program should include 30 to 60 minutes of aerobic exercises that increase the heart

Nursing Tip

PAMPERING YOURSELF POSTPARTUM

Suggest to the new mother to prepare a "Personal Postpartum Pampering Plan Checklist" to follow once she returns home after childbirth. A sample plan follows:

- Ask friends and family to cook meals (double menus, and freeze half). Ask friends to bring food if they are coming to visit, or let them cook for you when they arrive.
- Wear a gorgeous bathrobe, or wear comfortable clothing.
- Take a warm, soothing bath. Have someone else watch your baby during this break.
- For routine household chores, hire cleaning help ask friends or family, or hire a neighborhood teenager.
- Get out of the house. Go shopping. Take a walk in the park. Go to the local fitness club. Call other new mothers to accompany you, and take the babies together.
- Take frequent naps.
- Enjoy your baby.

rate at least four times a week. Even exercising 1 hour a day, such as taking a brisk walk while pushing the baby in a stroller or carrying the infant in a sling will burn off 400 calories. The exercises should include abdominal and back strengthening exercises to support the organs, protect the back, improve posture, and improve appearance. Abdominal exercises can include those that isolate different abdominal muscles, such as stomach crunches. The addition of weight-lifting training for all major muscle groups at least three times a week will assist in building muscle. Muscles operate at a much higher metabolic rate than does fat therefore more calories are burned (Gilbert, 2000).

New mothers may report that they do not have the time or ability to exercise. The nurse can suggest that she find another mother to trade babysitting favors or a neighborhood teen to help watch the baby. New baby strollers allow the mother to jog or run with her baby. The mother may not fit into the clothing she wore at very early in her pregnancy. Although she may not relish the idea of wearing maternity clothes again, she can wear pants with an elastic waist and a loose top.

**A. Deep breathing**

Breathe deeply, expanding your abdominal muscles; then slowly exhale, tightening your abdominal muscles.

**B. Arm raises**

Place your arms at right angles to your body: slowly raise them, touch your hands together, then slowly lower your arms.

**C. Pelvic tilt**

Place your arms at your sides and your feet flat on the floor. Tighten abdominal and buttock muscles, press back into floor, then tilt pelvis toward ceiling.

**D. Head raises**

Lie with your knees flexed, feet flat on the floor. Contract your buttocks, lift your head.

**E. Knee flexes**

Flex one knee towards your abdomen; lower your foot towards the floor, then straighten your leg.

**F. Leg raises**

Straighten legs and point toes. Slowly raise then lower one leg and then the other using your abdominal muscles.

Figure 28-16 Postpartum exercises

Weight Loss

Although the client's figure does not automatically return to prepregnancy form, there is immediate loss of weight after delivery, representing the combined weights of the infant, placenta, and amniotic fluid. Average weight loss is 12 to 15 lb after delivery. An additional 5 lb is lost during the first week postpartum owing to extracellular fluid diuresis. Another 10 lb may be lost in the next 6 weeks.

Most women return to their prepregnancy weight 6 months after delivery; however, postpregnancy weight loss is difficult to achieve for some women. The client's ability to lose weight is related to the amount of weight gained during pregnancy, number of pregnancies, smoking, and the opportunity to return to work outside the home.

Exercises that flatten the stomach muscles and eating a healthy diet will help the client return to her prepregnant

size and weight. The client should keep in mind that because the skin has been stretched greatly during pregnancy, the abdomen may not return to a totally flat appearance. The stretched muscles also may not return completely. First, the client should set goals and tailor her exercise and nutrition programs to her needs. She should include foods from the four basic food groups, increase her fluid intake, and avoid eating junk food.

The main approach to losing weight should be to change her metabolism gradually with a healthy diet. She should avoid fad and starvation diets that include in their regimens the practice of skipping meals. She should calculate her basic daily caloric needs, which is the number of calories of balanced nutrition she can consume to maintain a feeling of well-being without gaining weight. The diet should contain 1,500 calories or more, while the client

Client Education

Performing Kegel's Exercises

Pregnancy, childbirth, and being overweight can weaken the pelvic floor muscles and cause leaking of urine and stool. The muscles are weak if the client notes symptoms such as leaking urine when she sneezes, coughs, or lifts heavy objects. As with other muscles, exercises can make the pelvic floor muscles stronger. The pelvic floor muscles between the legs attach to the front, back, and sides of the pelvic bone. Two pelvic muscles do most of the work. The largest muscle stretches as does a hammock; the other is shaped like a triangle.

You should teach the client to perform Kegel's exercises properly. The client should be instructed to find the muscles that are stretched using two methods:

1. She should try to stop and start the flow of urine when sitting on the toilet.
2. She should imagine she is trying to stop passing gas or complete a bowel movement. She should squeeze the rectal muscles she would use. She will feel a pulling sensation when she is using the correct muscles.

There are two types of Kegel's exercises: quick and slow. In doing the quick ones, the client should

tighten and relax the muscles rapidly. In doing the slow ones, she should tighten the muscles for 5 to 10 seconds and then relax.

The client should work up to doing 10 to 15 repetitions each time, three times a day. It is important to instruct the client about the following:

- She should not overdo exercising the muscles.
- She should not hold her breath.
- She should take care not to tighten other muscle groups, such as the stomach, buttocks, and legs. Squeezing the wrong muscles can put more pressure on the bladder control muscles.

Kegel's exercises can be done anywhere: sitting in a chair while watching television, standing in the kitchen cooking, or sitting in a car while stopped at a red light. The client should do the exercises in three different positions: sitting, lying, and standing. Doing so makes the muscles the strongest.

The client should be advised to have patience in seeking results. Improvement in bladder control may not occur for 3 to 6 weeks but may occur earlier. The client should try to tighten her muscles before sneezing, lifting, or jumping to protect them from more damage.

simultaneously increases the intensity and duration of exercise (Sears & Sears, 2000). Breast-feeding mothers need at least 500 extra calories for lactation. Abstaining from only one nonnutritious snack a day (e.g., one chocolate chip cookie contains about 100 calories) will reduce the daily caloric intake by 500 calories, or 3,500 calories a week, which is enough to lose 1 lb of weight. The mother can keep track of her success by monitoring her eating habits and weekly weight loss.

The client must approach losing weight in positive way and try to do it slowly (about 1 lb a week). The slower the weight loss, the better she will feel and the more likely the weight will stay off. The exercise program will invigorate her physically and mentally. Although the changes will be gradual, she will feel satisfied with herself once she reaches her weight and fitness goals.

Sexuality

There is no prescribed time when to resume sexual intercourse after childbirth. Mothers are warned to avoid sexual

activity until their episiotomy has healed, which can take 6 weeks or more, or until they are comfortable and desire to have sex. Some women feel like resuming sexual activity as early as 2 weeks after birth; others may wait for 5 or 6 months until they are ready physically and emotionally. Bleeding and infection are less likely to occur once 14 postpartum days have passed. Because of perineal discomfort or swelling, some mothers often wait to resume sexual intercourse until after the 6-week checkup.

Several factors affect a woman's desire for sexual activity after the birth of her child. The birth experience places incredible stress on the body. Episiotomy stitches (if present) will have tightened the vagina, making it less elastic at first so that intercourse may hurt the first time after delivery. Breast-feeding mothers may have decreased estrogen production, leading to vaginal atrophy and dryness, making sexual intercourse difficult and painful.

The physical demands of taking care of a newborn infant with frequent feedings often leave both parents deprived of sleep. The new father may feel some cautiousness because he may be afraid of hurting his partner

TIPS FOR MAKING SEXUAL INTERCOURSE AFTER BIRTH EASIER

You can give the client the following tips to educate her on how to make sexual intercourse easier after delivery:

- Try positions that may be more comfortable for the newly delivered mother. The woman-on-top position gives her greater control over the depth of penetration and allows her to move in a way that is most pleasurable for her.
- Use a water-based lubricant to ease vaginal dryness.
- Try having sex at different times of the day if you are too tired when you go to bed at night.
- Move your baby into another room to preserve the privacy and intimacy of your bedroom.
- If sex is too painful, engage in noncoital sex as a safe and satisfying alternative.
- Keep the lines of communication open by talking about and exploring new ways to satisfy each other physically.

during sexual activity. Both partners must communicate openly about their feelings and discuss what is compatible and what is painful. It is important to convey to each other that a lack of interest or hesitancy is not indicative of a lack of interest or love in their marriage. The first attempts at sexual closeness can include massaging, cuddling, and touching without requiring penetration. Both partners will need to be sensitive and approach sex slowly according to their own timetable (Mayo, 2000).

The nurse should teach the new mother that, as a rule, it is acceptable to wait to have sexual intercourse after childbirth until both partners feel comfortable and secure. Sex after childbirth may not be exactly the same as it was before but can be satisfying. The client should use a water-based lubricant, such as K-Y jelly, for vaginal dryness to assist in making sexual intercourse easier and more pleasurable. The new mother may experience feelings of unattractiveness and loss of sexual appeal. She may be inhibited and hesitant to resume sexual openness with her partner. The nurse should inform the mother that these feelings are natural and that she should take it slowly and be patient with herself. The mother who is nursing may feel a decreased sex drive because breast-feeding produces lower levels of estrogen, the hormone that stimulates the sex drive. The breasts also are more sensitive to

Critical Thinking

Too Tired for Sex

New parents often feel overwhelmed by the birth of a child, which brings major changes into their lives. Suddenly, there are numerous diaper changes and 2 a.m. feedings. New parents may complain of their baby crying during the night, every night. They stagger into bed, knowing that the next feeding is right around the corner. Because of sleep deprivation, the last thing they may be thinking about is having sex.

You can teach the client that after a few months, the new baby will settle into a routine. Inform her that the baby's new schedule eventually will allow her and her partner to again have a satisfying sexual life. Provide the client with solutions for the problems that new parents face in resuming their sexual relationship. One solution is not to confine sex only to nighttime hours. The partners should try to make time for each other during the day, for example, when the baby is napping. They can try waking up earlier in the morning to provide themselves with some quiet, private time to enjoy before facing the responsibilities of the day.

How would you counsel new parents who confide their frustration in resuming regular sexual relations?

stimulation and might be tender to touch. The milk might leak or let-down might occur during breast stimulation and orgasm; wearing a nursing bra or nightgown or having a towel nearby may help with this problem.

Contraception

Many women may not think about contraception immediately after birth, or they may be waiting for their 6 week check-up, or for the return of menses. However, many women resume sexual activity prior to the 6 week check-up and may get pregnant before return of menses. Therefore, it is important for the nurse to discuss contraception before discharge from the hospital.

The decision about contraception depends on many things: the client's and her partner's motivation, the number of children desired, the state of the client's health, whether she is breast-feeding, and the couple's religious beliefs.

The use of oral contraceptives while lactating is controversial (Bowes, 1996). It is thought that oral contraceptives can suppress milk production. When prescribed, providers often suggest starting contraceptives after breast-feeding

has been firmly established. The mother who is not breast-feeding can begin to take oral contraceptives as early as 2 to 3 weeks after delivery.

Other choices in steroid contraception include depot medroxyprogesterone acetate (DMPA), which is given IM every 3 months. The major advantages of this method are patient convenience and easy administration. Another form is the insertion of levonorgestrel subdermal implants (Norplant). The normal time of insertion is 4 to 6 weeks postpartum; insertion also can be done immediately after delivery. In one study, implants placed 4 weeks after delivery showed no effects on lactation (Bowes, 1996).

If the client chooses to use a barrier method, such as a diaphragm, she will need to be fitted for the proper size at her 6-week postpartum checkup even if this method was used previously. The cervix will require time to return to the more normal prepregnancy size. The breast-feeding woman will experience vaginal dryness and tightness secondary to involution, which will make fitting more difficult. Use of the diaphragm also requires a spermicidal lubricant.

If an intrauterine device (IUD) is the method of choice, it usually is inserted after the 6-week postpartum checkup. Some providers may decide to insert it in the immediate postpartum period because fewer perforations occur when it is inserted between weeks 1 and 8; however, the risk of expulsion is higher, with rates from 10% to 21% (Bowes, 1996).

If the couple is undecided on the method of family planning or is postponing oral contraceptive therapy until 6 weeks, the use of condoms or in combination with spermicides may be a good choice. If the couple is sure about permanent sterilization, this can often be accomplished during a cesarean delivery or 24 to 48 hours after delivery. The timing must be carefully planned. Immediate postpartum sterilization often is associated with guilt and regret (Bowes, 1996). If the couple decides to postpone the procedure until 6 to 8 weeks after delivery, it will provide them time to ensure their infant is healthy and to be sure they are making the correct decision.

Pain Management

After delivery, the mother is at risk for various types of discomfort. She may complain of perineal discomfort, uterine cramping, sore nipples, or a headache if she received incorrectly administered spinal anesthesia. A great source of discomfort is from the afterpains related to uterine contractions.

Postpartum medications commonly given for episiotomy or uterine pain may be oral nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen (Motrin), 400 to 800 mg orally every 4 to 6 hours as needed. Acetaminophen with codeine (Tylenol with Codeine) may be

Nursing Tip

RELIEVING AFTERPAINS

Suggest to the client an exercise called mini head lifts that can assist in managing afterpains. The client should be instructed to lie down with her knees bent. She should take a deep breath and as she exhales, lift her chin so it rests on her chest. She should perform the head lifts 5 to 10 times each time afterpains are felt, several times a day, to encourage uterine contraction.

given for more severe cramping. Emptying the bladder every hour or so is an effective measure to reduce afterpains. Another useful method is for the client to lie on her abdomen with a pillow against her lower abdomen because this creates pressure that keeps the uterus contracted (Jordan, 1998).

Topical anesthetics (e.g., Chloroprocaine [Nesacaine]) may provide temporary relief from episiotomy pain. The anesthetic spray should be used sparingly 3 to 4 times a day after voiding. As previously mentioned, ice packs and sitz baths also may provide relief for the mother. (See the accompanying Client Education box for herbal remedies.)

Immune System

Before discharge, the nurse should check the client's record for proper immunization status, particularly against rubella. If the mother is rubella nonimmune with a titre below 1:8, she should be vaccinated before leaving the hospital. The client must sign a consent form to receive the vaccine. Because the effects of congenital rubella syndrome (CRS) have devastating teratogenic effects on a fetus, it is important that the nurse counsel the client

Nursing Alert

ASSESSING UNRELIEVED PERINEAL PAIN

When medications do not relieve complaints of perineal pain, you should assess the site more carefully. Pain unrelieved by other means may indicate a possible perineal hematoma. Episiotomy pain normally is reduced and asymptomatic by 3 weeks after delivery. The postpartum client with a perineal hematoma will be in severe pain, often unable to sit comfortably.

Client Education

Perineal Comfort Measures

A midwife suggests alternative nonpharmacologic methods of relieving perineal discomfort:

- Use of herbal mixtures for postpartum perineal discomfort: shepherd's purse, uva-ursi (bearberry), comfrey leaves and roots, sea salt, *Calendula* flowers, rosemary, lavender flowers, fresh garlic, myrrh, and ginger.
- A tea bag concoction with powdered comfrey and plantain on the perineum can relieve perineal tearing and soreness. The mixture can be placed in unbleached paper coffee filters and sealed or infused together (sewed by hand or glued). Pour boiling water over the coffee filter and tea bag in a small bowl and let steep for about 10 minutes. Check the temperature and when comfortable, press out some of the excess water and apply directly onto the perineum. Leave on until it becomes cold. Dip it into the warm water again, and use the other side. Can be repeated with the same tea bag three times on each side.
- A homemade-type recipe called "people paste" or "goose poops" is placed directly on the area causing the most discomfort. The base is made of three equal parts of powdered slippery elm, goldenseal, and myrrh. Comfrey and plantain can be added for vaginal tears. Clover powder can be added for stronger pain relief. Honey, molasses, aloe vera, and water can be added to the base. Combine the mixture, keeping it a little on the dry side so it can be shaped into a teardrop shape. Place the mixture on the perineum when relief is needed.
- Soothing sitz bath herbs that can be used include a mixture of 2 oz of comfrey, 1 oz of uva-ursi (helps prevent infection), one eighth to one fourth cup of sea salt, 1 oz of shepherd's purse, and 1 clove of garlic.
- Place lukewarm comfrey tea in a squirt-bottle to cleanse the perineum in the bathroom to help reduce healing time.
- Use frozen pads soaked with comfrey tea to reduce pain and swelling. Make a strong pot of comfrey tea. Bring about 2 quarts of water to a boil; remove from heat; and add 8 to 10 large, fresh, clean comfrey leaves, or 0.5 to 1 oz dried leaves. Let steep overnight or at least 4 to 5 hours. Fold 4 to 6 sanitary pads in half and hold the top and bottom ends together, with the adhesive on the inside, or cut up oversized pads to make two smaller ones. Dip the pads into tea, soaking the middle. Lay dipped pads side by side in a container (a shallow baking pan or plastic container). Place waxed paper or saran wrap on top of the pad layer and then make another dipped pad layer on top of that (like making a lasagna). The wax paper will keep the pads separated and prevent them from sticking together. Place the entire container of pads in the freezer. To use, wrap one frozen pad in a soft, white paper towel, washcloth, or layers of sterile gauze to prevent freezer burn. Place in a waterproof pair of underwear (e.g., Kotex Personals) or disposable underwear. Wear the underwear with the frozen pad. Use a new pad each time you void or for about 45 to 60 minutes until it becomes soggy.
- Use tea tree oil to promote tissue healing, relieve itching, and reduce the risk for infection. Mix three drops of tea tree oil (essential oil only) and 1 cup of distilled water. Place in a spray-bottle and mist onto the perineum.

against becoming pregnant again before receiving the vaccine—if she has declined to receive it in the hospital—and for the next 2 to 3 months after receiving the vaccine (ACOG, 1992). The client should know that she may experience a brief period of rubella-like symptoms such as a rash, lymphadenopathy, joint symptoms, and a low-grade

fever 5 to 21 days after the vaccination. The vaccine is safe to give to breast-feeding mothers.

Unsensitized mothers who are RH₀(D)-negative and have given birth to an infant who is Rh-positive also should receive 300 µg of RH₀(D) immune globulin (RhoGAM) within 72 hours of delivery (Table 28-6) (ACOG, 1990b).

Table 28-6 Pharmacology in the Postpartum Period: Rh_o(D) Immune Globulin Vaccination

Pharmacologic Class	Immune serum
Therapeutic Class	Anti-Rh _o (D)-positive prophylaxis agent
How Supplied	IM, 300 µcg vial (standard dose); 50 µg vial (microdose)
Indications for Use	Anti-Rh _o (D)-positive prophylaxis agent during situations such as abortion, miscarriage, ectopic pregnancy, postpartum
Chemical Effect	Suppresses active antibody response and formation of antibodies to antigens from Rh-positive fetal blood, which results in erythroblastosis fetalis
Therapeutic Effect	Blocks the adverse effects of Rh-positive exposure; prevents sensitization and subsequent development of antibodies to antigens from Rh-positive fetal blood, which results in erythroblastosis fetalis
Dosage	300 µg vial (standard dose) IM if fetal erythrocyte count <15 mL; provide more than one vial if fetomaternal hemorrhage is >15 mL
Side Effects	Low fever, anaphylaxis, discomfort at injection site
Nursing Considerations	Must administer medication within 72 hours of delivery; obtain confirmation of fetal blood type from sample of cord blood and maternal blood type before administration
Client Teaching	Ensure client knows the reason for receiving RhoGAM
Laboratory Finding	Rh _o D is negative and direct Coombs is negative test, give RhoGAM

RhoGAM is administered even if the mother received RhoGAM in the antepartum period. Depending on the extent of the hemorrhage and exchange of maternofetal blood, a larger dose of RhoGAM may be necessary.

Although standard precautions should be practiced with all clients, particular care must be taken with the postpartum client who has the human immunodeficiency virus (HIV) or acquired immunodeficiency syndrome (AIDS). Personal protective gear (e.g., latex gloves and safety glasses) should be worn to prevent the transmission of blood and other bodily fluids. The nurse should advise the mother to avoid contact of her bodily fluids with her

Client Education

Congenital Rubella

Although the incidence of congenital rubella has decreased over the years, about 10% to 20% of women are susceptible. Congenital rubella is a serious disease, with the fetus experiencing severe physical abnormalities.

You have the opportunity to teach the client that if she is not immunized, the rubella virus can cross the placental barrier. The frequency and intensity of infection depends on the timing of the infection. The more severe infections occur in the first 4 weeks of pregnancy, that is, at a time when she will not know she is pregnant. During this time, half of infants exposed to the virus will become infected. The rate decreases to less than 1% when the infection occurs after the first trimester.

Inform the client that a wide variety of severe abnormalities result from congenital rubella syndrome. The four most common problems are deafness, eye defects, central nervous system (brain) defects, and cardiac malformations (patent ductus arteriosus). Other abnormalities include a small head (microcephaly), mental retardation, susceptibility to pneumonia, small size (intrauterine growth restriction), enlarged liver, and blood dyscrasias (hemolytic anemia and thrombocytopenia).

You can instruct the client about prevention. Prevention of congenital rubella can be obtained by receiving the rubella vaccine. About 95% of women who receive it become immunized. Inform the client that there are only a few rare side effects from the vaccine, for example, a low-grade fever, fatigue, and arthralgia. When the vaccine is given immediately after delivery the effects may be delayed for up to 21 days (Bowes, 1996). The vaccine is not contraindicated in women who are breast-feeding.

infant's mucous membranes and open skin areas. The client also should be cautioned not to breast-feed and thus take the risk of transmitting HIV to her infant (Duff, 1996). Clients with HIV or AIDS may receive medications postpartally, such as zidovudine.

Family Considerations

When a subsequent child is born into the family, the other children must adjust to the new family member. Mothers

Client Education

Receiving RhoGAM During Pregnancy

You should educate the client by telling her that if she has Rh-negative blood, she may need to receive RhoGAM after delivery. If the father's blood is Rh-positive, the blood of the baby also may be Rh-positive. If the baby has Rh-positive blood, small amounts of the baby's blood may have escaped into the mother's bloodstream during delivery. Natural antibodies are then released into the bloodstream as the body tries to destroy the foreign Rh-positive cells from the baby. When this happens, the client will become permanently sensitized to Rh-positive blood cells. If she has an Rh-positive baby in a future pregnancy, her body will have sensitized antibodies that will attack her baby's blood cells during pregnancy. Her baby may then develop a disease called erythroblastosis fetalis.

Instruct the client that to avoid this potentially fatal disease in an unborn baby the immune globulin RhoGAM should be given after the first pregnancy. Once her body becomes sensitized, it can never be reversed, even if given RhoGAM. Once she receives RhoGAM, future pregnancies with Rh-positive babies will not be affected because her blood will be free from anti-Rh-positive antibodies.

who have other children should be encouraged to include them in the bonding process. Other children, depending on their ages, will be curious about their new brother or sister.

Older siblings may be jealous of a new baby in the family and thus may demonstrate sibling rivalry. Signs of such behavior may include squabbling or jealousy among brothers and sisters, rejection of the new baby, anger, and introversion. An only child and children under 5 years of age may resent the new baby and may exhibit regressive behavior such as bed-wetting and biting. For instance, the toddler who is potty-trained, may revert back to dirtying the diaper, or the school-aged child may begin sucking on a pacifier again or begin biting others. This is the child's way of coping with a situation that he or she may not be able to handle in any other way. The other children may be jealous and afraid that the new baby will take away their mother's and father's love and attention.

Sibling rivalry is normal. When children live together, they often feel a need to compete and thus display emo-

tions of jealousy and anger. In some instances, sibling rivalry can be positive because small doses of competition can be healthy by teaching children how to negotiate. Children can learn to love someone and still be able to disagree with their point of view.

To minimize sibling rivalry, caregivers should begin to discuss the new baby's arrival before the actual birth. The other children should be encouraged to take part in preparation for the baby's arrival. Another suggestion is on birth of the infant, the older brother or sister can receive a present from the new baby as a way to show them they are important and loved. Care activities such as diaper changes and feedings can include an older sibling (Figure 28-17). Even toddlers can help by bringing a clean diaper to mommy, and so on.

At times when she is not caring for her newborn, the mother should plan on reserving personal time for herself and older children. The new mother needs time to rest and possibly reflect on the changes in her life and family. Although a newborn infant demands a great amount of attention, the new mother needs to ensure that she spends time with her other children. Her children need to know that their mother still loves them and has time for them.

Family pets (i.e., a dog or cat) also can begin to act strangely when a new baby is brought into the home. They also can be prepared to adjust to the change. Before bringing the baby home from the hospital, allow the pet to sniff the baby's scent on a piece of the baby's clothing or receiving blanket. This way, the animal can become familiar with the smell.

Figure 28-17 Encouraging older siblings to be involved in the new baby's care through simple tasks such as holding, comforting, and playing with the new baby may help them feel less threatened by this new family member.

Research Highlight

Sibling Behavior with a Newborn: Parents' Expectations and Observations

Purpose

To investigate parents' expectations and perceptions of their firstborn child's behavior before and after the birth of their second child.

Methods

As part of a larger longitudinal study, a sample of 70 couples with one child aged 6 years or younger completed two questionnaires plus a demographics form at home during two time periods (late in pregnancy and about 4 weeks after the birth of the second child). Both developed by Gullicks, the first questionnaire was the Older Child Expectation (27 items)/Older Child Observations inventories (23 items) and the second one was the Sibling Behavior Inventory (50 items). The questions were the same at both times, although those dealing with pregnancy were asked only the first time. For each question on the Older Child Expectation/Older Child Observation inventory, the parents rated behaviors at the two different times, responding on a 5-point scale ranging from 1, "Will almost never behave that way," to 5, "Will almost always behave that way."

Findings

The authors determined that "Parents expected their firstborn child's behavior to be more negative than they actually observed it to be." There were similar levels of appropriate behaviors particular to the developmental level in their firstborn before and after the second child's birth.

Nursing Implications

Findings indicated that parents expected less positive behavior from their first child, with behaviors changing little over time. Working closely with parents, nurses may help guide parents toward realistic expectations of their firstborn child, helping to encourage positive behaviors and coping with the arrival of the baby as a new member of the family.

Gullicks, J. N., & Crase, S. J. (1992). Sibling behavior with a newborn: Parents' expectations and observations. *Journal of Obstetric, Gynecologic, and Neonatal Nurses*, 22, (5), 438-443.

Documentation

Daily care of the woman after delivery encompasses assessments of the same parameters, such as episiotomy, lochia, and so on. If written in narrative format, the nurse may use the acronym BUBBLE-HE to assist her in ensuring all pertinent assessments are charted completely at least every shift or more frequently, depending on the client's acuity and the facility's policy on nursing documentation (Figure 28-18). In general, nursing documentation should follow the nursing process.

Flowcharts facilitate the documentation process (Figure 28-19). The use of flowcharts and graphs provide the ability to quickly note trends and changes from one shift to another. Columns at the top of the flowchart provide ease

Figure 28-18 Careful documentation is the closing step of each assessment encounter.

in checking off a box or placing the nurse's initials, as appropriate.

POSTPARTUM COMPLICATIONS

In caring for the low-risk healthy woman after delivery, the nurse must monitor and prevent the development of complications that may occur during the puerperium. The most common complications discussed in this section include hemorrhage, perineal hematoma, and infection.

Postpartum Hemorrhage

Obstetric hemorrhage is the most common complication in the postpartum period and is one of the three leading causes of maternal morbidity and mortality in the United States (ACOG, 1990a). Hemorrhage may be classified as early or late. Acute or early hemorrhage may occur within the first 24 hours after delivery, with the first 2 hours being the most crucial. Late hemorrhage occurs after 24 hours after delivery and before 6 weeks postpartum. Late postpartum hemorrhage is most likely to present on days 6 to 14 after delivery (ACOG, 1990a). Normal blood loss during an uncomplicated vaginal delivery is 500 mL or less (Benedetti, 1996). Hemorrhage is defined as blood loss greater than 500 mL for a vaginal delivery; however, providers tend to underestimate the measured blood loss. Hemorrhage is greater than the normal blood loss. The diagnosis of postpartum hemorrhage is based on the clinician's judgment of estimated blood loss.

Causes for early hemorrhage include retention of placental fragments, uterine atony or hypotonia, trauma or lacerations of the birth canal or lower genital tract, systemic coagulopathies, uterine inversion, and uterine rupture. Other risk factors are cesarean delivery, unusually large episiotomy, use of operative devices (e.g., forceps and vacuum extraction), precipitous labor, atypically attached placenta, and fetal demise. Risk factors for bleeding caused by uterine rupture include previous uterine surgery and internal podalic inversion (ACOG, 1990a).

The most common reason for early postpartum hemorrhage, accounting for 80% to 90% of the cases, is uterine **atony**, or lack of uterine muscle tone. Uterine atony occurs when the uterus fails to contract and becomes boggy. The failure to contract leads to continued bleeding from the site of placental insertion. Risk factors for uterine atony include the following:

- Uterine overdistention (e.g., from hydramnios, multiple gestation, or macrosomia)
- Uterine anomaly
- Poor uterine contractility (often present in women with high parity, rapid or prolonged labors, Pitocin-

induced or augmented labors, use of uterine-relaxing medications [e.g., halogenated agents, magnesium sulfate, or general anesthetics], chorioamnionitis, and a history of uterine atony)

- Placentas that do not separate wholly at the site usually leave behind fragments that prevent adequate uterine contraction and subsequently lead to bleeding. Risk factors for retained placental fragments include the following:
- Mismanagement of the third stage of labor
- Second trimester delivery related to an immature placenta
- Abnormal uterine anatomy
- Abnormal placental implantation (e.g., placenta accreta or placenta percreta)
- Abnormal placental implantation site (e.g., succenturiate lobe)
- Placental malformation

Another cause for bleeding are tears or lacerations of the birth canal from the following (ACOG, 1990a):

- Operative or instrumental deliveries (e.g., vacuum extraction and forceps delivery)
- Precipitous delivery
- Abnormal tissue or scarring (e.g., conization secondary to abnormal cervical cells)
- Extensions of perineal lacerations
- Varices
- Hematomas of the vulva or vagina
- Abnormalities of the soft tissue

Bleeding also may be related to systemic coagulopathies, such as disseminated intravascular coagulation (DIC). The risk of DIC is higher in women having PIH, abruptio placenta, clotting abnormalities, thrombocytopenia, fetal demise or retention of a dead fetus, amniotic fluid embolism, and infectious processes, and in whom anticoagulants have been used.

Nursing Tip

SIGNS OF DISSIMINATED INTRAVASCULAR COAGULATION

Bleeding from other nongenital sites in the body, such as venous puncture sites, may suggest the development of disseminated intravascular coagulation (DIC).

Table 28-7 Signs and Symptoms of Shock

Signs and Symptoms	Causes
Hypotension	• Stroke volume and cardiac output
Tachycardia, weak thready pulse	• Symptomatic vasoconstriction; chemoreceptor stimulation, progressing to medullary respiratory stimulation secondary to metabolic acidosis
Decreased pulse pressure	• Stroke volume
Cool, pale, clammy skin	• Peripheral vasoconstriction
Cyanosis	• Excessive vasoconstriction of reduced hemoglobin in blood
Oliguria or anuria	• Renal perfusion
Extreme thirst	• Extracellular fluid
Hypothermia	• Metabolism
Apathy, lethargy, confusion, coma	• Cerebral blood flow, acidosis
Irritability and anxiety	• Epinephrine secretion; hypoxia

Postpartum hemorrhage can be very rapid, and often is very dramatic. Health care providers must be able to recognize the signs and symptoms early and respond immediately. During the immediate postpartum period the nurse bears great responsibility in assessing for potential hemorrhage. Knowledge of predisposing factors and careful examination of the client alert the nurse to the potential for hemorrhage and help anticipate it, preventing further complications. Many cases of postpartum shock are not recognized until the client is in moderate to severe shock, which requires more aggressive treatment to reverse. Table 28-7 lists the signs and symptoms seen in shock and the reasons for these conditions. Table 28-8 differentiates among mild, moderate, and severe shock.

ASSESSING FOR DECREASED PERFUSION

To subtly test for decreased perfusion in the extremities, squeeze the hypothenar area of the hand for 1 to 2 seconds and then release the pressure. If the client has a normal volume, the skin will initially blanch and then return to a normal color after 1 to 2 seconds. Circulatory refill in the blanched hand will be delayed in the client with a 15% to 25% volume deficit.

Management of acute hemorrhage includes determining the cause of the bleeding, estimating blood loss, and trying to control the bleeding. Hemorrhage often occurs immediately before or after delivery of the placenta (Beneditti, 1996). Treatment of hemorrhage is based on identification of the classification and percentage of blood loss (Table 28-9).

Clients with Class 2 hemorrhage will begin to demonstrate clinical signs, such as tachycardia or tachypnea (Beneditti, 1996). Tachypnea is considered a nonspecific and early sign of mild volume deficit. Minute ventilation often is double its normal rate and should be interpreted as a sign of impending problems. Blood pressure changes include orthostatic hypotension and decreased perfusion to the extremities. The pulse pressure begins to narrow; when it decreases to 30 mm Hg or less, the client may be experiencing further volume loss (Beneditti, 1996).

The pregnant client with a Class 3 hemorrhage will begin to exhibit marked tachycardia (120 to 160 bpm) and tachypnea (30 to 50 bpm). Overt hypotension is present, and the nurse may note cool clammy skin. The client with a greater than 40% blood loss has a Class 4 hemorrhage. The nurse may not be able to detect a blood pressure in a

Table 28-8 Classifications of Hemorrhagic Shock

Signs and Symptoms	Blood Pressure	Pulse	Respiration	Skin	Urinary Output	Level of Consciousness
Mild	Normal or hypertensive	Increased, tone becoming weaker	Increased, deep	Cool and pale	Normal (average 30 mL/h)	Alert, oriented, mildly anxious
Moderate	Systolic, 60–90 mm Hg	Tachycardic, tone becoming irregular	Tachypneic, becoming shallow	Cool, pale, and moist	Decreased (10–22 mL/h)	Oriented, increasing anxiety and restlessness
Severe	Systolic, <60 mm Hg	Tachycardic, thready and irregular	Tachypneic, irregular	Cool, clammy, central cyanosis	Oliguric (<10 mL/h)	Lethargic

Table 28-9 Classifications of Hemorrhage

Class	Percent of Blood Loss	Estimated Blood Loss (mL)
1	15	<900
2	20–25	1200–1500
3	30–35	1800–2100
4	40	>2400

patient with profound shock. Pulses often are absent and urine output is minimal (oliguria) to none (anuria). Examination of the hematocrit may assist in estimating a large blood loss if it significantly changed from the previous baseline. Significant hematocrit changes will not occur until after 4 hours of the time of hemorrhage (Beneditti,

Nursing Alert

HEMABATE PRECAUTIONS

You should not administer carboprost tromethamine (Hemabate) when a client has a history of bronchospasms. Carboprost tromethamine is a prostaglandin that stimulates smooth muscles, such as the lungs, to contract. When given, clients usually develop diarrhea. You should use medications such as diphenhydlate and atropine prophylactically to prevent diarrhea.

1996). The client also may exhibit signs of air hunger, anxiety, visual disturbances, and unusual thirst.

The overall goal in postpartum hemorrhage management is to prevent cardiovascular collapse—the bleeding must be controlled immediately. If the cardiac output decreases, renal blood flow will be compromised. The physi-

Critical Thinking

Beliefs about Blood Transfusions

You must be attuned to the client's cultural or religious values regarding health care. Members of some groups, such as the Jehovah's Witness faith, have deep religious convictions against receiving blood transfusions because doing so directly violates their beliefs. Blood transfusion is forbidden for them by Biblical passages noted in the following citation: "Only flesh with its soul—its blood—you must not eat" (Genesis 9:3-4); "[You must] pour its blood out and cover it with dust" (Leviticus 17:13-14); and "Abstain from . . . fornication and from what is strangled and from blood" (Acts 15:19-21). These beliefs include not accepting homologous or autologous whole blood, packed red blood cells, white blood cells, or platelets. The religious understanding of the Jehovah's Witness does not absolutely prohibit the use of other components such as albumin and immune globulins. Nonblood replacement fluids, such as colloid or crystalloid fluids, are allowed.

Health care professionals face this challenge as a major health issue. There are over half a million (and the numbers are increasing) Jehovah's Witnesses in the United States who do not accept blood transfusions. A liability concern for health care personnel exists; however, Jehovah's Witnesses will take adequate

legal steps to relieve liability as to their informed refusal of blood. Many physicians and hospital officials previously viewed refusal of a transfusion as a legal problem and sought court sanctions to proceed as they saw fit medically. Current medical literature indicates changes in attitudes of medical professionals. Nonetheless, the medical community has been trying to adapt other methods of treatment and practice the doctrine of treating the "whole person."

Caring for minors presents the greatest concern, often resulting in legal action against parents under child-neglect statutes. However, many people believe that Jehovah's Witnesses seek good medical care for their children. These parents urge that the legal and medical community give consideration to the family's religious beliefs.

How would you feel if your client is bleeding heavily and urgently needs a blood transfusion to replace her volume deficit?

Source: Jehovah's Witnesses Official Web Site. (2000). *Jehovah's Witnesses: The surgical/ethical challenge*. [On-line], Available: www.watchtower.org/library/hb/jw_surgical_ethical.htm. Reprinted with permission from *Journal of American Medical Association* (1981). 246, (21), 2471–2472.

cian will play a major role in evaluating the reason for hemorrhage. A careful exploration of the uterus for retained placental parts and the cervix and vagina may show the source of bleeding.

Intravenous access should be available to administer fluids, medications, and replacement blood products, as needed. Pharmacologic agents to control bleeding include ergovine and synthetic prostaglandins. Packed erythrocytes most commonly are ordered to expand blood volume; other blood products, such as whole blood, platelets, fresh frozen plasma, and cryoprecipitate, also may be used. A CBC and typing and crossmatching for erythrocytes may be ordered as well as a coagulation profile (prothrombin time, partial thromboplastin time, platelets, fibrinogen, fibrin split products, and a clot retraction test). Blood products normally are given when the hemoglobin is 7 g/dL or less. If all else fails, surgical intervention with laparotomy may be indicated (Benedetti, 1996).

The nurse, along with the provider, should continually try to keep the client informed of her current medical status, especially as interventions are performed in an urgent manner. The nurse should explain what the actions being taken are and why they are being performed. The nurse should assist the client into a supine position, with legs slightly elevated to facilitate blood return to the heart. Other interventions include avoiding administering sedatives, analgesics, or other central nervous system depressants because they depress the vasomotor center. Overheating also should be avoided because it causes vasodilation.

Late hemorrhage occurs 24 hours or more after delivery and is defined as a sudden increase in bleeding 8 to 14 days postpartum (Bowes, 1996). At a time when the lochia transitions to lochia serosa, the client may experience a return to lochia rubra. The bleeding usually lasts for a short period of time and is self-limiting. Subinvolution at the placental site, vulvar hematomas, and infection (endometritis) are some of the reasons for the delayed or late bleeding. Of all cases, 40% are caused by retained placental parts (Bowes, 1996). Ultrasonography assists in identifying retained placental fragments, and suction evacuation is performed to remove the fragments.

Pelvic Hematoma

Pain that does not go away despite treatment with analgesics should be examined more closely. A common cause of severe perineal pain is the presence of a hematoma. This condition is potentially dangerous because blood loss may not be visible. Hematomas may be categorized into three types: vulvar, vaginal, and retroperitoneal.

The most common hematoma is located on the vulva, which forms when ruptured arteries and veins in the superficial fascia seep into the nearby vulvar tissue (Bene-

detti, 1996). Signs of a vulvar hematoma are local pressure; discoloration, such as ecchymosis (bluish-purplish); and a visible outline of a hematoma (Figure 28-20). Blood loss is subacute and the client may complain of perineal pain. Management involves surgical incision and evacuation of the blood and clots. Once sutured, the space is compressed with a large sterile dressing. An indwelling urinary catheter inserted at the start of the procedure should remain in place for 24 to 36 hours.

Trauma to maternal soft tissues during delivery (e.g., by the use of forceps) may result in formation of a vaginal hematoma. Large amounts of blood usually do not form. The client frequently complains of severe, unrelenting rectal pain. On examination, a large bulging mass may be protruding into the vagina. A large enough vaginal hematoma can make urination difficult. A vaginal hematoma is treated with incision and evacuation. The incision need not be closed; a vaginal pack is used to put pressure on the incision edges and is removed after 12 to 18 hours (Benedetti, 1996).

Least common but most dangerous to the mother are retroperitoneal hematomas. They occur when one of the vessels from the hypogastric artery is lacerated. A large amount of bleeding may ensue until the signs and symptoms of hypotension or shock are noted. Treating this life-threatening hematoma requires surgical exploration and ligation of the lacerated vessels (Benedetti, 1996).

Figure 28-20 Hematoma of the vulva.

It is important for the nurse to examine the perineal area with the client in a supine as well as side-lying positioning to adequately detect a hematoma, especially when a new mother presents with severe perineal pain. Opened hematoma sites should be kept clean, with frequent pad changes. Smaller hematomas usually are allowed to resolve spontaneously, with ice packs used for comfort.

Many health care providers may order a postpartum CBC to evaluate hemoglobin and hematocrit values, especially if blood loss is significant. Otherwise, no other laboratory tests are required until clinical indications dictate.

Postpartum Infections

Postpartum infections, commonly known as **puerperal sepsis**, involve infections of the genital organs that occur during the first 6 weeks after childbirth. Postpartum infections are the leading cause of nosocomial infections and maternal morbidity and mortality (Clark, 1995). Postpartum infection is significant in that it delays mother-infant bonding and breast-feeding, the hospital stay is prolonged, or re-admission occurs. Nurses have the opportunity to identify women at risk for infection and recognize the subtle and early signs and symptoms. Because of early discharge, the nurse also must provide preventive care and anticipatory teaching to minimize the risks.

The classic definition of postpartum infection is an oral temperature greater than 38°C (100.4°F) taken twice 6 hours apart on any two of the first 10 days postpartum, excluding the first 24 hours after delivery (Bowes, 1996). Postpartum infections may occur within or outside of the pelvis. Pelvic infections include endometritis (the most common), pelvic cellulitis, pelvic abscesses, hematomas, and septic pelvic thrombophlebitis. Extrapelvic infections are those that occur in the urinary tract, at the episiotomy site, in the breasts (mastitis), or in the legs (thrombophlebitis). Refer to Table 28-10 for a description of the most common postpartum infections.

The causes of postpartum infections are related to anatomic and microbiologic factors. Microorganisms may enter the body at the site of the placental implantation. The infection then becomes systemic. With prolonged rupture of membranes, endogenous or exogenous flora may enter and ascend the vagina, causing infection. Dilation of the cervical canal after delivery makes it susceptible to bacterial invasion from normal flora.

The duration of labor (>18 hours), route of delivery, and colonization of amniotic fluid are the strongest predictors of developing a puerperal infection. Other factors that predispose clients to infections are obesity, anemia, malnourishment, cigarette smoking, diabetes, drug abuse, and immunosuppression. Other risk factors for developing infection include the following (Bowes, 1996):

Nursing Tip

POSTPARTUM URINE CULTURES

Postpartum women often have midstream urine contaminated with lochia. When obtaining a clean-catch urine specimen to evaluate the client for a urinary tract infection, you should instruct the client in the proper technique. Because catheterization increases the risk of infection, it should be avoided.

To obtain a clean-catch urine specimen, instruct the client to separate the labia with two fingers of one hand. Using the other free hand, she should clean the labia with sterile wipes moving from front to back. The client should try to wipe three times: once on each side of the urethra along the labia and the third in the middle, cleansing the urethra. The specimen can then be collected.

- ✦ Cesarean section (changes in hemostasis; the incision site becomes a focal point for infection)
- ✦ Frequent vaginal examinations intrapartum (greater chance of introducing microorganisms)
- ✦ Prolonged delivery after rupture of membranes (>24 hours)
- ✦ Internal fetal monitoring (fetal scalp electrodes, intrauterine pressure catheter)
- ✦ Positive amniotic fluid culture (*Escherichia coli* and *Klebsiella* are commonly obtained from cultures of amniotic fluid)

Physical examination of the client with a suspected infection includes assessment of a change in the color, amount, odor, and consistency of the lochia. The episiotomy, if present, should be examined for redness, warmth, edema, tenderness, or disruption in the wound incision. The nurse should assess for fundal tenderness or pain when massaged. Costovertebral tenderness that may suggest pyelonephritis should be ruled out. Vital signs may indicate elevated temperature and tachycardia. Laboratory findings from blood, cultures, urinalysis, and culture and sensitivity tests may indicate the presence of infection. Culture reports will help determine the diagnosis and type of antibiotic therapy needed.

General Approach to Management of Infection

Infection with a single organism is rare. Broad spectrum antibiotics directed at multiple organisms often are administered prophylactically for cesarean sections and

Table 28-10 Common Postpartum Infections

Infection	Definition	Causative Organism	Comments	Clinical Findings	Management
Endometritis	<ul style="list-style-type: none"> Infection of endometrium, lining of uterus 	<ul style="list-style-type: none"> <i>Escherichia coli</i> <i>Chlamydia trachomatis</i> <i>Gardnerella vaginalis</i> <i>Mycoplasma hominis</i> 	<ul style="list-style-type: none"> Major risk factor: cesarean section (C/s) (especially after laboring or rupture of membrane [ROM]) Incidence increases with presence of bacterial vaginosis Degree of fever can indicate extent of infection 	<ul style="list-style-type: none"> Uterine distention or tenderness Abdominal pain Malaise, lethargy Nausea and vomiting Anorexia Foul-smelling lochia Fever, chills Tachycardia Anemia Increased leukocytes with shift to the left Increased erythrocyte sedimentation rate 	<ul style="list-style-type: none"> Broad spectrum antibiotics (double or triple) If single antibiotics: high-dose Clindamycin or cephalosporins for 24–72 h Supportive treatments Rest Hydration Analgesia
Wound site	<ul style="list-style-type: none"> Infections include various sites Episiotomy C/S, at abdominal incision site 	<ul style="list-style-type: none"> <i>E. coli</i> <i>Mixed group A streptococcus</i> <i>Clostridium perfringens</i> 	<ul style="list-style-type: none"> Encompasses infections of C/S, episiotomy, lacerations, and so on Usually develops after hospital discharge Risk factors: <ul style="list-style-type: none"> -Obesity -Diabetes -Prolonged labor -Prolonged ROM -Frequent vaginal examinations -Chorioamnionitis -Immunodeficiency -Hematoma formation 	<ul style="list-style-type: none"> White line along the episiotomy Edema Skin discoloration Erythema Warmth Tenderness Seropurulent drainage Wound edge separation Fever Pain Lochia odor Lochia color change 	<ul style="list-style-type: none"> Re-admission Debride wound; excise all necrotic tissue Open and drain abdominal wound; pack as required Antibiotics (if late onset, then no antibiotics) Cephalosporins Penicillin-resistant drugs Vancomycin Comfort measures Frequent perineal care Sitz baths Warm compresses Client teaching Frequent pad changes Good handwashing technique Wipe “front to back” (avoid cross-contamination) Modify activities No isolation precautions from infant Self-care Adequate diet and fluids
Urinary tract infection (UTI)	<ul style="list-style-type: none"> Infection of bladder or ureters 	<ul style="list-style-type: none"> <i>E. coli</i> <i>Other gram-negative aerobic bacilli</i> <i>Other enterococci</i> 	<ul style="list-style-type: none"> Most common extrapelvic infection Risk factors: <ul style="list-style-type: none"> -Bladder hypotonia -Urinary stasis -Intermittent catheterization -Epidural anesthesia 	<ul style="list-style-type: none"> Manifestations of lower UTI: <ul style="list-style-type: none"> -Dysuria -Frequency -Urgency -Low-grade fever -Bladder overdistention 	<ul style="list-style-type: none"> Monitor for client complaints of infrequent or insufficient urination, discomfort, burning, foul-smelling urine 10-d antibiotic therapy

prolonged rupture of membranes. The issues of treatment and timing of the treatment, however, vary among health care providers. With the high incidence of antibiotic-resistant organisms, antibiotic medications should be used as a last resort. Health care providers should identify measures to prevent infection and encourage herbal and holistic means of increasing the immune response. General nursing practice in preventing infection is targeted at maintaining health with diet, exercise, and diligent hygiene practices, such as good hand-washing technique.

The nurse can provide anticipatory teaching to help clients prevent infection. The client should be instructed on how to use a squeeze-bottle with warm water after using the toilet to better cleanse the area and on how to wipe anteriorly to posteriorly. Perineal pads should be changed in the same manner, that is, removed from anterior to posterior, and should be replaced each time she goes to the bathroom. Client education includes the side effects of therapy, prevention of spread of infection, maintenance of adequate fluid intake, adherence to the prescribed treatment regimen, the signs and symptoms of worsening infection, and when to contact her provider.

Caregivers also should be cognizant of preventing the transmission of infection among staff and clients. Standard precautions and careful conscientious hand-washing should be practiced. Shared equipment (e.g., heat lamps and tubs) should be thoroughly cleaned and disinfected. Staff members with signs of infection (i.e., respiratory infection) should refrain from providing direct client care.

Endometritis

Endometritis is an infection of the uterine lining occurring from pathogens that ascend from the lower genital tract (Bowes, 1996). Endometritis occurs in 2% of vaginal deliveries and 10% to 15% of cesarean deliveries. When endometritis presents after 1 to 2 days after delivery, the

causative agent usually is group A streptococcus. Infections that occur after 3 or 4 days usually are caused by anaerobic organisms, such as *Escherichia coli* (Bowes, 1996).

The client with endometritis may complain of symptoms of lower abdominal pain, chills, anorexia, malaise, and a malodorous vaginal discharge. The nurse should assess for fever, abdominal tenderness, and mucopurulent vaginal discharge. Laboratory studies will include a CBC, urine culture, and blood cultures.

Prompt IV antibiotic therapy is used to treat suspected endometritis. Treatment is continued until all symptoms have been resolved for 48 hours, including fever. A combination of clindamycin and gentamycin usually is ordered, which will provide coverage for aerobic and anaerobic organisms (Bowes, 1996). Single antibiotic therapy may be prescribed with either a cephalosporin or extended spectrum penicillin (Bowes, 1996).

Mastitis

An infection of the breast, **mastitis**, usually involves the ducts and lactiferous glands of the breast. Mastitis usually is endemic in nature, resulting from *Staphylococcus aureus*, which comes from the infant's mouth (Clark, 1995). It is not harmful to the infant. Other causes of mastitis include cracked nipples, missed or shortened feedings, and consistent pressure placed on the breast (Kimm, 1997). Incomplete emptying of the breast will result in the breasts being overly full and, subsequently, development of plugged milk ducts. The nurse should teach the client steps to prevent mastitis.

The client most often will present with complaints of swollen tender breasts around 5 or 6 weeks postpartum but as early as 2 weeks (Bowes, 1996). The breast (normally unilateral) will feel very warm, with areas that may appear reddened with hardened nodules. The client may report a sudden onset of flulike symptoms, including

Client Education

Preventing Mastitis

You should instruct the breast-feeding mother to avoid missing or shortening feeding times. She should be mindful of the times her baby begins to suddenly sleep longer at night, begins an irregular nursing pattern (nursing a lot one day and less the next), she begins to supplement feedings with formula, or she begins to give the baby a pacifier frequently.

The client should be instructed to avoid putting pressure on the breasts. She should try not to sleep on her stomach or hold her baby too tight against her chest while feeding. She should be told that shoulder straps from purses and diaper bags may place pressure on her breast. The client should make sure her bra fits correctly. Underwire bras may cause a problem. Thick breast pads or breast shells also may make her bra too tight.

Instruct the client to pay attention to proper positioning and how her baby is latching on. She can massage the hardened area to try to open plugged milk ducts. Finally, she should be sure to take care of herself by getting enough rest. Mastitis often is the first sign a new mother is doing too much and not taking care of herself. She should try cutting back on activities and start relying on family members and friends to help.

aching joints, malaise, nausea, vomiting, severe headache, chills, and fever (Overfield & Tully, 1997). Mastitis resulting from an endemic nature may be characterized by a demarcated V-shaped area of redness and inflammation (Clark, 1995).

The nurse should instruct the client with mastitis to continue breast-feeding. If she prefers, the client may continue to express milk either through pumping or manual expression to ensure complete emptying of the affected breast. The client will require increased fluids and ample time to rest. The nurse should instruct the client to place warm compresses on the affected area and take NSAIDs to relieve pain and fever. The mother should avoid supplementing with infant formula, nipple shields, and pacifiers (Clark, 1995). Nursing pads should be changed when they become wet. Antibiotic therapy using penicillin, ampicillin, or dicloxacillin (Bowes, 1996) often is prescribed to complete the treatment. When mastitis recurs, the infant's throat may be cultured to determine if the baby is reinfect-

ing the mother. Reassure the mother that although the course of mastitis may be very painful and frustrating for her and her baby, the infection will eventually resolve within a few days of antibiotic treatment.

CLIENT EDUCATION

Client education comprises much of the nurse's responsibilities and postpartum nursing practice. With shortened hospital stays, the nurse must streamline her teaching methods, assessing the new mother's and family's personal teaching needs. Client interactions should become more efficient, focusing on communicating knowledge to clients. The focused interactions should be directed toward desired client outcomes, empowering the woman and her family. Ideally, the nurse should assess the mother's current knowledge regarding self-care and infant care because the mother's prior experiences with pregnancy and infant care may change the direction of the nurse's teaching plans.

Depending on the facility, client teaching may incorporate a wide range of methodologies. Group classes scheduled for specific times of the day enable educating many clients at one time. One-on-one teaching may be more effective for those mothers requiring individual attention but is not realistic in terms of cost. Closed-circuit television programs also provide a medium of individualized education in the privacy of the client's room. Various printed materials and videotapes are widely available commercially. Specific information developed by the hospital also may be available.

Before being discharged the new mother must learn how to care for herself and her infant (Figure 28-21). Self-care topics include those activities that help her to manage, anticipate, and recognize health problems or danger

Figure 28-21 Infant care, self-care, and family adaptation are topics typically covered in postpartum education classes.

Box 28-4 List of Community Resources

- Hospital advice lines.
- Newborn clinics for follow-up.

- Library-loan books and videos.
- Client educational materials and resources.

signs. Infant care encompasses activities such as feeding, dressing, and recognition of health problems.

General instructions, in addition to other client education discussed throughout this chapter, should be given to the client. The nurse should also instruct the client on warning signs of complications after delivery. Suggestions for community resources for support and education also should be offered (Box 28-4).

Client Education

General Discharge Instructions

You should provide these general discharge instructions to the new mother:

- Take it easy when you go home.
- Do not lift anything heavier than your baby. Do not move furniture or vacuum for the first few weeks. No driving for the first 2 weeks or until approved by your physician. Limit stair climbing to only when necessary for the first 2 weeks.
- Get lots of rest. Sleep when the baby sleeps.
- Take advantage of offers of help from others.
- Ignore housework for the first few weeks. Enjoy your baby.
- If you have an episiotomy, avoid having sexual intercourse until it heals or until your bottom feels better. You may need to use a lubricant to help with dryness.
- Try to take older siblings' feelings into consideration.
- Take your medications as prescribed.
- Keep your postpartum follow-up appointment.
- Call your health care provider if you have any of the warning signs of sickness.

Client Education

Warning Signs of Illness after Delivery

You should inform the client to call her provider if she experiences any of the warning signs of sickness after she is discharged from the hospital:

- Fever greater than 100.4°F.
- Severe pain, redness, or swelling in the episiotomy or cesarean section incision.
- Foul-smelling vaginal discharge.
- Increased bleeding; soaking of a peripad more than once an hour or a large amount of bright-red lochia after your discharge has turned dark red or pink.
- Passing of several large clots greater than the size of a half dollar coin.
- Backache or severe abdominal pain or cramping (unrelieved by medication), or pain in the episiotomy or perineal area.
- Reddened, tender, swollen breasts that may have hardened lumps (may be related to flulike symptoms).
- Pain, redness, and swelling of your legs.
- Burning when you urinate, or frequent urination.
- The blues or crying that lasts for days.
- Depression that is severe or does not go away.
- Thoughts of harming your baby.
- Suicidal thoughts.

As part of the discharge process, the nurse may use a facility-specific checklist to ensure all care has been provided (e.g., birth certificate completed, laboratory testing obtained, and teaching handouts and pertinent information received). The nurse should ensure the client is instructed on any discharge medications ordered and where to obtain them. Some women may continue to take their prenatal vitamins and iron until the postpartum checkup, especially if the hematocrit is low. If the woman experienced a third- or fourth-degree laceration, she may be prescribed a stool softener. The provider may order over-the-counter or prescription pain medication for home use.

Before discharge the new mother should leave the hospital with a follow-up clinic appointment already in hand or with clear instructions on how to obtain one. A postpartum follow-up examination usually is scheduled for 6 weeks after delivery. The examination may be sched-

ASSESSMENT OF LIGHT BLEEDING WEEKS AFTER DELIVERY

At the 6-week postpartum checkup the provider will perform a Pap smear, which may cause light bleeding.

Some women may experience light bleeding for up to 3 months postpartum, which is considered normal when the following criteria are present:

- The uterus has returned to its normal size.
- No fever is present.
- Clots or tissue are not being passed.
- The client is not feeling exceptionally fatigued.
- No foul odor is associated with the bleeding.

Postpartum bleeding also can be caused by exercise, sexual intercourse, and breast-feeding. Certain oral contraceptives and depot provera cause postpartum spotting. The bleeding also can be the start of the first menstrual period.

uled for as early as 2 or 4 weeks if the client has experienced complications.

The provider will perform a complete well-woman examination, checking the client's physical and emotional health. The follow-up includes an examination of the epi-

REFLECTIONS FROM FAMILIES

"I fell in love with my baby after she was born. I couldn't wait to be the best mother I could be to her. However, I happen to be the main breadwinner in the family. It would cost us financially if I were to stop working or even only work part-time.

After the normal 6 weeks of maternity leave, I have to return to work. I am torn between having to return to work so soon and being able to stay at home with my baby. I want to be able to see her crawl or sit for the first time. It won't be fair if the day-care provider experiences my child's milestones before I do."

siotomy (if one was performed), Pap smear, bimanual examination, and breast examination. The client will have an opportunity to ask questions and discuss concerns. If not already done, the client should discuss her contraceptive options at this time.

EARLY DISCHARGE

Hospital stays for new mothers have decreased to an average of 48 hours or less (based on client preferences). To qualify for early discharge, it must be determined that the mother is at low risk and has had an uncomplicated antepartum and intrapartum course and a normal vaginal delivery. Guidelines for discharge vary with each hospital. Each facility should have policies in place that identify the circumstances and processes that must occur for the new mother and infant to be discharged early from the hospital. The Guidelines for Perinatal Care (AAP & ACOG, 1992) state specific criteria that must be met before a mother and her infant may qualify for early discharge from the hospital (Box 28-5). Refer to the Chapter 32 Newborn for more guidelines regarding infant-care client teaching.

Before the new mother's discharge, the postpartum nurse should include an assessment for adequate support at home (Figure 28-22). Does she have a designated support person available to help with the household duties, such as cleaning and preparing meals? The new mother may become overwhelmed with the responsibility of caring for herself and her new infant without adequate support.

The nurse should be cognizant of other referrals for services the client may require. For example, consultations with a nutritionist, physical therapist, nursery nurses, social services, home care services, maternal-child clinical nurse specialist, or lactation expert may be of benefit to the client. Referrals for high-risk care and follow-up and community resources for breast-feeding assistance (e.g., La Leche League) also are available. Many of these services are not covered by insurance, except for those for high-risk mothers. The local community may have programs (e.g., "First Steps") designed to assist high-risk clients, such as adolescents and women in low-income families. Canada has several programs ("Healthiest Babies Possible" and "Brighter Futures") that begin prenatally and continue postnatally for these clients.

Social services may help coordinate the discharge process by obtaining needed psychosocial support, monetary assistance, and referrals to community resources. Mothers who meet the criteria (i.e., financial and physical needs) for such services may qualify for food supplied by federal programs, such the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC). First-time mothers may benefit from a family-advocacy nurse specialist who may provide counseling on parenting. Family-advocacy nurses focus on the high-risk client who may require further follow-up, including home visits and

Box 28-5 Criteria for Early Discharge Mother

- Uncomplicated pregnancy, labor, birth, and postpartum course.
- No evidence of premature rupture of membranes.
- Stable blood pressure and no fever.
- Ability to ambulate.
- Ability to void without difficulty.
- Intact perineum without third- or fourth-degree perineal laceration.
- Hemoglobin level greater than 10 g.
- No significant vaginal bleeding (mild to moderate).

Infant

- Term infant (37–41 weeks) with birth weight of 2,500–4,500 g
- Normal findings on physical assessment.
- Normal laboratory data, including negative results for Coombs test and hematocrit.
- Stable vital signs.
- Stable temperature.
- Successful feeding (normal suckling and swallowing).
- Apgar score greater than 7 at 1 and 5 minutes.
- Normal voiding and stooling.
- Newborn screening test completed.

ensuring the new parents obtain the necessary cognitive and performance skills to care for their infant.

HOME VISIT GUIDELINES

With high health care costs impacting postpartum hospital stays, the new mother may benefit from home visits from a community health nurse or family-advocacy nurse specialist after hospital discharge. Often, a hospital postpartum teaching program with limited nurse-client interactions cannot address all the client's learning needs in 48 hours or less. The client also may not be ready to learn after delivery. A postpartum home visit program may provide a safe and economical alternative to extended hospital stays.

Referrals for a home visit should be assessed during the discharge planning process and discussed with the client. Clients at risk for complications should be identified early and plans made accordingly. The home visit also can provide support and address concerns the mother may have after leaving the hospital. The visiting nurse may provide a positive impact on the new mother. The new parents, especially a primipara mother, may require extra encouragement and instructions on infant care. Self-esteem and self-confidence are valuable elements in the mother's adaptation to the maternal role. The nurse can help build these characteristics through education and demonstration.

The visiting nurse should assess the mother's physical well-being and self-care activities. Assessments should include the following: normal changes in lochia pattern, uterine involution, appropriate bowel and bladder functioning, rest and activity patterns, pain management, nutrition, infection, and coping. The nurse may be able to identify problems with episiotomy healing or development of mastitis.

A.

B.

Figure 28-22 Discharge planning includes assessment of the new mother's support systems. A. This single mother may benefit tremendously from the support and experience of her mother and sister. B. This new father is eager to assume an active role in his newborn son's life.

Case Study/Care Plan

THE CLIENT WITH POSTPARTUM BLEEDING AND PAIN

Cristina, grava 4, para 4, is a married, 32-year-old, Hispanic woman who gave birth to a healthy, term baby boy at 8:48 a.m. by forceps delivery. Her membranes ruptured 6 hours before the start of active labor. She had an episiotomy with a second-degree laceration. The estimated blood loss was 450 mL. Apgar scores were 8 and 9 at 1 and 5 minutes after birth. No resuscitation was required. The infant weighed 9 lbs, 10 oz., and was 21 in long. During the intrapartum course, Cristina received only IV analgesia for pain relief. She was catheterized once when she was unable to urinate. She quickly progressed through labor, totaling only 5 hours and 22 minutes for the entire labor. Her perineum was moderately swollen.

During fundal massage the first hour after childbirth, the nurse noted the peripad was saturated with a large amount of lochia rubra. The fundus was boggy, firmed up on massage, but became soft again once massage was discontinued. The location of the fundus was U+2 deviated to the right side. Christina had not voided for the past 4 hours. The client was awake, alert, and mildly tired after labor. Vital signs were as follows: blood pressure 105/72 mm Hg, pulse 94 bpm, respirations 20 breaths per minute, and temperature 99.2°F. An IV of lactated Ringer's solution with 20 U of oxytocin is infusing at 125 mL/h. Bowel sounds are present and active. She complains of moderate cramping. She plans to breast-feed. Her husband is at her bedside holding their new baby.

Assessment

Cristina presents with two major nursing problems related to bleeding and pain. First, she delivered a large infant by forceps delivery, making her at risk for bleeding. The bleeding may be caused by atony secondary to uterine distention and lacerations from the use of forceps. Having a full bladder and delivering rapidly also are risk factors for bleeding. Second, the client is a multipara who previously has experienced very uncomfortable afterpains. Her discomfort is increased with her episiotomy and, most likely, the full bladder.

Nursing Diagnosis

Deficient fluid volume related to postpartum hemorrhage secondary to uterine atony.

- Expected Outcome**
- Maintain a firm fundus within normal assessment parameters.
 - Saturate no more than one pad an hour during the recovery period.
 - Maintain normal fluid balance as evidenced by vital signs and hematocrit within normal limits.

- Planning**
- Closely observe normal fluid volume balance within the first 24 to 28 hours following delivery.

Nursing Interventions

1. Monitor fundal height, position, and tone as per the protocol. Massage as appropriate.
2. Monitor amount, color, and type of lochia as per the protocol. Note the amount of blood saturated on the peripad and on the pad under the buttocks and bed sheets. Weigh peripads as necessary.
3. Observe for vital sign changes and report acute or critical values to the primary care provider.
4. Ensure adequate IV access. Administer IV fluids with oxytocin as ordered.

Rationales

1. Ensures the uterus remains firmly contracted.
2. Obtains an accurate estimate of blood loss.
3. Ensures prompt identification and treatment of complicating.
4. Maintains uterine tone and involution after delivery.

(continued)

5. Interventions beyond nursing may be necessary.
6. Monitor levels.
7. To prepare for transfusion if needed.
5. Administer other medications as needed if bleeding continues. If bleeding continues despite above actions, notify provider for further evaluation.
6. Obtain hemoglobin and hematocrit levels as ordered.
7. Ensure or prepare for administration of blood or blood products. Obtain blood for typing and cross-matching.

Evaluation Cristina's bleeding may decrease to a small amount of lochia rubra 12 hours after delivery; however, the nurse must continue to assess for bleeding until discharge. Ongoing evaluation may demonstrate that although the fundus remains firm, the continuation of moderate vaginal bleeding and changing vital signs may indicate bleeding coming from an overt site, such as an overlooked vaginal or cervical laceration.

Nursing Diagnosis

Urinary retention related to trauma to tissues secondary to childbirth and perineal discomfort.

Urinary Retention

Expected Outcome • Resume normal bladder function as evidenced by minimal urinary output of greater than 150 mL per voiding and absence of urinary distention.

Planning Work with client to set time-bound goals for voiding.

Nursing Interventions

Rationales

- | | |
|---|---|
| 1. Assess the time and amount of last voiding. | 1. Provides baseline data. |
| 2. Palpate symphysis pubis and evaluate location of fundus in relation to the umbilicus the first 8 hours after delivery. | 2. Notes bladder distention. |
| 3. Assist client to ambulate to bathroom if able, providing privacy as needed. Palpate bladder after voiding. | 3. To assure adequate emptying. |
| 4. Offer various methods to encourage urination. Use ice packs to decrease perineal discomfort. | 4. Instructing in various bladder management techniques increases likelihood of client finding successful method. |
| 5. If unable to void, perform straight catheterization as ordered. | 5. To avoid urinary stasis and retention. |
| 6. Encourage minimum fluid intake of 2,000 mL/d. | 6. Maintains hydration. |

Evaluation If Cristina continues to experience urinary retention, she may be discharged with an indwelling catheter or be taught how self-catheterization. Christina's input and output are within targeted parameters within 6 hours.

Nursing Diagnosis

Acute pain related to uterine cramping (normal uterine involution), perineal pain, and breast tenderness.

Expected Outcome • Experience pain relief or moderate control of pain.
 • Verbalize methods of satisfactory pain relief.
 • Obtain restful pain-free periods and the ability to return to normal activities of daily living and self-care.

(continued)

Planning

Plan care procedures to minimize disruptions in client rest; ask client about her preferred methods of pain management (therapy, guided imagery, medications, and so forth).

Nursing Interventions**Rationales**

- | | |
|---|--|
| 1. Assess location, intensity, and duration of pain. Determine pain. Determine pain intensity by asking the client to describe her pain on a scale from 1 to 10, with 10 being the strongest intensity of pain. | 1. Clarifies client's interpretation of the pain experience. |
| 2. Administer the appropriate prescribed analgesia to the client. A combination or altering different prescribed medication also may be effective in controlling pain if the client is very uncomfortable (e.g., nursing frequently). | 2. Regularly administered medications may control the pain more effectively. |
| 3. Support client's use of nonpharmaceutical pain control, such as patterned breathing, touch therapies, and visualization. | 3. These may provide effective pain relief avoiding rests associated with medications. |
| 4. Provide ice packs to the perineum for the first 24 hours after delivery, then warm therapy with sitz baths afterward. | 4. Reduces inflammation and promotes healing. |
| 5. Provide ordered anesthetic sprays or creams as desired. | 5. Reduces discomfort. |
| 6. Instruct the client to position herself differently while sitting or lying in bed. | 6. Position changes may alter pain levels. |
| 7. Ensure proper positioning and latch-on when breast-feeding. Instruct client to massage colostrum into nipples to soothe them. | 7. Proper positioning and breast care will alleviate discomfort. |
| 8. Encourage rest and relaxation strategies. | 8. These will help reduce pain and tension and facilitate let-down response. |

Evaluation Christina continued to experience uterine cramping 6 hours after delivery; it intensified significantly when she breast-fed her son. Lying on her side to nurse seemed to dull the intensity of the afterpains.

Infant care issues include the method and success of feeding, be it breast-feeding or bottle-feeding; sleep patterns; safety; cord care; circumcision care, if applicable; bowel and bladder elimination; bathing, dressing and diapering; infection; and skin integrity. Problems such as jaundice and infection of the umbilical cord site may be identified and treated early. Other topics to discuss include postpartum exercise, fertility and sexuality, and infant anticipatory guidance regarding behavior and development.

Because emotional changes (i.e., postpartum blues) may not be manifested until after discharge, assessing how the mother is coping at home is very important (Box 28-6).

Box 28-6 Assessing Emotional Changes at Home

- What is the mother's demeanor? Is she happy? Is she able to cope with the demands of motherhood?
- Is she getting enough rest? Does she look and behave as if she is tired?
- How does she act toward her baby and other children in the house?
- Does she have support and help available?
- How does the home environment appear?

NURSING IMPLICATIONS

Health care facilities may choose to use a critical pathway in providing direction in client care. Other facilities may choose to use the traditional nursing care plan. The nursing care plan should clearly delineate the process of assessing client information, developing a nursing diagnosis, performing the interventions, and evaluating the outcomes of that intervention. Depending on the documentation policies of the institution, the nursing care plan may be a preprinted care plan with common obstetric nursing problems. The nurse caring for the postpartum client should be able to individualize the care plan to meet her client's needs.

Web Activities

- Which online site provides information on recovering from labor and delivery?
- Which resources on the Internet can you find regarding general postpartum care?
- Where can you find information on how to perform Kegel's exercises?
- Where can you find a sample postpartum exercise routine?
- Where can you find a website that offers recipes for cooking large quantities of food that you can place in the freezer?
- Where can you find information regarding obtaining maternity leave from your employer?

Key Concepts

- Although pregnancy is considered to be wellness-oriented, the postpartum nurse must use clinical decision-making and critical thinking skills to provide safe, high-quality nursing care.
- Vital signs indicative of problems, such as hemorrhage and infection, are important elements in the assessment of the client postpartally.
- A systemic evaluation of postpartum women consists of examining the breasts, uterus, bladder, bowels, lochia, episiotomy, Homan's sign, and emotional status.
- Uterine involution to nonpregnant size and return of other pregnancy changes to normal functioning occur 4 to 6 weeks after delivery.
- Postpartum hemorrhage, often attributable to uterine atony, is most often prevented with astute fundal and lochia monitoring.
- Although eager to lose her pregnancy weight, the new mother must approach weight loss and exercise slowly and in a healthy manner.
- Various approaches to pain relief can include traditional pharmacologic interventions as well as holistic alternative treatments.
- Before discharge the nurse must ascertain the client's immune status; the Rh-negative mother who delivered an infant who is Rh-positive should receive RhoGAM, and the mother who is rubella nonimmune should be immunized with rubella vaccine before her next pregnancy.
- Because of short hospitalizations, the postpartum nurse should try to identify key self-care and infant-care information that the new mother needs and wants to learn; the nurse should guide her teaching plan toward meeting these needs.
- The nurse incorporates consideration of client and family needs into planning her nursing care, including being aware of cultural diversity.
- Throughout the hospital stay, the nurse should educate and counsel the client (and family) as she encourages the client to progress toward confident, independent care of herself and her new baby.

Review Questions and Activities

The following review questions relate to the previous case study. Melanie Jones is the day shift registered nurse caring for Cristina for the first 12 hours after delivery.

1. Cristina was unable to urinate 4 hours after delivery. Which risk factors did she have that would predispose her to having problems?

- a. Delivery of a male infant
- b. Forceps delivery
- c. Blood loss of 450 mL
- d. Rapid labor

The correct answer is b.

- 2.** Which of the concepts regarding assessment of vaginal bleeding are incorrect?
- a. Lochia rubra is a normal characteristic the first few days after delivery.
 - b. The passage of a large amount of bright-red blood with multiple clots is a normal finding the first 24 hours after delivery.
 - c. Blood may accumulate in the vaginal vault and gush out when the client moves from a horizontal to a vertical position.
 - d. Bleeding usually is controlled with up to 40 U of oxytocin added to an IV bag of fluids.
- The correct answer is b.
- 3.** Which intrapartum factor put Cristina at risk for increased bleeding?
- a. Ruptured membranes more than 4 hours before the start of active labor

- b. Catheterization
- c. Overdistended uterus
- d. Administration of a narcotic analgesic

The correct answer is c.

- 4.** Nursing actions that can help relieve Cristina's complaints of pain may include:
- a. Applying ice packs to the perineum for the first 24 hours after delivery
 - b. Administering an analgesic, such as ibuprofen, for relief of uterine cramping
 - c. Ensuring the client is able to completely empty her bladder after delivery
 - d. All of the above
- The correct answer is d.
- 5.** Lochia undergoes changes over the course of a few weeks. What does lochia consist of during the first 24 hours?
- a. A large amount of bright-red blood
 - b. A small amount of light-pink blood
 - c. A large amount of brownish-white blood
 - d. A small amount of brownish-white blood
- The correct answer is a.

Postpartum Family Adjustment

Working with families as they adjust to a new baby is challenging and requires perception and excellent assessment skills to identify needs before they become problems. Answer the following questions to increase your awareness of the needs of families during the postpartum period.

- How has my new role as a student nurse affected my perception of others?
- How do I feel as I adjust to my role as a student nurse?
- How comfortable am I with my new role?
- What factors helped to make my role transition easier?
- What factors slowed the process of my role transition?
- Who helped support me with my role transition?
- How can I apply what I learned to help others with their role change?

Key Terms

Attachment
En face
Engrossment

Kangaroo care
Letting-go phase
Maternal-infant bonding

Role attainment
Role transition
Role mastery

Sleep-wake cycle
Taking-hold phase
Taking-in phase

Competencies

Upon completion of this chapter, the reader should be able to:

1. Describe the attachment process.
2. Identify theories related to maternal and paternal attachment behaviors.
3. Identify infant behaviors that enhance the attachment process.
4. Outline three phases of maternal role adjustment.
5. Assess maternal and paternal role adjustment.
6. Describe sibling adjustment.
7. Describe the grandparent's role.
8. Examine cultural variations related to parental role transition.
9. Assess the impact of adolescent pregnancy on developmental tasks.

The birth of a baby is one of life's most exciting and challenging events. Brazelton (1981) pointed out that parenthood is an opportunity for personal growth and maturity, because a baby presents parents with the task of becoming a family with all the feelings and responsibility that entails. Adapting to the role of parent can be challenging, because developmental tasks must be successfully accomplished to integrate the new role. **Role transition**, or the process of adopting new behaviors related to change and developmental tasks, involves not only the birth of a firstborn child for the new parents but also the expanding of the family. Since family adjustment and attainment of developmental milestones are complex, health care providers can be helpful in helping families make these transitions.

Adaptation to parenthood is not an easy process. There has been a great deal of research about the developmental course of early attachment relationships (Waters, Posada, Crowell, & Lay 1994). **Attachment** is the process of connecting with another human being. Ideally, a mother's attachment to her offspring is a strong bond that lasts a lifetime. Attachment usually begins during pregnancy and intensifies as the pregnancy progresses and a fantasy child is perceived.

In the period after birth, or the postpartum period, the mother-infant acquaintance begins as the infant is compared to the child who was perceived in the womb. This

"getting-to-know-you" period is characterized by behaviors that initiate the attachment process. Researchers speak of this period as a time when parents begin to identify with their newborn. It is a time when parents begin to integrate the newborn into their lives as they reconcile the fantasy child with the real child and begin to view their role as parents.

Adams & Cotgrove (1995) reported that the mother-child attachment pattern is generally established by age 1 and the effect of early attachment exerts a powerful influence on the child's future development. They also point out that the established attachment pattern directly affects the child's future psychological health, marital relationships, and the relationship the child will have with his or her children. Early intervention by health care professionals can assist in preventing impaired attachment.

MATERNAL-INFANT ATTACHMENT

Major theoretical ideas stem from early studies examining infant attachment to mother figures. In 1958, John Bowlby introduced a biologic model that identified secure attachment to a parental figure as being necessary for normal child development (Biringen, 1994). Bowlby's definition of attachment is based on the formation of an affectionate

Figure 29-1 Meeting the newborn's physical needs is an important step in the maternal-infant attachment process.

link between a child and its mother figure that occurred during the child's first year of life. The identified attachment behaviors were crying, sucking, smiling, and clinging. These behaviors initiated attachment interactions between an infant and its mother. Thus, by meeting the child's physical needs, mutual satisfaction resulted and the foundation for maternal-infant attachment was laid (Figure 29-1).

Mary Salter Ainsworth, a colleague of John Bowlby, also studied infant attachment to a primary caregiver. She reported that an infant must have sufficient interaction with a mother figure to become attached. Ainsworth is best known for her "strange situation" experiment that tested the strength and style of an infant's attachments to its primary caregiver. As the infant grows, a strong attachment to a specific mother figure is seen around 8 months of age, when the child exhibits "stranger fear" (Ainsworth, 1997).

The attachment process does not occur overnight. Brazelton (1981) reported that parents often believe in the romanticized version of parenthood characterized by instinctive, instantaneous attachment, which is not necessarily immediate, but often a continuing process. Early research conducted by Klaus and Kennel (1982) examined maternal attachment and found that the period when a mother falls in love with her baby was not easily identified. They reported it was common for mothers to experience distress and disappointment if they did not experience feelings of love for their infants in the first minutes or hours after birth. Many of the mothers studied developed an affection for their infant within the first week; however, the onset of maternal feelings of affection toward their infant was delayed if labor was painful, amniotic membranes were ruptured artificially, or the mother had received narcotic drugs for pain relief.

Klaus and Kennel (1982) referred to the first hour following birth of an infant as a period when maternal-infant attachment begins and labeled this attachment as **maternal-infant bonding**. In the past, much emphasis was placed on early mother-infant bonding as being instantaneous and crucial. Troy (1993) found that a relationship between mother and infant occurred when the infant was first held, regardless of how long after delivery the holding occurred. The mothers in the study were found to develop feelings of maternal attachment towards their infant anywhere from 10 minutes to 2.5 days after the delivery. Crouch and Manderson (1995) reported that the ideal birth experience does not always occur and the expectations of women regarding instant bonding with their newborn may be incongruent with the actual experience, causing feelings of guilt and anxiety. They also pointed out that maternal attachment develops over an extended period and the term "bonding" has a wide range of meanings related to process and outcome. Because a mother's physical and emotional state can be adversely affected by exhaustion, pain, anesthesia, the absence of support persons, or an unwanted outcome, a delay or block in the attachment process can occur.

While most of the early research focused on observed infant behavior, models and assessment tools were developed to examine mother-infant interactions. Researcher Kathryn Barnard (Tomey & Alligood, 1998) developed a model that identified caregiver-parent characteristics that promoted attachment. These were: a sensitivity to cues, the alleviation of distress, and provision of growth-fostering situations. These characteristics were compared to infant characteristics, which were identified as: clarity of cues and responsiveness to caregiver. Barnard also developed a satellite-training project in which 4,000 nurses, throughout the nation and in foreign countries, were taught how to use a series of standard child assessment instruments. Her child health assessment interaction theory has been widely used to assess parent-child interactions. This theory is based on 10 theoretical assertions:

1. The goal of assessment is to identify problems in which intervention would be most effective.
2. Environmental factors are important for determining the child's health outcomes.
3. The caregiver-infant interaction reflects the nature of the child's environment.
4. The caregiver brings to the caregiver-infant relationship a basic style and level of skills that is readily influenced by the infant's responses as well as environmental support.
5. The process of mutual modification is one in which the parent's behavior influences the child and, in turn, the child influences the parent, so that both are changed.

6. The adaptive process is more modifiable than the mother's or infant's basic characteristics, and nursing intervention should lend support to the mother's sensitivity in response to her infant's cues, rather than try to change her characteristics or style.
7. It is important to promote the child's learning by permitting child-initiated behaviors and reinforcing the child's attempt at a task.
8. A major goal for the nursing profession is to support the child's caregiver during the first year of life.
9. Assessment of interactions is important.
10. Assessment of the child's environment is important.

By encouraging early maternal-infant contact, nurses can provide an environment that fosters attachment behaviors (Figure 29-2). Klaus (1998) examined early mother-infant emotional ties and found that maternal-infant attachment may be biochemically modulated through oxytocin stimulated in the mother by the infant sucking. Newborn infants have the ability to crawl toward the breast to initiate suckling. The close contact aids in thermoregulation of the infant. In addition, by encouraging attachment behaviors, such as early contact, suckling, and *rooming-in*, infant abandonment was reduced. Rooming-in involves the infant remaining in the mother's room throughout hospitalization. Mothers who had early and extended infant contact through rooming-in arrangements were found to interact with their infant more and exhibited more touching behavior (Prodromidis, Field, Singer, Yando, & Bendell, 1995). In contrast, maternal reluctance to engage in attachment behaviors may occur if the mother has min-

Figure 29-2 The nurse can help create an environment conducive to parental attachment behaviors by encouraging early parent-infant contact.

Critical Thinking

Mother-Infant Attachment and Early Infant Contact

The concept of early contact immediately after birth has been discussed as a necessary experience for mother-infant attachment. However, some mothers are too exhausted during the first hour after a difficult labor and delivery or deliver a high-risk infant, who is immediately taken to the nursery. Do you think these mothers experience less attachment toward their infant? Do you think they feel a sense of loss, depression, and anxiety because they missed an experience that has been promoted as important to the mother-child relationship? Is the first hour a critical period or can maternal-infant attachment behaviors be postponed? If so, how long can the postponement be? Is there a long-term negative effect on mother-child attachment if early contact does not occur, as in the case of an ill newborn? Do you think the presence of a support person enhances the attachment process? How can nurses facilitate early maternal-infant contact? What nursing behaviors may interfere with early maternal-infant contact?

imal contact with the infant or if the infant is unwanted, has a disorder, or was born after a difficult labor and delivery. Diamond (1995) reported that the presence of a father in the role of protective watchfulness has been observed to facilitate a nurturing environment for the mother and infant that promotes the development of maternal-infant attachment.

Maternal Adjustment and Role Attainment

The postpartum period is a time for mothers to adjust to the new role of motherhood as the attachment process continues. During this time, the mother experiences many psychological and physiologic changes. It is a critical transition period for initiating maternal role attainment. Nurses can assist the mother and family with role transition by understanding maternal **role attainment**, which is the process of accomplishing the developmental tasks of a new social role. Classic research by Reva Rubin (1984) explored the process of maternal role attainment. Her published work describes the relationship between maternal identity and role attainment. According to Rubin, after the

Table 29-1 Rubin's Phases of Maternal Adjustment

Phase	Maternal Characteristics
Initial: <i>Taking-in</i>	Passivity and dependence Preoccupation with self Reviews the reality of giving birth Compares infant to her "fantasy child" Concerned with rest, food, and comfort
Second: <i>Taking-hold</i>	Resumes control over her life Concerned about self-care Interested in caring for her newborn Begins to gain self-confidence
Third: <i>Letting-go</i>	Maternal role attainment Relationship adjustments

delivery, the mother shifts her attention from an inward focus that is characteristic of labor and delivery to focusing outward on her relationship with her infant. This relationship is personal and unique between a mother and her infant. Rubin identified three adjustment phases involved in the process of assuming the maternal role (Table 29-1).

Taking-In Phase

The **taking-in phase** of maternal adjustment is characterized by basic maternal needs for food, care, and comfort. The mother's initial goal is to recover physically from the birth; depending on cultural variances, this period may be characterized by a dependency on others to meet needs related to rest, comfort, and nutrition. These needs must be met before the mother can begin to care for her infant. Psychologically, the mother is "taking-in" the reality of having given birth. It is not uncommon for the mother to be talkative as she relives the birth of her child with a sense of euphoria. Some mothers may express a sense of unreality as they view their infant and wonder, "Is this really *my* baby"? Some mothers may feel disappointment as they compare the infant with the perceived "fantasy child." Fatigue and physical exhaustion commonly follow the initial euphoric feelings. It is not uncommon for mothers in this stage to exhibit little interest in providing care for their infant. They frequently are content to be a passive observer of their infant's care. The nursing focus at this stage is to provide a quiet, restful environment to facilitate the mother's recovery and promote mother-child interaction.

Taking-Hold Phase

Following the initial phase of dependency, mothers move on to the **taking-hold phase**, which occurs after they

have had a chance to rest and have received relief from discomfort. This phase may begin 24 to 48 hours after delivery. Characteristically, mothers in this phase begin to show an increased interest in participating in their infant's care. However, it is not uncommon for some mothers, especially first-time mothers, to continue to exhibit dependency behaviors. Cultural beliefs also influence the transition to this stage. The primary goal of a mother at this stage is achieving self-confidence in caring for her infant. Mothers usually exhibit a keen interest in assessing their infant's cues and begin to participate in the infant's care as their confidence increases. First-time mothers may take longer to achieve the level of confidence needed.

Today, with early hospital discharge, this phase often occurs earlier or may occur after discharge. The nursing focus in this phase is to foster self-confidence by helping mothers learn infant care. It is not unusual for many new mothers to feel anxious and fearful as they begin to assume care of their infant. Nurses can facilitate learning by collaborating with the mother to establish goals that can help her learn to care for herself and her newborn. It is important to begin by assessing learner readiness and level of understanding. Also, it may be helpful to incorporate a support person in the teaching process (Figure 29-3) and to reinforce learning by providing resources, such as printed materials, videos, lactation consultant referrals, and a written summary of what was taught. Berger and Loveland Cook (1998) suggested that learning can be facilitated by addressing topics in the hospital that were initially presented in prenatal classes and by reinforcing these topics through outpatient classes or group sessions. Nurses have a key role in assisting the mother to feel confident in her ability to care for herself and her newborn. It is important to assess learning needs and provide positive reinforcement during the teaching-learning process. By praising the mother's accomplishments, the nurse can foster maternal

Figure 29-3 Including support persons in postpartum teaching encourages parental self-confidence.

confidence in the mother's ability to care for herself and her infant.

Letting-Go Phase

Mothers move last to the **letting-go phase**. This phase is characterized by role attainment and relationship adjustments. It may take several weeks to reach and is influenced by cultural beliefs. Maternal role attainment often occurs slowly, as maternal self-confidence increases and maternal-child attachment strengthens. However, not all mothers go home with their infants. Their infant may be ill and hospitalized or given up for adoption, which can lead to a situational crisis. Nurses must be aware that maternal role attainment is affected by such factors as maternal age, cultural beliefs, a difficult delivery, postpartum complications, a sick or impaired infant, or a lack of adequate support systems. Prenatal expectations that conflict with actual experiences may directly impede maternal role adjustment. The goal of the "letting-go" stage is to achieve relationship and role stability.

Role Attainment

Researcher Ramona Mercer was influenced by the work of Reva Rubin. Mercer's research looked at maternal role attainment in diverse populations: adolescents, older mothers, ill mothers, mothers of children with anomalies, families experiencing antepartal stress, parents at high risk, and mothers who have had a cesarean section. Her research focused on factors that affect maternal role attainment from delivery to 12 months postpartum. Tomey and Alligood (1998) presented Mercer's theoretical framework as a useful guide for assessing maternal role attainment:

1. Increased maternal age appears to be an asset in child care behavior.
2. The older the woman, the more experience she has had in acquiring new roles.
3. Greater knowledge and early experiences enhances competency in moving to new roles.
4. The maternal role is socially accepted as an adult role but is inappropriate for the psychologically immature teenager.
5. The events of labor and delivery have the potential to affect the mother's self-esteem in either a positive or negative way along with the experience of early interaction with her infant.
6. Social stress has been correlated to complications of pregnancy and parenting.
7. A relationship exists between the woman's support system and her mothering capability.
8. The woman's ego strength, self-confidence, and nurturant qualities have been observed to be basic determinants of her capacity as a mother.

9. Maternal illness during pregnancy or birth affects the woman's self-esteem and drains energy that would otherwise be available for mothering.
10. Child-rearing attitudes, how parents handle irritating child behaviors, and parent-child interaction and communication all sharply differentiate abusive from nonabusive parents.
11. Mothers who rate high in adaptive maternal behavior have been observed to have infants with easy temperaments.
12. Culture and socioeconomic levels affect the maternal role.
13. Attainment of the maternal role may be accomplished in 12 months.

During maternal-infant interaction, the mother often displays a heightened awareness and interest in exploring her infant. Maternal attachment behaviors, such as holding the baby close, cuddling, stroking, making eye contact, and talking softly to the infant can serve to facilitate maternal role attainment. Nurses can promote maternal-infant attachment by encouraging the mother to hold her infant closely, with skin-to-skin contact, and giving the mother time to see and hold her newborn. Skin-to-skin contact, often referred to as **kangaroo care** (Figure 29-4), has many beneficial effects, especially with the premature infant, in whom it was found to facilitate neurobehavioral development, promote parenting interventions, decrease maternal stress, and enhance maternal confidence (Ludington-Hoe & Swinth, 1996). Nurses can also facilitate maternal role attainment by carrying out a complete assessment of family interactions and available support systems. Mothers should be encouraged to verbalize concerns and identify stressors that may impede maternal role attainment. By using therapeutic communication skills and active listening, nurses can develop a collaborative plan of

Figure 29-4 Kangaroo care (skin-to-skin contact) promotes bonding and attachment, which is especially important for the premature infant.

PROMOTING ATTACHMENT BEHAVIORS

Nurses have a special role in promoting maternal-infant attachment behaviors:

1. Always refer to the infant by name.
2. Unwrap the infant and initiate exploration of the infant's body.
3. Answer concerns that the parents may have (such as those regarding cord care or circumcision).
4. Encourage the mother to pick up and hold her infant.
5. Encourage the mother to hold her infant in a *en-face* (face-to-face) position.
6. Talk directly to the infant in a calm, soothing voice.
7. Use the infant's grasp reflex to hold onto the mother's finger.
8. Demonstrate comforting techniques, such as gentle patting and rocking (Figure 29-5).
9. Assess the mother's readiness to learn infant care.
10. Point out the infant's response to maternal stimulation.

care and initiate referrals to support services when indicated.

The importance of understanding maternal attachment behaviors and role attainment cannot be underestimated. Carter-Jessop and Yoos (1994) reported that understanding the beliefs parents hold about parenting may yield more important information than observing parenting behaviors. The researchers also emphasized that early intervention to encourage communication between the parents can promote positive role adjustment. A randomized, controlled trial by Midmer, Wilson, and Cummings (1995) studied the effects of middle-trimester parenting communication classes on postpartum anxiety, marital satisfaction, and adjustment. Classes contained didactic sessions, role-playing sessions, and value-clarification exercises. The researchers found that prenatal parenting communication classes had a significant positive effect on postpartum anxiety, marital satisfaction, and adjustment. Since many hospitals offer prenatal classes for breastfeeding, childbirth, and sibling adjustment, perhaps the findings of this study could pave the way for nurses to develop prenatal parenting communication classes.

Figure 29-5 Nurses should help parents of high-risk infants to find ways to bond with and comfort their newborns.

Maternal adjustment to role change is dependent on many factors. Gjerdingen and Chaloner (1994) examined factors affecting maternal role adjustment at 1 month postpartum and found correlations among maternal fatigue, lack of sleep, concerns about appearance, infant illnesses, and poor mental health. They reported that adverse effects on postpartum adjustment were related to previous mental problems, physical problems, poor general health, poor social support, fewer recreational activities, young age, and low income. A maternal mental health study by Beck (1996) examined the interactions of postpartum depressed mothers with their infant. The findings showed that depressed mothers went through the motions of mothering, were emotionally detached from their children, and failed to respond to their infants' cues. Parental responsibilities, guilt, irrational thinking, and anger overwhelmed these mothers.

Postpartum adjustment difficulty may be related to the depletion of energy stores, lack of sufficient sleep, hormonal shifts, and an overwhelming sense of responsibility. A study conducted by Smith-Hanrahan and Deblois (1995) focused on maternal fatigue and found that severe fatigue affected 25% of the mothers at 1 and 6 weeks postpartum. Merchant, Affonso, and Mayberry (1995) reported two psychosocial factors, i.e., marital adjustment and childcare stress, significantly influenced maternal depression at 9 months and pointed to the need to follow mothers beyond

REFLECTIONS FROM A MOTHER

"When I delivered my first baby at age 21, my husband was not able to attend the birth because of a military assignment. After the delivery of our son, the nurse gave him to me to hold and encouraged me to put the baby to breast. However, I really did not want to nurse at that time, because I was in too much pain from a difficult delivery and was upset about not having my husband with me. I felt so guilty about not having an immediate attachment to my baby; it felt like I was looking at someone else's baby. These feelings made me feel like crying; I thought I was being a bad mother. With extreme feelings of guilt, I asked the nurse to take the baby and give me some pain medication. She seemed to disapprove of my unwillingness to nurse my baby. It made me feel so sad and confused."

the traditional 6-week postpartum checkup. Thus, nurses must adequately assess maternal physical and mental health and social support structures to establish early interventions and referrals that assist mothers with maternal role adjustment. During postpartum visits, the nurse must observe the mother for signs of fatigue, feelings of sadness, or inability to cope with infant demands. Nurses were found to be more aware than physicians of the emotional effect of postpartum depression, and nurses who demonstrated empathic understanding were more aware of the postpartum depressive phenomenon (Lepper, DiMatteo, & Tinsley, 1994).

Seven characteristics that enhance nurses' caring for depressed mothers were identified (Beck, 1995):

1. Having sufficient knowledge about postpartum depression.
2. Using observation and intuition to recognize depression.
3. Providing hope to mothers.
4. Taking time to listen to the mother's concerns.
5. Initiating referrals.

Client Education

Helping Parents Adjust to Parenthood

Adjusting to the birth of a baby involves many changes, both physiological and psychological. It is important that parents:

- Recognize that adjusting to parenthood takes time.
- Discuss feelings with support persons.
- Obtain adequate rest and nutrition.
- Use community resources.
- Seek out support from family and friends.
- Understand postpartum and newborn care.
- Refer to written plans of care for postpartum and newborn care.
- Keep postpartum and newborn followup appointments.

6. Providing continuity of care.

7. Having empathic understanding.

Because of shorter hospital stays, nurses should be aware of the availability of outpatient maternity support services to assist mothers with postpartum transition (Figure 29-6). Fishbein and Burggraf (1998) studied the concerns of early postpartum discharge and reported that

Figure 29-6 Outreach programs that include home visits are especially helpful to new parents who are adjusting to their new family.

Research Highlight

Prenatal and Postnatal Attachment: A Modest Correlation

Purpose

To determine whether a correlation exists between prenatal and postnatal attachment.

Methods

Participants (228 women) were recruited from childbirth education classes. Most of the women were young, Caucasian, well-educated, married, and employed. The Prenatal Attachment Inventory (PAI) was administered to measure attachment before birth. The Maternal Attachment Inventory (MAI), the How I Feel About my Baby Now Scale, and the Maternal Separation Anxiety Scale were used to measure maternal attachment after birth.

Findings

One hundred ninety-six women completed the inventories and scales. A correlation was found between the Prenatal Attachment Inventory and the Maternal Attachment Inventory ($r = 0.41$, $p < 0.0001$). The modest size of the correlation suggests other factors influenced postnatal scores. One factor of marital status was found to significantly influence both the PAI and MAI scores. Single women had higher prenatal attachment scores than married women. Mean maternal attachment scores were higher for single women than for women who were living with a partner.

Nursing Implications

Because the findings indicate that a modest correlation exists between prenatal attachment and postnatal attachment, nurses should support the natural progression of attachment but not attempt to intervene to reach high levels of prenatal attachment, which may interrupt a natural process causing disappointment and self-blame. Instead, nurses should promote the mother's self-esteem, reassure her that maternal-child attachment is a lifelong process, and provide interventions that promote confidence related to being a good mother.

Muller, M. A. (1996). Prenatal and postnatal attachment: A modest correlation. *JOGNN*, 25(2), 161–166.

early postpartum concerns were related to fatigue and physiologic concerns such as perineal sutures, breast care, etc. They found that over half of the respondents would use outpatient postpartum resources if they were offered. Thus, nurses should be aware of the availability of outpatient services for postpartum mothers. In some communities, nurses have answered the need by establishing postpartum outreach programs. These programs include home visits, telephone contact, information lines, lactation information, mother-infant outpatient care, and parent support groups (Evans, 1995). Additionally, nurses have been instrumental in creating online resources to assist parents. These Internet websites provide parents with information related to pregnancy, delivery, the postpartum period, and newborn care.

PATERNAL ADJUSTMENT

Marks and Lovestone (1995) found that the common experience during the months immediately following childbirth is contrary to the idealized images of parenthood, and the process of attaining the role of father is influenced by the man's internal and external experiences as well as his relationship with the infant's mother, who acts as mediator in the father-infant relationship. Grant, Duggan, Andrews, and Serwing (1997) gave support to the effects of maternal influence on paternal role attainment when they reported that maternal expectations of the father's role during infancy were dependent on the strength of the parents' relationship and the mother's desire for the father's participation. Initial research by Jordon (1990) examined paternal

role attainment and found that a father's quest towards role identification and relevance involved three steps:

1. Initial acceptance of the reality of the pregnancy.
2. Being recognized by his mate in the role of father.
3. Becoming more involved as a father.

Ferketich and Mercer (1995) reported that inexperienced, first-time fathers, at 4 and 8 months following birth of their child, had greater anxiety and depression than experienced fathers and that a sense of mastery and family functioning were predictors for paternal role competence. Nurses can facilitate paternal adjustment by encouraging fathers to participate in childbirth preparation classes, during which they are given an active supportive role. In years past, fathers assumed a passive role, sitting in a waiting area anxiously awaiting the birth. Today, their role as coaching partners allows them the opportunity to experience the birth process with the mother and be actively involved in attachment behaviors immediately after birth.

Similar to maternal attachment, paternal attachment is a gradual process that occurs over weeks or months. Paternal attachment is usually manifested by **engrossment** behaviors, in which the father exhibits an intense interest in his newborn. Most fathers display a feeling of pride and satisfaction as they begin to develop a strong attraction toward their child. One study of paternal parenting attitudes revealed a decrease in happiness at 3 months postpartum, which may be related to the effects of fatigue and stress that result from added responsibilities (Tiller, 1995). Fathers need assistance in adjusting to role change. Nurses can guide fathers by including them in maternal and infant care. After delivery, the father should be encouraged to hold his newborn and private time should be provided for the couple to absorb the reality of the birth experience as they become acquainted with their newborn. By including the father as a support person, many fathers continue to assist the mother and are usually very interested in learning how to care for their infant (Figure 29-7). Some fathers take leave from work to help their partner at home. By providing opportunities to learn infant care and addressing concerns, nurses can assist in guiding fathers to reach paternal role attainment. Nurses have also been successful in developing prenatal and postnatal classes for fathers, and some hospitals have adopted policies whereby fathers can room-in with their partner and newborn.

Anderson (1996) explored fathers' experiences of becoming connected to their infant. They identified three major categories as important in the initial attachment between the father and newborn. These categories were identified as: making a commitment, becoming connected, and making room for baby. Paternal-infant attachment begins with the acceptance of the pregnancy as a reality. Participation in childbirth preparation classes facilitates pa-

Figure 29-7 Most fathers are eager to learn how to care for their newborn.

ternal antenatal attachment behaviors and prepares the father for the birth process and the needs of the expanding family.

Minton & Pasley (1996) examined the relationship between paternal role identity and involvement in child-related activities. They found that nonresidential fathers felt less competent and satisfied in their paternal role but had higher scores on role identity that correlated with more frequent involvement with their children. It is interesting to note that fathers of high-risk newborns perform significantly more infant care ($p < 0.005$) and were found to have a better adjustment to parenthood ($p < 0.0381$) at 1 month after discharge than fathers of healthy newborns. There were no differences found at 3 months after discharge (Brown, Rustia, & Schappert, 1991).

While it may not be easy for a father to adjust to his new role when the infant is healthy, the adjustment is more difficult when the infant is ill or disabled. Western cultural expectations promote male toughness during hard

REFLECTIONS FROM A FATHER

"When my daughter was born I was elated and very proud. In the early weeks, there was little chance for me to play with her because all she did was sleep and eat. Then one day, when I was changing her diaper, she looked directly at me and smiled. I felt extreme love and attachment. I was hooked for life."

Critical Thinking

Transition to Fatherhood

Male emotions are not well accepted in Western culture. Men are taught to be strong, and crying is thought to be a sign of weakness. Do you think that fathers experience strong emotional feelings at the birth of their child? How do you feel when you see a man cry? Are men conditioned to hold in their emotions? What is the result of emotional restraint? What do you think is the impact of the added responsibilities on the new father? How can the nurse help the father adjust? How does culture influence the father's response?

times. Little boys are often scolded for crying and peers may call them sissies. Finding support for conflicting difficult emotions when dealing with ill or disabled newborns may be difficult. Many men grieve inwardly, and depression is often hidden. May (1996) found that fathers of children with chronic illness or disability often felt isolated as they came to terms with loss and were required to strengthen caretaking capabilities. Thus, it is important for nurses to help fathers adjust to their role by taking time to listen to their concerns, letting them know it is acceptable to express their emotions, and showing them how they can become involved in the care of the child with special needs. By slowly introducing fathers to the care needs of their child and assessing their readiness to participate, nurses can reduce role strain and enhance family adjustment. It is also important to refer the grieving father to resources, such as support groups for fathers or counseling services. Today's technology provides online support resources that may be acceptable to the grieving father.

Nursing Tip

ASSISTING PARENTAL ROLE ADJUSTMENT

1. Establish rapport early to promote effective communication and verbalization of positive and negative feelings.
2. Assess the goals of the parents and include them in the planning process.
3. Give parents a feeling of empowerment by giving them choices regarding participation in maternal and infant care.
4. Encourage alone time with the infant to explore and get acquainted.
5. Promote rooming-in for the infant and the mother's partner to foster knowledge of their infant's normal patterns and encourage touching and holding behaviors.
6. Assess readiness to learn and participate in providing care.
7. Identify support figures and encourage involvement.
8. Encourage sibling visitation where possible.
9. Refer to community classes for parenting, nutrition, new fathers, infant massage, or similar activities.

INFANT BEHAVIORS INFLUENCING ATTACHMENT

As a new mother begins to get acquainted with her newborn, infant behavioral cues can assist in facilitating maternal-child attachment. Nurses should be aware of infant behaviors to assist parents to understand their infant's cues and to recognize when their infant is most receptive to stimulation. Brazelton (1981) identified six stages in the infant's **sleep-wake cycle** that affect alertness and responsiveness: deep sleep, light sleep, drowsiness, quiet alertness, active alertness, and crying (Table 29-2). A mother must be able to identify an infant's state of quiet alertness when they are most responsive to stimulation. During this state, the infant responds to stimulation with a widening of the eyes and increased alertness; this is an optimum time for maternal-infant interaction. When placed in a face-to-face (*en face*) position, the infant is able to briefly focus on the mother's face and attend to her vocal sounds. Infants often are seen to move their body in synchrony with the mother's voice. Brazelton (1981) identified this behavior as mutual regulation. When stimulated, the infant responds with coordinated, synchronous body movement and may imitate vocal sounds and facial gestures. Also, the face-to-face position is an important position for optimal interaction. Failure to assume the *en face* position may be an early symptom of maternal maladjustment.

Mothers should recognize infant behavior when overstimulation occurs: infants take a break from the interaction and intermittently look away to reduce the intensity of the interaction when overstimulated. Nurses can assist parents to recognize infant behaviors to optimize parent-newborn interactions and facilitate the attachment process.

Table 29-2 Newborn Sleep-Wake States

State	Observed Activity
Deep sleep	Very little movement Occasional startle motion Regular breathing
Light sleep	Some body movements Eye fluttering Smiles occasionally Irregular breathing
Drowsiness	Mild startle movements Intermittent eyelid opening Glazed eyes
Quiet alertness (most attentive state)	Some increase in activity Widening of the eyes More alert face
Active alertness	Increased motor activity Fussiness Decreased attention to stimulation Increased reaction to discomfort
Crying	Increased motor movement Extreme response to discomfort

Data from Brazelton, T. B. (1984) *Neonatal behavioral assessment scale*, 2nd ed. London: Heineman.

SIBLING ADJUSTMENT

Another challenging aspect of adjustment for the growing family involves the adjustment of siblings. Brazelton (1981) pointed out that small children can recognize changes in their mother as she becomes more internalized during the pregnancy, and it is not unusual for these children to turn elsewhere for nurturing. When a newborn is introduced into the family structure, siblings must adjust and assume the role of the older brother or sister. Anxiety and feelings of jealousy may occur as the sibling reorganizes his or her place in the family. It is not unusual to see regression to earlier behaviors, such as bed wetting and thumb sucking. Jealousy may also be used to gain parental attention. Sibling adjustment can be made easier if the parents involve the older child in a sibling preparation class. Nurses have developed these classes to assist the child in adjusting when they visit the hospital nursery and are addressed as the “big brother” or “big sister.” In many areas, older children are permitted to attend the birth. The sooner the older child is involved in the preparation for a new family member, the more positively involved they are likely to be (Brazelton, 1981). By allowing visitation time for older children to greet their new sibling, nurses can foster behaviors that initiate a positive attachment (Figure 29-8). This attachment is further strengthened by finding ways in which the older child can carry out the role of “big

Figure 29-8 Encourage parents to introduce older siblings to the newborn as soon as feasible.

brother” or “big sister” through participation in the infant’s care. Older children can feel important when they help by retrieving supplies or carrying the diaper bag. Many parents find it helpful to set aside special time alone with the older child in a play activity. During this time, the older child should be encouraged to express their feelings.

Nursing Tip

SIBLING VISITATION POSTPARTUM

Early inclusion of older siblings helps to facilitate adaptation of older children to their new role and promotes a sense of being a family.

1. Promote early contact with the newborn to facilitate integration into the family unit.
2. Enhance the older sibling’s feeling of importance within the family as a “helper.”
3. Include the sibling in a celebration party to promote a feeling of belonging.
4. Take precautions against cross-infection by questioning parents to see if their older child has been exposed to a communicable disease in recent weeks or presently has symptoms of a infection, such as vomiting, coughing, runny nose, fever, diarrhea, or rash.
5. Educate parents regarding sibling handwashing to promote safe sibling contact with the newborn and facilitate appropriate sibling attachment behavior.

Client Education

Strategies for Managing Sibling Rivalry

Observed Behavior: Regression

Strategy

Regression is a coping mechanism whereby the child returns to a coping behavior of an earlier stage of development. This is a normal behavior for young children to exhibit in times of stress. Behaviors such as thumb sucking, temper tantrums, and increased dependency help the child cope with stress. Be patient, don't scold, and use a calm, caring approach. With time, the behavior will pass.

Observed Behavior: Jealousy

Strategy

This is a normal behavior when young children see a new baby taking most of the parents' time. Set aside special times for outings with the older child. Don't address negative coping behaviors. Focus on encouraging the older child to express feelings through verbalization, drawings, or play. Listen attentively and help older children sort out their feelings. Most of all, older children need to feel important and loved.

Observed Behavior: Anger or Tantrums

Strategy

Recognize this as attention-getting behavior. Ignore the tantrum by avoiding eye contact and moving out of view, but nearby. Do not make statements such as, "Stop acting like a baby," or threaten to spank the child. If anger is directed toward harming the baby, set rules in a calm manner; "time out" may be enforced. Encourage positive interactions with supervision and give praise for positive behavior. Involve the older child by asking them to get supplies and to help by carrying the diaper bag, and praise the child for being a big helper (Figure 29-9). Never leave an angry child unattended near the newborn. With time, love, positive involvement, and rule setting, the problem behaviors will pass. Older children need praise, hugs, and a parent's undivided attention to help them adjust to the change.

Figure 29-9 Older siblings feel important if they can help care for the new baby through simple tasks, such as retrieving a clean diaper.

GRANDPARENT ADJUSTMENT

Grandparents can be a source of support for new parents. Grandparents are unique in that they have the experience to assist new parents as they adjust to the role of parent (Figure 29-10). A grandmother's expertise can be helpful to a new mother as she learns to care for her infant. Having someone who has raised children is a valuable source of information and support that can lessen the anxiety of new parents and give the mother a chance to rest and focus on her role.

However, the role change can be a stressful time for both the parents and grandparents. It is not unusual for grandparents to be unsure of how much involvement they should have. Many grandparents are still employed and

Figure 29-10 Grandparents can be a source of help and wisdom for new parents and sometimes may even take over the parenting role, if the new parents are unable to manage the responsibilities.

REFLECTIONS FROM AN OLDER SIBLING

"I was about age 4½ when my younger brother Joey was born, but I still remember that day. (Boy, do I remember that day!) Let's just say it involves a grandma, bathroom cleanser, and one really upset (spoiled) little girl. . . .

Picture it: the Bronx, 1982. A cute little girl storms into the bathroom at her grandparents' home, a bathroom complete with a claw-footed bathtub and difficult-to-manage locks. She was feeling particularly high-spirited (ok, evil) on that day, the first day my mother had ever left me for such a long time. I didn't care that she had been in labor for hours with her first 'normal' delivery, (being of the difficult type, I was delivered by cesarean section.) I was determined to wreak havoc and take all of my emotion out on my poor, gentle grandma. So I did what any protesting individual does: I staged a 'sit in,' right in my grandparents' bathroom. And I did the unspeakable: I locked myself in. Needless to say, my grandma was a little nervous for a while. But that stopped when she became extremely worried after the third hour. I heard my mild-mannered grandma become a fire-breathing dragon right on the other side of that thick oak door. She began screaming for me to open the door and to stay away from everything in the bathroom. But like the protestors of the 60s, I held tight. I even chanted a little. But after the sixth hour, I became hungry and eventually figured out how to open the difficult lock. My grandma, so relieved that I wasn't dead from drinking the bathroom cleanser, was ecstatic.

And I've been a 'protestor' ever since."

unable to provide assistance, or they may give unsolicited advice and spoil the child with gifts. This can be a source of disagreement between the parents and grandparents. Today, many grandparents are active with their own lives and may not demonstrate the expected interest and involvement with their grandchild. In addition, today's mobile society has made it difficult for many grandparents to have close contact with their children because they live too far away. Thus, the parent-grandparent relationship can be a challenging one.

The inclusion of grandparents is a personal decision the couple makes and is based on relationship factors, distance, economics, and cultural expectations. Many cultures rely heavily on the grandmother to be actively involved in a child's life. Likewise, many grandparents are excited about their new role as it adds a positive dimension to their life. Today, there is a growing trend in society for grandparents to assume the parenting role because of their child's single parenthood, divorce, illness, or substance abuse. A study by Kelley and Damato (1995) reported that the experience of parenting grandchildren was emotionally rewarding but psychologically and physically stressful. However, some of the respondents reported an improvement in their emotional health as they provided care for their grandchildren. Those who found the experience to be psychologically stressful found that they were restricted in their social life. Some felt isolated from friends and resented being tied down. Repressed anger and depression often occurred. Physically, many reported being too old to be able to keep up with the demands of childrearing. However, some reported that the rewards of doing the right thing gave them joy but that they felt heartache when their grandchild questioned why they did not live with their mommy and daddy. Many of the respondents reported their other adult children as their greatest support, but 54% reported difficulty in relationships with their other children, who often expressed feelings of envy and resentment about the time spent with the grandchild. In addition, 15% reported that nurses or teachers were a source of support. In another study, Patterson (1997) examined the involvement of the maternal grandmother with the children of an adolescent child. Interestingly, 72% of the children were found to be securely attached to their grandmothers, and 44% of the children were securely attached to their mother. Thus, a grandparents' role change to parenting grandchildren is an important support but causes stress for many grandparents, who, at this stage in life, feel they should be free from the burdens of raising children.

FACTORS AFFECTING ROLE MASTERY

Role mastery involves successful attainment of developmental goals. Duvall (1971) outlined task-oriented goals

that are to be mastered at each stage in the life cycle. In the stage of *family with infants*, the developmental tasks to be completed are to provide a safe, nurturing home and adapt to new roles and relationships. Transition to parenthood is a crucial time when parents must assess their perception of themselves while striving to successfully complete developmental tasks. Parents need to realistically appraise and successfully integrate their new role to prevent a crisis. Thus, the nurse should assess the parent's emotional and physical needs. By encouraging parents to verbalize their feelings, the nurse can help them clarify their perception of their role as parent and assist them to set realistic goals towards role mastery.

Role mastery is dependent on developing competence in infant care, successfully assessing and meeting the infant's needs, integrating the infant into the family structure, and redefining relationships with a spouse, children, and extended family members. These tasks can be overwhelming and difficult for new parents to achieve. A study conducted by Sullivan (1997) focused on maternal problem solving and found that mothers were often not certain of their infant's problem even after comforting them and that nurses must use planned and unplanned encounters to effectively teach mothers about their infants. Also, including fathers in the teaching process increased their comfort level with infant care and assisted them in supporting their partner. Leathers, Kelley, and Richman (1997) reported that high levels of maternal depressive symptoms were related to the mother's perception of low levels of emotional support from her partner along with low control and gratification in the parenting role. Stamp (1994) analyzed three dimensions salient to the appropriation of the parental role: (1) the accuracy of role expectations, (2) the facilitation of role enactment, and (3) the openness in role negotiation with one's spouse. Self-esteem was found to be a major predictor for maternal role competence for both primiparas and multiparas (Mercer & Ferketich, 1995).

THE POSTPARTUM ADOLESCENT MOTHER

Adolescence is a time of great change as teens address developmental milestones of independence and strive to achieve self-identity. When developmental progress is interrupted, a situational crisis occurs that affects the entire family. An unplanned pregnancy during the teen years generally results in a major personal and family crisis. The pregnancy can block the adolescent's successful completion of developmental tasks and can put a teenage mother in a state of crisis as her sense of identity becomes blurred. The pregnant adolescent has an increased dependence on others at a time when she is striving for independence. Nurses can assist the pregnant adolescent by fostering independence and a sense of self. It is important to listen to

Critical Thinking

The Impact of Adolescent Pregnancy

Adolescence is a time of change when many teens are trying to develop a sense of identity and begin to move toward independence. Do you think adolescent pregnancy impedes the developmental process? Do you think pregnant adolescents suffer from low self-esteem? Do you think adolescents can successfully attain the maternal role? Do you think single adolescent mothers are able to parent effectively? Do you think adolescent mothers can successfully adapt to the role of mother if they actively participate in planning interventions? Do you think adolescent mothers need close follow-up during the postpartum period? Do you think the unwed father should play an active supporting role throughout the pregnancy and after birth?

the teen mother's concerns, include her in health care decisions, collaborate with her when planning interventions, and include support persons to assist the teen mother throughout the pregnancy, delivery, and postpartum period to facilitate positive adjustment. The adolescent's ability to adapt to the pregnancy and respond with realistic expectations depends on effective sources of support to assist her to clarify feelings and set realistic goals.

Burke and Liston (1994) reported that the experience of parenting could give the adolescent a sense of responsibility and an opportunity for growth (Figure 29-11). The researchers also found that adolescents identified the baby's father as their key support person. Diehl (1997) reported that paternal involvement was a significant factor in fostering a positive interaction between adolescent moth-

Figure 29-11 This teenage mother is accepting the responsibility of caring for her newborn.

Research Highlight

Depressive Symptoms, Stress, and Social Support in Pregnant and Postpartum Adolescents

Purpose

To prospectively assess the incidence and course of depressive symptoms among pregnant and postpartum adolescents and explore the roles of stress and social support.

Methods

Participants (n=125) were pregnant teenagers who were enrolled in a pregnancy and parenting program during the third trimester of pregnancy and followed through for 4 months postpartum. Depressive symptoms were measured with self-administered instruments during the third trimester, and at 2 and 4 months postpartum. The teens were predominantly African American (93%) and were from 12 to 18 years of age. Assessments were received from 114 teens at 2 months and 108 at 4 months postpartum.

Findings

During the third trimester, 42% reported significant depressive symptoms, and stress levels increased significantly from the third trimester to the postpartum period ($p < .01$). There was a positive association between stress and depression. Lower rates of stress and depression occurred when the teen mother received social support from her mother or the infant's father. Conflict with the infant's father was seen in conjunction with increased depressive symptoms.

Nursing Implications

Social support is important in decreasing stress and depressive symptoms among teenage mothers. Early identification of depressive symptoms, increased stress levels, and a lack of support is important in helping teen mothers to receive early intervention through support services and referrals.

Barnet, B., Joffe, A., Duggan, A. K., Wilson, M. D., & Repke, J. T. (1996). Depressive symptoms, stress, and social support in pregnant and postpartum adolescents. *Archives of Pediatric & Adolescent Medicine*, 150 (1), 64–69.

ers and their children. Bloom (1998) examined the role of the father in adolescent pregnancy. The findings supported Rubin's theory of maternal identity formation in that a close and satisfying relationship with the father of the baby had a positive influence on adolescent maternal-infant attachment behaviors. When possible, it is important to involve the father as a support person for the adolescent mother to facilitate positive role transition.

CULTURAL CONSIDERATIONS

Culture is the value or belief system of a group of individuals and directly affects maternal role transition. Western

culture, in past years, encouraged a long hospitalization for the mother to recover from delivery. This time, known as the "lying-in period," was several weeks, during which the mother was expected to maintain bedrest and rely on nurses and family for assistance. It was not unusual for the mother to maintain bedrest for 7 days and to stay in the hospital for 10 to 14 days. Problems with thrombophlebitis were commonplace.

Today's fast-paced society places emphasis on preparing for the birth, but little time is given to recovery. Mothers now experience short hospital stays that are referred to as "drive-through" delivery. However, many Eastern cultural traditions continue to support the "lying-in" concept, and these families are stressed by Western cultural expectations. Nurses should take time to ask women about their

Research Highlight

An Early Intervention Program for Adolescent Mothers

Purpose

To improve health outcomes in a vulnerable population of adolescent mothers and their infants.

Method

The effects of an early intervention program (EIP) were compared with the interventions of traditional public health nursing care. Participants (n=63) were provided intensive early interventions by means of four prenatal classes and approximately 17 home visits by specially trained public health nurses. Interventions addressed health issues, sexuality and family planning, life skills, the maternal role, and social support systems. Participants (n=58) in traditional public health nursing care received three home visits regarding intake, prenatal care, and postpartum and well-baby care information.

Findings

Early program interventions indicated a reduction in premature birth rates for both groups compared with national data for adolescent mothers. In addition, there were fewer days of infant hospitalization during the first 6 weeks postpartum for the EIP participants. Thus, both traditional and intensive early intervention in adolescent pregnancy significantly improved perinatal outcomes.

Nursing Implications

Both the traditional and intensive EIPs improved perinatal outcome in terms of infant birth weight and gestational age. The teaching of self-care and the initiation of referrals for prenatal care were common aspects of both programs. The more intense and frequent nursing contacts maintained through prenatal classes, home visits, and telephone interactions seemed to have a positive influence on infant outcome. The adolescents who received the intensive intervention program had an opportunity to discuss their concerns about their infants and other issues. The environment created was one that allowed the adolescent to develop rapport with and a sense of trust in their health care provider. The planned activities served to facilitate maternal role adaptation and heighten awareness of infant behavior and development. The program was shown to be cost-effective by decreasing infant morbidity and hospitalization because of prematurity.

Koniak-Griffin, D., Mathenge, C., Anderson, L. R., & Verzemnieks, I. (1999). An early intervention program for adolescent mothers: A nursing demonstration project. *JOGNN*, 28 (1), 51–59.

cultural practices to individualize the teaching plan and help them recover from the birth.

New examples of cultural traditions (Schott & Henley, 1996) that affect the postpartum period include:

- Traditional African-Caribbean mothers are expected to rest for 2 weeks after giving birth and to avoid chilling. Thus, they may not want to shower. Breast-feeding is seen as best for the baby, and it is not uncommon to squirt a little breast milk into the infant's irritated eyes. Support is obtained from older women in the family. Food preferences for the new mother

include the main dietary staple of starchy vegetables, such as potatoes, yams, rice, and plantains. Fish is the main protein source, and spices are always included. Western hospital food is considered bland.

- Traditional Chinese mothers are viewed as being in a period of *yin* (cold) and require hot foods for at least a month to recover from the birth. A special broth of sweet black vinegar, ginger, and stewed pigs' trotters is served with a freshly boiled egg. The postpartum period is seen as a rest period of 1 month, with emphasis on serenity and harmony and avoidance of

any stress. Traditionally, men are not present during labor and birth and the woman receives support from her mother or other married women in the family. Modesty is an important consideration, because some families believe the husband should stay away on grounds of modesty. In many cases, bottle feeding is preferred because it is seen as an indication of high financial status compared with breastfeeding, which is mostly seen in poor families. A study by Chong-Yeu Liu-Chuang (1995) explored the practice of the Chinese ritual, *Tso-Yueh-Tzu* (doing-the-month), which is a 30-day postpartum seclusion observed by Taiwanese women. During this time, physical care was provided by an older family member and focused on promoting emotional stability. However, today's modern career women have been experiencing difficulty with this ritual and rely heavily on their husband.

- Traditional South Asian women from India, Pakistan, Bangladesh, and Sri Lanka regard childbearing and raising of children as a woman's greatest fulfillment and the act that permits the bride to be accepted into the groom's family. Older women of the family are important for support and guidance and have firm expectations that the new mother will follow their advice. It is traditional for newly delivered mothers to go to their parents' home for postnatal seclusion. During this time, mothers are expected to rest and be cared for by other women in the family for 6 weeks. The emphasis is on sleep, warmth, and good food. The mothers are also encouraged to stay in bed and request help. Their baby may be in bed with them or may be with them only for feeding. Breastfeeding is highly regarded and expected to continue for at least 1 year, but many do not believe in giving colostrum to the baby. It is believed that if mothers do not follow the expected routine, the mother's long-term health and emotional well-being will suffer. The husband is expected to stay with his parents during this time. The Western practice of initiating bonding by placing the baby on the mother's abdomen is particularly distressing to some women because they believe that the baby is covered with impurity from the birth canal and should be washed before handling.
- In traditional Hispanic culture, mothers rely heavily on their partner for assistance. A study by Khazoyan and Anderson (1994) studied Hispanic women and found that they expected their partner to have an active role in the birth by being nearby and offering words of love, encouragement, and support, which they believed enhanced the mother's inner strength and promoted calmness. During the postpartum period, Hispanic women observe a lying-in period, during which they receive help from their mother and

grandmother. Health restoration focuses on correcting imbalances by ingestion of proper foods, medications, or herbal remedies. Certain foods, such as pork, are considered to be "hot" and to upset balance within the body. Foods that are defined as "hot" or "cold" are an individual preference. Thus, the nurse should assess individual preferences and needs and respect them accordingly. Also, nurses should recognize that the grandmother has a great deal of influence in the decisions made regarding postpartum care.

Cultural Assessment

Nurses need to be aware of how to conduct a sensitive cultural assessment, which is critical in providing care for today's ethnically diverse population (Campinha-Bacote, 1995). To provide care for people of different cultures, nurses must be knowledgeable and culturally competent (Leininger, 1996). Seideman, Jacobson, Primeaux, Burns, & Weatherby (1996) outlined important cultural aspects to consider, using a Native American family as an example:

- Native American families differ from each other in their traditional beliefs and family structure.
- Generally, grandparents have an important role in parenting grandchildren.
- Extended family networks remain constant.
- Problems with parents and tradition occur when there is marriage with other tribes or ethnic groups.
- Distrust of Caucasian caregivers can interfere with interactions.
- Time is expected to be spent in establishing rapport before beginning an assessment.
- Learning by observation is preferred because asking questions is considered rude and intrusive.
- Unhurried observation is the best assessment approach.
- Positive reinforcement regarding observed strengths is important.
- Addressing areas that need improvement is best done in a neutral, indirect manner.
- A genuine interest in understanding the Native American culture is desirable.
- Referrals are more successful if a Native American professional or a person who is appreciative and sensitive to the culture is recommended.

NURSING PROCESS

For the postpartum family, the nursing process is an ongoing process that is used to develop an individualized plan

of care. It involves careful collection of a database that supports a problem-solving approach to client care. The nursing process identifies areas in which the postpartum family requires nursing intervention.

Assessment

Family assessment begins with the initial nurse-family interaction, and focuses primarily on maternal and father-partner assessment. When taking a history and observing family dynamics, nurses begin to identify problem areas for collaborative intervention.

Maternal Assessment

Assessment of maternal behaviors that reflect a positive adjustment to the maternal role must take into consideration the expected behaviors of the “taking in” and the “taking hold” phases. Early indicators of a positive maternal adjustment include that the mother:

- Appears concerned when the infant cries and seeks to hold the infant.
- Uses eye contact in a face-to-face position when holding the infant.
- Is interested in getting to know the infant by gently exploring.
- Handles the infant lovingly and talks affectionately.
- Wants to review the birth and comments positively about the birth experience.
- Demonstrates a positive relationship with her partner or support person.

If the mother displays a negative attitude, does not have eye contact with the infant, does not want to hold the infant, or expresses anxiety and a lack of interest in the infant, maladaptation may be occurring. Nurses should assess maladaptive behaviors, therapeutic communication skills, help the mother to clarify her feelings, and assess cultural beliefs that may be affecting postpartum behaviors. What may seem to be rejection behaviors may well be an accepted cultural norm. Other factors that must be considered are the mother's perception of the maternal role, her physical and emotional status, stressors that may be affecting role attainment, lack of support systems, young age, and poor coping mechanisms.

Father or Partner Assessment

The family-centered approach to postpartum care allows the nurse to view family dynamics. Paternal adaptation depends on a feeling of being included. Assessment of the father's perception of the birth and his behavior as a support person can give insight into the status of family adjustment. Many fathers want to discuss their feelings but

are denied the opportunity when attention is focused primarily on the mother and infant. Fathers should be given the opportunity to express their feelings and to participate in the attachment process. By assessing the father's readiness to participate, nurses can assist in fostering the protective, watchful environment many fathers display.

Nursing Diagnosis

Identification of actual or potential problems early in the postpartum period is necessary for effective planning and intervention. On the basis of assessment data, cultural influences, spiritual needs, medical considerations, and family interactions, problem areas are analyzed and nursing diagnoses are developed. Examples of common nursing diagnoses that affect maternal role attainment are anxiety, fear, deficient knowledge, ineffective breast-feeding, ineffective role performance, and impaired parenting.

Outcome Identification

Outcomes for nursing interventions lay the pathway for nursing care. Goals are set through mutual determination of priorities between the nurse and the mother. The expected outcome or goal is specifically to reduce or eliminate the identified problem within a specified time frame. For example, if a mother is afraid to interact with her newborn, the nurse and mother need to explore the cause, identify the relationship of the cause to the problem, and assign priority to attainable goals. Identified outcome criteria act as a pathway for nursing interventions. An example would be: the nursing diagnosis of knowledge deficit related to inexperience with infants could have as one possible goal that the mother is able to demonstrate proper infant positioning during feeding.

Planning

Mutual planning involves assessing problem areas, considering expected outcomes, and setting realistic goals within a specified time period. Individualized nursing plans of care are established to include nursing actions, available resources, and client willingness to participate. For example, when developing a plan for a mother who is unsure about breastfeeding, the plan of care could include a referral to a resource, such as a lactation consultant.

Nursing Intervention

An individualized plan is based on identification of reasonable actions that can achieve desired outcomes. These actions may be independent nursing actions or collaborative actions involving other members. Actions are developed to resolve or lessen an identified problem and provide direction for nurses and other health care

Box 29-1 Nursing Care of the Postpartum Family**Nursing Diagnosis**

Ineffective coping (potential) related to maturational crisis as evidenced by inability to meet role expectations.

Goal

The mother will begin to demonstrate positive coping behaviors by discharge.

Outcome

The mother is able to express feelings and set realistic goals and role expectations.

Intervention

Take time to explore the mother's role expectations.

Nursing Diagnosis

Risk for impaired parent, infant, or child attachment related to anxiety associated with the parent role as evidenced by lack of desire to interact with the infant.

Goal

The family will begin the attachment process by discharge.

Outcome

Parents are able to demonstrate attachment interactions with their infant.

Intervention

Slowly involve parents in infant care, guiding them from passive observers to active participants.

Nursing Diagnosis

Deficient knowledge related to lack of experience with infant care as evidenced by anxiety and hesitancy to provide infant care.

Goal

The parents will begin to provide infant care.

Outcome

Parents are able to initiate infant care before hospital discharge.

Intervention

Mother will demonstrate correct cord care.

professionals. Examples of interventions directed towards assisting the mother with role performance may include:

1. Using therapeutic communication to encourage verbalization of feelings and clarification of areas of concern.
2. Assessing cultural beliefs and incorporating them in maternal and infant care.
3. Involving the mother, her partner, and support persons in discharge planning.
4. Incorporating alternative therapies to reduce stress, such as music, massage, or guided imagery.
5. Referring parents to community resources, such as parenting classes, breastfeeding classes, or father's support classes.
6. Referring to counseling services as indicated.

Evaluation

Evaluation involves appraisal of identified outcomes and goals to decide if the goals have been reached (Box 29-1). Evaluation of goal achievement starts by assessing the client and gathering data to determine if outcomes have been reached or need adjusting. Questions to consider are whether or not the identified problems have been resolved or to what extent they still exist. Are there new problems to consider? Were the outcomes, goals, and interventions appropriate for this client? Were the nursing interventions consistently followed? What changes need to be made in the plan of care? Factors that hindered or helped goal attainment can be identified by interviewing the client and the family. Does the family need to be more involved in assisting with goal attainment? Is a planned conference with members of the health care team needed? If the client has achieved the established goals, and no new problems are present, the plan of care is considered successful and the client is in a stabilized health pattern.

Web Activities

- What sites could you recommend to new families who are looking for self-help information, chat rooms, or other electronic information sources?
- Is there a listing on the Internet of books, videos, or other media on postpartum adjustment? Are these resources available in your local library or through purchase from a website?

Case Study/Care Plan

POSTPARTUM TEEN MOTHER

Megan is a 16-year-old primigravida who delivered an 8-lb. girl by cesarean section. She is unwed and has no contact with the baby's father. She was in her junior year in high school, until her parents sent her to another state to live with an aunt for the last trimester and delivery. The parents are busy with their professional careers and have no interest in raising a grandchild. Because they are attorneys, they were able to arrange for adoption.

On the day following delivery, Megan was found crying. She told the nurse that she wanted to see her baby but was afraid to hold her. She expressed a desire to stay with her aunt and keep the baby. She also wanted to finish high school and get a job. Her aunt has been very loving and supportive, but she is raising three children alone as a divorced parent and cannot take on the added responsibility. Megan asked the nurse for pain medication while looking sadly at and holding her swollen abdomen. She tearfully said she would never get her figure back.

Assessment

Subjective data obtained through the interview process:

- Client was sent away to have her baby and give it up for adoption.
- Client is an unwed adolescent.
- Client desires to finish high school.
- Client has expressed a desire to keep her baby.
- Client desires to see her infant and is afraid to hold her.
- Client has no contact with the baby's father.
- Client has busy parents who give her monetary support and arranged the adoption.
- Client has an aunt who is supportive but unable to care for her niece and newborn.
- Client requested pain medication.
- Client states she will not get her figure back.

Objective data obtained through observation:

- Client is tearful and crying.
- Client looks anxious when talking about the baby.
- Client is holding her hands over incisional area.
- Client looks at the physical changes in her body.

Nursing Diagnosis

Pain related to cesarean incision as evidenced by supporting the incisional area and requesting medication.

Expected Outcome Client will have significant pain reduction within 1 hour after medication administration.

Planning Collaborating with client, determine how pain medication is to be administered and how often.

Nursing Interventions

1. Assess need for pain medication using a scale from 1 to 10. Use guided imagery to refocus and enhance medication effectiveness.

Rationales

1. Relief of pain is achieved with pharmacologic and nonpharmacologic means.

(continued)

Evaluation Pain medication schedule is effective in reducing client's pain within 1 hour after administration.

Nursing Diagnosis

Ineffective coping related to personal vulnerability in a situational crisis as evidenced by ineffective coping skills, and lack of support.

Expected Outcome Client will be able to clarify feelings and improve coping skills by discharge.

Planning By collaborating with client and support services, determine interventions to increase coping with situational crisis.

Nursing Interventions

Rationales

1. Take time to listen and assist to clarify feelings and improve coping skills. Address situational crisis via referral to a social worker.

1. Showing respect to client by listening and offering referrals will encourage confidence and realistic view of situation.

Evaluation Client is able to collaborate with social worker through family counseling to clarify feelings, improve coping skills, and set realistic goals regarding situational crisis by discharge.

Nursing Diagnosis

Anxiety related to situational crisis as evidenced by conflict with adoption issue.

Expected Outcome Client will demonstrate use of alternative relaxation techniques to reduce anxiety by discharge.

Planning Collaborating with client, determine methods to reduce level of anxiety.

Nursing Interventions

Rationales

1. Encourage ventilation of feelings; take time to listen. Incorporate alternative relaxation techniques, such as music, therapeutic touch, or focal breathing.

1. Encouraging verbalization of feelings and relaxation exercises will help to lessen anxiety.

Evaluation Client is able to effectively carry out alternative relaxation techniques to reduce anxiety by discharge.

Nursing Diagnosis

Disturbed body image related to physical changes as evidenced by concern about appearance.

Expected Outcome Client will demonstrate an understanding of postpartum body changes and exercise and nutritional program by discharge.

Planning Collaborating with the client, determine actions to increase realistic perception of self through physical and nutritional interventions.

Nursing Interventions

Rationales

1. Address concerns related to physical changes. Review postpartum exercise program, which may include yoga or walking. Refer to dietitian if calorie reduction is indicated.

1. Realistic understanding of physical changes promotes acceptance of body image. Knowledge of available resources assists in maternal adjustment.

Evaluation Client is able to understand physical changes during postpartum and incorporate a progressive exercise program by discharge.

Key Concepts

- The parent-child attachment process occurs over a period of time.
- Role adjustment to parenthood involves developmental task attainment.
- Maternal adjustment passes through three phases.
- Newborn sleep-wake behaviors influence the attachment process.
- Paternal adjustment occurs over time and is related to maternal influences.
- Siblings are affected by role change and seek nurturing by significant others.
- Grandparent's role adjustment may be positive or negative depending on the situation.
- Nurses need to be aware of cultural influences that affect parental role adjustment.
- Postpartum adolescents require assistance in achieving role adjustment and meeting the developmental tasks of adolescence.
- The nursing process provides a mechanism for assessing individual and family role transition.
- Alternative therapies can assist in maternal adjustment.

Review Questions and Activities

1. What does it mean to be a parent?
2. What nursing actions facilitate parent-child attachment?
3. How can nursing theory be applied to maternal role attainment?
4. How can culture affect maternal role attainment?
5. List infant behaviors that can facilitate the parent-child attachment process.
6. Compare and contrast paternal and maternal role attainment.
7. What community resources are available in your community to assist teen mothers?
8. What role do new grandparents have?
9. How can sibling adjustment be facilitated?
10. List 10 indicators of positive maternal adjustment.
11. Identify three salient dimensions related to paternal role attainment.

Lactation and Nursing Support

Helping new mothers and mothers-to-be with breast-feeding decisions requires the nurse to examine her own biases regarding feeding methods. Working with mothers and families to support the decision that is best for them and their infants can have an empowering effect on these new mothers.

- *Do I really believe that “breast is best”?*
- *Which feeding method would I choose for my own infant?*
- *Do I feel embarrassed to see a woman breast-feed in public?*
- *How do I feel when trying to help a woman breast-feed for the first time?*
- *Do I feel angry when a client doesn’t do what I think is best for her or her infant?*
- *Can I allow a client to tell me how she really feels without judging her?*
- *Do I respect cultural beliefs about breast-feeding that may not be scientifically sound?*

Competencies

Upon completion of this chapter, the reader should be able to:

1. Identify the health and financial benefits related to breast-feeding.
2. Explore the motivations and perceived barriers related to breast-feeding.
3. Describe effective strategies to promote breast-feeding in a culturally sensitive manner.
4. Develop interventions that lead to successful breast-feeding outcomes.
5. Delineate nursing responsibilities for patient education and informed consent related to breast-feeding decisions.
6. Assess the nutritional status of the breast-fed infant.
7. Describe the physiology of lactation.
8. Apply the nursing process to the woman who is breast-feeding.

The health, nutritional, and psychologic benefits of breast-feeding are widely recognized in the medical, lay, and scientific communities. Breast-feeding is the infant feeding method recommended by the American Academy of Pediatrics, American Public Health Association, and American Dietetic Association for the first 12 months after birth (American Academy of Pediatrics, 1997). The practice guidelines of the American Academy of Pediatrics are straightforward and supported by solid research. These recommendations include the following:

- Newborns should be nursed when they show signs of hunger (crying is identified as a late sign of hunger). Newborns should be nursed approximately 8 to 12 times every 24 hours until satiety.
- No supplements should be given to newborns unless a medical indication exists. Supplements and pacifiers should be avoided if used at all, and only used after breast-feeding is well established.
- Exclusive breast-feeding is ideal and sufficient to support optimal growth and development for approximately 6 months.
- Gradual introduction of iron-enriched solid foods in the second half of the first year should complement breast milk.

- Breast-feeding should continue for at least 12 months, and thereafter for as long as mutually desired.

Breast-feeding provides the optimal nutrition for infants during the first year of life when there is rapid physical and developmental growth. In addition to providing essential nutrients, breast-feeding provides unique opportunities for positive interactions and bonding between infants and mothers. A woman's decision to breast-feed is determined by many factors. Feeding her new infant can be an exciting, satisfying, and personally empowering experience for many women. The nurse can provide vital support to women who choose to breast-feed and do not have role models in their families who have successfully breast-fed. This area of health care is one in which the nurse and other health care professionals really can make a difference that has long-lasting effects. Breast-feeding will result in immediate positive health outcomes for infants and mothers. The financial savings of increasing the number of infants who are breast-fed will be realized immediately by the families and the entire health care system.

Promotion of breast-feeding has become a worldwide health goal for all nations because of the many unique components found only in human milk (WHO/UNICEF, 1994). The priority health goal for the United States, as

published in the “Healthy People 2010” document, is to increase breast-feeding for infants among all women, especially those who have low incomes and are African American, Hispanic, Native American, and Alaskan Native (U. S. Department of Health and Human Services, 2000). Specifically, the goal is to increase the number of women who initiate breast-feeding in the early postpartal period to at least 75%, with a 50% continuation rate at 5 to 6 months (U. S. Department of Health and Human Services, 2000).

In the 1970s the deleterious effects of manufactured formula on infant health and survival became better appreciated throughout the world, and the role of advertising became increasingly suspect. For decades the World Health Organization (WHO) has included as a part of their Code for Infant Feeding, a statement designed to protect developing countries from being inundated with formula advertising, which discourages breast-feeding. In many Third World countries that have poor sanitation and contaminated water supplies, infant survival depends on being nourished at the breast (WHO/UNICEF, 1994). In 1998, in a controversial step, the United Nations (U.N.) revised its breast-feeding recommendations because of the soaring rates of human immunodeficiency virus (HIV) infection in much of the world. In 1997, HIV transmission through breast-feeding accounted for up to one third of the 600,000 children infected, according to UNAIDS, the U.N. agency that developed the policy (Weinberg, 2000). The U.N. has issued recommendations intended to discourage women who are HIV-positive from breast-feeding by informing them about the risk of transmission to their babies through breast milk and about the alternative use of formula. Some experts have voiced concern that the increased use of formula will result in other deadly infections because of the use of contaminated water that may occur in formula preparation (Altman, 1998).

HISTORY OF BREAST-FEEDING

Historically, writings on breast-feeding can be found in the Bible and in many ancient texts of Greece, Rome, Egypt, and the European world. A wet nurse (a woman employed to breast-feed an infant not her own) was used when the mother died or when a child was abandoned. Hammurabi’s code from about 1800 B.C. contained regulations on the practice of wet nursing, that is, nursing another woman’s infant for pay. In 1472, Paul Bagellardus, a Renaissance medical writer in Padua, described the characteristics of a good wet nurse. In the 1700s, French orphanages were staffed by carefully selected wet nurses. From 1500s to 1700s, however, many wealthy English women did not nurse their infants but used wet nurses and fed in-

fants cereal or bread gruel from a spoon. The death rate in foundling homes from feeding infants cereal or bread gruel approached 100% (Lawrence, 1999).

The benefits of breast milk from the biologic mother have long been well known. Over two thousand years ago, Hippocrates wrote, “One’s own milk is beneficial, other’s harmful” (Lawrence, 1999). Breast milk was commonly accepted as the best milk for infants until 1884, when physicians and chemists entered the field of infant feeding. The competition among infant formula manufacturers was launched by the end of the 19th Century. In the United States, during the 1920s, women were encouraged to raise their infants scientifically, which led to the conclusion that prepared foods, such as formula, were superior because they could be measured and calculated to meet specific dietary requirements (Lawrence, 1999).

The benefits of breast-feeding have been scientifically supported beginning in the 1970s. Since then, more women have been nursing their infants. Statistically, however, the numbers of women who breast-feed are far from those proposed by the health goals stated in the “Healthy People 2010” document (U.S. Department of Health and Human Services, 2000).

Epidemiology

Breast-feeding rates are higher among women who are Caucasian, of higher socioeconomic status, older, married, and have a high educational level. Women who are African American, single, younger, unmarried, enrolled in the federal Special Supplemental Nutrition Program for Women, Infants, and Children [WIC], working outside the home, and of low educational level are less likely to initiate breast-feeding (McClurg-Hitt & Olsen, 1994). These mothers and infants of low-income status have a high risk of morbidity and mortality and would benefit most from breast-feeding because of the health, financial, and psychologic advantages.

In the United States the breast-feeding rate among highly educated women in families of high socioeconomic status is encouraging (54%); however, among women who are less educated, of low-income status, and members of a minority the rate is lower (30%). Ironically, infants born into poverty are exactly those who would benefit most from the protection that breast-feeding affords (Ryan, 1997). Figure 30-1 illustrates the breast-feeding rates of three cultural groups in the United States.

Incidence

The Ross Products Division of Abbott Laboratories has been a significant resource for breast-feeding statistics since 1955. The Ross Mothers’ Survey is an ongoing mail survey that is sent to new mothers at the time their new

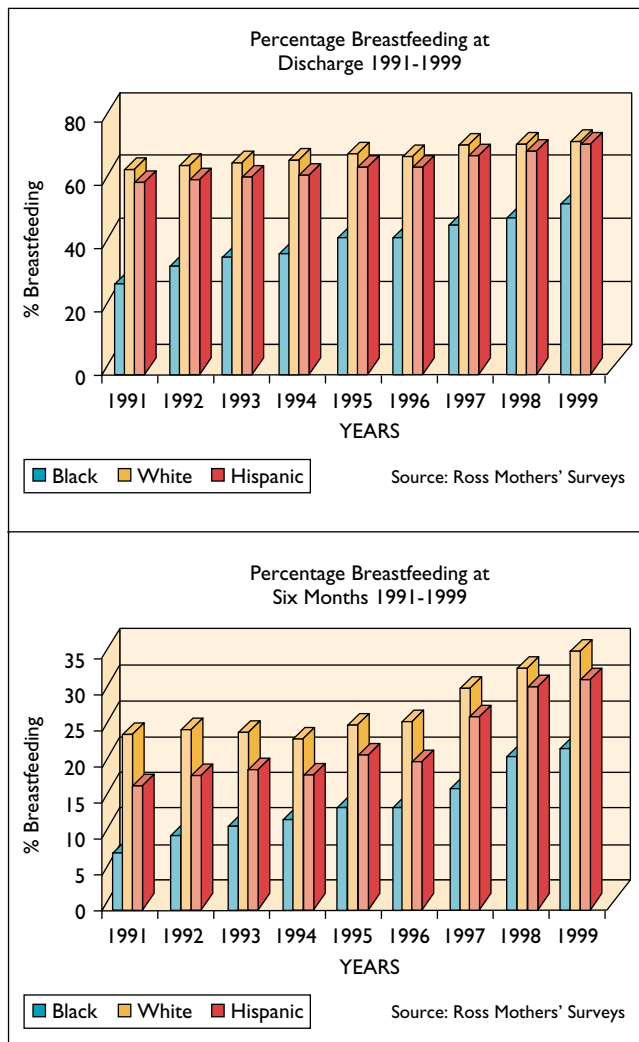

Figure 30-1 Breast-feeding rates in the United States. (Source: Ross Mothers' Survey).

Figure 30-2 Breast-feeding rates in the United States: 1971–1999. (Source: Ross Mothers' Survey).

infant is 6 months of age. Results of the survey are weighted based on selected demographic variables associated with adoption of breast-feeding behaviors. Since 1992, more than 725,000 new mothers have received this questionnaire annually (Ryan, 1997). Figure 30-2 shows the change in breast-feeding rates over the past 30 years, as reported in the Ross survey.

Prevalence

Breast-feeding rates differ greatly by region of the United States in which the mother resides, with higher rates in the West and lower rates in the East and Southeast. Western states, such as Washington and California, have breast-feeding initiation rates as high as 98% on discharge from the hospital. In contrast, some Southern states, such as Mississippi, have much lower rates than the national average (Mothers Survey, 2000).

Socioeconomic Status and Ethnic Patterns

According to the Ross Mothers' Survey, breast-feeding rates are lowest among African American infants, infants born into homes with annual incomes of less than \$10,000 per year, and mothers with only a grade-school education. All demographic categories experienced increases in breast-feeding initiation rates from 1990 to 1999. The groups with the historically lowest breast-feeding initiation rates experienced the largest increases during the same time period. (Ryan, 1997). This increase in breast-feeding rates can be attributed to the promotion efforts of many nurses and other health care workers.

Cultural Values, Beliefs, and Traditions

In human beings, breast-feeding behavior is highly variable from one culture to another. Different cultures have different “rules” about lactation. Cultural tradition dictates the initiation, frequency, and cessation of breast-feeding.

Within the United States there are many regional and ethnic cultures. Dealing effectively with these various groups requires that the nurse be knowledgeable about and sensitive to the cultural influences contributing to the values and beliefs of each client. Persons who have immigrated to the United States may have come from a culture in which traditionally all infants are breast-fed. After coming to the United States, however, some of these women may feel that bottle-feeding is more modern and therefore better for their infants. Other women may adopt formula-feeding because they want to be more like Americans, and perceive that bottle-feeding is the custom in the United States. Some women may choose breast-feeding because it

seems more natural to them and is healthier for infants and because the women enjoy the closeness that breast-feeding provides.

It is clear that culture and economics greatly influence decisions regarding infant feeding. Breast-feeding behavior is highly variable from one culture to another. Variables such as the degree of body contact, how often an infant is held, and how the infant is carried vary greatly from culture to culture. Studies of world societies reveal that North American and European women are concerned about the beliefs that it is indecent to expose the breast, children are spoiled by holding them too much, and early weaning is a sign of maturity in a child (Lawrence, 1999). Many women rely on knowledge obtained from their immediate families and the experiences of women in the community when making decisions about infant care and feeding. It is generally believed that a mother's decision regarding infant feeding is based on beliefs about growth and development. Considering the variability among ethnic groups, however, many researchers are recognizing the roles culture and ethnicity play in those decisions (Underwood et al., 1997).

Many factors are related to a woman's personal choice of infant feeding method. Her attitude, personality, cultural belief, biologic adaptation, genetic endowment, response of her infant, past interpersonal relationships, family support, and previous pregnancies all contribute to the decision-making process regarding infant feeding. Conflicts regarding the function of the breast as a sexual organ versus an organ for infant nourishment may play an important role in the choice of feeding method.

In Stuart-Macadam and Dettwyler's (1995) book on the biocultural perspectives of breast-feeding, cultural forces that conflict with breast-feeding are presented as perspectives influencing human behavior. These authors propose that infant feeding practices are influenced by geography and culture. In many countries of the world (such as Finland) breast-feeding is the norm, and no infant formula is manufactured. In some developing countries, safe formula feeding is almost impossible because of contaminated water supplies.

Women from other cultures, such as Filipino, Mexican American, and Vietnamese, do not give **colostrum** (thin fluid in the breast from pregnancy into the early postpartal period, which is rich in antibodies and high in protein) to newborns. Women in these societies prefer to wait until their milk is established to initiate breast-feeding. In some cultures, colostrum is believed to be "old" milk that has been in the breast too long or milk that is contaminated and must be removed and disposed of before the infant is put to the breast (Lawrence, 1999). In some Asian cultures the infant is only given boiled water until the mother's milk supply is established.

Modesty is important for the Mexican-American mother, and some women will avoid breast-feeding in

Critical Thinking

Cultural Views on Colostrum

Clients from some cultures, such as Hispanic, Navajo, Filipino, and Vietnamese, will not give their infants colostrum. These women begin breast-feeding only after the transitional milk comes in and therefore will reject attempts to begin breast-feeding behavior in the immediate postpartum period.

How can nurses ensure good breast-feeding outcomes and still respect cultural differences, values, and beliefs?

public because they find it embarrassing. In Western cultures, breasts are regarded as sexual objects and the biologic role of the breasts for infant nutrition is downplayed. African American women breast-feed at much lower rates than do Caucasian and Hispanic women. Most Muslim women breast-feed because the Qur'an encourages it until the child is 2 years old (Hutchinson & Baqi-Aziz, 1994). Many research studies have collected data on attitudes toward breast-feeding in an attempt to understand the cultural and ethnic differences that influence breast-feeding decisions. The nurse needs to be aware of and understand the impact of culture on infant feeding methods to evaluate the effect of the belief or value on breast-feeding decisions.

Research studies on breast-feeding have examined the factors that influence adoption of breast-feeding (initiation), factors that seem to predict the length of time a woman will continue breast-feeding (duration), and how much supplementation of formula will be used along with breast-feeding (exclusivity). The purpose of these studies is to be able to predict the women who will breast-feed successfully compared with women who will not do so. This information can then be used to design interventions that will increase breast-feeding in the groups of women who are less likely to choose breast-feeding.

BIOLOGY OF LACTATION

Lactation is the biologic completion of the reproductive cycle. Starting at about 16 weeks' gestation the breast develops and prepares for full lactation. In the first few postpartal hours and days the breast responds to hormones and the stimulation of the infant's sucking to produce and release milk.

Anatomy of the Breast

Nurses caring for new mothers need to have accurate knowledge about the anatomy and physiology of the lactating breast to facilitate the client's understanding. Prepared with adequate knowledge, the client will be able to achieve a successful breast-feeding experience.

The breasts or mammary glands are specialized sebaceous glands located in the superficial fascia between the second rib and sixth intercostal cartilage. The pectoral and anterior serratus muscles lie beneath each breast. Cooper's ligaments support the breast, extending from the deep fascia to the skin covering each breast. The breasts are composed of adipose, fibrous, and glandular tissues. Deep within the glandular tissue are the treelike branching **alveoli** (secretory units of the mammary gland in which milk production takes place), or acini, arranged in a series of 15 to 42 lobes. Lobes are separated by adipose and fibrous tissues and are arranged like spokes converging on the central nipple. Each lobe is made up of many lobules. The lobules are made of many grapelike clusters of alveoli (acini) around small ducts. The ducts combine to form larger lactiferous ducts that open on the surface of the nipple (Figure 30-3).

At the center of each breast is the nipple, a conic elevation composed of erectile tissue that becomes more rigid

during sexual excitement, pregnancy, and lactation. Each nipple contains 15 to 25 lactiferous ducts that end as small orifices near the tip of the nipple (Figure 30-4). The tissue surrounding the nipple is heavily pigmented and called the **areola**. Montgomery's tubercles, small papillae, are located in the areola. These tubercles secrete a substance that lubricates the nipples and areola during pregnancy and lactation.

The blood supply to the breast is mainly from the internal mammary artery (60%). The lateral thoracic artery, intercostal arteries, and branches of the axillary and subclavian artery supply the remaining 40% of blood supply (Figure 30-5). Innervation of the breasts is from the branches of the fourth, fifth, and sixth intercostal nerves. Sensory fibers innervate the smooth muscles in the nipple, areola, and skin.

Lymphatic drainage of the breasts is mainly due to the axillary and parasternal nodes along the internal thoracic artery (Figure 30-6). The lymphatics originate in the lymph capillaries of the mammary connective tissue and drain through the breast tissue. Some drainage goes to the opposite breast, liver, intraabdominal nodes, and subclavicular nodes deep to the clavicle (Lawrence, 1999).

Figure 30-5 Blood supply to the breast.

Physiology of Lactation: Hormones and Processes

One of the biologic functions of the breasts is to supply nourishment and protective antibodies to infants during the lactation process. Cyclic hormonal stimulation of the breast occurs during each menstrual cycle, puberty, and

especially pregnancy and lactation. The nonpregnant breast does not ordinarily secrete any milklike substance but may enlarge slightly during the menstrual cycle. During pregnancy, changing levels of circulating hormones profoundly change the growth of the ducts, alveoli, and lobes in the breasts. During lactation, the breast tissue is characterized by large numbers of alveoli. After lactation, when milk is no longer removed from the breast by the infant, the alveoli gradually collapse and adipose tissue increases. The hormonal control of lactation can be described under three main headings: **mammogenesis**, or mammary growth; **lactogenesis**, or initiation of milk secretion; and **galactopoiesis**, or the maintenance of established milk secretion.

Lactogenesis

Complex nervous and endocrine factors are involved in the establishment of milk production in the first 2 to 5 days postpartum (lactogenesis) and in maintenance of lactation (galactopoiesis). Childbirth results in a rapid decrease in estrogen and progesterone and an increase in prolactin secretion. **Prolactin** is a hormone produced by the pituitary gland that triggers milk production by stimulating the alveolar cells of the breast. Prolactin levels increase in response to tactile stimulation of the breast, such as in response to sucking by the infant.

The synthesis of human milk involves a cellular site at which the epithelial cells of the acini are active in milk production (Figure 30-7). Most milk is synthesized during the process of suckling. The cellular components of human milk are enzymes, proteins, fats, ions, water, and glucose.

Let-down Reflex and Milk Ejection

The infant's sucking also stimulates the release of oxytocin. **Oxytocin** is a hormone produced by the posterior pituitary that stimulates uterine contractions and release of milk from the mammary glands. Oxytocin increases the contractility of the myoepithelial cells that line the walls of the mammary ducts, resulting in the let-down reflex (Figure 30-8). The **let-down reflex** is the ejection of milk from the breast and milk flow toward the nipple triggered by nipple stimulation or emotional response to the infant. Once lactation is well established, prolactin decreases while oxytocin and suckling continue to be important in maintaining milk supply.

Three main hormones are involved in the lactation process: human placental lactogen (HPL), human growth hormone (HGH), and prolactin. The progressive increase in prolactin during pregnancy parallels the increase in HPL. HGH is thought to have a synergistic effect with prolactin and glucocorticoids in the maintenance of lactation. Both prolactin and oxytocin release is accomplished by nipple stimulation. Milk ejection involves both neural and

Figure 30-6 Lymphatic drainage of the breast.

Figure 30-7 Physiology of lactation.

endocrinologic stimulation and response. A neural afferent pathway and an endocrinologic efferent pathway are required. Interference with the ejection reflex usually is due to psychologic inhibition caused by stress of some kind, such as disapproval of breast-feeding by a family member.

Galactopoiesis

The nurse also needs to teach the new mother that because breast milk is based on supply and demand, the best way to increase breast milk supply is for the infant to

Figure 30-8 Physiology of the let-down reflex.

demand more by nursing often. It therefore follows that the more supplementation with formula or glucose water is used, the less the demand. Thus, the supply diminishes. The nurse should advise the new mother to avoid giving supplemental bottles because doing so will interfere with establishing her milk supply and may cause *nipple confusion* (the inability of the infant to go from bottle to breast and vice versa). Encouraging night feedings and preparing the client for infant growth spurts (that usually occur 10 to 14 days, 6 weeks, 3 to 4 months, and 6 months) will reduce concern about the lack of an adequate milk supply.

The client also needs to be taught that breast-feeding usually requires the infant to be fed every 2 to 3 hours during the first 3 to 4 weeks. Frequent demand for feedings may concern the new parents, and they may wonder if the infant is getting adequate nutrition. Signs of adequate intake include 8 to 10 wet diapers in 24 hours, frequent stooling, steady weight gain, and contentment after breast-feeding. The stools of breast-fed infants differ from those of formula-fed infants in color and consistency. Stools from the breast-fed infant are golden yellow, sweet smelling, and loose or liquid in consistency. Breast-fed infants usually regain their birth weight by 14 days of age, then gain approximately 15 g/d (0.5 oz/d) in the first 6 months of life. Birth weight usually is doubled by approximately 5 months of age (Riordan & Auerbach, 1999).

Interference with Lactation

Many factors can interfere with the lactation process. Physical factors, medical conditions, poor diet, and maternal anxiety all can contribute to unsuccessful breast-feeding.

Anxiety

Mothers who are breast-feeding may experience some problems coping with their new maternal role and may develop fears or anxieties. For example, mothers may worry about not producing enough milk, particularly during the first few days of breast-feeding and during infant growth spurts. The nurse can help prepare the new mother to handle these fears by reminding her that these emotions are common and can be expected as the infant's demand may occasionally exceed the supply for a few days. Milk production for these growth spurts will correct itself quickly when the breast is offered more often and for longer periods of time.

New mothers need to be reassured that all infants cry as a way of communicating and that crying is not a sign that the breast milk is inadequate. Frequently, it may be necessary to remind new mothers that retreating to a private area to breast-feed may help them relax and be able to reduce the stresses surrounding new motherhood. If someone in their environment is causing stress or anxiety, such as a relative, it may be best to deal with that person in an open and direct manner to correct the uncomfortable situation.

Medical Problems

The breast-feeding mother who has a serious medical condition or who suddenly develops a condition that requires hospitalization or management with surgery presents an unusual situation. It is obvious that the medical condition must be addressed promptly; however, it is also important to treat the mother as a lactating woman. Questions must be answered such as whether or not the condition is life-threatening or contagious and will the drugs necessary for treatment pass into the breast milk and adversely affect the infant? The other questions that must be taken into consideration are what is the prognosis for recovery and how long will recovery take. When the prognosis is poor and drugs prescribed for the mother are contraindicated in the infant, the decision must be made to discontinue breast-feeding. However, abrupt cessation of breast-feeding can cause an influenza-like syndrome in the mother that may confuse the medical picture (Lawrence, 1999).

Nutrition and Fluid Intake

Breast-feeding mothers will need approximately an additional 500 cal/d compared with mothers feeding their infants artificial formula (Figure 30-9). Approximately 2,500 cal/d are needed while lactating. This calorie intake can be met through a properly balanced diet. A daily increase in some food groups, such as meat and dairy products, is of great importance. A daily increase in fluids, calcium, protein, and folic acid also is essential. A proper diet promotes a good supply of milk and good maternal health.

Figure 30-9 Breast-feeding mothers need an additional 500 cal/d.

Prenatal vitamins also may be continued. Fluid requirements can be met by drinking at least six 8-oz glasses of water or caffeine-free drinks every day (Figure 30-10). Increasing fluid intake above normal levels, however, will not increase the milk supply (Reifsnider & Gill, 2000).

Figure 30-10 Increased fluid intake is especially important for the breast-feeding woman.

REFLECTIONS FROM A FATHER

"My wife breast-fed all three of our children. I enjoyed watching her develop a close bond with each child as they nursed. I admit that sometimes, as a new dad, I felt left out. So we decided that my role was to burp the baby during and after each feeding. I loved this! Feedings became a family event, each of us with our own important role to play."

Mechanics of Lactation

The nurse working with the breast-feeding mother must be knowledgeable about the basic anatomy and physiology of breast-feeding, know how to assist the new mother with early feedings, and help with interventions for common problems. Although breast-feeding is a natural process, breast-feeding skills must be learned and practiced. It may help to tell the new mother that she and her infant are both learning new skills. The nurse can promote successful breast-feeding through timely interventions to correct any problems before they undermine the mother's confidence in her ability to feed her baby.

Maternal

The nurse should help a new mother initiate breast-feeding without making her feel like a failure for not knowing these skills. The mother needs to find a comfortable position before beginning so that she can relax. She will enjoy breast-feeding much more and experience the let-down reflex more easily when comfortable. Next, she must position her infant so that she and her infant are comfortable and the breast is supported. She needs to cup her breast in one hand with all four fingers underneath and the thumb on top, making sure that the fingers and thumb are not touching the areola, while supporting the baby's head with the other hand (Figure 30-11).

When the mother touches the baby's lips with her nipple she will activate the rooting reflex in her baby, and the infant will open the mouth wide (Figure 30-12a). The mother can pull the baby's head to her breast, and the infant will latch on to the nipple (Figure 30-12b). Correct latching-on will occur when the nipple and most of the areola are in the baby's mouth, and the baby's lips are pursed out as opposed to tucked under, forming solid suction. The sucking may cause discomfort for the first few

A.

B.

Figure 30-11 C-hold technique. A. Hand placement. B. Position of infant.

seconds; however, the discomfort will stop when the baby settles into a rhythmic sucking pattern (Methodist Hospital, 1999).

Research suggests that nipple soreness is not related to the length of time the infant is at the breast but to improper positioning or improper removal of the infant from the breast (Mohrbacher & Stock, 1997). Inserting a finger into the corner of the sucking infant's mouth to break the suction will facilitate removing the infant without damage to the nipple (Figure 30-13).

A.

B.

Figure 30-12 Initiating latch-on. A. Touching the baby's lips with the nipple stimulates the rooting reflex. B. Once the baby opens the mouth wide, the mother can pull the baby's head to her breast.

After removing the infant from the breast, the mother needs to be taught how the infant may be burped in any one of three positions (Figure 30-14). Burping will allow any swallowed air to be released from the infant's stomach. The mother should position the infant upright, with the head resting on the mother's shoulder. The mother can then rub or pat the infant's back with her hand, while supporting the infant's buttocks with her other hand. A mother may prefer to burp the infant by placing the infant face down across the mother's lap. While holding the infant's head with one hand, the mother can rub or pat the infant's back with the other. An infant also may be burped by holding the infant upright on the mother's lap, supporting the head from the front with one hand and patting or rubbing the back with the other.

Figure 30-13 Removing the infant from the breast.

Infant

In order to determine if the neonate is ready to be breast-fed, the nurse or mother can test the rooting and sucking reflexes (Figure 30-15). Stimulation of the rooting reflex can be accomplished by stroking the infant's cheek toward the lips. The infant should turn toward the side that is being stroked. The mother can insert her finger into the infant's mouth and gently stroke the soft palate to trigger the sucking reflex. Sucking should be strong, and the tongue should curve around the finger. When the infant sucks strongly on the mother's finger, breast-feeding can begin. Researchers such as Smith et al. (1988) have used ultrasound studies to observe the dynamics of breast sucking. These studies have confirmed that sucking patterns differ in bottle-fed versus breast-fed infants. The tongue presses the nipple against the hard palate, forcing milk from the ducts and sinuses (Figure 30-16).

Latching-on

The nurse can help the new mother by teaching her to position her infant's nose at the level of her own nipple and then to brush the nipple across the baby's lower lip. Doing so will cause the infant to open the mouth wide (**rooting reflex**), allowing the mother to bring her nipple in toward the upper part of the infant's mouth. The rooting reflex is the normal response of the newborn to move toward whatever touches the area around the mouth. The rooting reflex facilitates proper **latching-on** (proper attachment of the infant to the breast for feeding) to the entire areola, not just the end of the nipple. Riordan and Auerbach (1993) state that for early feedings both breasts should be offered at each feeding to stimulate milk production quickly. Each

breast should be offered frequently for at least 15 minutes every 2 hours or on demand, whichever occurs first. After breast-feeding is established the client should let the infant complete a feeding on one breast before offering the other. As milk volume adjusts to the infant's needs this pattern may change, depending on the infant's requirements during growth spurts. Frequently, mothers will report feeling very relaxed, almost sleepy, during breast-feeding. This relaxed state is a side benefit of the hormone oxytocin, which also stimulates the let-down reflex.

Nursing Implications

Most mothers who are breast-feeding for the first time have a possible nursing diagnosis of ineffective breast-feeding related to deficient knowledge about breast-feeding. The

**A.****B.**

nurse can take advantage of the opportunities to teach the new mother during the postpartal stay. For the healthy full-term newborn, no contraindications exist to feeding immediately after delivery. Most infants are highly responsive and eager to suck during the first 30 minutes after delivery. The nurse can use this time to teach and help initiate successful breast-feeding behaviors.

When working with a new mother, the nurse should always stay at her eye level to decrease the anxiety that any new activity causes the learner. Proper positioning at the breast can decrease the problem of ineffective breast-feeding by teaching the mother different comfortable positions that enhance feeding behaviors. The mother should be made as comfortable as possible either in her bed or chair and given as much privacy as needed. Mothers who have delivered by cesarean section usually need more help to find a comfortable position because of the abdominal incision and the pain related to movement. The woman may need to void before beginning to breast-feed, and she should be instructed to wash her hands each time she nurses her infant.

There are three common breast-feeding positions that can be used by most mothers. These positions are the cradle hold, the football hold, and the side-lying position (Figure 30-17).

**C.**

Figure 30-17 Breast-feeding holds. A. Cradle hold. B. Football hold. C. Side-lying hold.

ISSUES RELATED TO BREAST-FEEDING

According to the American Academy of Pediatrics policy statement (1997, pp. 1035–1039), “Extensive research, especially in recent years, documents diverse and compelling

advantages to infants, mothers, families, and society from breastfeeding and the use of human milk for infant feeding. These include health, nutritional, immunologic, developmental, psychological, social, economic, and environmental benefits.”

Benefits

The benefits of breast-feeding include but are not limited to superior species-specific feeding that provides optimum infant growth, health, and development. Breast milk also has been shown to decrease the incidence and severity of many childhood illnesses, provide a protective effect against several diseases, and enhance cognitive development. A number of research studies indicate there are health benefits for mothers who breast-feed. In addition to these individual benefits, breast-feeding provides significant social and economic benefits to the nation. These include reduced health care costs and reduced employee absenteeism (American Academy of Pediatrics, 1997).

Maternal Benefits

Maternal benefits include lactational amenorrhea, which promotes a longer period of decreased fertility after the birth of an infant, and less blood loss from menstruation. New research demonstrates that lactating women have an earlier return to prepregnant weight, improved bone remineralization, reduction in hip fractures in the postmenopausal period, and reduced rates of ovarian cancer and premenopausal breast cancer (American Academy of Pediatrics, 1997).

Promotion of Involution

Breast-feeding has many benefits for the mother. The release of oxytocin during breast-feeding causes the uterus to contract, hastening the involution of the uterus to its prepregnant state (Figure 30-18). This same action also reduces the chances of postpartal hemorrhage by keeping the uterus contracted.

Assistance in Weight Control

Breast-feeding promotes weight loss after delivery because of the great expenditure of energy and calories needed during lactation. The nursing mother should increase her caloric intake by 200 cal over the pregnancy requirements. This increase in calories results in a 500-cal increase from her prepregnancy requirements. An intake of 2,500 to 2,700 cal/d is required for most women during lactation (Dewey, 1993).

Psychologic Benefits

Breast-feeding also provides new mothers with many psychosocial advantages. The increased levels of oxytocin in

Figure 30-18 Breast-feeding immediately after delivery stimulates involution of the uterus.

the nursing mother's bloodstream are believed to coincide with more even mood responses and increased feelings of maternal well-being (Lawrence, 1999). Many researchers believe that increased levels of oxytocin promote maternal-infant bonding and protective behavior. Many animal and human studies have provided documentation for this belief. One study in female rats demonstrated increased maternal behaviors after oxytocin administration (Pedersen, 1992). Breast-feeding enhances attachment by providing many opportunities for direct skin contact, eye contact, and closeness between mother and baby. This increased time of closeness helps mothers learn their infant's cues and needs and also helps the new mother to slow down and relax during feedings. Many lactation consultants will attest to the fact that as the mother's milk "lets down," many times the mother will close her eyes and almost fall asleep. Successfully breast-feeding also will increase the new mother's sense of accomplishment and self-esteem as she sees her infant being nourished and comforted by breast-feeding (Lawrence, 1999). Many women have reported that this contact has long-lasting, positive results on her feelings as a competent and powerful woman.

Many researchers have looked at the relationship between postpartum depression and the infant feeding method. Mothers with depression had more problems breast-feeding and tended to think that the infant did not want their milk or did not like it (Riordan & Auerbach, 1999).

Several authors, including Klaus et al. (1995) have cited a calming effect on mothers during breast-feeding as a positive outcome of breast-feeding behavior. These authors hypothesize that a cascade of interactions between the mother and baby occurs with early skin-to-skin contact, suckling, rooming-in, and increased maternal oxytocin levels. Manipulation of estrogen, progesterone, and prolactin has been studied to detect maternal behavior en-

hancement or inhibition by each. Klaus et al. (1995) have stated that early and continuous mother-infant contact appears to decrease infant abandonment and increase the length and success of breast-feeding. The long-term psychophysiologic response of unrestricted nursing is a more even mood cycle compared with the mood swings associated with the menstrual cycle. The long-term benefit of amenorrhea for as long as the woman continues breast-feeding is one of the more desirable effects of breast-feeding.

Contraceptive Benefits

Exclusive breast-feeding has been found to delay ovulation and thus acts as a natural birth control method. Breast-feeding makes a woman less likely to conceive; however, the degree of protection depends on many variables, such as hormonal levels, nipple stimulation, and frequency of feedings. After delivery, levels of progesterone and estrogen decrease, allowing the gradual return of secretion of luteinizing hormone and follicle-stimulating hormone. Ovulation and a return to fertility typically will occur within 4 to 6 weeks in the nonnursing mother. Breast-feeding extends the normal period of anovulation by sending impulses to the hypothalamus that decrease the release of gonadotropins. Decreasing gonadotropin levels suppress ovulation by preventing follicle development. Prolactin also plays a direct role in preventing ovulation by making the ovaries less responsive to luteinizing hormone and by suppressing the effects of estrogen (Lawrence, 1999). Lactational amenorrhea is regarded as a period of natural infertility after childbirth and during lactation.

The Lactational Amenorrhea Method (LAM) of family planning is based on the principle that a “woman who continues to fully or nearly fully breastfeed her infant and who remains amenorrheic during the first 6 months postpartum is protected from pregnancy during that time” (Perez, Lobbok, & Keenan, 1992, p. 968). LAM allows clients to take advantage of the natural decrease in fertility provided by breast-feeding. The woman who desires the use of this method of contraception needs to continue to fully or nearly fully breast-feed her infant, must remain amenorrheic, and must be feeding frequently (including during the night) for the method to work (Lawrence, 1999).

Long-term Benefits

Research studies also have found a link between breast-feeding and a decrease in the development of breast cancer in women who have breast-fed. Newcombe et al. (1994) state that there clearly is a protective effect of lactation on the development of breast cancer among premenopausal women. In another study of 521 Asian women, breast-feeding was found to play a protective role

against breast cancer, regardless of confounding effects of age at first pregnancy, parity, and closely related factors (Yoo, Tajima, & Kuroishi, 1992).

According to a report recently issued by the Society of Gynecologic Oncologists, National Cancer Institute, and Office on Women’s Health of the U.S. Department of Health and Human Services, ovarian cancer rates have remained the same for almost 50 years. However, the good news is that women who have breast-fed have a 50% decreased risk for developing ovarian cancer (O’Brien, 1998).

Cost Savings

Breast-feeding saves money for families, taxpayers, and the health care system. Infant formula is expensive. The cost of formula is about twice that of the extra food needed by the lactating mother (Jarosz, 1993.) Providing formula to women who are not breast-feeding costs the WIC program, and thus the U.S. taxpayers, a large amount of money every year. WIC is the largest purchaser of infant formula, buying 40% of all formula sold in the United States. In 1991, the cost of formula given to WIC participants for free was \$404 million (Riordan, 1997) (Table 30-1). There are some costs to the family associated with breast-feeding. A breast pump is needed, as are plastic bags and bottles for milk storage.

Riordan (1997) suggests that if breast-feeding were universal, 5,000 lives would be saved in the United States annually. The financial implications are staggering. The costs of increased morbidity and mortality include medical costs, physician visits, medicine, and hospitalizations. The hidden costs associated with these problems are lost wages to parents of sick children and increased premiums for health care insurance. The savings associated with reducing the number of otitis media infections in children is estimated at \$660 million in the United States alone. Table 30-2 examines additional health care costs for four medical conditions frequently seen in infants.

Table 30-1 Hidden Costs of not Breast-feeding

Decreased intellectual development	Incalculable
Infant formula distributed by the Women, Infants, and Children (WIC) program annually	\$2,665,715
Increased parental absenteeism	Incalculable
Increased potential for additional pregnancies	Incalculable
Prenatal and postnatal care for increased pregnancies	Incalculable

Adapted from Riordan, J. (1997). The cost of not breastfeeding: A commentary. *Journal of Human Lactation*, 13, (2), 93–97.

Table 30-2 Additional U.S. Health Care Costs for Four Medical Conditions Owing to not Breast-feeding

Condition	Annual Health Care Costs
Infant diarrhea	\$291.3 million
Respiratory syncytial virus	\$225 million
Insulin-dependent diabetes mellitus	\$9.6–124.8 million
Otitis media	\$660 million
Total costs	>\$1 billion

Maternal-Infant Attachment

Breast-feeding provides ideal opportunities for mother-infant interactions, which include closeness, touching, holding, talking, mutual gazing, and reciprocal socialization. Attachment is the development of an enduring relationship between the infant and the caregiver (Klaus, Kennell, & Klaus, 1995). Breast-feeding increases the quantity and quality of early contact between the mother and her infant, thus enhancing the strength of the relationship. Studies on the psychologic benefits to the infant suggest that breast-feeding may increase the emotional union between mother and infant. Widstrom et al. (1990) measured the psychophysiologic responses of mothers who were breast-feeding or bottle-feeding to their infants' signals. Mothers who were breast-feeding were physiologically more relaxed, were more likely to interact with their infants, and expressed greater satisfaction with the feeding experience.

Benefits to the Infant

Breast milk has been called the perfect food for infants because it contains all necessary nutrients in readily bioavailable forms, while providing many immunologic components at the same time. Human milk is considered a living tissue, such as blood, and is capable of affecting biochemical systems, increasing immunity, and even destroying pathogens (Newman, 1995). The main selling point for manufacturers of infant formula continues to be the comparison of how closely the product conforms to the gold standard of breast milk.

Nutritional Benefits

Breast-feeding provides infants many nutritional benefits. Breast milk supplies all the nutrients, vitamins, and minerals needed by the infant until 6 months of age. Breast milk is nonallergenic, and its composition varies according to the age and needs of each infant. Mothers of infants born preterm make milk that is higher in fat because the pre-

Critical Thinking

Comparison of Breast Milk with Formula

- Breast milk is nutritionally superior to formula.
- Breast milk contains immunoglobulins, enzymes, and leukocytes to protect against infection.
- Breast milk is less expensive than formula.
- Breast milk is easily available at a perfect temperature and with no preparation.
- Breast milk may reduce allergies.
- Breast-feeding may enhance mother-infant attachment.
- Breast-feeding promotes the development of jaw and facial muscles.
- Breast milk reduces the risk of bacterial contamination.

How can a nurse help promote breast-feeding as a superior feeding method among all women of childbearing age?

term infant needs more fat content for myelination of the neurons of the undeveloped neurologic system.

Components of Breast Milk. Breast milk is composed of lactose, lipids, polyunsaturated fatty acids, and amino acids, such as taurine, and has a whey-to-casein ratio that facilitates digestion, absorption, and full use when compared with formulas (Worthington-Roberts & Williams, 1993). Research also suggests that the high levels of cholesterol may trigger the production of specific enzymes that may reduce the harmful effects of cholesterol on the cardiovascular system (Worthington-Roberts & Williams, 1993). Breast milk provides infants with minerals in more appropriate amounts than do formulas. The iron in breast milk, although much lower in concentration, is more readily digestible and more fully absorbed than that found in formulas. The iron in breast milk is sufficient to supply the infant's needs for the first 4 to 6 months of life. Giving an infant iron supplements during this period can actually decrease the ability of lactoferrin to enhance iron absorption and protect against infection. According to the American Academy of Pediatrics Committee on Nutrition (1992), the only supplements a breast-fed baby will need are vitamin D and fluoride beginning at 6 months of age.

The caloric needs of the newborn range from 105 to 110 cal/d per kilogram of body weight, or 50 to 55 cal/d per pound, and are divided among protein, carbohydrates, and fat. Water requirements are high (140 to 160 mL/d per

Research Highlight

Does Breast-feeding Protect Against Diabetes Mellitus?

Purpose

To note a link between infant feeding method and insulin-dependent diabetes mellitus.

Methods

While many advocates of breast-feeding can and do correctly cite studies indicating that breast-feeding reduces children's risk of developing insulin-dependent diabetes mellitus (IDDM), many are not aware of the ongoing debate among researchers on this issue. The first report associating breast-feeding with a reduction in risk for juvenile onset IDDM was published in 1984 by Borch-Johnson et al. This study observed that Norwegian children born during the years when breast-feeding rates were high were less likely to develop IDDM than were children born in years of low breast-feeding rates. Since that time, more than 90 articles have been published in this area, some supporting and some refuting this association.

Findings

Most of the studies were case-controlled studies, in which characteristics of children with IDDM were compared with those of healthy children. Many of these studies indicated that children with IDDM were breast-fed for a shorter duration or were exposed to cow's milk proteins earlier than were healthy children. These relationships remained statistically significant after controlling for confounding factors such as maternal age and education. However, other studies found no association (Meloni et al., 1997).

Nursing Implications

Findings indicate that scientific truths are not validated overnight but are a result of an evolutionary process. You must be prepared to critically evaluate all studies, even when they do not support your point of view. Staying current with the latest research increases your credibility, promotes communication with professional colleagues, and increases your knowledge of breast-feeding.

Heinig, M. J. (1997). Staying abreast of the latest scientific controversies: Infant feeding and insulin-dependent diabetes mellitus. *Journal of Human Lactation*, 13, (2), 91–92.

kilogram of body weight, or 64 to 73 mL/d per pound). Fluid needs also increase during illness and hot weather (Worthington-Roberts & Williams, 1993). The protein requirement per unit of body weight is greater in the newborn than at any other time of life. The recommended daily allowance (RDA) for protein during the first 6 months is 2.2 g per kilogram of body weight. Carbohydrates should provide at least 40% of the total calories in the newborn's diet. At least 15% of the newborn's calories should be provided by fat (triglycerides). The fat in human milk is easier to digest and absorb than is that in cow's milk (Behrman, Kliegman, & Arvin, 1996).

Natural Variation in Composition of Human Milk. Over 200 constituents have been identified in breast milk, and researchers are just beginning to understand the

impact that these changing constituents have on the infant. Moreover, milk composition changes as the infant nurses at each feeding.

Formula-fed infants gain weight faster than do breast-fed infants because larger quantities of food are needed to obtain the same nutrients. The nutrients in breast milk are more easily obtained because breast milk is completely digested. Bottle-fed infants usually regain their birth weights within 10 days. Breast-fed infants may not regain their birth weights until 14 days after birth. Formula-fed infants generally double their birth weight by 4 months, and breast-fed babies double their weight at about 5 months (Lawrence, 1999).

Transitional milk is produced at the end of colostrum production and immediately before mature milk comes into the breast. **Foremilk** is the thin, watery breast

milk secreted at the beginning of a feeding. Foremilk is low in calories but high in water-soluble vitamins. **Hind-milk** is the thick, high-fat breast milk secreted at the end of a feeding. Hindmilk is ejected approximately 10 to 15 minutes after the initial “let down” and has the highest concentration of calories. Hindmilk is thicker and richer in appearance than is foremilk owing to its higher fat content essential for the infant’s proper growth and development. **Mature milk** is breast milk that contains 10% solids for energy and growth.

The nutritional needs of the infant vary with the unique differences of each stage of the new baby’s development. Breast milk supplies all of the nutrients to meet the ever-changing demands of the baby from newborn to toddler stage. The infant’s diet must provide adequate calories and must include sufficient protein, carbohydrates, fat, water, vitamins, and minerals to meet the rapid rate of both physical and mental growth and development (Lawrence, 1999).

Long-Term Benefits

Epidemiologic research shows that human milk may provide a possible protective effect against sudden infant death syndrome (SIDS), insulin-dependent diabetes mellitus, lymphoma, Crohn’s disease, ulcerative colitis, allergic diseases, and other chronic digestive diseases. Breast-feeding also has been related to enhancement of intelligence and visual acuity (American Academy of Pediatrics, 1997).

Immunologic Benefits

The immunologic benefits of breast-feeding for infants include varying degrees of protection against many types of infections. Breast-feeding has a positive effect on the overall health of the infant because it provides increased protection from meningitis, sepsis, otitis media, and respiratory and gastrointestinal (GI) diseases. For years, physicians have believed that infants who are breast-fed contract fewer infections than do those who receive formula because breast milk contains no bacteria. Research has now demonstrated that human milk actively helps newborns avoid disease in a variety of ways. These benefits are due to the many components of colostrum and breast milk present in varying amounts, depending on the specific environment of the mother-baby dyad. Colostrum is the thin fluid present in the breast from pregnancy into the early postpartal period. Colostrum is rich in antibodies, which provide protection from many diseases; high in protein, which binds bilirubin; and acts as a laxative, speeding the elimination of meconium and helping loosen mucus.

Breast-feeding helps protect the infant by maximizing the baby’s defenses against the contaminated environment outside of the uterus. Newborns do not have adequate levels of immunity to protect themselves against infection by pathogens of all types.

Newborns have a deficiency of neutrophils, which are necessary in the early phagocytic response to injury. Deficiencies of specific immunoglobulins also predispose newborns to infection, particularly in the first 4 to 6 weeks of life. The infant receives passive immunity to bacterial toxins from the placenta through immunoglobulin E (IgE). Immunity against common viral infections, such as measles, may last 4 to 8 months; whereas immunity to certain bacteria may last only 4 to 8 weeks. The newborn is normally deficient in immunoglobulins M (IgM) and A (IgA). These immunoglobulins are thought to protect against gram-negative entero-organisms and some viruses and to supply protection on the secretory surfaces of the respiratory, urinary, and GI tracts (Newman, 1995). These immunoglobulins are found in human milk and are transferred to the newborn during breast-feeding. Cells contained in human milk include macrophages, polymorphonuclear leukocytes, lymphocytes (T- and B-), neutrophils, and epithelial cells.

The intestinal flora of the breast-fed newborn is strikingly different from that of the formula-fed infant. Researchers have shown that colostrum and human milk contain a specific factor called bifidus factor that supports the growth of *Lactobacillus bifidum*. The presence of this type of bacillus offers protection against many intestinal disorders, such as diarrhea and necrotizing enterocolitis (NEC). NEC is generally associated with gram-negative organisms, especially *Klebsiella*. According to Lawrence (1999), colonization of breast-fed infants with *Klebsiella* does not occur. Breast-feeding protects against infection through the provision of host resistance factors in human milk, including immunoglobulins, lactoferrin, bifidus factor, and lymphocytes. Exclusive breast-feeding also reduces the likelihood of exposure to infection that arises when contaminated food is introduced (Kovar, Serdula, Marks, & Fraser, 1984) (Table 30-3).

Breast milk has been shown to combat many types of infections, such as cholera and salmonella, staphylococcal, and viral infections. Lipase found in human milk has been found to inactivate protozoans that also may cause many disease processes. Human milk also protects against intestinal and respiratory pathogens without causing inflammation. The antiallergic properties of human milk have been studied in an attempt to discover how antibodies are formed by the infant’s immune system (Lawrence, 1999).

Immediate Protection against Environmental Infectious Agents. The collection of antibodies transmitted to the infant is highly targeted against pathogens in the child’s immediate surroundings. The mother synthesizes specific antibodies when she inhales or ingests an environmental disease-causing agent. The antibody she produces is specific to that agent and binds to a single protein or antigen present in the infant’s immediate environment,

Table 30-3 Immune Benefits of Breast Milk

Leukocytes	Benefits
Neutrophils	May act as phagocytes by ingesting bacteria
Macrophages	Kill microbes in infant's intestinal tract
B lymphocytes	Produce antibodies against specific microbes
T lymphocytes	Kill infected cells directly and strengthen immune response
Molecules	Benefits
Bifidus factor	Promotes growth of harmless bacteria to stop growth of harmful bacteria
Antibodies secretory immunoglobulin A	Bind microbes in gut to prevent passage into other tissues
Firbronectin	Assists macrophages and repairs damaged tissues in gut
B ₁₂ binding protein	Reduces bacteria by decreasing vitamin B ₁₂
Fatty acids	Destroy virus membranes
Interferon gamma	Promotes antimicrobial activity of immune cells
Hormones and growth factors	Enhance maturity of infant's digestive tract
Lysozyme	Kills bacteria by attacking cell wall
Lactoferrin	Reduces available iron, thus reducing growth of bacteria
Oligosaccharides	Bind to microorganisms before they can attach to mucosa surfaces
Mucins	Interfere with attachment of bacteria and viruses to mucosal surfaces

thus protecting the infant against those specific infectious agents most likely to cause illness (Newman, 1995). Therefore, if an older sibling develops an upper respiratory infection, the mother will make antibodies to protect her new infant against the specific bacteria or virus causing the infection. Secretory IgA has antiviral, antibacterial, and antigenic-inhibiting factors. Secretory IgA decreases the permeability of the intestines to macromolecules that cause disease. Many other components of breast milk inhibit the growth of both bacteria and viruses. Lactoferrin, *L. bifidum*, lysozymes, and many other immunoglobulins, such as one that acts against poliomyelitis, are present and offer immunity to various disease-producing substances.

Passive Immunity with Childhood Implications. Human milk is a biochemically unique substance perfectly adapted to each individual infant's needs. The

ASSISTING WITH BREAST-FEEDING

When teaching clients about breast-feeding, you should wear disposable gloves while:

- Assisting new mothers to breast-feed immediately after delivery.
- Handling the mother's breasts during expression of milk.
- Handling breast pads.
- Handling breast milk for storage or milk banking.

You must wash your hands before and after gloving!

breast milk that is made by each mother is individually suited to meet the needs of her infant. Mortality rates of breast-fed infants clearly are lower in all studies and countries than are the rates of formula-fed infants. Mortality rates are lower at all ages for breast-fed infants. The incidence of illness (morbidity) in artificially fed infants, particularly in Third World countries, is equally impressive. Formula-fed infants have a 50% greater chance of becoming sick enough to require hospitalization than do breast-fed infants. Breast milk provides immunologic protection against death from infectious diseases, such as diarrhea, respiratory infections, otitis media, and pneumonia. Breast milk also offers some protection against allergies and SIDS.

Sudden infant death syndrome is the leading cause of death in infants after 1 month of age. A 3-year multicenter study of SIDS in New Zealand reported on in 1993 found four modifiable risk factors: sleeping prone, maternal smoking, lack of breast-feeding, and the infant sharing a bed. New Zealand launched a major prevention program to educate the public about these risk factors (Scragg, Mitchell, & Tonkin, 1993).

Psychologic Benefits

The psychosocial benefits of breast-feeding have been studied by many researchers. Maternal-infant attachment appears to be enhanced owing to the close skin-to-skin contact that occurs during breast-feeding behavior. The newborn's sense of touch is highly developed at birth, and the tactile stimulation of breast-feeding contributes to the infant's sense of closeness and comfort.

BARRIERS TO LACTATION

Barriers or deterrents to breast-feeding may be biologic, psychologic, or social in nature. The risk-to-benefit ratio of breast-feeding compared with bottle-feeding must be

Research Highlight

Breast Milk and Subsequent Intelligence Quotient in Children Born Preterm

Purpose

To determine whether nutrition in early life has a long-term influence on neurodevelopment.

Methods

Babies under 1,850 g at birth admitted to the special-care baby units at five hospitals in England were entered into four parallel trials of preterm infant feeding. Mothers chose whether or not to provide breast milk for their infant within 72 hours of delivery. The researchers collected information about family structure, social class, mother's education, pregnancy, labor, delivery, and the neonatal period. Intelligence quotient (IQ) was assessed with the Wechsler Intelligence Scale for Children. Testing was done at 18 months and at 7.5 to 8 years of age.

Findings

Children who had consumed mother's breast milk in the early weeks of life had as significantly higher IQ at 7.5 to 8 years than did those who received no maternal milk. An 8.3 point advantage (over half a standard deviation) in IQ remained even after adjustment for differences between groups in mothers' education and social class ($P < 0.0001$).

Nursing Implications

Findings indicate that the differences in IQ may be attributed to docosahexaenoic acid (DHA). DHA is the primary structural fatty acid of the gray matter of the brain and retina of the eye. It is a critical building block essential for normal brain and eye development. DHA is found naturally in breast milk but is not present in formula available in the United States, providing another excellent reason to promote breast-feeding among all women. This study also has implications for manufacturers to add DHA to their infant formula. Research studies comparing cognitive and physical development of breast-fed with bottle-fed children have revealed many interesting differences. More body activity, a more alert state, and a stronger arousal reaction in breast-fed newborns have been reported by researchers both in England and the United States. The longer the infant was nursed, the more profound the differences. In several studies using achievement tests to test IQ, children who were breast-fed for 4 to 6 months scored significantly higher than did children who were bottle-fed. It appears that there are specific proteins, amino acids, and fatty acids that contribute to enhanced brain development in the breast-fed infant (Lucas et al., 1992).

Lucas, A., Morley, R., Cole, T., Lister, G., & Leeson-Payne, C. (1992). Breast milk and subsequent intelligence quotient in children born preterm. *The Lancet*, 339, 261–264.

assessed by the woman and her health care provider to arrive at the best decision for both the mother and her infant.

Biologic Barriers

Although most women are physically capable of breast-feeding, a biologic problem may occasionally interfere with lactation. The problem can be due to abnormal

anatomy such as unilateral or bilateral hypoplasia. Acquired abnormalities of the breasts from trauma, burns, or radiation also may interfere with lactation. Patients with biologic barriers must be carefully evaluated on a case-by-case basis to determine if lactation is possible.

Maternal Barriers

Maternal barriers to breast-feeding can be due to physical problems, medical or disease conditions, hormonal factors,

or psychiatric disorders. Insufficient milk supply may be attributed to many factors, including insufficient glandular tissue, diet, illness, fatigue, psychologic factors, drugs, and smoking. When these factors have been ruled out, the cause may involve imbalances in hormone production or secretion. Low prolactin levels cause poor milk production, and low or inhibited oxytocin release causes a poor milk-ejection reflex (Bodley & Powers, 1999).

Psychiatric problems can interfere with lactation and rarely may require hospital admission. The incidence of psychiatric disorders increases dramatically in the postpartum period. Studies in postpartum women who were clinically depressed have revealed that two of three have major depression. Although breast-feeding mothers have been found to be more relaxed and have less mood swings, a mother experiencing depression may find breast-feeding difficult (Lawrence, 1999).

Maternal Breast Surgery

Augmentation mammoplasty has become an acceptable surgical procedure that can have implications for the breast-feeding mother. Breast-feeding can be successful when there is no destruction of breast tissue or interruption of ducts, nerve supply, or blood supply to the breast tissue or nipple. After extensive research the Food and Drug Administration (FDA) has concluded that it is not necessary to remove intact implants when a woman wishes to breast-feed.

Reduction mammoplasty is a surgical procedure to reduce the size of very large breasts. This type of surgery is more destructive to breast tissue than is augmentation because of the necessity of replacing the nipples symmetrically, which requires interruption of the milk ducts.

Breast surgery for nonmalignant tumors usually does not preclude breast-feeding unless the ductal structure has been interrupted. Women with a periareolar incision have a fivefold risk of lactation insufficiency (Lawrence, 1999).

Nipple Inversion

Flat or inverted nipples do not preclude breast-feeding and may respond to breast shells. Breast shells are vented plastic disks with holes in the center and a dome cover that allows the nipples to evert (Figure 30-19). The shell is slipped into the cup of a brassiere. The shells can be worn during the last trimester by women who choose to do so. However, research has shown no significant difference between groups of women who have used breast shells and groups who have used exercises that pull and stretch the nipple (Hoffman exercises) before delivery. Physicians caution women to avoid nipple stimulation because of the possibility of causing uterine contractions or preterm labor (Lawrence, 1999).

Nipple shields made of silicone are now frequently used to help women gradually pull out the inverted nip-

Figure 30-19 Breast shells.

Figure 30-20 Nipple shields.

ples to allow the infant to latch on to a nipple that is more difficult to grasp (Figure 30-20). The mother is taught to pump her breasts after each nursing session to build up her milk supply while using the nipple shields. After the nipples are everted and the milk supply is built up the mother is encouraged to gradually wean the infant to the bare nipple (Martin, 2000).

Nipple Sensitivity

Most women will quickly adapt to the nursing experience naturally; however, often there may be nipple discomfort or pain during the initial breast-feeding sessions. Nipple sensitivity during breast-feeding is created by the negative pressure on the ductules within the breast, which are not yet filled with milk. The most common cause of nipple discomfort in the first few days is improper positioning. The nurse can help the mother to prevent discomfort by stressing proper positioning and making sure that the areola is grasped by the infant and not just the nipple. Occasionally

the maternal tissues are unusually tender and delicate. Applying breast milk to the nipple at the end of the feeding and allowing it to dry is helpful to most mothers. Nipple shields, a device worn over the nipple and areola while the infant is sucking, do offer some protection to sensitive nipples. However, nipple shields should be used with caution because it is sometimes difficult to wean the infant back to the bare breast and the shields may decrease milk production (Riordan & Auerbach, 1999).

Hormonal Barriers

Confusion about the compatibility of contraceptives with breast-feeding may pose a barrier that influences the feeding decision for some women. Use of a contraceptive method in a breast-feeding mother is a particularly important decision, because ovulation may occur before the onset of menses and some methods may interfere with milk production. Nonhormonal methods, such as condoms, cervical caps, and diaphragms, can be effective in preventing pregnancy when used correctly and consistently. Spermicides may be used in the postpartum period; however, the medication may be transferred to the maternal blood, and minute amounts can be passed on in breast milk. No adverse effects have been observed in infants. It is also helpful to discuss the hormonal effect of lactation on the vagina. Vaginal dryness from hormonal influences during breast-feeding may cause dyspareunia for some nursing mothers. Vaginal lubricants, such as K-Y jelly, can sometimes help alleviate this problem. A sudden change in vaginal lubrication can sometimes indicate ovulation.

Intrauterine devices (IUDs) are a very effective method of contraception available to nursing mothers. According to FDA regulations, however, IUDs can be inserted only after uterine involution is complete. Periodic abstinence using symptomatic and temperature methods to detect ovulation also may be used during breast-feeding. Tubal ligation after delivery also can be compatible with breast-feeding but usually requires anesthesia for the procedure. According to Hale (1999), because many anesthetic medications have brief half-lives, rapid redistribution from the plasma to other remote sites (adipose tissue, muscle, and so on), or both, the overall amount of exposure of the breast-feeding infant is quite small. When pain medication is given postoperatively it can be given immediately after the infant is fed to permit the level to peak before the next feeding. Medications used should be limited to short-acting drugs that are excreted within 4 hours and that the newborn is able to excrete (Martin, 2000).

Hormonal contraceptive methods must be used in the breast-feeding mother with caution because some hormonal methods will interfere with milk production. Oral contraceptives containing only progestin are very effective when used in combination with breast-feeding. A small amount of hormone passes to the infant; however, no known adverse effects have been reported (Adams, 2000).

In 1981, the American Academy of Pediatrics approved the use of combination oral contraceptives in women electing to breast-feed once lactation is well established. Estrogen has been reported to reduce milk supply in several studies (Lawrence, 1999; Riordan & Auerbach, 1999). Therefore, alternative contraceptive methods should be considered as a first choice in lactating women, particularly during the first 6 weeks postpartum. The WHO has suggested that the combination oral contraceptive should not be the first choice for women who are lactating (World Health Organization, 1988, 1994).

Depot medroxyprogesterone acetate (Depo-Provera) does not suppress milk production and is an effective contraceptive method for breast-feeding women. Subdermal implants that contain the progestin levonorgestrel do not affect the breast-fed infant and may be inserted at 6 weeks postpartum after lactation is established (Lawrence, 1999).

Decreased Lactogenesis

“Relactation is the process by which a woman who has given birth but did not initially breastfeed is stimulated to lactate” (Lawrence, 1999, p. 555). Historically, relactation has been used to provide nutrition to an infant whose mother has died. A relative or friend would take on the care of the infant at the breast. Many women who have adopted infants have the desire to breast-feed. Mothers of premature infants also have expressed the desire to breast-feed their infants after the time in the neonatal intensive care unit is over. Pharmacologic manipulation of lactation has been used to induce breast-feeding. Some medications seem to work only if the breast has been stimulated by pregnancy, whereas other drugs have been used to increase prolactin levels in the absence of pregnancy. Drugs such as thyrotrophin-releasing hormone, and drugs that block hypothalamic catecholamines, such as phenothiazines, reserpine, meprobamate, and amphetamines, have been used to manipulate lactation (Lawrence, 1999). The use of an electric breast pump and frequent nursing of the infant with various lactation devices also will help establish lactation. Milk production by mothers of premature infants has been evaluated by many researchers who have concluded that frequent expression is significantly associated with greater milk production (Brown, 1996).

Infant Barriers

Most normal full-term infants can breast-feed with only minor adjustments. The infant with a medical or surgical problem presents a need for special interventions that ensure adequate newborn nutrition.

Prematurity

Low-birth-weight and premature infants present unique nutritional problems. Optimal growth for premature in-

infants is considered to be the growth curve they would have normally followed if they had remained inside the uterus. Although human milk provides the ideal nutrients, it would require an inordinate, physiologically infeasible volume to achieve adequate amounts of some nutrients. These needs can be met by artificial formula or supplementation.

Preterm milk has been found to contain special properties that are uniquely suited to meet the needs of the premature infant (Figure 30-21). Preterm milk contains higher levels of fat, protein, and other necessary nutrients than term milk. Many mothers of preterm infants need to be given instructions on how to build up their milk supply with electric breast pumps. The milk may be used to feed very low-birth-weight infants by feeding tube until the infant is strong enough to nurse on his own.

A.

B.

Figure 30-21 This preterm infant, who has been gavage feeding, is trying breast-feeding for the first time. A. The mother elicits the rooting reflex, and the baby responds by opening the mouth wide. B. The baby gets the nipple into the mouth but not much of the areola.

The protective properties of human milk against infection are considered a very important reason to provide human milk to preterm infants. NEC is an acute inflammatory disease of the GI mucosa commonly seen in the premature infant. Human milk has been associated with a decreased incidence of this very serious condition (Lawrence, 1999). When the infant nurses at the breast, there is a large outpouring of 19 different GI hormones in both the mother and infant, including cholecystokinin and gastrin. These hormones stimulate the growth of the baby's and mother's intestinal villi and increase the surface area for the absorption of calories with each feeding. The increased gut motility with each breast-feeding episode also removes a large amount of meconium from the infant's colon, with its large load of bilirubin (Ulvnas-Moberg, 1989).

Recent research has demonstrated that the use of small, thin, silicone nipple shields in preterm infants significantly increases milk transfer (Meier et al., 2000). Immature feeding behaviors, such as short, ineffective sucking bursts and falling asleep easily, predispose premature infants to underconsumption of breast milk. The nipple shield makes it easier for the preterm infant to stay latched on to the breast and extract milk. This research demonstrated that not only did milk intake increase significantly but the use of nipple shields also resulted in most mothers breast-feeding for a longer duration than did mothers who had not used shields.

Illness and Disability

Infants who have been compromised in utero or during delivery will need special treatment. Infants who will have the best outcomes when breast-feeding can be maintained are those experiencing postmaturity, fetal distress, and hypoxia; acute illnesses, such as fever; or contagious diseases. Some problems such as galactosemia or inborn errors of metabolism may require that breast-feeding be terminated.

Down syndrome or other congenital anomalies may make breast-feeding more difficult. Breast-feeding in these infants will require patience and support of the mother and infant by all members of the health care staff. Feeding of any sort may be greatly hindered by abnormalities of the jaw, nose, or mouth, such as cleft lip or cleft palate. These infants may need to have surgical correction during the first few weeks of life. The mother may have to express or pump her breast milk and offer it by dropper when sucking is ineffective (Lawrence, 1999).

Hypoglycemia

Hypoglycemia during the early neonatal period of a term infant is defined as a blood glucose concentration of less than 35 mg/dL, or a plasma concentration of less than 40 mg/dL. Hypoglycemia occurs because the infant's glucose supply is stopped when the cord is cut. Signs of

hypoglycemia include jitteriness; irregular respiratory effort; and cyanosis, apnea, feeding difficulty, and lethargy. Many nurseries routinely obtain a blood glucose test soon after birth because hypoglycemia can sometimes be asymptomatic. Infants at high risk require more frequent testing (Lawrence, 1999).

According to the International Lactation Consultants Association's guidelines for breast-feeding management during the first 14 days (1999), hypoglycemia during the first 3 hours after delivery usually has a physiologic cause. These guidelines further state that early, frequent breast-feeding helps prevent lowered blood glucose levels. Because colostrum contains 18 cal/oz compared with 6 cal/oz for 5% glucose water, newborns are less likely to experience hypoglycemia when feeding is not supplemented with glucose water after delivery. Colostrum also has higher levels of protein than does glucose water and therefore has a stabilizing effect on blood glucose levels.

Jaundice

Physiologic jaundice is a normal occurrence in 50% of term and 80% of preterm newborns. Neonatal jaundice occurs because the newborn has a high rate of bilirubin pro-

duction. The number of fetal erythrocytes per kilogram of body weight is greater than in an adult, and there is considerable reabsorption of bilirubin from the neonate's intestine. Meconium is extremely high in bilirubin and is a source of reabsorbed bilirubin. Jaundice appears 24 hours after delivery in an otherwise healthy infant. Although many causes for physiologic jaundice have been investigated, research has documented that the number of breast-feedings during the first 3 days of life relates to bilirubin levels. The greater the number of breast-feedings, the lower the bilirubin levels (Lawrence, 1999). The newborn should be fed at least 8 or more times a day. Colostrum is a natural laxative and promotes the excretion of meconium, thus decreasing bilirubin levels.

Psychologic Barriers

Bryant (1992) conducted extensive qualitative research using focus groups throughout the United States in an effort to determine which perceived barriers are keeping women with low incomes from breast-feeding. Bryant analyzed data and found several consistent responses among these women:

- Lack of confidence in their ability to breast-feed. Many women lacked confidence in their ability to produce adequate quality or quantity of breast milk.
- Embarrassment. The embarrassment that many women feel when nursing in front of others is a major deterrent to breast-feeding.
- Loss of freedom. Many women feel that breast-feeding will prevent them from going to work, school, or social events.
- Concerns about dietary and health practices. Many women feel that they will have to change many of the things that they like to do in order to breast-feed.
- Influence of family and friends. Many women do not feel that they have the courage or strength to go against the negative influence of family members or friends.
- Women expressed many other concerns, such as pain, fear of disfigurement, sexual feelings about breasts, invalid medical concerns, and a lack of social support.

Modesty

According to Bryant (1992) many women view their breasts as sexual objects and associate them with their ability to attract and please men. Because of these feelings many women are apprehensive about breast-feeding in front of other people, particularly men. Women may worry that nursing their infant in public will arouse men, make

Nursing Alert

MANAGEMENT OF EARLY PHYSIOLOGIC JAUNDICE WHILE BREAST-FEEDING

You should:

- Monitor all infants for initial stooling.
- Initiate breast-feeding early and frequently.
- Discourage water, dextrose water, and formula supplementation.
- Monitor weight, voidings, and stooling associated with breast-feeding.
- When the bilirubin level approaches 15 mg/dL, stimulate stooling by feeding the infant more often and stimulate breast milk production with pumping. When the bilirubin level exceeds 20 mg/dL, use phototherapy.

No evidence exists that early jaundice is associated with an abnormality of the breast milk; therefore, withdrawing breast milk is indicated only when jaundice persists for more than 6 days, the bilirubin level increases to above 20 mg/dL, or the mother has a history of having had an affected infant (Lawrence, 1999).

Client Education

Sexuality and the Breast-feeding Woman

Sexual stimulus can trigger the milk ejection reflex in breast-feeding women, particularly during orgasm. This “let-down” of milk during sexual relations may have either a negative or positive effect on the sexual partner. Psychologic conflicts in the partner may be a result of misunderstanding of the “let-down” reflex. Practical solutions to unwanted spraying of milk - “let-down” during sexual relations include the following:

- Breast-feeding the infant immediately before sexual relations.
- Expressing milk before beginning sexual relations.
- Explaining the biologic phenomenon to couples, thus avoiding negative reactions.
- Teaching couples that oral and manual manipulation and fondling of the breasts during love-making need not be restricted (Lawrence, 1999).

their husbands or boyfriends jealous, or look disgusting to others. Women say they will feel uncomfortable breast-feeding in front of anyone unless they are sure their breasts are not exposed. Finding a private place to breast-feed while out in public is a very real concern for many women. Women may resent being forced to hide in restrooms or cars to keep from feeling embarrassed by breast-feeding.

The nurse can help allay these fears by teaching the woman how to breast-feed discreetly by demonstrating how to cover her breasts while she is nursing and assuring her that most women are apprehensive about breast-feeding in front of others but usually adjust quickly once they begin to nurse. If she is one of the women who does not adjust, she can pump her breast milk and give the baby a bottle when she is in public.

A small proportion of women feel they cannot even consider breast-feeding because they associate the breast with sexual arousal. These women may consider the idea of putting their baby’s mouth on the breast as disgusting. Survivors of sexual abuse also may have unresolved issues about the breasts and may not be able to breast-feed their infants.

Lack of Confidence

Some women lack confidence in their abilities to produce an adequate supply of nutritious breast milk. Few women understand the mechanics of breast milk production and are easily influenced by stories from other women whose milk “dried up” or couldn’t satisfy their child’s nutritional needs because it was too weak, blue in color, or too thin. If these stories come from an important social influence, such as a grandmother, they may take on special significance because of the possibility that the problem may have been passed on genetically to the new mother.

When women lack confidence in their own ability to make adequate and nutritious breast milk, they frequently will begin supplementing with formula. Doing so creates a downward spiral in breast milk production that becomes a self-fulfilling prophecy. Because infant formulas have labels that list the ingredients, many women will trust these products more than their own bodies. Not being able to accurately measure the amount of breast milk the infant is taking during nursing also seems less scientific than being able to measure formula taken in ounces, leading women to worry about the amount of milk being produced.

Educational materials on breast-feeding usually depict women as being confident, secure, and completely in control of their lives. Use of promotional materials that picture average and minority women may help overcome these worrisome perceptions. Helping the woman analyze and resolve her fears and concerns about breast-feeding can build her confidence and self-esteem.

Social Barriers

Social support has been recognized as a very important component of successful breast-feeding. Social support has been defined as input directly provided by another person (or group) that moves the receiving person toward goals that the receiver desires (Baranowski et al., 1983). In order for breast-feeding support to succeed, it is necessary to have a person desiring to learn how to breast-feed and a support person who can teach the skills that must be achieved. Social support can be provided by a nurse, a lactation consultant, a family member, friends, peers, or a significant other. Factors influencing attitudes and social support include personal networks, attitude of the baby’s father, health care provider’s attitudes and help, and maternity ward policies and practices (Figure 30-22). The nurse plays an important role in facilitating the new skills necessary to promote successful breast-feeding because the nurse frequently has the most direct and personal contact with new mothers. However, some mothers complain that nurses frequently give conflicting information or may be ill-prepared to offer advice (Hill, 2000).

Figure 30-22 Involvement of the baby's father or other support persons in the breast-feeding process is more likely to result in successful breast-feeding.

Lack of Social Support

The negative influence of family and friends or lack of social support is associated with a decrease in breast-feeding initiation and duration (Raj & Plichta, 1998). Studies of socioeconomic factors associated with lower breast-feeding rates include women who are unmarried, single, widowed, or divorced. For many women, especially teens, who may not have a strong support network, peer support groups and lactation consultants have been shown to increase both initiation and duration of breast-feeding.

Misperceptions and Misconceptions

Many women have misinformation about breast-feeding and may decide it is not an option for them. Stories from other women that suggest breast-feeding is painful or may even permanently disfigure the breasts can be real barriers. Some women have heard that contraceptives cannot be used while breast-feeding and may bottle-feed because of this misconception. Nurses need to elicit the client's misconceptions and misperceptions to deal with them effectively. Simply saying, "Tell me what you have been told about breast-feeding" will help the client state her concerns in a nonthreatening environment (Bryant, 1992).

Other Barriers

In addition to personal and social barriers to breast-feeding, subliminal messages linked to specific hospital policies and institutional procedures also can play an important role in feeding decisions.

Hospital Policies

Many studies have looked at the effect of formula supplementation on breast-feeding outcomes. Most of these stud-

Critical Thinking

Breast-feeding Myths

Can you answer clients' questions about breast-feeding myths? What information would you offer to counter each myth? Research and continue to dispel myths about breast-feeding.

- Women do not need to drink large amounts of fluids to produce large amounts of breast milk.
Advice is simple: Drink fluids when thirsty.
- Women do not need to restrict the food they eat while breast-feeding.
Advice is simple: There is no need to eliminate foods from the diet unless consumption of a certain food, such as onions, is followed by symptoms in the breast-fed baby, such as excessive crying or gas.
- A mother can drink alcohol in moderation and continue breast-feeding.
Advice is simple: There is no need to completely eliminate drinking alcohol while breast-feeding.
- It is safe and recommended that mothers and babies sleep together if the infant is kept supine and soft materials are not allowed in the bed.
Advice is simple: Co-sleeping is safe and facilitates breast-feeding for mother and baby unless the parents use medications that impair arousal (Heinig, 2000).
- Breast-feeding does not make breasts sag or become disfigured.
Advice is simple: Wear a good supportive bra.
- A mother's anger will ruin or curdle her milk.
Advice is simple: Angry feelings may cause mothers to feel tense and the infant may sense this tension; however, the quality of the breast milk will not be affected (Lamaze International, 1998).

ies have reported a decrease in milk supply that seems to be directly related to the amount of supplementation of formula. A study by Bliss et al., (1997) clearly showed that mothers who requested formula in the hospital and requested a discharge pack of formula were more likely to discontinue breast-feeding than were mothers who exclusively breast-feed. Other studies have looked at the effect of giving formula samples on discharge from the hospital. Simpson (1999) found that mothers who were given for-

Client Education

Working and Breast-feeding

You should teach the client to consider the following information for successfully combining working with breast-feeding:

- Take full advantage of maternity leave to establish a supply of milk.
- Keep in mind that breast-feeding can reduce the amount of sick days taken because breast-fed infants usually are sick less often than are formula-fed infants.
- Try to introduce a bottle once you have a milk supply established (in 4 to 6 weeks) to prepare the baby for bottle-feeding during the day by someone else.
- Purchase or rent a high-quality, automatic, electric breast pump.
- Purchase a double-pumping kit with the electric pump so that both breasts can be expressed simultaneously in only 10 to 15 minutes (Figure 30-23).
- Gradually become familiar with the process by simulating the pumping schedule to be used at work for 2 weeks before returning to work.
- Breast-feed once in the morning; pump every 2 to 3 hours at work; and then breast-feed as soon as possible on returning home, during the evening, and at bedtime.
- Try to find a private area if a pumping room is not available at your place of employment.
- Store the breast milk pumped at work in a refrigerator or cooler. Milk can be kept refrigerated for 72 hours; it also can be labeled, dated, and frozen for 6 months when kept in the deep-freeze section of the freezer.

You can teach the mother to keep the following in mind:

- Pumping the breasts at work can be easy, fast, and painless.
- Many working mothers combine breast-feeding and bottle-feeding with few problems.
- Your child-care provider can feed the baby breast milk from a bottle while you are at work.
- Breast-feeding creates a special bond between you and the baby that no one else can have.
- Plan and commit yourself to breast-feeding because it is a worthwhile endeavor for your baby.

Figure 30-23 Expressing milk from both breasts simultaneously is a time saver for the busy mother.

mula discharge packs were significantly less likely to be breast-feeding at 1 month and were more likely to have introduced solid foods by 2 months.

One of the possible explanations for the breast-feeding problems associated with formula supplementation is a phenomenon called *nipple confusion*. This problem seems to be related to the fact that infants must use a completely different method of sucking to extract milk from the breast compared with the bottle and therefore have problems changing from one to the other. While sucking at the breast, the infant's tongue moves in a peristaltic motion from front to back, causing milk to be squeezed out of the nipple. When an infant sucks on an artificial nipple, the tongue pushes forward against the nipple to control the milk flow. Some breastfed babies make the necessary adjustments without problems; however, others do not and push the mother's nipple out of the mouth.

Many lactation consultants recommend the use of special nipples to help infants switch between breast-feeding and bottle-feeding. A specially designed nipple made of silicone that is broad, soft, and naturally shaped allows infants to suckle using their tongues and lips, similar to the way they use their muscles when breast-feeding.

Other hospital policies that can negatively affect breast-feeding include taking the newborn to a transitional nursery immediately after delivery, no rooming-in policy, routine supplementation of breast-feeding infants in the nursery, inconsistent or contradictory advice from hospital staff, and infants being allowed to nurse only on a strict hospital schedule. The woman who wants to breast-feed her infant may need to find out about the breast-feeding policies of the hospital before she chooses where to deliver.

Return to Work

The largest number of women choosing to breast-feed today are women who intend to return to work (Bar-Yam, 1998). Some women may feel that returning to work is a barrier to breast-feeding because of the added commitment and effort needed to combine work and breast-feeding the baby. Most companies have a written policy that establishes how long the maternity leave will be extended, and many companies find it beneficial to support breast-feeding to keep a high-quality workforce (Bar-Yam, 1998). The new mother must make decisions about child care and whether to continue breast-feeding after returning to work. Although breast-feeding will require some extra commitment and effort, many women find that the rewards far outweigh the difficulties.

The most important thing a new mother can do to get ready to return to work is to learn how to stimulate the production of milk. Frequent feedings and emptying the breasts completely increase milk production because these actions signal the breasts that there is a need for more milk. About 2 weeks before returning to work, the new mother should start pumping after and between feedings, and begin to store the breast milk in the freezer so that an adequate supply will be available to the baby's caregiver. Returning to work gradually or leaving the baby with a sitter for practice sessions will help to make an easier transition for both baby and mother.

Choosing a person to care for the baby who supports the mother's commitment to breast-feeding is an important first step in preparing to return to work. The client who plans to breast-feed after returning to work will need anticipatory guidance and support. The client can breast-feed when she is home and pump her milk while at work. She can leave breast milk for the infant to be given by a babysitter while she is away. The client's work wardrobe should include clothing that will allow her easy and private access to her breasts so that pumping while at work will be as easy as possible. Breasts may also leak during the first few weeks after returning to work. To help minimize leakage, instruct the client to press against the nipples when she feels the tingling feeling associated with the let-down reflex. The client also may want to place breast pads in her bra so that the milk will not stain her clothing. Wearing patterned clothing or bringing along a sweater to wear over other clothes also will prevent embarrassment if leaking occurs.

Nursing More Than One Child

Many women may wonder if pregnancy, multiple births, or being unable to establish lactation immediately after delivery are barriers to successful breast-feeding. Pregnancy can and does occur while lactating. It is possible to lactate throughout pregnancy and then to nurse both infants at

REFLECTIONS OF A NEW MOTHER OF TWINS

"During an interview with a new mother of twins, she was asked how in the world she could possibly breast-feed twins. The mother replied with absolute sincerity: 'I breast-feed because it is the easiest way to feed two babies. How would I ever keep up with bottles and formula for both of them? This way I can nurse both of them at once. It just makes good sense!'"

the breast postpartum. This is presently happening often enough to be called *tandem nursing*. The amount of nourishment provided to the first child depends on age and the other supplements being given. It has been shown that both infants can be nourished at the breast without any apparent adverse effect on either infant (Lawrence, 1999). The mother should be advised to get adequate rest, nourishment, and psychologic support to help her cope with the added demand on her both physically and mentally.

It is also possible for a mother to nurse twins and triplets (Figure 30-24). Research reports the fact that a single mother can provide adequate nutrition for more than one infant (Mohrbacher, & Stock, 1997). If the mother can nurse both twins at once the time needed to feed twins can be minimized. The mother will need adequate nutrition, rest, help, and support from relatives and friends to care for twins during the first busy year of life. The breast is capable of responding to nutritional demands placed on it by more than one infant, and many mothers of twins report that breast-feeding is much easier than trying to keep up with bottles for more than one infant.

CONTRAINDICATIONS TO BREAST-FEEDING

When discussing the contraindications to breast-feeding, it is necessary to examine the specific conditions that put the mother or infant at risk. The risk-to-benefit ratios must be weighed by the clinician and mother to arrive at the best decision for both mother and child. Life-threatening or severely debilitating illnesses in the mother may necessitate avoiding lactation.

A.

B.

Figure 30-24 Breast-feeding multiples. A. The nurse is helping this mother of triplets with her efforts at breast-feeding two babies at once. B. This mother and her babies will learn how to breast-feed together.

Maternal Disease

A new mother with a diagnosis of breast cancer should not nurse her infant so that the mother can begin definitive treatment for the disease. Breast-feeding is incompatible with chemotherapeutic agents. The question has been asked whether tumor cells can be transmitted to the infant by breast milk? At the present time no documented evidence exists of women with breast cancer having RNA of tumor virus in their milk (Lawrence, 1999).

Hepatitis B virus transmission from mother to infant has been described in several studies worldwide (Centers for Disease Control and Prevention, 1998). All infants born to mothers who have active disease or are carriers now receive both hepatitis B immune globulin (HBIG) immediately after birth plus a dose of human hepatitis B vaccine, followed by a second dose at a week of age or later. The Committee on Infectious Disease of the American Academy of Pediatrics states that newborns of mothers who test positive for hepatitis B and who have received the HBIG vaccine may be breast-fed (Lawrence, 1999).

Hepatitis C virus is the major agent causing blood-transmitted forms of non-A, non-B hepatitis. Because of the probable transmission of the hepatitis C virus into breast milk, the chance of chronic liver disease, and the lack of effective treatment, breast-feeding is not recommended when a mother is infected with the virus (Lawrence, 1999).

Cytomegalovirus (CMV) has been identified in human milk of women with the CMV antibody. However, the risk of CMV infection or other serious complications to the infant of a lactating woman with CMV in her milk is negligible because the milk also contains appropriate antibodies that protect the infant.

Studies on acquired immunodeficiency syndrome (AIDS) have found that breast milk has been implicated in person-to-person transmission of the HIV virus. The Center for Disease Control and Prevention (CDC) and the U.S. Public Health Service recommend that women in the United States who test positive for the HIV antibody should not breast-feed to avoid postnatal transmission to a child who may not have been infected in utero or during

delivery. In Third World countries where infant mortality from diarrhea and other diseases is 50%, breast-feeding is still the feeding method of choice (Lawrence, 1999; Popkin et al., 1990).

In the United States, human T-cell leukemia virus type I (HTLV-I) is a disease endemic in intravenous drug users and their sexual partners. Transplacental transmission of HTLV-I is virtually nonexistent; however, evidence exists of horizontal transmission through breast milk. Therefore, breast-feeding is not recommended for women who test positive for HTLV-I and for any mother who is abusing drugs because of the possibility of the infant receiving substantial amounts of the drug through breast milk (Lawrence, 1999).

Infant Disease

Most breast-fed infants are healthy, and many illnesses are less severe than those described previously; however, an infant may be born with a disease or may develop an illness after birth. Diarrhea and intestinal tract disease are much less common in breast-fed infants; however, if they occur, the infant should continue on breast milk if at all possible. Human milk is a physiologic solution that normally causes neither dehydration nor hypernatremia. Colitis in infants may be caused by a metabolic disorder; a dietary insult; some types of bacteria; and several types of viruses, such as the rotavirus. Respiratory tract illnesses and otitis media are less likely in the breast-fed infant. However, infants who develop respiratory tract illnesses can be maintained on the breast. The advantages of breast milk are the presence of antibodies and many neutralizing agents that protect the infant from many common childhood illnesses (Lawrence, 1999).

Drugs and Medications

Riordan and Auerbach (1999) emphasize the three “knows” about drugs and human milk:

1. Most drugs pass into breast milk.
2. Most medications appear only in small amounts in breast milk.
3. Few drugs are contraindicated for breast-feeding mothers.

Many variables affect the passage of drugs into breast milk: amount of drug taken, frequency and route of administration, timing of the dose in relationship to feeding the infant, and characteristics of the drug involved.

The effects of the drug on the infant are influenced by the infant's age, amount of milk ingested, frequency of feedings, and degree of absorption that occurs in the infant's GI tract. Lawrence (1999) suggests that long-acting

forms of drugs be avoided and that drugs be administered immediately after the woman has nursed her baby so that peak levels of the drugs will occur long before the next feeding time. Lawrence also suggests that infants be carefully assessed for drug reactions and that when alternative drugs are available that are less likely to pass into breast milk, they be used.

The mother who is breast-feeding should always inform her physician that she is doing so to avoid harming the infant. Information on potential effects of drugs given during lactation can be obtained from the American Academy of Pediatrics Committee on Drugs, 1994. Some drugs also may affect breast milk volume and therefore must be used cautiously. When dispensing medications to a nursing mother, the health care provider should always weigh the benefits of the medication against the possible risks to the infant (Table 30-4).

Herbs and herbal teas currently are very popular remedies for a variety of problems. Many herbs have been reported to enhance milk production (Lawrence, 1999). Mothers should be aware of the effects of herbal compounds that are ingested and the possible reaction in the breast-feeding infant. The nurse needs to inquire about all

Table 30-4 Drug Recommendations During Lactation

Contraindicated Drugs	Drugs to Use Cautiously
Bromides	Atropine
Chloramphenicol	Barbiturates
Cocaine	Chloral hydrate
Coumadin	Dihydratichysterol
Crack cocaine	Ergonovine
Cyclophosphamide	Ethinyl estradiol
Diazepam	Medroxyprogesterone acetate
Dicumarol	Methadone
Diethylstilbestrol	Metronidazole
Ergot alkaloids	Nalidixic acid
Gold salts	Nitrofurantoin
Heroin	Norethisterone
Indomethacin	Phenothiazines
Iodides	Quinine
Lithium carbonate	Senna
Methotrexate	Sulfonamides
Methylergonovine	Thiazide diuretics
Phenylbutazone	
Radioactive iodine

foods and beverages when taking a medical history. When excessive amounts of any herbal substance are being consumed, its contents need to be checked. Education of the lactating client on avoidance of plants and herbs that may adversely affect her newborn is an essential nursing intervention.

According to the National Institute on Drug Abuse (1998) persons with the highest rate of illicit drug use are those between the ages of 18 and 25 years. Of women between 18 and 34 years of age, 30% reported using an illicit drug during the past year. Most breast-feeding women do not use drugs. Because some do, however, it is important that the nurse have accurate information to inform these women about the possible adverse effects of specific drugs on breast-feeding and newborns (Riordan & Auerbach, 1999).

Marijuana is probably the most common illegal drug used today by breast-feeding women. It is estimated that 5% to 15% of pregnant women use or have used marijuana. Although impairments in DNA and RNA have been reported in laboratory animals, there are no reports of infant health problems solely from marijuana use during lactation. Thus, the question is raised of whether a woman should be advised not to breast-feed if she refuses to give up smoking marijuana. Although not an ideal situation, there is little evidence that marijuana causes serious harm; therefore, it may be better for these mothers to continue to breast-feed rather than wean their babies (Riordan & Auerbach, 1999).

Cocaine use in the United States has dramatically increased because it has become less expensive, and the more popular form known as crack cocaine has emerged. This drug is entirely different from marijuana. Cocaine harms the fetus and the nursing infant. Cocaine is highly lipid-soluble and readily crosses into human milk. For at least 36 hours after the mother's last use of cocaine, the results of tests on milk samples will be positive for cocaine and its metabolites. Infants exposed to cocaine can exhibit irritability, vomiting, tachycardia, and seizures. Therefore, the recommendation is very clear: cocaine should never be used by a mother who is breast-feeding. A mother who uses cocaine is putting her infant at risk for great harm and also may have the baby removed from her custody if legal action is pursued (Hale, 1999–2000).

Amphetamines are readily transferred to breast milk, and levels in the infant may be three times higher than maternal blood levels. Despite these high levels in a large study of 100 mothers taking amphetamines, no adverse changes occurred in the infants' behavior (Riordan & Auerbach, 1999).

The effects of alcohol on the infant of a mother who is breast-feeding seem to be directly related to the amount of alcohol ingested by the mother. When the mother who is breast-feeding drinks a small amount of alcohol, the alcohol may not affect the infant or may cause a little sedation.

One study in mothers who were breast-feeding and who drank alcohol found the motor development of their infants to be slower; however, no effect on the infants' mental development was noted (Little, 1989).

PROBLEMS ENCOUNTERED WITH BREAST-FEEDING

There are many problems that can result in a nursing diagnosis of ineffective breast-feeding. Many of the so-called breast-feeding problems are merely normal phenomena that simply need to be addressed and worked through. The fact that breast-feeding problems have received so much attention probably accounts for the reluctance of many women to even give breast-feeding a chance. By focusing on the problems and not the rewards, health care professionals are doing a great disservice to clients and their infants. Nurses can offer anticipatory guidance to new mothers and support them with referral services after discharge, if necessary.

Client Education

Milk Supply

You must teach clients to cope with fears about adequate milk supply:

- Remember that the more milk the baby removes from the breasts, the more will be produced.
- Expect to breast-feed every 2 to 3 hours until the milk supply is established.
- Do not skip feedings or supplement feedings. Night feedings are necessary to establish adequate milk supply for the first few weeks after delivery.
- Breast-feed for at least 15 to 20 minutes so that the baby will receive the rich hindmilk.
- Try to rest and relax as often as possible, and accept offers from friends and family for help.
- Offer both breasts to the infant at every feeding.
- Eat an adequate healthy diet, and drink plenty of liquids.
- Remember that infant growth spurts are to be expected and are only temporary.

REFLECTIONS FROM A CLIENT

When talking to a new mother who had been breast-feeding for 3 months, she shared this story of how difficult it was to learn to trust her body to make good-quality and an adequate quantity of breast milk.

"During the first 4 weeks I would breast-feed my baby every 1 to 2 hours all day long. By nighttime my breasts felt completely empty. I was afraid to put my baby to sleep for the night when she might be hungry or starving to death, so each night I would breast-feed first and then offer a bottle of formula. She would sometimes take one ounce and then go off to sleep. When I took her back for her well-baby check-up at 6 weeks, her weight was off the top of the chart. I decided to confess to the pediatrician that I had been supplementing. When I told him how much formula she was taking each day, he laughed and said, 'If you think your baby is gaining this much weight from one ounce of formula a day, you must be kidding me.' Then he said, 'Your breast milk is what is making this child gain weight so well.' From that day on, I never supplemented again because I finally trusted and believed in my own body. It was just a matter of gaining confidence in myself."

Many of the problems can be avoided if the nurse provides anticipatory guidance in assessing and planning the care of the new mother who wishes to breast-feed. The nurse's role in working with the woman who is breast-feeding includes developing a plan of care that includes teaching of proper feeding techniques and interventions to correct any related problems.

Maternal Problems

Mothers may experience some difficulties when beginning to breast-feed. Most complications can be avoided if the

mother receives appropriate guidance, education, and support during initiation of breast-feeding after delivery. Early recognition and resolution of problems are essential to prevent disruption of breast-feeding. Because the nurse usually is the first person to interact with the new mother, the nurse is in a unique position to offer timely assessment, help, and effective interventions.

Cracked or Sore Nipples

Sore nipples are another common concern for breast-feeding mothers. Sore nipples usually are due to improper infant attachment, although some soreness is normal during the first few days or weeks of breast-feeding. Letting the nipples air dry after feeding, applying a few drops of breast milk to the nipples after feeding, and avoiding soaps and other drying agents usually will relieve soreness. Probably the most important intervention for this concern is observing the placement of the infant on the breast and helping the mother to ensure the infant is on the areola and not just the nipple.

Nipple soreness may be decreased by encouraging the mother to rotate positions when feeding the infant. Changing position alters the focus of greatest stress and promotes more complete breast emptying. Nipple soreness also can develop because of faulty infant sucking habits. Nipples can develop bruises, scabs, or blisters during improper sucking episodes when the nipple is rubbing against the roof of the infant's mouth. Nipples can be chewed because of improper positioning when the baby is just getting on the nipple and not the areola, resulting in cracked and tender areas near the base. Mothers need to be taught how to get the baby's mouth wide open and on the areola and how to remove the infant without causing more damage to the nipple. Nipple soreness also can result in cracked nipples. Cracked nipples need to be assessed for fissures, and the breast-feeding position must be observed. The mother may want to begin the feeding session with the nipple that is less sore or may need to temporarily use a nipple shield made of silicone to allow time for the nipple to heal.

The mother needs to be made aware that nipple soreness is most uncomfortable during the first few minutes of breast-feeding. Because the let-down reflex takes a few minutes to occur, she needs to try to keep nursing long enough for the milk to begin flowing. When the infant is overeager because of extreme hunger, nipple pain can be compounded. Feeding more often and applying ice to the nipples before beginning may help.

The best way to care for the nipples is simply to apply some breast milk to them at the end of the feeding and allow them to air dry. The use of creams or ointments is discouraged. Washing the nipples with plain water (no soap) prevents drying and helps healing. If the mother's

nipples are irritated by clothing, breast shields or pads may be worn under the bra.

When a mother has persistent sore nipples, candidiasis is a possibility. It is caused by a fungus, *Candida albicans*, also called *Monilia* or thrush when it occurs orally. This condition should be suspected when the mother has been breast-feeding without discomfort and then suddenly complains of very sore nipples, itching, burning, or pain deep in the breast. When the mother has signs of deep pink inflammation on her nipples, the infant's mouth also needs assessment for signs of white patches. Treatment of all infected areas in both mother and baby are necessary to eliminate the infection and prevent reinfection (Heinig & Francis, 1999). Antifungal medication is given by mouth to the infant, and the mother must apply antifungal cream to her nipples before each breast-feeding (Riordan & Auerbach, 1999).

Inverted Nipples

Assessment of the mother's nipples for protractility when stimulation occurs can be done by asking the mother to gently pinch her nipple and observing each as it everts (Figure 30-25). Inverted nipples can be successfully treated during the prenatal period by using breast shells that exert a gentle suction on adhesions anchoring the nipple. This will usually allow the inverted nipple to protrude when the baby latches on (Riordan & Auerbach, 1999). If a mother has flat or inverted nipples, a breast shield made of thin latex may help to draw the nipple out but may reduce milk transfer to the infant by 22% (Lawrence, 1999). The use of an electric breast pump also may help pull the nipple out before the infant tries to latch on. The mother should also be encouraged to help shape the nipple by using her hands or apply ice before feedings.

Breast Engorgement

Breast **engorgement**, which results in swelling and fullness, occurs in all women who are lactating from three to seven days after delivery. Engorgement usually involves

the vascular system as blood flow is increased to the breasts to prepare for milk production after delivery (Figure 30-26). The breasts are described as full, red, warm, and uncomfortable. This type of engorgement will subside on its own within 3 to 5 days and is a natural response.

Another type of engorgement involves overdilatation of breast milk in the alveola. This overdilatation may be

Client Education

Prevention and Treatment of Engorgement

You should teach the client how to prevent engorgement:

- Breast-feed the infant frequently, 8 to 12 times in 24 hours to prevent discomfort and mastitis.
- Avoiding supplements of water or formula for the first 3 to 4 weeks.
- Express milk when feedings are missed.
- Gradually wean the baby.

You should teach the client how to treat engorgement:

- Apply hot, moist towels to the breasts for 2 to 5 minutes, or take a hot shower before nursing.
- Hand express some milk to soften the areola after using moist heat, making it easier for the baby to attach to the breast.
- Use gentle breast massage before and during breast-feeding.
- Avoid bottles, pacifiers, and nipple shields during this period, which can cause nipple confusion for the infant.
- Apply cold compresses to the breasts after feeding to relieve discomfort.
- Use relaxation techniques before and during feeding.
- When the baby will only take one breast at a time, use a breast pump or hand express milk from the other breast during engorgement periods.
- Use a breast pump or hand express milk to soften the areola when the baby cannot latch on to the nipples because the breasts are too full.

Figure 30-25 Assessing for nipple inversion.

Figure 30-26 Breast-feeding is the best relief for breast engorgement.

due to restricted sucking time, large volumes of milk, or incorrect infant attachment. Some mothers experience plugging of one or more milk ducts, especially during or after engorgement. This problem is manifested by a lumpy area of tenderness in the breast and also is referred to a “caked breasts.” Treatment consists of the use of heat, breast massage, and frequent breast-feeding to ensure complete emptying of the breast (Lawrence, 1999).

Mastitis

Mastitis is an infection of the breast generally caused by *Staphylococcus aureus* and seen primarily in women who are breast-feeding. The most common source of the bacteria is the infant’s mouth. This infection usually occurs after discharge from the hospital; therefore, the client needs to be taught symptoms and preventive measures before discharge. The symptoms of mastitis are erythema, swelling, and pain, usually occurring in the upper outer quadrant of the breast. Enlarged and painful axillary lymph nodes also may be present. The woman with infectious mastitis also may present with influenza-like symptoms, such as fever, and a headache, along with a reddened and painful area in the breast.

Many factors may contribute to the development of mastitis and most can be prevented: poor drainage of milk;

Nursing Alert

MASTITIS

Evaluating outcomes of nursing care for the client with mastitis include the following:

- Client has knowledge of proper breast-feeding techniques.
- Client is aware of signs and symptoms of mastitis.
- Client reports the condition early.
- Treatment is successful.
- Client is able to maintain milk supply and continue breast-feeding.
- Client understands preventive measures to avoid recurrence.

cracked or damaged nipples; a tight bra or improper breast support; poor hygiene; engorgement; or a change in the infant’s feeding habits, such as sleeping through the night or being ill. The nurse can help prevent mastitis by teaching proper breast-feeding techniques, encouraging mothers who are breast-feeding to wear a good supportive bra, and teaching methods of preventing milk stasis.

New mothers should contact their physician, nurse practitioner, or Certified Nurse Midwife immediately if they experience signs of mastitis. A diagnosis of mastitis usually is based on symptoms and physical examination. Treatment consists of feeding the baby frequently or pumping the breasts, bed rest, increased fluid intake, a supportive bra, local application of heat, medications for pain, and with a 10-day course of antibiotics (Lawrence, 1999). Most antibiotics are safe for the breast-feeding mother. If the antibiotic can be given to an infant, it is then safe to give the breast-feeding mother. However, because most antibiotics transfer into breast milk, the antibiotic may cause loose stools or candidiasis in both the mother and infant (Riordan & Auerbach, 1999).

Mastitis occasionally may develop into an abscess that needs to be incised and cultured. If breast-feeding becomes impossible, it is necessary to maintain the mother’s milk supply and prevent engorgement by using an efficient pump to remove the milk.

Alternative Therapy for Breast-feeding Problems

There are many alternative therapies for problems mothers have with their breasts when breast-feeding. Rapid healing has been achieved by applying breast milk to the mother’s nipples and allowing it to dry. Applying tea bags mois-

Research Highlight

Effects of Cabbage Leaf Extract on Breast Engorgement

Purpose

To compare the effectiveness of cabbage leaf extract and a placebo in the treatment of breast engorgement in lactating women.

Methods

In a double-blind experiment with a pretest-posttest design, 21 participants received a cream containing cabbage leaf extract and 18 received a placebo cream.

Findings

The placebo and treated groups reported receiving equal relief, with the two groups showing no difference on all outcome measures. However, mothers perceived both creams to be effective in relieving discomfort. Feeding had a greater effect than the application of cream on relieving discomfort and decreasing tissue hardness.

Nursing Implications

It is recommended that lactation consultants encourage mothers to breast-feed if possible to relieve the discomfort of breast engorgement.

Roberts, K., Reiter, M., & Schuster, D. (1998). Effects of cabbage leaf extract on breast engorgement. *Journal of Human Lactation*, 14, (3), 231–236.

tened in warm water is receiving new acceptance. The tannic acid in the tea helps toughen the nipples, and the warmth promotes healing.

Lawrence (1999) reports that application of cabbage leaves is a favorite treatment for breast engorgement that has been handed down for generations. Two reports in the literature are cited. Treatment consists of application of refrigerated cabbage leaves to the breast, leaving the nipple exposed. The leaves are left on for 20 minutes or until wilted. Whether it is the coolness of the leaves or some innate property of the leaves that helps the engorgement is yet to be proved.

Many herbs and foods have been used to encourage and promote the flow of milk and to treat some of the problems of breast-feeding. Simple teas such as raspberry leaf, alfalfa, and comfrey are used to stimulate a plentiful supply of breast milk and a relaxed mother and infant. All leafy greens such as parsley, watercress, and green beans are considered helpful in maintaining lactation. Other herbs and leaves, including hops, are thought to increase milk production.

Nursing mothers may rely on herbal products to help produce more or a better quality of milk. However, the

scientific efficacy of these remedies is limited. Few data exist on the excretion of herbal products into breast milk. Some common herbal remedies, such as chamomile, have been used for thousands of years and are considered safe for use during lactation by the FDA. However, many other common herbs are considered dangerous and should be avoided while breast-feeding: aloe vera, basil, black cohosh, bladderwrack, comfrey, ginseng, licorice, and golden seal (Kopec, 1999).

Many poultices, compresses, and soaks also are recommended as being beneficial to stimulate circulation and ease pain in sore breasts. The use of warm compresses soaked in a variety of herbs and leaves is suggested as a remedy for sore nipples, clogged milk ducts, engorgement, and mastitis (Hoffman, 1992).

The use of relaxation techniques, such as deep breathing, imagery, and body massage, also can be used to promote relaxation and thus the “let-down” reflex. Accupressure massage techniques also can be used to help create relaxation and decrease stress and anxiety. Many women find that they need a quiet, private place to breast-feed their infant to allow the flow of milk to occur. A warm, relaxing bath or shower also will stimulate the flow of milk.

After the first few weeks, the let-down reflex occurs more easily and just the thought, sight, or sound of the infant frequently will trigger milk flow.

Return to Work: Pumping, Storing, and Supplementation

When a mother wishes to breast-feed and is unable to nurse her baby because the infant is premature or she must return to work, she can express the milk either manually or with a breast pump. During the postpartum period, if a baby is unable to nurse at the breast, the mother needs frequent breast stimulation to help establish her milk supply. She should use an electric breast pump with a double setup (pumps both breasts at once) at least 8 times in a 24-hour period (Riordan & Auerbach, 1999). The milk obtained can be refrigerated and given by gavage or fed from a tiny plastic cup made especially for premies, until the infant is able to nurse on its own.

There are many kinds of breast pumps on the market (Figure 30-27). Breast pumps generate a suck-release action by way of a flange that is placed over the areola. The milk obtained is passed into a reservoir. The new mother should be taught to use a breast pump before leaving the hospital postpartum unit. The new mother should be taught to first wash her hands and gather all equipment, which should be clean. The let-down reflex can be triggered before beginning to pump by rolling the nipple between the thumb and forefinger for a minute or two. Pumping, using an electric pump on each breast for at least 10 minutes every 3 to 4 hours around the clock, will stimulate milk production. Milk can then be transferred to sterile containers and frozen until needed. Breast pumps can be hand pumps, which are inexpensive but inefficient. Battery-operated pumps are more efficient than hand pumps but also are more expensive. Electric pumps are the most efficient but are very expensive. Most agencies now offer clients the option of renting an electric breast pump that is easy to use and very efficient in collecting and stimulating milk production. Most hospitals offer new mothers a list of suppliers of these types of pumps.

Milk also can be expressed manually by squeezing toward the nipple using the thumb and fingers around and above the areola and rotating 360 degrees around the breast (Figure 30-28). Massaging the breasts and nipples to stimulate the let-down reflex will help make the milk flow more readily.

Breast milk should be stored in clean plastic containers because leukocytes in the milk adhere to glass containers and thus their protective effect may be lost. When breast milk is frozen, leukocytes are destroyed. To safely use frozen breast milk, it must be thawed by running warm water over the container and then shaking it well to return the milk to suspension. It should not be warmed in

Client Education

Breast Milk Storage

For the client to successfully store breast milk, the nurse must teach the following about storage and preparation of the breast milk:

1. Refrigerated breast milk must be stored at 40°F or below and used within 72 hours.
2. Frozen breast milk must be stored at 0°F or below and used within 6 months.
3. To thaw frozen breast milk, run warm water over the container and shake it to return the milk to suspension.
4. Frozen breast milk that is thawed must be refrigerated at 40° or below and used within 24 hours.

a microwave oven because doing so causes uneven heating and may burn the infant.

Many businesses are now starting to provide comfortable, private places that allow new mothers to nurse their infants or to pump breast milk to be given to their infant at a later time. These pumping rooms, with breast pumps and refrigerators for breast milk storage, are being offered to employees by companies that realize the health benefits and resulting cost savings that can result from encouraging their female employees to breast-feed their infants. Because many new mothers must return to work before they are ready to wean their infants, it is imperative that these mothers be allowed the time and opportunity to remove the breast milk to prevent the breast engorgement. The newest electric pumps are extremely effective in removing the milk, and most mothers can finish pumping in 20 to 30 minutes. This type of support from employers can enable new mothers to continue their commitment to breast-feeding while maintaining their commitment to their jobs.

Weaning

The decision to stop breast-feeding and either place the infant on a bottle or a cup (**weaning**) may be considered a potential problem by the mother. In fact, some women have heard horror stories about the difficulties of weaning and are afraid to even try breast-feeding because of these fears. Women who are comfortable with breast-feeding and understand the weaning process will know when the time comes to wean because of sensitivity to the child's cues. In our society weaning frequently occurs very early

in the infant's life. The latest recommendation from the American Academy of Pediatrics is to breast-feed for one year (American Academy of Pediatrics, 1997). The slow method of weaning by gradually substituting one cup or one bottle for one breast-feeding session over days or weeks helps prevent breast engorgement and allows the infant to slowly adapt to the new feeding method (Lawrence, 1999).

Early introduction of solid and semisolid infant foods varies depending on the culture. Worldwide there is a high rate of breast-feeding initiation and too early supplementation with other foods. At some time, every breast-fed infant reaches a point when breast milk alone can no longer meet his or her nutritional needs, and solid foods are necessary. Three types of weaning have been described:

1. Gradual weaning takes place slowly over several weeks or months.
2. Deliberate weaning is a conscious effort instituted by the mother to end breast-feeding at a certain time.
3. Abrupt weaning is an immediate cessation of breast-feeding, usually initiated by the mother.

The timing and type of weaning can affect the infant's health and may even be associated with a feeling of being rejected in either the infant or the mother.

RESOURCES FOR BREAST-FEEDING MOTHERS

An important breast-feeding promotion strategy that has developed to help provide support for women's breast-feeding efforts is the lactation consultant. **Lactation consultants** are specially trained health care providers whose primary focus is assisting new mothers in establishing breast-feeding. These consultants provide a variety of services, including individual consultations, collaboration with other health care providers to develop a plan of care for new mothers, teaching classes, and instruction on the use of products such as breast pumps. These consultants also serve as informational sources, researchers, and data collectors and may help in developing special breast-feeding programs.

The U.S. Department of Agriculture, Food and Consumer Service (USDA/FCS), which promotes good nutrition for women and children, sponsors the WIC program. For a woman to be eligible for WIC, she must be at nutritional risk as designated by her individual state of residence and meet federal poverty level income qualifications. This program has provided formula free of charge and food stamps that can be redeemed for nutritious fruits, dairy products, and vegetables. Many people felt that giving free formula promoted the choice of bottle-feeding among women with low incomes. Since 1989, each state

has been required by the USDA to spend a specified amount on breast-feeding promotion and support. Since that time, many new programs have been set up to encourage mothers on the WIC program to breast-feed their infants. The WIC program strongly supports breast-feeding and encourages mothers to nurse their infants through its nutrition education, breast-feeding promotion, and special food packages for nursing women and their other children (McClurg-Hitt & Olsen, 1994).

Recently, due to extra funding, the Secretary of Agriculture announced a new program, “Loving Support Makes Breastfeeding Work.” This program will encourage mothers on the WIC program to begin and continue breast-feeding by providing more breast-feeding materials, referrals, and professional support. These programs are designed to increase public awareness and support of breast-feeding and provide technical assistance to WIC professionals in helping mothers breast-feed. WIC has tried many innovative projects to help promote and support breast-feeding. Programs of peer counselors who have been trained to assist new mothers have met with great success (Kistin, Abramson, & Dublin, 1994).

Many national and international organizations also are available that use the media to promote breast-feeding worldwide. The World Alliance for Breastfeeding Action was formed in 1991 as a group that coordinates international breast-feeding advocacy efforts by its members, which include organizations such as the International Lactation Consultants Association (ILCA) and International Breastfeeding Association (IBFAN). Two of the most notable activities are coordinating World Breast-feeding Week during the first week of August each year and lobbying for breast-feeding at international conferences (Bailey, 1997). *The Journal of Human Lactation* is a scientific journal devoted entirely to the publication of research and information on breast-feeding. Many books also are available to

ILCA

The International Lactation Consultant Association (ILCA) promotes breast-feeding awareness among health care providers and the public. The ILCA also helps define the scope of practice of lactation consultants. The ILCA publishes the *Journal of Human Lactation*.

help not only the health care professional but also new mothers. Dr. Ruth Lawrence is considered a leading authority on breast-feeding and has written a book entitled *“Breastfeeding: A guide for the medical profession”* (Lawrence, 1999).

Clients may be referred to resource groups, which provide education, support, and public awareness of breast-feeding. The ILCA promotes breast-feeding awareness and helps define the scope of practice of lactation consultants. **La Leche League** is a self-help group for breast-feeding mothers and is available worldwide. Members also are available for individual consultation and support.

NURSING IMPLICATIONS

Currently, nurses are faced with the challenge of providing care that is based on the most current evidence available. Evidence-based practice in nursing is a fairly new concept and allows nursing to move away from basing interventions on rituals, unverified rules, anecdotes, opinions, traditions, customs, intuition, or unit culture. Organizations such as the Association of Women’s Health, Obstetrics and Neonatal Nurses (AWHONN) and the ILCA are introducing evidence-based guidelines to help nurses change practices so that the care they offer women and infants is the most effective and safest they can provide.

Internet technology can now be used for clinical decision-making, creating policies and protocols, patient and staff education, and researching information. With over a million web sites available, however, accessing electronic sources can be an overwhelming task. The Cochrane Pregnancy and Childbirth database is an ongoing meta-analysis of evidence documenting effective health care practices for childbearing women and their infants (Callister & Hobbins-Garbett, 2000). One example of the importance of using evidence-based practice is a breast-feeding publication produced by ILCA in 1999, “Evidence-based guidelines for breastfeeding management during the first fourteen days.” This publication can be used to change hospital

LA LECHE LEAGUE

La Leche League is a self-help group for breast-feeding mothers with members around the world. LaLeche sponsors workshops and has an extensive publication list. The organization consists of small neighborhood groups in all major cities and rural areas. La Leche group leaders also are available for additional information and support. The groups usually have a lending library and newsletter.

policies such as routine supplementation of breast-feeding with water, dextrose water, or infant formula by providing the research evidence that contradicts such a policy (Heinig, 1999).

Although most women in the United States know that breast milk is best for infants, the breast-feeding rates still remain low. Traditional education programs that promote breast-feeding have not adequately influenced the adoption of breast-feeding in a large segment of the population. Social marketing is a communications strategy that has been used in the commercial market for many years to convince the public to purchase items such as cars and clothing. Recently, the social marketing strategy has been used to promote several socially beneficial products, such as exercise and smoking cessation.

The use of social marketing techniques to encourage breast-feeding among women with low incomes was conceptualized by Carol Bryant, an anthropologist and researcher, who created a company called Best Start. Best Start was organized to research, develop, and provide a multifaceted campaign aimed at new mothers, family members, health professionals, and the community at large. The materials that were designed can be obtained and used by a variety of breast-feeding promotion programs at a low cost (Bryant, Bailey, and D'Angelo 1989). This company, in cooperation with the USDA/FCS, has recently announced a pilot project in 10 states to include:

- Formative research.
- Development of a national breast-feeding resource guide and community organizer's kit.
- Training of WIC staff in coalition building, use of media, breast-feeding counseling strategies, and other aspects of breast-feeding promotion.
- Implementation of a state-wide media campaign (ILCA Globe Newsletter, 1997).

Overcoming Barriers

Prenatal education should begin as early as possible so that breast-feeding information can be presented to each client as often as possible to clear up misinformation and resolve doubts. Most women make their infant feeding decisions before becoming pregnant or during the first trimester (Grossman et al., 1990). Although most women know breast-feeding is best for infants many women have specific barriers that keep them from trying to breast-feed.

Education

Most women decide on an infant feeding method either before getting pregnant or during the first trimester. Therefore breast-feeding education programs need to be designed to provide information either preconceptually or

during the early prenatal period. Breast-feeding education can be accomplished by formal classes, informal discussions, printed materials, video tapes, and even by way of the Internet (Riordan, 2000). Educational programs should emphasize the benefits of breast-feeding and the potential hazards of formula-feeding. A complete promotion program has two essential components. First, counseling on how to overcome barriers to breast-feeding must be provided. Second, educational sessions must be held covering the mechanics of breast-feeding, how to deal with common breast-feeding problems, and how to assess adequate nutrition in the infant.

Another attempt to increase breast-feeding initiation in hospitals is shown in Box 30-1.

Cultural Negotiations

The nurse and other health care providers need to provide culturally appropriate care and guidance when helping

Box 30-1 The WHO/UNICEF “Ten Steps to Successful Breastfeeding”

Hospitals that are willing to adopt 10 specific steps and complete an accreditation process are then named “Baby-Friendly” hospitals. These 10 steps follow:

1. Have a written breast-feeding policy that is routinely communicated to all health care staff.
2. Train all health care staff in the skills necessary to implement this policy.
3. Inform all pregnant women about the benefits and management of breast-feeding.
4. Help mothers initiate breast-feeding within a half hour of birth.
5. Show mothers how to breast-feed and maintain lactation, even when separated from their infants.
6. Give newborn infants no food or drink other than breast milk, unless medically indicated.
7. Practice rooming-in (keeping the infant in the mother's room), and allow mothers and infants to remain together 24 hours a day.
8. Encourage breast-feeding on demand (whenever the infant is hungry).
9. Give no pacifiers.
10. Foster the establishment of breast-feeding support and refer mothers on discharge from the hospital or clinic.

WHO/UNICEF. (1994). Protecting, promoting and supporting breastfeeding: The special role of maternity services. *A joint statement by WHO/UNICEF*, Geneva, 1989, World Health Organization.

DECISION TO BREAST-FEED

When working with pregnant women who may be interested in learning about breast-feeding, you can:

- Begin with open-ended questions to elicit the client's specific concerns. For example, "What do you know about breast-feeding?"
- Acknowledge her concerns and reassure her that her feelings are normal. For example, "Many women worry about that same thing."
- Educate each woman using carefully targeted messages that address specific concerns.

new mothers breast-feed. The nurse needs to consider breast-feeding beliefs about health, support or resource persons, parenting responsibilities, and infant care. Because breast-feeding is a sensitive and personal matter for all women, it is important to assess attitudes toward modesty and cultural norms for each woman. Breast-feeding in a public place or in the presence of other people is an extremely sensitive issue for most women. Teaching women that breast-feeding can be accomplished in a modest manner and acknowledging variations in comfort are essential to successful feeding experiences.

In many cultures, colostrum is viewed as "old" milk that is not healthy for infants. In other cultures, this first milk is viewed as "poison" or "pus" that must not be given to babies. Nurses need to assess beliefs about colostrum in each client and attempt to educate the client while being careful not to insult her cultural beliefs. Well-meaning efforts to acculturate women to the nurse's beliefs may actually disrupt breast-feeding efforts. It is important to demonstrate understanding and value of the client's beliefs while helping her establish successful breast-feeding behaviors (Riordan & Auerbach, 1999).

Facilitating the Process

A renewed interest in the first minutes, hours, and days of life has been stimulated by several behavioral and physiologic observations in both mothers and infants. A special area of study on bonding has focused on increasing mother-infant time together by keeping newborns on the mother's chest in skin-to-skin contact during the first hour after birth.

Research has demonstrated that when infants are immediately dried (except the hands) with warm towels and it is clear they have good color and are active and normal,

they can go safely to their mothers. At this time the warm and dry infant is placed between the mother's breasts or on her abdomen. The mother's chest is able to maintain the infant's body temperature quite nicely. One of the most significant findings in this early period is related to breast-feeding. Six of nine studies have revealed that when a mother wants to breast-feed, is permitted to have early contact with her infant and an opportunity for suckling in the first hour of life, and is rooming-in with her infant, she is more successful at breast-feeding than mothers who do not have these experiences (Widstrom, Wahlberg, & Mathiesen, 1990).

One of the most exciting observations made is the discovery that newborns have the ability to find their

SUPPORTING BREAST-FEEDING

You should encourage breast-feeding by:

- Enthusiastically promoting and supporting breast-feeding.
- Simplifying breast-feeding. There is no need to eat or drink differently because only an additional 500 cal/d are needed along with a normal amount of fluid, six 8-oz glasses a day.
- Helping women understand the ability of their infant to communicate readiness to feed, latch on, and breast-feed well.
- Talking about parenting styles that promote and facilitate breast-feeding, such as holding and cosleeping.
- Communicating the rewards and benefits of breast-feeding after returning to work.
- Discussing ways women can influence their workplace to become breast-feeding-friendly.
- Working to change hospital practices that sabotage initiation of breast-feeding, e.g., providing formula discharge packs, separation from the baby, and lack of adequate help to initiate breast-feeding.
- Encouraging the media to present breast-feeding as positive and normal.
- Keeping informed regarding new breast-feeding knowledge.

Lamaze International. (1998). A special report on breastfeeding. *ASPO/Lamaze*, 1, (7), 3.

Critical Thinking

Informed Consent for Infant Feeding Decisions

In order for women to make an informed decision about infant feeding methods, mothers must be given facts about the nutritional and immunologic needs of the infant that can best be met by human milk, potential benefits to the mother, and potential risks associated with formula-feeding. The nurse is required to give the parents complete information, document that she has done so, and record the mother's choice in her medical record.

How can you make sure that your client makes informed decisions regarding health care for herself and her family?

mothers' breast on their own and decide for themselves when to take their first feeding (Klaus & Klaus, 1998). Infants use the taste and smell of the amniotic fluid on their hands to make a connection with a substance on the nipple. This scenario may take place in a matter of minutes, or within 30 to 60 minutes. Because the mother and infant are kept together both immediately after birth and during rooming-in, the new mother learns to recognize the infant's readiness for feeding and can feed the infant on demand. These signals of hunger from the infant include lip smacking, flow of saliva, finger sucking, and mouthing movements (Buransin, 1991).

Prenatal Decision-making

The most effective time to prepare for breast-feeding is early in the prenatal period or even preconceptually. An early conference with the pregnant woman's health care provider will allow time for discussion regarding the importance of breast-feeding and the benefits to mother and infant. An examination of the breasts is part of good prenatal care. If any anatomic abnormalities are observed, they can be discussed at that time. The health care provider can supply literature on breast-feeding and answer questions during the prenatal visits. There is no specific prenatal preparation of the breasts or nipples proved to be effective in relieving initial discomfort associated with breast-feeding. Breast shells have been found to be effective in treating women with flat or inverted nipples (Lawrence, 1999).

The First Feeding

Early feedings after birth are important for several reasons. The infant's suckling stimulates uterine contractions, helps

control postpartal bleeding, and hastens involution of the uterus. The infant will be most interested in breast-feeding within the first 20 to 30 minutes after birth, and the colostrum will begin to provide immunologic benefits immediately. The infant's digestive system will be stimulated by 19 different GI hormones, and passage of meconium will be enhanced by the ingestion of colostrum. The milk supply will be stimulated, and attachment between mother and baby will be increased (Ivnas-Mobert, 1989).

Research has examined many variables that have an effect on breast-feeding initiation and duration. Several studies have collected data on the length of time between delivery and the first breast-feeding session. Most of these studies have found that the sooner breast-feeding is initiated after delivery the better the outcomes. All studies found that both early initiation of breast-feeding and frequent feedings contribute to longer breast-feeding duration (Lawrence, 1999). There appears to be an "early window of opportunity" for the infant's sucking to stimulate prolactin receptors, which enhance milk production (Riordan & Auerbach, 1999).

Critical Thinking

Early Interventions

Swedish researchers have shown that the normal infant, when dried and placed nude on the mother's chest and then covered with a blanket, will maintain body temperature, cry significantly less than an infant placed in a bassinet, and crawl to the breast and latch on within the first hour. It seems likely that each of these features—crawling ability, decreased crying, and warming capabilities of the mother's chest—are adaptive and have evolved genetically over more than 400,000 years to help preserve the infant's life (Christensson, Selis, & Moreno, 1992).

When the infant suckles from the breast, there is a large outpouring of 19 different GI hormones in both the mother and infant, including cholecystokinin and gastrin, which stimulates growth of the baby's and mother's intestinal villi and increases the surface area for the absorption of calories with each feeding. These responses were essential for survival thousands of years ago when periods of famine were common (Ivnas-Moberg, 1989).

- How can you change hospital policies that are not based on evidence?
- Where can you access current evidence-based practice research?

Early Postpartum Period

When working with a new mother immediately after delivery, the nurse can begin her assessment of the nursing mother and infant during the initiation of the first breast-feeding session. A systematic assessment of several breast-feeding episodes provides the nurse with the opportunity to teach the new mother, provide anticipatory guidance, and plan for the need of follow-up care both in the hospital and after discharge. During these initial sessions the nurse should evaluate maternal and infant cues, latch-on, positioning, and maternal and infant responses to the feeding episode. As the mother prepares to feed her infant, the infant's level of hunger and state of arousal must be evaluated.

This is a good time to teach new parents about the cues that infants may use to communicate their needs. Breast-feeding is designed to be led by the baby. Babies are born capable of communicating readiness to eat in many ways. Crying is actually a late sign of hunger. Early signs of hunger include rapid eye movements, hand to mouth movements, mouth and tongue movements, body movements, and small sounds. Responding to these feeding cues, rather than waiting for crying, results in a baby and mother who are relaxed and a baby who is not too frantic to latch on and feed properly (Lamaze International, 1998). For a sleepy baby it may be necessary to show the new mother some easy ways of increasing the infant's alertness. Activities such as rubbing gently, taking the infant out of the blanket, and moving and talking to the infant usually will stimulate infants to come to a more awake state. For an overly hungry or upset infant, rocking or talking quietly may provide an opportunity for the infant to calm down so that breast-feeding can begin.

Figure 30-29 Nurses can help new mothers learn to balance the many demands on their time.

Discharge Planning

Early discharge from the hospital markedly reduces the time to teach beginning breast-feeding skills and assess how well the baby is nursing. Many hospitals are now beginning to provide support and follow-up by using telephone calls and home visits. In endeavoring to prevent premature weaning and help new mothers deal with common problems (Figure 30-29), hospitals are now providing written instructions on breast-feeding and telephone numbers of community referrals and resources (Riordan & Auerbach, 1999).

NURSING PROCESS

The nurse can use the nursing process to provide a framework to help guide the assessment, nursing diagnosis, planning, implementation, and evaluation of the nursing pair. The nursing process is a systematic method that uses information in a meaningful way to plan care for the patient in an optimal manner.

Breast-feeding is an interdependent, constantly evolving, and reciprocal relationship between mother and infant. Nurturing mothers and babies during the initiation of breast-feeding can help new mothers learn the skills necessary for successful and satisfactory infant feeding. Although most women have made a decision about whether to breast-feed or bottle-feed by the time they have delivered, some women may just need information and encouragement to decide to breast-feed their infants.

Assessment of the Nursing Pair

Some factors that attract women to breast-feeding are consistent with their aspirations to be good mothers. Mothers want to protect their children from disease and have heard about the benefits that breast-feeding offers in protecting their children. Most mothers also want to be close to their infants and establish a special bond with them that no one else can. Mothers also enjoy the special moments that breast-feeding and motherhood allow them to experience.

Assessment of the Mother

Although the process of breast-feeding is natural, many of the skills and techniques must be learned by both the mother and infant. Nurturing mothers so that they can nourish their newborn should be done through education. Nurses need to dispel myths and misconceptions about breast-feeding and help the new mother embrace her natural inclination to provide her infant with the best nutrition possible.

Nursing Tip

ASSESSMENT CHECKLIST FOR THE BREAST-FEEDING MOTHER

You should document the following in the breast-feeding client:

1. Maternal vital signs.
2. Maternal and infant intake and output.
3. Maternal position and comfort level during breast-feeding.
4. Condition of nipples and breasts.
5. Maternal sensations during breast-feeding (tingling).
6. Maternal understanding of breast care and nutrition.
7. Maternal understanding of assessment of adequate infant intake.
8. Maternal understanding of proper infant positioning.
9. Maternal understanding of pumping methods.
10. Maternal and paternal attitudes toward breast-feeding.

You should teach the mother the signs that the infant needs to be seen by a health care provider:

1. The infant is putting out scant or no urine.
2. The infant has infrequent stools, less than four a day by end of first week.
3. The infant is very fretful and never appears satisfied after feedings.
4. The infant is lethargic, i.e., hard to awaken.

5. The infant does not make swallowing sounds during feedings.
6. The infant is not gaining weight.

Initially the neonate's intestines contain meconium, which is a dark, thick, greenish-black tarry stool. Normally, the infant will pass the first meconium stool within the first 24 hours. Early and frequent breast-feeding stimulates the passage of stool much earlier and helps decrease bilirubin reabsorption from the meconium in the infant's intestinal tract. The type of infant feeding determines the characteristics of subsequent stools. Formula-fed infants pass pasty, pale-yellow stools with a strong odor. Formula-fed infants may have problems with constipation owing to a more solid stool formation than breast-fed infants. Breast-fed infants pass stools that are golden yellow, sweet smelling, and more liquid in consistency. Breast-fed infants have more frequent bowel movements than do formula-fed infants because breast milk is more easily digested than formula.

You should assess the following factors in the infant:

- Excessive drooling, coughing, gagging, or respiratory distress.
- Time spent at the breast.
- Sucking reflex.
- Signs of lactose intolerance, e.g., cramping, distention, and diarrhea.
- Response after a feeding session.

Nursing Diagnoses

Nursing diagnoses provide the basis for the selection and implementation of nursing interventions to help the client achieve satisfactory outcomes. The following are potential nursing diagnoses for the client who is breast-feeding. The following nursing diagnoses related to breast-feeding are diagnostic labels approved by the North American Nursing Diagnosis Association (NANDA):

- ✿ Effective breast-feeding: the state in which a mother-infant dyad/family exhibits adequate proficiency and satisfaction with the breast-feeding process.
- ✿ Ineffective breast-feeding: the state in which a mother or child experiences difficulty with the breast-feeding process.

- ✿ Interrupted breast-feeding: a break in the continuity of the breast-feeding process as a result of the inability or inadvisability to put the baby to breast for feeding.

Outcome Identification

A client outcome is a statement of the progression toward goal achievement. Collaborative planning with the new mother helps promote goal attainment. The breast-feeding mother would expect to progress toward the outcome of providing her infant with optimal nutrition supplied by breast milk in a specific time period.

Nursing Alert

IS THE INFANT GETTING ENOUGH MILK?

You should assess the infant's nutritional status:

- The infant should be breast-fed from 8 to 12 times in 24 hours.
- The infant should swallow every two to three sucks when attached properly, and the mother should see and hear the swallowing.
- The infant should gain weight.
- The infant should have at least six wet diapers in a 24-hour period by day 5 to 7.
- The infant should have frequent stooling, i.e., four stools a day.
- Infants older than 3 weeks may have fewer stools but should continue to have six or more heavy, wet diapers a day.

Planning

After assessing the client and formulating the nursing diagnoses, the nurse must develop and implement a plan of care. Interventions are planned strategies, based on scientific rationale, devised by the nurse to assist the client in meeting the client's desired outcomes. Planning for breast-feeding clients would include discussion of proper feeding methods and infant positioning, and client demonstration of breast-feeding to assess the client's abilities.

Planning statements for breast-feeding mothers would include statements such as:

- ✱ The nursing plan for teaching breast-feeding information will include a discussion of proper feeding techniques and positioning, written materials, and a client demonstration of breast-feeding.
- ✱ The nurse's role includes teaching of proper feeding techniques and help in correcting any related problems.

Nursing Intervention

Implementation is the execution of the interventions that were devised during the planning stage. The nurse should use respect, empathy, and understanding when working with clients to encourage collaboration in this planning process. Many new mothers need help in ensuring proper positioning of the infant, correct attachment, and assistance in establishing a breast-feeding pattern.

Evaluation

Evaluation is the last phase of the nursing process. During the evaluation, the client's progress in reaching outcomes is determined. The nurse, in collaboration with the client, evaluates the effectiveness of the plan of care. The nurse evaluates both subjective and objective data on an ongoing basis. When the client's outcome goals have been met, then the plan of care has been effective. When the client's outcome goals have not been met, then the nurse and client must revise the nursing plan to include different interventions.

Evaluation of the breast-feeding plan of care would include statements such as the following:

- ✱ The client was able to demonstrate proper breast-feeding techniques.
- ✱ The client was able to explain proper self-care methods.
- ✱ The client was able to list signs and symptoms that would require medical care.
- ✱ The client was able to demonstrate proper pumping techniques.
- ✱ The client was able to list the signs that her infant was obtaining adequate breast milk.
- ✱ The client showed no signs of breast problems.
- ✱ The client was able to state support systems available to her after discharge.

Evaluation

How effective was the plan of care for this client?

Case Study/Care Plan

THE CLIENT WITH INTERRUPTED BREAST-FEEDING

Judy Martin, aged 31, delivered her first child, a boy weighing 7 lb, 4 oz, 15 hours ago. Ms. Martin had a traumatic delivery and ran an elevated temperature of 102°F during the birth. Her infant was taken to the neonatal intensive care unit (NICU) for a sepsis workup to rule out infection. During Ms. Martin's first attempt at breast-feeding in the NICU, the infant had a difficult time latching on and both became agitated and anxious. Ms. Martin's nipples are slightly inverted, and her infant is having trouble latching on. Ms. Martin calls the nurse and is crying and very upset. She says that every time she attempts to nurse her infant, "He acts like I am killing him." She says either she has to have help today or she is going to quit breast-feeding.

Assessment

Subjective Data

- Client denies prenatal problems.
- Client states that because she had an elevated temperature (102°F) during a prolonged (more than 20 hours) labor and vaginal delivery, her infant was taken to NICU to rule out sepsis.
- Client states that the nurses have told her that her infant cannot be brought to her room for 48 hours.
- Client states that she had a very traumatic delivery, has a fourth-degree episiotomy, and is in pain.
- Client states she is a registered nurse and "really wants to breast-feed as soon as possible because she knows it is best for the baby."

Objective Data

- Client is a para 0, gravida 1, delivered at 39 weeks' gestation.
- Client vital signs: temperature, 98.8°F; pulse, 90; respirations, 20; blood pressure 110/80 mm Hg.
- Client has an intravenous infusion of 1000 mL lactated Ringer's with ampicillin, 500 mg, dripping at 100 mL/h.
- Client appears to be in pain when moving or sitting and needs help with ambulation.
- Breasts are soft; nipples have no cracks and are slightly inverted.
- Client is 15 hours post delivery.
- Infant is male, appropriate for gestational age.
- Infant's Apgar scores were 8 and 9.
- Gestational age assessment was 39 weeks.
- Infant weight is 7 lb, 14 oz, and length is 21 inches.
- Infant temperature is 98.2°F rectally.

Nursing Diagnosis

Interrupted breast-feeding related to possible illness in infant.

Expected Outcome Client wants to breast-feed her infant successfully as soon as possible and plans on breast-feeding for 6 months.

Planning

Before leaving the hospital, the client will do the following:

1. Initiate breast-feeding behaviors as soon as the infant's condition allows.
2. Demonstrate proper breast-feeding techniques.
3. List three positions for breast-feeding.
4. Demonstrate appropriate techniques for attaching the infant to the breast.

(continued)

5. Maintain close contact with her infant.
6. Explain criteria to assess infant's hydration and weight gain status.
7. List proper pumping and storage techniques.
8. Discuss support resources she can use after hospital discharge.

Nursing Interventions	Rationales
1. Assist client to the NICU in a wheelchair to hold and breast-feed her infant as soon as permitted.	1. Client's physical condition requires assistance for ambulation.
2. Teach the client breast-feeding techniques, including positions and proper latching-on.	2. Many new mothers need help with the skills and techniques that must be learned for successful breast-feeding.
3. Provide the client with privacy and help in the NICU, as needed.	3. Privacy helps to allay some embarrassment and anxiety associated with breast-feeding for the first time.
4. Teach the client with information on infant nutritional assessment in short sessions using appropriate terms and language.	4. Teaching clients in short sessions helps prevent information overload and allows the client to process and remember the material presented.
5. Instruct the client on the use of breast pumps and milk storage.	5. The client may need to establish a milk supply with a pump and store her milk until the infant is discharged from the NICU.
6. Provide lists of breast-feeding resources and support available after discharge.	6. Written material allows the client to review information after discharge. Support for breast-feeding has been found to be an essential element in successful lactation.

Evaluation

- Client was taken to the NICU 15 hours after delivery to hold her infant and initiate breast-feeding.
- Client demonstrated proper breast-feeding techniques behind a movable screen, which provided privacy from the rest of the nursery.
- Client became anxious because her infant was unable to latch-on because of inverted nipples.
- Client was able to explain information provided to her, including proper pumping and storage of breast milk.
- Client stored the written materials in her suitcase for use after discharge.

Nursing Diagnosis

Ineffective breast-feeding related to poor latching-on.

Expected Outcome Client will effectively breast-feed her infant.

Planning

1. Client will call a lactation consultant today to obtain a visit to assess the breast-feeding pair.
2. Client will pump breast milk and use a specially designed nipple to feed the infant until the infant is able to latch on (a nipple specially designed to mimic the breast in both form and function).
3. Client will use a breast shield made of silicone to help the infant latch on and to stimulate the nipples to evert.
4. Client will use an electric breast pump to help maintain an adequate milk supply and to help pull out the nipples.
5. Client will have someone in her family take care of her and her infant when she is discharged to home to encourage rest and relaxation in new mother.

(continued)

Nursing Interventions**Rationales**

- | | |
|---|---|
| <ol style="list-style-type: none"> 1. Use a silicone breast shield to facilitate infant latch-ing-on. 2. Apply ice compresses to the nipples just before feed-ing to stimulate them. 3. Lubricate the nipples with a few drops of expressed milk before feeding. 4. Let the nipples dry thoroughly after feeding. 5. Apply warm tea bags to the nipples if soreness oc-curs. 6. Avoid applying soaps to the nipples. 7. Encourage frequent feeding. 8. Use prophylactic breast massage after each feeding. 9. Express milk by using an electric breast pump, if nec-essary. 10. Take a warm shower. | <ol style="list-style-type: none"> 1. A silicone breast shield can protect sore nipples from further damage and make the nipples easier for the in-fant to grasp. 2. Ice numbs the nipples and makes them firmer and easier for the infant to grasp. 3. Expressed breast milk put on the nipples helps pre-vent tenderness. 4. Air drying helps promote healing and comfort. 5. Tannic acid in warm tea bags toughens the nipples, and the warmth promotes healing. 6. Soaps directly applied to the nipples can cause dry-ing and cracking. 7. Frequent feedings help stimulate milk production, prevent stasis of breast milk, and reduce the risk of mastitis. 8. Breast massage helps prevent breast engorgement and stasis and promotes the let-down reflex and milk flow. 9. Expression of milk using an electric pump relieves overdistention and promotes milk drainage while maintaining the milk supply. 10. Warm water promotes the let-down reflex and milk flow and enhances relaxation in the mother. |
|---|---|

Evaluation Ms. Martin met with the lactation consultant that day and felt very encouraged and more positive about continuing breast-feeding. Ms. Martin's infant nursed well with the breast shields in place and latched on well. Ms. Martin was aware that using breast shields can decrease milk supply and was instructed to gradually wean her infant off of the shields. She was also in-structed that she should continue to pump after nursing to maintain milk supply. Ms. Martin continued to successfully breast-feed her infant and gradually weaned her infant to her own nipples.

Web Activities

- Which resources can you locate on the Internet for new mothers experiencing difficulties initiating breast-feeding?
- Where can a new mother locate a lactation consultant?
- Where can a new mother locate an electric breast pump?
- Where can a pregnant woman find a hospital that is "breast friendly"?

Key Concepts

- Breast-feeding provides unparalleled health benefits for infants and cost savings for mothers, families, the health care system, and taxpayers.
- Understanding the motivations and perceived barriers felt by many women can help health care professionals develop effective breast-feeding promotion strategies.
- When caring for a client whose culture is different from the nurse's culture, it is necessary to evaluate the impact of the client's values and beliefs on infant feeding practices.
- Interventions that lead to successful breast-feeding need to be individualized to fit the needs of each client.
- Promotion of successful breast-feeding requires that the nurse be sensitive to the needs of the mother so that a trusting relationship will permit the sharing of knowledge about techniques to facilitate lactation.
- Informed consent can only be obtained by providing women with both the advantages and disadvantages of breast- and formula-feeding.
- Although breast-feeding is a natural process, the necessary skills must be taught and learned by both mother and baby.

Review Questions and Activities

1. Compared with most prepared formulas, which does mature breast milk have?
 - a. A thicker consistency
 - b. More calories per ounce
 - c. Greater immunologic value
 - d. More nitrogenous wastes

The correct answer is c.

2. How long after birth is colostrum replaced by transitional milk?
 - a. 8 hours
 - b. 12 to 24 hours
 - c. 2 to 4 days
 - d. 1 week

The correct answer is c.

3. When should the nurse provide information about breast-feeding?
 - a. First trimester
 - b. Second trimester
 - c. Third trimester
 - d. First attempt at breast-feeding

The correct answer is b.

4. What will a newborn do to indicate hunger to the mother who is breast-feeding?
 - a. Wave the arms in the air
 - b. Make sucking motions
 - c. Have the hiccups
 - d. Stretch the legs out straight

The correct answer is b.

5. Which of the following hospital policies can interfere with breast-feeding duration?
 - a. Distribution of formula samples
 - b. Single-room maternity care
 - c. Beginning breast-feeding during the first hour after delivery
 - d. Encouraging mothers to feed on demand based on feeding readiness cues

The correct answer is a.

6. A breast-feeding mother develops engorged breasts at 3 days postpartum. Which of the following actions would help reduce engorgement?
 - a. Reducing fluid intake for 24 hours
 - b. Breast-feeding her infant every 1 to 2 hours
 - c. Avoiding use of a breast pump
 - d. Skipping feedings to let her breasts rest

The correct answer is b.

7. A new breast-feeding mother asks, "Is it true that breast milk will prevent my baby from catching colds and other infections?" Which reply can the nurse give that will reflect the results of current research?
 - a. Breast-fed infants will have increased resistance to illness but may still get sick.
 - b. Mothers of breast-fed infants do not have to worry about exposure to contagious diseases until breast-feeding stops.
 - c. Breast milk offers no greater protection to breast-fed infants than does formula.
 - d. Breast milk will give infants protection from all illnesses to which the mother is immune.

The correct answer is d.

8. A new breast-feeding mother calls the nurse while breast-feeding her infant. The mother tells the nurse, "Something must be wrong. Every time I breastfeed my baby I feel like I am having labor pains again." Which of the following responses should the nurse give?

- "Your breasts are secreting a hormone that causes your abdominal muscles to contract."
- "Prolactin hormone is causing more blood to go to your uterus, resulting in pain."
- "The same hormone that is released in response to your baby's sucking and that causes the milk to flow also causes your uterus to contract."
- "You may have a small blood clot in your uterus, and you are trying to expel it."

The correct answer is c.

9. When should a breast-fed infant be nursed?

- Every 4 hours
- Four to six times in 24 hours
- Eight to 12 times in 24 hours
- Every 3 hours, unless sleeping

The correct answer is d.

10. Which of the following observations will allow a new mother to feel confident that her breast-fed infant is receiving enough milk?

- Six wet diapers in 24 hours, and four stools a day
- Three to four wet diapers in 24 hours and two stools a day
- One to two wet diapers in 24 hours, and six to eight stools a day
- No problem sleeping after nursing

The correct answer is a.

UNIT VIII

Newborn Development and Nursing Care

Physiologic and Behavioral Transition to Extrauterine Life

The journey to birth is nothing more than an incredible miracle of life. This journey requires a number of successful transitions if the newborn is to survive. In utero, the fetus is entirely dependent on the placenta to sustain physiologic functions and to provide nutrition necessary for optimal growth and development. Following birth, a number of major physiologic changes must occur if the infant is to make a successful transition to extrauterine life, including pulmonary, cardiovascular, and gastrointestinal changes.

The first few hours after birth of a baby are also a time of transition for the parents. Perinatal nurses play an important role in helping parents to make a successful transition to parenthood by facilitating positive parent-infant interactions and providing education on routine baby care. Anticipatory guidance and crisis intervention are also important aspects of the perinatal nurses' role in caring for parents who experience delivery complications or the birth of a sick newborn.

Key Terms

Asphyxia	Foramen ovale	Persistent pulmonary hypertension	Secondary apnea
Behavioral state	Habituation	Postnatal circulation	Sepsis
Congenital heart defects	Hypoglycemia	Preterm	Surfactant
Diaphragmatic hernia	Hypothermia	Primary apnea	Systemic vascular resistance
Ductus arteriosus	Hypovolemia	Pulmonary vascular resistance	Thermoregulation
Ductus venosus	Meconium staining	Resuscitation	Transient tachypnea of the newborn
Extrauterine life	Neutral thermal environment		
Fetal circulation			

Competencies

Upon completion of this chapter, the reader should be able to:

1. Describe the primary features of the fetal pulmonary and cardiac systems.
2. Identify the physiologic changes that occur at birth as the newborn makes the transition to extrauterine life.
3. Describe the neurobehavioral changes that occur during the first 12 hours after birth as the newborn makes the transition to extrauterine life.
4. Discuss the parenting and family issues that occur during the period of newborn transition to extrauterine life.
5. Understand the major complications that can occur during the transition process.
6. Discuss the effects of prematurity on the transition to extrauterine life.
7. Understand the role and responsibilities of the nurse during the transition process.
8. Discuss appropriate resuscitation of the asphyxiated infant, using the American Academy of Pediatrics and American Heart Association Neonatal Resuscitation Program guidelines.

Transitions by nature are challenging, but this is never more true than it is for transition from intrauterine to **extrauterine life**. In fact, the essence of life depends on this successful transition. Successful transition requires the initiation of spontaneous breathing; significant cardiopulmonary changes, including the shift from fetal to postnatal circulation; and a variety of other important adaptations, including but not limited to, thermoregulatory and metabolic adjustments. Failure of the infant to make a successful transition may result in varying degrees of morbidity or mortality.

Two major factors have contributed to today's awareness of the importance of the process of the infant's transition to extrauterine life in the first critical hours after birth. First, the technology and assessment techniques available to monitor the well-being of the fetus and the neonate have increased in sophistication, availability, and routine use. Strategies, such as fetal monitoring, sonography, and development of training and certification in the assessment

of fetal heart rate monitoring and resuscitation, have all heightened the awareness of the complexity of the physiologic changes the neonate undergoes in the hours before, during, and after birth. Second, the changes in health care policy that have led to shorter and shorter hospital stays for mothers and babies have created an increased need for careful assessment of the infant's transition process during the hours before discharge from the hospital (Behram, Moschler, Sayegh, Garguillo, & Mann, 1998).

This chapter, therefore, explores the physiologic changes that occur during the newborn's adaptation to extrauterine life and discusses common newborn complications that may impede the newborn's ability to adapt successfully. First, this chapter explores physiologic and neurobehavioral transitions of the newborn, at and immediately following birth. Common neonatal conditions and diseases that may interfere with the newborn's smooth transition to extrauterine life and require resuscitation and stabilization in the delivery room are discussed, as well as

the effect of prematurity on pulmonary and cardiac transition. Finally, standards for resuscitation of newborns in the delivery room established by the American Academy of Pediatrics and the American Heart Association are discussed.

PHYSIOLOGIC TRANSITIONS OF MAJOR SYSTEMS

Physiologic transition from intrauterine to extrauterine life involves a number of major changes that are necessary for newborn survival. These include pulmonary, cardiac, thermoregulation, metabolic, and gastrointestinal changes.

Pulmonary System Transition

During uterine development, the placenta is the organ of respiration, with the lungs receiving little of the cardiac output (Guyton & Hall, 1996). The blood bypasses the lungs through shunt pathways, such as the ductus venosus, the ductus arteriosus, and the foramen ovale. This occurs primarily because of pressure gradient differences between pulmonary and systemic vascular systems. In the fetus, the lungs are a high-resistance, low-flow organ (Guyton & Hall, 1996).

Pulmonary vascular resistance (PVR) is the resistance in the pulmonary vascular bed against which the right ventricle must eject blood. High levels of fetal PVR are caused by a number of interrelated factors that promote constriction of the pulmonary capillaries. These factors include the thick muscular medial layer of the small pulmonary arteries (Sansoucie & Cavaliere, 1997), the low PO_2 levels normally present during fetal life (Pridjian, 1994), and possibly, the compression of the pulmonary capillaries by fetal lung fluid. The high level of PVR is also thought to be influenced by the absence of air-fluid interface in the alveoli, the lack of rhythmic distention of the lung, and the large amount of active vasoconstricting substances present within the pulmonary bed (Sansoucie & Cavaliere, 1997).

Because of this high-pressure gradient in the pulmonary system, the oxygenation of the fetus occurs in the placenta (Guyton & Hall, 1996; Nelson, 1994; Sansoucie & Cavaliere, 1997). The exchange of oxygen (O_2) and carbon dioxide (CO_2) within the placenta occurs by simple diffusion at the intervillous space (Sansoucie & Cavaliere, 1997). Differences in diffusion pressures of O_2 and CO_2 between the fetal and maternal sides of the placenta facilitate and regulate the exchange of gases between mother and fetus (Guyton & Hall, 1996; Pridjian, 1994). Because blood on the fetal side of the placenta has a lower (30 mm Hg) partial pressure of dissolved oxygen (PO_2) than blood on the maternal side (50 mm Hg), oxygen readily diffuses from the maternal side of the placenta to the fetal side (Guyton & Hall, 1996). Blood on the fetal side of the pla-

centa, with a higher partial pressure of dissolved carbon dioxide (PCO_2), is readily diffused to the lower pressure maternal side of the placenta (Guyton & Hall, 1996). In addition, with the exchange of gases, the relative changes in serum pH between the maternal and fetal sides of the placenta also contribute to fetal oxygenation (Guyton & Hall, 1996). For example, as CO_2 from the fetal circulation diffuses into the maternal circulation, the maternal PCO_2 increases and, correspondingly, maternal plasma pH falls. This increase in acidity interferes with the ability of maternal hemoglobin (Hgb) to bind oxygen and thereby promotes the transfer of the oxygen to blood on the fetal side of the placenta. Simultaneously, as the fetal blood loses CO_2 and the fetal pH increases, the fetal Hgb binds the oxygen released by the maternal Hgb more readily.

In addition to the simple diffusion processes just described, differences in O_2 content (i.e. dissolved and hemoglobin-bound O_2) and higher concentrations of fetal Hgb also serve to facilitate oxygenation in the fetus (Box 31-1). The O_2 content of the blood on each side of the placental membrane is determined in large part by the different affinities of maternal and fetal Hgb for O_2 (Pridjian, 1994). Oxygen-carrying capacity is enhanced by the increased presence of fetal Hgb. At any given PO_2 , fetal Hgb has a higher affinity for oxygen than does maternal adult Hgb (Guyton & Hall, 1996; Sansoucie & Cavaliere, 1997). Furthermore, the shift of the fetal oxyhemoglobin dissociation curve to the left of the maternal curve allows enhanced oxygen delivery to the peripheral tissues when capillary PO_2 is low (Guyton & Hall, 1996; Pridjian, 1994).

Pulmonary adaptation at birth is accomplished via a complex series of events that switches the function of respiration from the placenta to the lungs. Various metabolic and environmental factors are responsible for the onset of breathing in the neonate. Mild hypercapnia, hypoxia, and acidosis act as powerful stimuli for the onset of breathing in the newly born infant and result from the intermittent cessation of uteroplacental perfusion during contractions, which occurs during normal labor (Guyton & Hall, 1996; Nelson, 1994). While the decreased pH stimulates the respiratory center directly, the low level of pO_2

Box 31-1 Factors Enhancing Oxygen Delivery to Fetus

- Lower PO_2 on fetal side of placenta
- Fall in level of maternal plasma pH from transfer of fetal CO_2
- Increased fetal pH
- Higher concentrations of fetal hemoglobin
- Left shift of fetal oxyhemoglobin dissociation curve

and high level of $p\text{CO}_2$ stimulate the respiratory center via central and peripheral chemoreceptors. Other external stimuli that also enhance rhythmic breathing at delivery include the environmental factors of cold, light, noise, and touch (Nelson, 1994).

During pulmonary transition, fluid within the lung must also be cleared. During labor, fetal lung fluid is beginning to be reabsorbed. During vaginal delivery, the chest wall is compressed and approximately one-third of the fetal lung fluid is expelled via the trachea. Following delivery of the chest, the chest wall recoils causing inspiration of air and expansion of the lungs (Nelson, 1994). The transpulmonary pressure generated by the first breath drives the remaining fetal lung fluid into the interstitium, where it is absorbed through the lymphatic and pulmonary circulation (Donn & Faix, 1996; Guyton & Hall, 1996; Nelson, 1994).

The work of inspiration is mainly devoted to overcoming the surface tension of the walls of the terminal lung units at the air-liquid interface (Guyton & Hall, 1996; Nelson, 1994). On expiration, the ability to retain air depends on surfactant. **Surfactant** is a complete lipoprotein produced by type II alveolar pneumocytes and plays a role in lowering surface tension at an air-liquid interface (Guyton & Hall, 1996). As surfactant lowers surface tension in the alveolus at end-expiration, it stabilizes the alveoli and prevents collapse (Nelson, 1994). There is an increased functional residual capacity with each breath; thus, less inspiratory pressure is required for subsequent breaths (Guyton & Hall, 1996; Nelson, 1994).

The establishment of normal resting lung volume or functional residual capacity is important because of its role in allowing the PVR level to fall postnatally. With initial lung expansion, the pulmonary arterioles dilate in response to the increase in PO_2 , and the PVR level falls (Guyton & Hall, 1996). With the abrupt lowering of resistance comes an equally abrupt increase in pulmonary blood flow (Guyton & Hall, 1996). Pulmonary vascular tone and blood flow are also modulated by vasoactive substances produced by the pulmonary endothelial cell. Prostaglandins and endothelium-derived relaxing factor are vasoactive substances that act directly to promote pulmonary vasodilation within the transitional pulmonary vasculature bed (Sansoucie & Cavaliere, 1997). As a result of the structural and physiologic adaptation of the pulmonary bed to lung inflation at birth, the lungs convert to a low-resistance, high-flow organ (Sansoucie & Cavaliere, 1997). Lung compliance continues to improve in the hours after delivery, secondary to the effects of circulating catecholamines. The increased levels of catecholamines (especially epinephrine) play important roles in increasing the release of surfactant at birth and in clearing the lungs by decreasing secretion of lung fluids and increasing their absorption through the lymphatic system. PVR progressively decreases until adult levels are reached at 2 to 3 weeks of age.

Cardiac System Transition

Cardiac transition from intrauterine to extrauterine life involves closure of fetal circulatory pathways and other cardiovascular adaptations that promote increased blood flow to the lungs for oxygenation and switch the fetal circulation to a postnatal (adult) circulatory pathway.

Fetal circulatory Pathways

Fetal circulation is anatomically and physiologically different than that of the infant in the extrauterine environment. This difference allows the oxygenation of the fetus to occur in the placenta rather than in the pulmonary system. Among the important differences are the existence of three anatomic shunts that, in utero, allow the most highly oxygenated blood to be preferentially delivered from the placenta to the brain and heart, while being diverted from the lungs (Donn & Faix, 1996; Guyton & Hall, 1996; Nelson, 1994; Sansoucie & Cavaliere, 1997). The three fetal circulatory shunts include the ductus venosus, the foramen ovale, and the ductus arteriosus. The **ductus venosus**, which connects the umbilical vein to the inferior vena cava, allows blood to bypass the liver. The **foramen ovale** allows blood entering the right atrium of the heart to go directly through the left atrium, left ventricle, and out the ascending aorta to immediately supply the brain, heart, and upper extremities. The **ductus arteriosus** shunts blood from the pulmonary artery to the descending aorta, bypassing the lung, to perfuse the lower body and return to the placenta for oxygenation. Figure 31-1 illustrates fetal circulation.

Blood oxygenated in the placenta travels to the fetus via a single umbilical vein. Fifty percent to 60% of the umbilical venous blood bypasses the liver through the ductus venosus to connect with the inferior vena cava (Sansoucie & Cavaliere, 1997). The other half passes through the liver and enters the inferior vena cava via the hepatic veins. To preserve the most highly oxygenated blood for the brain and heart, umbilical venous blood that bypassed the liver tends to stream separately from blood returning from lower portions of the body within the inferior vena cava (Sansoucie & Cavaliere, 1997). From the inferior vena cava, blood enters the right atrium. As a consequence of right atrium anatomy, the more highly oxygenated blood from the inferior vena cava tends to stream directly across the atrial septum via the foramen ovale to the left atrium (Donn & Faix, 1996; Guyton & Hall, 1996; Sansoucie & Cavaliere, 1997). Once in the left atrium, the blood from the right atrium mixes with a small amount of pulmonary venous return that arrives via the pulmonary veins. Blood from the left atrium passes through the mitral valve and enters the left ventricle, where it is pumped out through the aortic valve to the ascending aorta to perfuse the brain, heart, and upper extremities (Sansoucie & Cavaliere, 1997; Donn & Faix, 1996).

Figure 31-1 Fetal circulation. Red shows arterial blood, dark purple shows venous blood, and light purple shows mixed arterial venous blood.

Unxygenated blood returning from the brain and upper extremities returns to the heart by way of the superior vena cava. In the right atrium, some mixing occurs between the unxygenated blood from the superior vena cava and coronary sinus and the inferior vena caval blood not shunted directly into the left atrium via the foramen ovale (Donn & Faix, 1996). The majority of the blood enters the right atrium and flows to the right ventricle. The

right ventricle is the dominant ventricle in fetal life, ultimately ejecting about two-thirds of the total cardiac output to perfuse the lower body and placenta (Sansoucie & Cavaliere, 1997). From the right ventricle, blood crosses the pulmonary valve, but because of high pulmonary vascular pressures, most of the blood is directed away from the lungs. Approximately 12% of the blood flows into pulmonary veins to nourish the lung (Guyton & Hall, 1996).

The majority of blood bypasses the lungs via the ductus arteriosus, which connects the pulmonary artery to the descending aorta. The blood flows right to left (pulmonary artery to aorta) across the ductus arteriosus because of high pulmonary vascular resistance (PVR) levels and low systemic vascular resistance (SVR) (a result of low placental resistance) (Guyton & Hall, 1996). The patency of the ductus arteriosus is maintained by the low oxygen tension in utero and by the vasodilating effect of prostaglandin E₂ (Sansoucie & Cavaliere, 1997). Blood from the descending aorta supplies kidneys and intestines, divides into two arteries, and returns blood to the low-resistance placenta for oxygenation.

Cardiovascular Adaptation

The first breath has significant effects on cardiovascular function. With the onset of ventilation, there is a concomitant decrease in PVR and an increase in pulmonary vascular flow (Nelson, 1994; Sansoucie & Cavaliere, 1997). Increased alveolar oxygenation is accompanied by a further decrease in PVR. As a result of these pulmonary changes, the pressure in the right side of the heart falls and pulmonary venous return increases to the left atrium (Nelson, 1994).

With cord clamping and the loss of placenta circulation, **systemic (peripheral) vascular resistance** (SVR) increases and exceeds PVR (Donn & Faix, 1996; Nelson, 1994; Sansoucie & Cavaliere, 1997). As a result, pressures within the aorta and left heart increase significantly. The reversal of relative pressures leads to diminished right-to-left shunting across the foramen ovale, causing the flap to shut between the two atria within minutes or hours after birth (Donn & Faix, 1996; Guyton & Hall, 1996; Sansoucie & Cavaliere, 1997). Anatomic closure caused by the deposit of fibrin and cell products is usually completed during the first month of life; the structure becomes the fossa ovalis. Until the foramen ovale is anatomically sealed, anything that produces a significant increase in right atrial pressure can re-open the foramen ovale and allow a right-to-left shunt.

The ductus arteriosus also undergoes rapid change after birth. In contrast to the pulmonary arterioles, the muscular ductus arteriosus constricts in response to the postnatal increase in PO₂; the decreased levels of or sensitivity to the dilating influences of prostaglandins (PGE₂, PGI₂); and the influence of certain vasoactive substances, such as endothelin 1 (Sansoucie & Cavaliere, 1997). Pressure changes within the cardiac chambers also lead to diminished flow across the ductus arteriosus. PVR rises and pulmonary vascular pressure falls within the first several hours after delivery, blood flow through the ductus arteriosus reverses and blood flows from left to right (from the descending aorta to pulmonary artery) (Guyton & Hall,

1996). Functional closure of the ductus is usually achieved within 96 hours in healthy, term newborns, and anatomic closure is generally completed within 4 months through endothelial and fibrous tissue proliferation (Guyton & Hall, 1996; Sansoucie & Cavaliere, 1997). As with the foramen ovale, during the functional closure stage, the ductus may be reopened under certain cardiopulmonary circumstances with a return to fetal circulation.

The third anatomic shunt, the ductus venosus, also undergoes change during the transition to extrauterine life. When the placenta is removed after birth, the ductus venosus constricts, as blood stops flowing through the umbilical vein (Guyton & Hall, 1996). Functional closure occurs within 2 to 3 days. Anatomic closure is achieved by fibrosis and is generally completed within 7 days, with the structure becoming the ligamentum venosum. Figure 31-2 shows the changes that shift fetal circulation to a postnatal (adult) circulatory pathway.

Postnatal Circulation

Once the placenta is removed, the neonate must change from a fetal circulatory pathway to a **postnatal (or adult) circulation** to survive in the extrauterine world. Systemic venous blood enters the right atrium from the superior vena cava and the inferior vena cava. Poorly oxygenated blood enters the right ventricle and passes through the pulmonary artery into the pulmonary circulation for oxygenation. The oxygenated blood returns to the left atrium through the pulmonary veins. This blood passes through the left ventricle and into the aorta to supply the systemic circulation. Following the oxygenation and perfusion of tissue beds, the blood returns to the right heart and the circulatory pathway is repeated.

Thermoregulation

Effective thermal management at the time of birth plays a significant role in promoting an optimal transition to extrauterine life. Most healthy term infants are capable of attaining a stable body temperature without difficulty if proper methods are employed in the delivery room to prevent heat loss postnatally. Newborns, however, are at a distinct disadvantage when it comes to their ability to maintain normal **thermoregulation** as compared with the older infant or child. First, the neonate has a much greater potential for losing body heat, primarily because of a large body surface area in relation to weight, as well as poor thermal insulation resulting from limited neonatal fat stores (Amlung, 1998; Guyton & Hall, 1996). Another disadvantage is that the neonate has a limited capacity for thermogenesis. Although the older child may use shivering to generate heat in the presence of thermal stress, the neonate has almost no ability to produce heat in this man-

Figure 31-2 The modifications that change fetal circulation to postnatal (adult) circulation.

ner (Amlung, 1998; Baumgart, 1996). The healthy, full-term neonate may use, to a limited extent, voluntary muscle activity to assume flexed postures, thereby minimizing heat loss through a reduction of exposed body surface area. The preterm infant, however, has almost no ability to generate heat through increased muscular activity, because motor immaturity often results in flaccid, extended postures (Amlung, 1998).

The primary source of heat production in infancy is chemical thermogenesis (Amlung, 1998; Baumgart, 1996; Hey, 1994). Heat production is activated in the presence of a cold stimulus (Baumgart, 1996). The hypothalamus responds by generating heat through the oxidation of glucose and free fatty acids (Amlung, 1998). In the healthy newborn, brown-fat metabolism is a primary mechanism of heat energy production in the first days of life (Amlung,

1998; Baumgart, 1996; Hey, 1994). Although brown fat is stored in small amounts throughout the infant's body, the majority of brown fat is located around the blood vessels and muscles in the neck, clavicles, axillae, and sternum (Figure 31-3). Brown fat also surrounds the major thoracic vessels and envelops the kidneys and adrenal glands (Amlung, 1998; Baumgart, 1996). Infants with limited brown-fat stores at birth are at particular risk for problems in maintaining a normal body temperature. Because brown fat stores are generally not complete until the last few weeks of gestation, preterm infants may be at risk for hypothermia (Amlung, 1998; Baumgart, 1996). In addition, brown-fat stores may have been consumed in utero for energy needs before birth in infants who are small for gestational age or who experience intrauterine growth retardation, thus also placing them at thermal risk (Amlung, 1998).

It has been estimated that heat loss in the delivery room may be as high as 0.2°C to 1.0°C per minute, depending on the infant's maturity and environmental conditions (Baumgart, 1996). This far exceeds maximal heat production in neonates and rapidly gives rise to the deleterious effects of hypothermia and cold stress. **Hypothermia** is defined as a rectal or axillary temperature below 97°F. In a cold environment, there is first a rise in oxygen consumption and endogenous heat production (Baumgart, 1996). If appropriate thermal interventions are not implemented promptly, heat loss exceeds heat production and the infant's skin and core temperature fall below the normal range (Baumgart, 1996). A body temperature outside the infant's neutral thermal range may result in development of hypothermia that has serious metabolic consequences for the infant, including the development of anaerobic metabolism, pulmonary vasoconstriction, tissue

hypoxia, metabolic acidosis, and eventually, hypoglycemia (Amlung, 1998; Baumgart, 1996).

Throughout delivery and the neonatal period, every newborn's thermoregulation needs must be carefully managed. The goal is to keep the infant in a **neutral thermal environment**, while maintaining a normal body temperature (Amlung, 1998; Baumgart, 1996). In a neutral thermal environment, the infant's axillary temperature is usually maintained in the range of 97°F to 99.5°F.

Nursing Process: Preventing Hypothermia and Maintaining a Neutral Thermal Environment

Full-term and preterm neonates are at risk for altered thermoregulation during the immediate postnatal period. This nursing process focuses on maintaining a neutral thermal environment for these infants.

Assessment

1. Assess factors related to the infant's risk of temperature fluctuation, including prematurity, sepsis, asphyxia, caregiving procedures, and high or low environmental temperatures. Assessment offers an opportunity to prevent cold stress.
2. Assess for potential or actual hypothermia by monitoring the infant's axillary temperature every 30 to 60 minutes after delivery until stable and then every 4 hours per nursery routine.
3. Monitor environmental room temperatures within the delivery room and nursery areas and readjust to avoid convective heat loss.

Nursing Diagnoses

Risk for imbalanced body temperature related to prematurity, abnormal disorders at birth, and exposure to cool environments.

Outcome Identification

Infant maintains an axillary temperature between 97°F and 99.5°F.

Planning

1. Identify the infant at risk for potential or actual temperature instability.
2. Prevent conditions that precipitate cold stress.
3. Provide a neutral thermal environment.
4. Teach parents how to maintain the infant's temperature.

Nursing Interventions

1. Minimize evaporative heat loss at delivery by immediately drying the infant and removing wet blankets.

Figure 31-3 Distribution of brown fat in the newborn.

Research Highlight

Effect of Timing of Initial Bath on Newborn Temperature Regulation

The practice of ensuring that babies have a normal body temperature has been a principal component to successful transition to extrauterine life and to the reduction in infant morbidity and mortality within the last several decades. Think about caregiving events that might predispose an infant to thermal stress during the immediate newborn period. For example, bathing is a thermal stressor for newborns that may have implications for their health and well-being. Because of increasing concerns about the transmission of communicable diseases through blood or body fluid contact, research is being done to determine how early newborns can be bathed after birth without compromising their thermal stability.

Purpose

To determine the effect of early bathing on axillary temperature stability after the bath.

Method

Eighty healthy full-term newborns were randomly assigned to one of two bathing groups: 40 neonates were bathed at 1 hour after birth and 40 were bathed at 2 hours after birth.

Findings

The axillary temperatures of newborns bathed at 1 hour did not vary significantly from those of newborns bathed at 2 hours when axillary temperatures were compared at 10, 20, and 60 minutes after the bath.

Nursing Implications

To reduce the exposure of health care providers and family members to bloodborne pathogens, healthy full-term newborns can be bathed after 1 hour when appropriate care measures (e.g. swaddling, avoiding drafts, using radiant warmers, and placing newborns on warm surfaces to minimize heat loss during bathing) are taken to support thermal stability.

Source: Varda, K., & Behnke, R. (2000). The effect of timing of initial bath on newborn's temperature. *JOGNN*, 29, 27–32.

2. Use hat and warm blankets to swaddle infant during parent bonding.
3. Avoid placing infant directly in contact with cold surfaces, such as radiant warmer table or infant scale. This prevents heat loss by conduction.
4. Avoid placing infant in drafts. This prevents heat loss by convection.
5. If body temperature is unstable, place infant under radiant warmer or in incubator.
6. Use heat source when bathing infant. Wash only small sections of the body at a time, being careful to immediately dry the area before proceeding to the next area.
7. When placing infant in an open bassinet in nursery, dress infant warmly and cover with two or more

blankets, as needed, to maintain normal axillary temperature.

8. Teach parents how to take their infant's axillary temperature and have them demonstrate the procedure. Talk with parents about causes of temperature fluctuation in newborns and how to prevent heat loss by appropriate clothing, avoiding drafts, and bathing techniques.

Evaluation

1. Assess and record the infant's axillary temperature every 30 to 60 minutes after delivery until stable and then every 4 hours per nursery routine.
2. Assess infant caregiving techniques in the delivery room and nursery and modify as necessary to prevent cold stress.

3. Assess infant's immediate environment for adequacy of thermal support, such as clothing and number of blankets.
4. Encourage parents' questions and requests for clarifications, and give demonstrations to ensure their knowledge of the infant's thermoregulation needs.

Healthy term infants are typically quite capable of thermal self-regulation when clothed and provided with a few ancillary support measures, such as swaddling. Swaddling minimizes heat loss by increasing insulation at the skin surface (Baumgart, 1996). Stocking caps may also assist the term infant in maintaining a normal body temperature, because they decrease heat loss from the large surface area of the head (Amlung, 1998; Baumgart, 1996).

Other methods of thermal stabilization focus primarily on minimizing heat loss that occurs in the infant's environment. A major source of thermal stress in babies occurs through evaporative heat loss. Drying the infant thoroughly after delivery, when the skin is wet with amniotic fluid, can minimize heat loss from evaporation. Additionally, when bathing the infant in the nursery, the nurse can minimize heat loss from evaporation by bathing the infant under a heat source and keeping as much of the infant covered with the bath towel as possible. When bathing the infant, the nurse should wash only small sections at a time, being careful to immediately dry the area before proceeding to the next area. Two other strategies nurses can use to minimize heat loss in the newborn period include avoiding drafts in the environment and pre-warming beds and infant scales that come into direct contact with the infant.

Metabolic Transition

In utero, the fetus is supplied with the necessary nutrients for growth and metabolic processes by the placenta and begins to prepare for postnatal energy demands. Primarily in the third trimester, the fetus begins the process of storing glycogen in the liver for conversion back to glucose during the immediate postnatal period (Brooks, 1997; Ogata, 1994). Although the fetal insulin response to maternal glucose load remains somewhat immature throughout gestation, fetal insulin also plays a role in stimulating fetal growth and body-fat deposition that is later used to maintain postnatal glucose homeostasis (Brooks, 1997; Ogata, 1994).

At birth, the continuous supply of glucose that diffused across the placenta is abruptly terminated. Although immediate newborn glucose levels are roughly equal to those of the mother, levels fall rapidly and reach their lowest point (approximately 40 mg/dL) within 1 to 3 hours in the healthy term newborn. Glucose levels begin to stabilize by 4 to 6 hours and typically are maintained in the range of 45

to 80 mg/dL. This rapid glucose homeostasis occurs as a result of glucose production from hepatic glycogen stores, a process known as glycogenolysis (Brooks, 1997). As hepatic glucose stores become depleted within the first couple of days after birth, the process of gluconeogenesis becomes more important for glucose production. Gluconeogenesis involves the formation of glucose by the liver from noncarbohydrate sources (Brooks, 1997). This transition to free fatty acids as the alternate fuel source is normally accomplished without incident in healthy term infants. However, the normal achievement of postnatal glucose homeostasis can be disrupted in high-risk infants who have low glycogen or fat stores, an increased glucose need, or immature hormonal regulation of glucose. These complications are discussed later in this chapter.

Gastrointestinal System Transition

The gastrointestinal tract undergoes major changes immediately after birth as a function of the initiation of respiration and the introduction of the first nutrients into the infant's gastrointestinal system. At birth, the infant's abdomen is relatively flat and bowel sounds are absent. With the initiation of respiration, the intestinal tract begins to fill up with air, the abdomen becomes more rounded and soft, and bowel sounds become audible with the stethoscope. This usually occurs within the first 15 minutes of life. Peristalsis may not be continuously audible over the next few hours but should be clearly initiated during the first period of reactivity. Some infants may pass meconium during this time, and voiding is common.

NEUROBEHAVIORAL TRANSITION IN THE FIRST 12 HOURS

The transition to extrauterine life begins with the birth of the infant and extends through the first 12 to 24 hours of life. It is a process in which the infant moves from a homeostatic metabolic state in the uterine environment to a homeostatic state in the extrauterine environment. It is a defined progression of events that is probably triggered by stimuli from the external environment. Before the early 1960s, detailed descriptions of the range of "normal" infant behaviors during this transition period were not available. It was, therefore, difficult to define the range of neonatal distress, to identify early signs of morbidity, or to evaluate the impact of clinical management decisions (Desmond, Franklin, Vallbona, Hill, Plumb, Arnold, & Watts, 1963). This concern led clinicians to begin systematically studying infant behavior during the first hours of life and describing the range of those behaviors (Arnold, Putnam, Barnard,

Desmond, & Rudolph, 1965; Desmond et al., 1963; Desmond & Rudolph, 1965). Observations in these studies began with the 1-minute Apgar evaluation, followed by a 10 to 15 minute observation period, during which routine care was provided. The infant was taken to the study nursery, where observations were taken every 15 minutes, including heart rate, respiratory rate, temperature, color, crying, activity, voiding, and stooling. The infant was observed for 6 to 18 hours, with follow-up examinations performed at 24 hours. From these studies, three basic patterns of activity were identified.

First Period of Reactivity

During the first few minutes after birth, the infant undergoes an intense period of activity and alertness that probably represents a sympathetic nervous system response to the intense stimulation of the labor and delivery process. The infant often responds with bursts of rapid, jerky movements of the extremities, alternating with periods of relative immobility. The infant may show high muscular tone during this period and demonstrate behaviors, such as finger splaying, arching, and hyperextension. The period is characterized by myoclonic movements of the eyeball, spontaneous startles and Moro reflexes, sucking activity, chewing, smacking and rooting, and fine tremors of the extremities. All of these behaviors indicate the infant's stress in coping with the sudden increase in environmental stimuli. During this period, the infant enters a state of alertness, peering intently at the surrounding people and environment. This may allow the infant to achieve and maintain eye contact with the parents or caregivers for brief periods of time.

This period of reactivity is also characterized by tachycardia and tachypnea. The infant's heart rate peaks in the first 2 to 3 minutes after delivery and typically falls over the first 30 minutes to 120 to 140 beats per minute. The respiratory rate remains rapid over the first hour, typically peaking at 1 hour and decreasing during the quiet period that follows the first period of reactivity. Some transient nasal flaring, chest retractions, and grunting are not unusual but should be decreasing by the end of the first period of reactivity. Fine rales and rhonchi are often heard in the first period of reactivity, usually clearing spontaneously within the first 15 minutes after birth.

Implications for Parent, Family, and Newborn Interaction

The first period of reactivity provides a unique opportunity to promote early family and newborn interaction. Two elements of the infant's behavior during this period are particularly conducive to this process. First, the infant is alert and responding to the immediate environment. This is a

time in the infant's normal transition process when it is possible for the mother and father to hold and interact with the baby. If both mother and baby are stable, the family should be allowed a quiet time and place to be with their baby. The infant may be placed in the parents' arms in an "en face" (face-to-face) position to promote eye contact between parent and infant (Figure 31-4). This time of physical closeness and quiet interaction has been found to be intensely emotionally gratifying for many parents. The mother may also enjoy having skin to skin contact with the infant. The infant, clad only in a diaper, may be placed on the mother's chest and then covered with a blanket to maintain body temperature. This physical contact may also enhance the infant's physiologic organization (Ludington-Hoe, Hadeed, & Anderson, 1991).

Additional infant characteristics that may contribute to family and newborn interaction in this period of reactivity are sucking, rooting, and chewing behaviors. If the infant is to be breastfed, this is an opportune time to initiate

Figure 31-4 Father interacting with his alert newborn infant in the "en face" position.

suckling, using the infant's normal behaviors to promote a successful experience (Figure 31-5). Again, the determination of whether or not to initiate breastfeeding at this time must be made through the assessment of the physiologic stability of both the mother and the infant and the mother's emotional readiness and preferences.

Period of Decreased Activity

This period follows the first period of reactivity and probably represents a parasympathetic nervous system response as the environmental activity decreases and the infant's ability to cope with stimuli increases. During this period the infant's alertness gradually decreases and sleep may occur. Motor activity may reach a peak and then decline over this period. The infant continues to demonstrate some tics, twitches, and involuntary startles, although these should gradually diminish throughout this period. Muscle tone, which was high in the first period of reactivity, should begin to moderate. Movements should become

Figure 31-5 Full-term infant ready for breastfeeding at 30 minutes of age.

smoother, less jerky, and less frequent. The infant's heart and respiratory rates decline, and heart rate variability decreases. Respiratory symptoms, such as grunting, chest retractions, brief apneic periods, rales, and rhonchi, may still occur but should be diminishing during this period.

Implications for Parent, Family, and Newborn Interaction

Depending on hospital policy, mothers and infants may remain together during this period, or the infant may be taken to an observation nursery, where some of the initial assessment data is collected. This may be an opportunity for the parents to have some quiet time together and for the mother to rest. If the mother indicates a readiness to learn about her baby during this period, some teaching about the process of the baby's adjustment to extrauterine life, the initial assessment process, and the meaning of some of the infant's behaviors may be appropriate.

Second Period of Reactivity

The second period of reactivity begins as the baby awakens and shows an increased responsiveness to environmental stimuli. At this time the infant may show both heart and respiratory accelerations, particularly in response to environmental stimuli, such as loud noises, bright lights, voices, and touch. There may also be an increase in respiratory symptoms, such as transient grunting, retractions, rales, and rhonchi, although the frequency and severity should be less than that of the first period of reactivity and should gradually diminish throughout this second period. This period is also characterized by an increase in peristalsis and, frequently, the first passage of meconium, although this may have occurred earlier. At the same time, infants may show an increase in hiccoughs, gagging, and spitting up as they become more interactive with the environment and challenged by it. Motor activity increases during this stage but should not reach the level achieved in the first period of reactivity. Motor activity should also be smoother and more organized than in the first period. Muscle tone may increase in comparison to the period of decreased activity but should continue to moderate throughout this period.

Implications for Parent, Family, and Newborn Interaction

The pace and rhythm of parent, family, and newborn interaction during this transition period depends on the readiness and availability of all the involved parties for interaction. The onset of the second period of reactivity represents a time when the newborn is alert, active, and available. The mother's readiness or availability depends on

her fatigue levels, her recovery from the delivery process, the amount and type of medication she has received, and her emotional status. It is common for the mother to desire to have her baby close and to want to participate in feeding and caring for the baby. It is equally normal for the mother to express a need for rest and recovery and to have minimal contact with the baby during this time. If the mother is ready for interaction with her baby, they should be provided with a quiet, comfortable environment in which to be together. The mother and father may have questions about behaviors they see in the baby at this time. If necessary, the parents should be helped to position the baby in a face-to-face position to promote interaction. Helping them to feed the baby or change a diaper are ways of strengthening their sense of competence in caring for their infant. Parents may also be encouraged to examine the baby and to ask any questions they may have.

Assessment Strategies and Newborn Competencies

The most widely used assessment strategies in this neonatal period are the Apgar score and the assessment of gestational age. Both of these assessment tools are discussed in detail elsewhere in this text and represent commonly used and valid one-time “snapshots” of the infant’s status (Jepson, Talashek, & Tichy, 1991). However, adequate assessment of an infant’s progress through the process of adjustment to extrauterine life requires that the nurse engage in serial observations of the infant. The determination that the infant is progressing normally through this transition period is based not on the observations of symptoms at one time point, but on the observation of an infant’s pattern of moving toward more organized behaviors and an increase in the infant’s ability to regulate his or her own physiologic responses. As an example, it is not uncommon for an infant to display symptoms such as grunting with respirations, chest retractions, or brief periods of apnea throughout the transition period. However, these symptoms should become less frequent and less severe over time. If these same symptoms appear to increase in frequency or severity over time, to continue beyond a normal transition period, or to be unresponsive to routine interventions, they may indicate a more serious medical complication and require a more extensive diagnostic workup and treatment.

Two infant neurobehavioral competencies, infant state and habituation, provide additional information regarding an infant’s adjustment to extrauterine life. Infant state, or **behavioral state**, refers to the quality and level of alertness the infant demonstrates. Infant state is viewed as a range of alertness levels from sound quiet sleep through levels of drowsiness to levels of wakeful attentiveness and finally to hyperalert, agitated, or crying states. Infant state

stability provides a valuable window into the maturing nervous system and a useful assessment measure for evaluating neurobehavioral stabilization over the first 24 hours. Behavioral state is evaluated in terms of the range of states the infant is able to achieve and their duration and stability. In the first stage of reactivity, most infants are able to achieve an alert, wakeful state and are able to focus on a face or object for brief periods of time (Figure 31-6). These periods of alertness, however, may be interrupted by agitated movements, respiratory disturbances, and other signs of disorganization. The infant is likely to be distracted and reactive to environmental stimuli and to move rapidly from alert to drowsy to fussy states. During the period of decreased activity, the infant is likely to sleep but may continue to demonstrate involuntary movements and respiratory disturbances during the sleep state, rather than achieving a quiet, well-organized sleep state. Throughout the first 24 hours, the infant’s ability to achieve and maintain an organized, quiet alert state and an organized quiet sleep state, as well as all of the intermediate states, should gradually increase. The nurse’s observation of the change in the duration, stability, and range of the infant’s state control is a valuable indicator of the infant’s neurobehavioral intactness.

The concept of **habituation** refers to the ability of the infant to become adjusted or adapted to a specific environmental stimulus. When an infant is first confronted with an unexpected environmental stimulus, the infant responds with startles, twitches, tics, or respiratory instability. In a mature, well-organized baby, the reaction to the stimulus gradually decreases and the startles, twitches and other behaviors subside. This is called habituation. In the period immediately after birth, many infants are not able

Figure 31-6 Newborn in organized, quiet, alert state during first 6 hours of life.

to habituate to an environmental stimulus. The startle reactions continue until the stimulus stops. Over the first 24 hours, the infant should increase the ability to habituate to environmental stimuli. This process, again, provides a useful indicator of the infant's neurobehavioral intactness.

COMPLICATIONS OF TRANSITION

Most healthy term newborns make the transition to extrauterine life without difficulty. However, this complex process does not always occur uneventfully. Complications occur that may be transient and require only minimal intervention or may represent a significant threat to the infant's well-being.

Common Complications

Conditions that may impede the newborn's smooth transition to extrauterine life include asphyxia, persistent pulmonary hypertension of the newborn, meconium staining, transient tachypnea of the newborn, hypoglycemia, and hypovolemia (shock). These are now discussed.

Asphyxia

One of the most serious of the complications of the transition process is asphyxia. **Asphyxia** is a metabolic process that arises from failure of the respiratory organ in the fetus or neonate. Failure of the organ of respiration leads to impairment of oxygen and carbon dioxide exchange. This results in hypoxemia, hypercarbia, and subsequently, acute respiratory acidosis. If such circumstances persist for a prolonged period, tissue hypoxia occurs, with superimposed metabolic acidosis. Without appropriate caregiver interventions to reverse and restore optimal gas exchange within the placenta or lung, permanent brain injury or death may result (Fisher & Paton, 1986; Kattwinkel, 2000).

Several prenatal and postnatal factors compromise the fetus and interfere with the physiologic transition to extrauterine life. Respiratory depression that leads to asphyxia may occur as a result of the reduction in placental perfusion or gas exchange or from umbilical cord accidents. Failure to establish spontaneous and effective respirations after birth may also result in postnatal asphyxia (Kattwinkel, 2000). In these circumstances fetal acid-base balance is normal at birth, but disturbances occur when adequate lung function cannot replace the detached placenta.

A classic series of events occurs when an infant becomes asphyxiated in utero or postnatally. The progressively severe clinical phases of asphyxia include primary apnea, gasping, and secondary, or terminal, apnea. By observing the infant's responses, the caregiver may be able to

establish the duration and severity of the asphyxia episode, thereby determining the actions that are required to intervene in a timely and appropriate manner (Fisher & Paton, 1986; Kattwinkel, 2000).

During the initial period of deprivation of oxygen, the infant exhibits rapid breathing. If hypoxic conditions persist, the heart rate begins to fall, and the infant's respiratory efforts cease. This is referred to as **primary apnea**. During this period, blood pressure is normal or slightly elevated and pulses are palpable. Although the infant's tone gradually diminishes, the infant is still responsive to tactile stimulation and oxygen. If resuscitation is provided at this point, the infant responds quickly with gasping respirations, rapidly followed by the establishment of normal oxygenation (Fisher & Paton, 1986; Kattwinkel, 2000).

If the asphyxia progresses, the infant begins to demonstrate deep gasping respirations, indicative of serious acidemia and the need for immediate initiation of resuscitation with positive pressure ventilation. If, however, the asphyxia continues, the infant's heart rate progressively falls, the infant's blood pressure begins to drop, and the infant becomes almost flaccid. The infant's respiratory efforts become progressively weaker until respirations cease, and the infant enters into the period of **secondary apnea**. During this period, metabolic derangements are severe, with marked hypoxemia, hypercarbia, and acidemia. Heart rate is extremely low, pulses are absent, and, without prompt intervention, death occurs. Tactile stimulation is ineffective for resuscitation of an infant in secondary apnea, thus requiring quick initiation of positive pressure ventilation with 100% oxygen. The infant usually becomes pink before the reestablishment of spontaneous respirations, because oxygenation is restored sooner than the brain can recover from the severely hypoxic event (Fisher & Paton, 1986; Kattwinkel, 2000).

Because primary and secondary apnea are often difficult to distinguish from one another, the health care provider should always assume the latter and initiate respirations using assisted ventilation. This approach facilitates rapid response to resuscitation efforts, ensures more rapid establishment of spontaneous respirations, and minimizes the potential for adverse neurologic outcomes (Fisher & Paton, 1986; Kattwinkel, 2000).

While the Apgar score has been widely used in the delivery room to evaluate the overall health status of the newly born infant, the Apgar score neither establishes nor rules out the presence of asphyxia. Apgar scoring frequently correlates poorly with the underlying acid-base status of the infant at birth. The need for resuscitation can be more accurately assessed by the evaluation of the infant's heart rate, respiratory activity, and color than by the Apgar score. Resuscitation, therefore, should not be delayed for the assessment of the 1-minute score but should be initiated immediately, based on criteria established by

the American Academy of Pediatrics and the American Heart Association's Neonatal Resuscitation Program (Kattwinkel, 2000). **Resuscitation** of the newborn consists of emergency life-support measures, including airway management, positive pressure ventilation, chest compressions, medications, and thermal support. These criteria are discussed later in this chapter.

Persistent Pulmonary Hypertension of the Newborn

Persistent pulmonary hypertension of the newborn (PPHN), or persistent fetal circulation, is a condition characterized by a high level of PVR in the absence of recognizable cardiac, pulmonary, hematologic, or central nervous system disease (DeBoer & Stephens, 1997). It may be seen in conjunction with a patent ductus arteriosus and foramen ovale, resulting in a cycle of right-to-left shunting, hypoxemia of the arterial blood flow, and continuing or increasing pulmonary vasoconstriction. PPHN is seen most commonly in infants who are appropriate for gestational age and born at or near term. There is frequently a history of perinatal asphyxia or other pathologic event, such as meconium aspiration, pneumonia, or pneumothorax, that results in alveolar hypoxia with a subsequent increase in PVR. PPHN may also occur secondary to pulmonary hypoplasia when there is a decreased pulmonary vascular mass and a resultant increase in PVR. Maternal use of aspirin or other nonsteroidal anti-inflammatory medication during the third trimester of pregnancy has also been seen in conjunction with an increased incidence of PPHN.

Infants with PPHN demonstrate tachypnea, respiratory distress, and rapidly progressing cyanosis that may be aggravated by activity and stimulation of the infant. Infants with severe PPHN may develop systemic hypotension and cardiac failure. PPHN is treated primarily with administration of maximal amounts of oxygen and mechanical ventilation. PPHN may also be treated with inhalational pulmonary vasodilators (particularly nitric oxide) and extracorporeal membrane oxygenation (ECMO). Infants may need to be maintained in an environment of reduced stimulation or be sedated if stimulation and activity aggravate symptoms.

Meconium Staining

Meconium staining of amniotic fluid occurs in 10% to 15% of all deliveries (Whitsett, Pryhuber, Rice, Warner, & Wert, 1994). **Meconium staining** occurs when the fetus passes meconium during the labor or birth process, usually in response to some distress, such as an episode of asphyxia. It is most common in infants born postterm and occurs less commonly with decreasing gestational age. Meconium staining rarely occurs in infants born before 34 weeks' gestation.

The concern in the case of meconium-stained amniotic fluid is the possibility that the infant may aspirate the meconium. Aspiration of meconium can be a cause of serious pulmonary disease in neonates, either by causing an obstruction of the airways or by producing a chemical pneumonitis. These conditions may be severe and life-threatening, even in the healthy full-term infant. Complications resulting from meconium aspiration are increased if: 1) passage of meconium occurs before the second stage of labor, thus increasing the possibility that aspiration will occur; 2) the meconium-stained amniotic fluid is thick, increasing the severity of airway obstruction if aspiration occurs; and 3) on assessment of the newborn, meconium is noted below the vocal cords, indicating that some degree of aspiration has already occurred. Symptoms of clinical disease may be immediate and severe, requiring resuscitation in the delivery room, or may occur gradually over the first few hours after birth with the infant demonstrating respiratory distress and hypoxemia. PPHN may be observed in infants who develop severe meconium aspiration syndrome.

When meconium-stained amniotic fluid is noted, special measures should be taken to prepare for the delivery. An extra person may be necessary to help with the suctioning procedure, including assembling endotracheal tubes and suctioning equipment and monitoring the infant's physiologic status. If possible, the mouth, nose, and posterior pharynx should be suctioned immediately after the head is delivered and while the chest is still compressed in the birth canal. After birth, the need for tracheal suctioning of the infant's airway is determined by whether or not the infant is vigorous at birth (defined by strong respiratory effort, good muscle tone, and a heart rate of more

Critical Thinking

Newborn Resuscitation

Parents are often restricted from being present while their infant is being resuscitated in the newborn stabilization area adjacent to the delivery room. Ask yourself if this practice is done for the benefit of the newborn infant or for the comfort level of the health care team? Also ask yourself: If this was your baby, how would you feel if you were excluded from the newborn stabilization area while the health care team attempted to resuscitate or stabilize your infant? Would you be more frightened by the procedures being performed or by not knowing how your infant was responding to the intervention measures?

than 100 beats per minute) (Kattwinkel, 2000). If tracheal suctioning is required, the infant should not be stimulated to cry or inhale until the infant is intubated and suctioning has been performed. Prompt intubation and suctioning of the infant at delivery has reduced but not eliminated the occurrence of meconium aspiration syndrome.

Parents are often unprepared for complications at delivery. In the accompanying box, a father shares the experiences of one family whose baby had thick meconium staining and respiratory depression at birth. Nurses must partner with parents to ensure that hospital policies and practices facilitate the parents' right to be with their baby and to participate in their infant's care, as the clinical situation allows.

Transient Tachypnea of the Newborn

Transient tachypnea of the newborn (TTN) is a condition in which the infant presents with grunting, retractions, and an elevated respiratory rate at birth or shortly after. The condition is self-limiting, usually resolving

within 5 days. It is characterized radiographically by increased central vascular markings, hyperaeration, evidence of interstitial and pleural fluid, prominent interlobar fissures, and cardiomegaly. Because the condition is self-limiting, infants with TTN usually require only supportive care, mainly oxygen therapy and intravenous fluid supplementation. Rarely is short-term ventilation necessary. In addition, if maternal risk factors for sepsis or other causes for respiratory distress cannot be ruled out, infants are usually treated prophylactically with broad-spectrum antibiotics.

Although the symptoms of TTN are similar to behaviors in the normal process of transition to extrauterine life, the clinical progression is quite different. Shortly after delivery, infants with TTN demonstrate tachypnea, grunting, nasal flaring, rib retraction, and varying degrees of cyanosis. Many healthy infants also demonstrate some respiratory grunting and chest retractions initially, but these symptoms are usually resolved and the respiratory rate should be stabilizing by the end of the second period of reactivity, during which grunting, retraction, and increased respiratory rate should occur primarily in response to environmental stimuli, not when the infant is at rest. The increased respiratory efforts normally noted in the first and second periods of reactivity are related to the clearance of fetal fluid from the infant's lungs after birth and are not usually accompanied by cyanosis. In TTN, these symptoms may persist for several days and occur even when the baby is at rest. Nursing observations of the infant, then, should focus on whether these respiratory symptoms appear to be resolving through the first and second periods of reactivity or persisting at the same level or increasing in severity and whether the distress results in the need for oxygen therapy.

REFLECTIONS FROM A FATHER

"We were so excited that the time had finally come for my wife to deliver our firstborn son. Everyone was there, even my parents who lived 2 hours away by car. When my wife went into labor, the doctor said everything was fine. What we had not prepared for was meconium staining which the health care team members noted when my wife's bag of water broke. When he was delivered, the neonatal team 'wisked' our baby away to a separate room. The neonatal doctor said that I could come be with my baby as soon as they were certain that everything was okay. I didn't understand why I couldn't go with them. What were they doing to my baby that I shouldn't see? I think my wife and I were more frightened by not knowing what was going on and how our son was doing, than we would have been if I would have been allowed to go with them and observe and be with my son."

Hypoglycemia

Hypoglycemia is a relatively common complication in the early newborn period and one for which the nurse should be continually alert. Plasma glucose levels of less than 40 mg/dL should be considered hypoglycemic, although this level is somewhat arbitrary and has not been correlated with the glucose use rate of the infant or with severity of symptoms. Symptoms of hypoglycemia include jitteriness, tremors, apnea, cyanosis, limpness or lethargy, and in severe cases, convulsions.

Several groups of neonates are at particular risk for hypoglycemia. Infants who are born small for gestational age (SGA) have inadequate hepatic glycogen stores at birth. During intrauterine life, the nutrients available to these infants were necessarily channeled toward growth rather than being set aside for glycogen storage. At birth, then, little glycogen reserve is available to meet the infant's metabolic needs. Hypoglycemia is usually short-lived in

these infants as nutrient intake is increased. Infants born prematurely are, similar to SGA infants, born with inadequate glycogen stores and are also vulnerable to hypoglycemic episodes. These infants have missed all or part of the third trimester of intrauterine development, during which much of the hepatic glycogen is stored. The younger the gestational age at birth, the less glycogen is present and the greater the risk for hypoglycemia. Furthermore, infants who are born both SGA and premature are at extremely high risk for hypoglycemia.

A third group of infants who have low glycogen stores at birth are those who have experienced perinatal stress. Stressful events, such as hypoxia, acidosis, and fluctuations in fetal blood pressure and flow, can increase catecholamine secretion in utero and subsequently increase mobilization of hepatic glycogen stores. At birth, these infants may have significantly depleted glycogen stores and are at increased risk for hypoglycemia.

Infants who experience a hyperinsulin state during intrauterine development, most commonly infants of diabetic mothers (IDM), carry over this hyperinsulin response to the extrauterine state. IDMs develop hyperinsulinism in utero in response to the mother's hyperglycemic state. In the neonatal period, the infants often have elevated plasma insulin concentrations and are hyperresponsive to increases in glucose levels. Infants with other conditions, including disorders of the pancreas and certain syndromes, may also have experienced a hyperinsulin state in utero and subsequently are at an increased risk for hypoglycemia postnatally.

Another group of infants at risk for hypoglycemia are those experiencing sepsis. Although the underlying mechanisms of this are not well understood, hypoglycemia or hyperglycemia are often the first indicators of sepsis in a neonate. An evaluation for sepsis should always be considered for infants with unexplained hypoglycemia.

The clinical management of infants susceptible to hypoglycemia begins with prevention and early identification. Although many neonates are asymptomatic, the symptoms most often described consist of respiratory distress, lethargy, apnea, or marked jitteriness (Brooks, 1997). Once the newborn is stabilized in the delivery room, feedings can be initiated as soon as possible after birth in healthy term infants. Such infants may be offered early breastfeeding or oral feedings with formula or glucose. Whenever hypoglycemic symptoms are observed or risk factors are present, glucose screening should be performed using a glucose oxidase strip or an approved blood glucose reflectance meter. If the screening test value is below 40 mg/dL, results should be confirmed with a laboratory venous blood glucose determination (Brooks, 1997; Ogata, 1994). Because asymptomatic or symptomatic hypoglycemia can result in serious neurologic sequelae to the neonate if untreated, it is recommended that therapy

be initiated before obtaining the blood glucose test results. Asymptomatic infants may be offered a feeding and a glucose determination repeated 20 minutes after the feeding. Management of symptomatic infants is usually best accomplished by treatment with an intravenous bolus of glucose, followed by a continuous glucose infusion (Brooks, 1997; Levitt-Katz & Stanley, 1996). Blood glucose levels should be checked 20 minutes after intravenous therapy is begun and should be monitored until stable.

Hypovolemia

Hypovolemia (shock), or low blood volume, is a relatively uncommon but critical complication for the newborn. Acute hypovolemia may occur as a result of blood loss from the fetal side of the placenta secondary to placenta previa or abruptio placenta. These two maternal emergencies are discussed elsewhere in this text, but can lead to a severely compromised infant at delivery. The delivery room management of these infants is a critical part of their survival. Resuscitation equipment and personnel trained in neonatal resuscitation must be present in the delivery room as soon as one of these maternal emergencies is identified. Other possible causes of fetal or neonatal hemorrhage include umbilical cord rupture (secondary to precipitous delivery) or superficially implanted umbilical vessels. Hypovolemia may also be seen with intrauterine asphyxia without evidence of frank hemorrhage. While the healthy newborn can compensate for some blood loss, asphyxia disrupts the infant's ability to do so. In spite of this, most infants experiencing asphyxia do not progress to hypovolemia. However, almost all infants who develop hypovolemia have a history of intrauterine asphyxia.

Babies with hypovolemia appear pale and have weak pulses. They may have a persistently high or low heart rate. Their extremities may feel cold and they may have delayed filling of the capillaries after blanching under normal pressure (provided that core temperature is normal). Infants with hypovolemia may have persistent metabolic acidosis and their circulatory status often does not improve in response to effective ventilation, chest compressions, and epinephrine during resuscitation. The treatment for hypovolemia is blood volume expansion through repeated small infusions of normal saline, Ringer's lactate, or O-negative blood that has been cross-matched with mother's blood (if time permits before delivery).

Major Pathologies that Affect Transition

Three major diseases that may impede the newborn's smooth transition to extrauterine life include congenital heart defects, sepsis, and diaphragmatic hernia.

Congenital Heart Defects

Congenital heart defects, or structural malformations of the heart in the developing fetus, may limit or prevent the neonate from making a successful transition to extrauterine life. Difficulties in transition may not become apparent until the organ of respiration changes from the placenta to the lungs and fetal circulatory shunts close, particularly the ductus arteriosus (Sansoucie & Cavaliere, 1997). In neonates with congenital heart malformations, the ductus arteriosus often maintains blood flow between the pulmonary and systemic circulations after birth, allowing the cardiac defect to go unrecognized. With spontaneous closure of the ductus arteriosus during transition to extrauterine life, the status of a previously asymptomatic neonate may suddenly deteriorate as blood flow between the pulmonary and systemic circulations is abruptly terminated (Sansoucie & Cavaliere, 1997).

Characteristics of cardiac blood flow in utero have an important influence on the structure of the developing heart (Sansoucie & Cavaliere, 1997). Aberrant flow patterns in utero significantly affect the size and shape of the heart postnatally (Serwer, 1992). For example, if blood flow from the right to left atrium is decreased in fetal circulation, diminished growth of the left atrium and ventricle may result and the infant may demonstrate signs of hypoplastic left heart in the early newborn period, such as poor perfusion and a mottled appearance of the skin.

Development of the pulmonary vascular bed may also be affected by structural malformations of the heart. A fetus with pulmonary atresia in utero may have an underdeveloped pulmonary vascular bed that leads to a delayed decline in PVR postnatally and the devastating and often fatal development of PPHN in the immediate postnatal period (Sansoucie & Cavaliere, 1997).

Sepsis

Successful transition to extrauterine life may also be affected by the presence of viral or bacterial endotoxins that are acquired in utero, at birth, or during the early newborn period. **Sepsis** is defined as a clinical syndrome of systemic illness accompanied by bacteremia. Infants at risk for complications related to sepsis include the preterm infant and the infant born to a mother who experiences a prolonged period between rupture of membranes and delivery, fever, chorioamnionitis, or other characteristics suggesting infection (Lott & Kenner, 1998).

Circulating bacterial endotoxins, particularly group B streptococcal endotoxin, can exert effects on both systemic and pulmonary circulations, rendering the neonate vulnerable to the effects of septic shock and possibly even compromising the infant's survival, if aggressive medical interventions are not rapidly instituted. The progressive effects of endotoxin on the capillary beds may lead to failure

to establish normal SVR as a result of decreased venous return to the heart and reduced cardiac output. This loss of effective blood volume within the circulatory system may further exacerbate tissue hypoperfusion and contribute to further cellular anoxia. Endotoxins also contribute to a rise in PVR and pulmonary congestion from increased capillary permeability. The effect of circulating bacterial toxins on the lung causes progressive compromise of pulmonary function with resultant hypoxemia. The infant who has sepsis at birth may exhibit apnea, poor respiratory effort, cyanosis, or frank signs of respiratory distress (Freij & McCracken, 1994). These infants may require initiation of oxygen and respiratory support, and all require the prompt initiation of antibiotics.

Diaphragmatic Hernia

Conditions requiring surgery may compromise the infant's ability to make a successful transition to extrauterine life. One of the most critical conditions requiring intense surgical intervention after delivery in the infant born with a diaphragmatic hernia. **Diaphragmatic hernia** is a condition in which the contents of the abdominal cavity are herniated into the thoracic cavity through a defect in the diaphragm. The herniation of the intestines into the chest cavity results in hypoplasia of the developing lung. The timing of the entry and the amount of abdominal contents that are herniated into the chest both determine the degree of pulmonary hypoplasia and degree of respiratory embarrassment experienced by the infant at birth. Most infants present with respiratory distress at birth or shortly after birth. Symptoms include cyanosis, increased work of breathing, and decreased breath sounds on the affected side. Heart tones may also be shifted from their normal point of maximal impulse. The abdomen is scaphoid as a result of the absence of intestines, and bowel sounds may be heard within the thoracic cavity. Cardiorespiratory symptoms exhibited by the infant are usually the result of decreased air exchange as a result of the pulmonary hypoplasia and thoracic compression of the lung. This leads to hypoxemia and increased PVR within the pulmonary capillary bed. With progressive increases in pulmonary vascular pressures and hypoxemia, right-to-left shunting through the fetal circulatory shunts is common. If the defect goes unrecognized, the infant is at serious risk for persistence of fetal circulation and pulmonary hypertension. The establishment of adequate oxygenation and systemic circulation are key components to infant survival and most infants require some measure of respiratory support, including oxygen, intubation, and positive pressure ventilation (Guzzetta, Anderson, Eichelberger, Newman, Rouse, Schnitzer, Boyajian, & Tomaski, 1994). If the infant with suspected diaphragmatic hernia requires prolonged positive pressure ventilation, ventilation should be delivered

Case Study/Care Plan

BIRTH OF INFANT WITH CONGENITAL DIAPHRAGMATIC HERNIA

A 3940-gram male infant was born to a 24-year-old woman at 40 weeks' gestation by spontaneous vaginal delivery. Apgar scores were 8 at 1 minute and 8 at 5 minutes. The infant did well initially; however, shortly after birth he developed cyanosis and respiratory distress and, 15 minutes later, required intubation and ventilatory support. On physical assessment, the abdomen was unusually flat (scaphoid). Breath sounds were diminished on the left, and heart sounds were shifted to the right side of the thorax. A chest x-ray film was done and revealed air-filled loops of intestine within the left side of the chest, confirming the presence of a left-side congenital diaphragmatic hernia. The priority nursing diagnosis is discussed below, though several other diagnoses would also apply.

Assessment

Term infant with respiratory distress, as evidenced by presence of cyanosis, ineffective breathing pattern requiring ventilatory support, and diminished breath sounds.

Nursing Diagnosis

Impaired gas exchange related to presence of congenital diaphragmatic hernia.

Expected Outcomes Infant will maintain adequate gas exchange (until surgery can be performed) as evidenced by lack of cyanosis, maintenance of arterial PO_2 of more than 60 mm Hg and PCO_2 of less than 45 mm Hg, clear breath sounds on unaffected side of chest, respiratory rate within normal limits (40 to 60 breaths per minute).

Planning

1. Frequent assessments to determine adequacy of gas exchange.
2. Provision of interventions (based on assessments and medical orders) to optimize effectiveness of breathing pattern and gas exchange.

Nursing Interventions

Rationales

- | | |
|--|--|
| 1. Assess and record respiratory rate, breath sounds, and signs and symptoms of respiratory distress every 1 to 2 hours. | 1. Monitors respiratory status. |
| 2. Take samples and record results of arterial blood gas tests when indicated. | 2. Determines adequacy of gas exchange. |
| 3. Check and record oxygen and ventilator settings every 1 to 2 hours. | 3. Provides baseline and measure of changing oxygen needs. |
| 4. Assess patency of endotracheal tube by listening to breath sounds every 1 to 2 hours. Suction endotracheal tube, using sterile technique, as clinically indicated. Record characteristics of secretions and tolerance of procedure. | 4. Ensures patency of ET tube. |
| 5. Position infant on left side with head of bed elevated. | 5. Optimizes gas exchange of unaffected lung and helps to encourage downward displacement of the abdominal contents. |
| 6. Prevent infant from crying whenever possible by using comfort measures and sedation if ordered. | 6. Crying allows the infant to swallow air, which will result in gastric and intestinal distention and increased respiratory distress. |

(continued)

Nursing Interventions

7. Ensure nasogastric tube is placed correctly and connected to suction.
8. Administer antibiotics as ordered.
9. Check and record results of chest x-ray film, if available.

Rationales

7. Decompresses the stomach and minimizes respiratory distress.
8. Minimizes potential for infection related to planned surgery and invasive procedures.
9. Identifies existence of congenital diaphragmatic hernia.

Evaluation Describe breath sounds and any signs or symptoms of impaired gas exchange, and any successful measures used to decrease crying. Record nasogastric suction pressures and characteristics of drainage. Record medications administered as ordered, including antibiotic and sedative agents.

with an endotracheal tube rather than a bag and mask to prevent further respiratory embarrassment, which may result from distention of the gastrointestinal tract (Kattwinkel, 2000).

TRANSITION OF THE PREMATURE INFANT

A **preterm** neonate is defined as an infant born at less than 38 weeks' gestation. Successful transition to extrauterine life is much more complicated in infants born prematurely. In this section, the effects of developmental immaturity of the pulmonary and cardiac systems on adaptation of the preterm neonate to extrauterine life are discussed. The general approach to education of prospective parents of preterm neonates in the delivery room is also discussed.

Complications of Pulmonary System Transition

Developmental characteristics of premature newborns predispose them to respiratory complications in the transition to extrauterine life. One such characteristic is the developmental stage of the alveolar structures in the lungs. At the beginning of the third trimester of fetal development, the respiratory system of the fetus has reached the end of the canalicular period. At this point, alveolar ducts, a primitive form of the future alveoli, have formed and the lungs are becoming increasingly vascular. When these alveolar ducts are first formed, the walls of the ducts are thick. At the end of this period, the alveolar walls are beginning to thin, allowing the newly formed capillaries to push into the ducts as capillary loops. It is at this intersection of the capillary and the alveolar wall that the exchange of oxygen and carbon dioxide occurs. This period, at about 24 to 26 weeks

of gestation, is the first point at which respiration is possible, because some but not all of the infant's alveolar ducts have developed into thin-walled, vascularized terminal sacs. This developmental period determines the lower limits of viability for the premature infant. By the 28th week of gestation, most preterm infants have sufficient terminal air sac development to permit survival. However, the process of terminal sac development continues through the next period of lung development, called the terminal sac or sacular period (24 to 36 weeks gestational age). This period is characterized by rapid development of thin-walled terminal sacs and by a rapid proliferation of the capillary system, with increasing numbers of capillaries bulging into the air sacs. Throughout this period, the surface available for the exchange of oxygen and carbon dioxide is increasing correspondingly with the infant's capacity to sustain independent respiratory function. In the period from 36 weeks' gestation through early childhood, the pulmonary system is considered to be within the alveolar period of development, during which the walls of the terminal air sacs become extremely thin and take on the form of the mature pulmonary alveoli (Moore & Persaud, 1993).

Another major factor influencing the respiratory transition of the premature infant is the presence or absence of surfactant in the lungs. Surfactant is a substance secreted by the epithelial cells in the terminal air sacs, beginning at about the 28th week of gestation. This substance provides a surface tension-reducing action in the alveoli, which allows the alveoli to expand more easily on inspiration and prevents their collapse on expiration. The lack of adequate surfactant in the infant's alveoli is a primary reason for the development of respiratory distress in the premature infant and the need for mechanical ventilation. Synthetic forms of surfactant have now been developed. They are administered shortly after birth and have greatly reduced the need for mechanical ventilation (Lott, 1998).

An infant born early in the third trimester of gestation experiences compromised respiration not because of any existing disease but because of the normal immaturity of the developing respiratory system. It is the combination of inadequate terminal sac development, incomplete vascular development, and inadequate surfactant secretion that leads to the development of the life-threatening condition of respiratory distress syndrome (RDS), formerly called hyaline membrane disease. RDS is a primary cause of mortality and morbidity in the premature infant. The lower the gestational age of the infant at birth, the higher the incidence of RDS and, generally, the greater the severity of the condition. Infants with RDS present, at birth or within a few hours of birth, with signs of respiratory distress, including grunting, chest retractions, cyanosis, rales, nasal flaring, use of the accessory muscles of breathing, and an increasing oxygen requirement. Chest radiographic findings are characterized by atelectasis, air bronchograms, and diffuse reticular-granular infiltrates (Whitsett et al., 1994).

Complications of Cardiac System Transition

One of the common complications of cardiac transition to extrauterine life in the premature infant is the occurrence of a persistent patent ductus arteriosus (PDA). In the fetus, the ductus arteriosus forms a bridge between the pulmonary artery and the dorsal aorta, inserting at the aortic isthmus. At birth, the ductus is a muscular contractile structure. The closure of the ductus at birth depends on multiple factors, including the increase in oxygen tension, the level of circulating prostaglandins, and the available ductal muscle mass. Each of these factors is compromised by premature birth. The hypoxia characteristic of extreme prematurity and the immaturity of the alveolar development may contribute to high PVR, which acts to maintain the right-to-left shunting activity, causing the unoxygenated blood to bypass the pulmonary system and to return to systemic circulation. Conversely, as the PVR decreases after delivery, left-to-right shunting may occur, causing pulmonary venous congestion and, eventually, symptoms of congestive heart failure and an inability to wean from the ventilator or to reduce oxygen requirements. Prostaglandin E₂ (PGE₂) appears to be responsible for maintaining the patency of the ductus arteriosus during fetal life. Before term birth, there is a reduction in the levels of circulating PGE₂ that allows the constriction of the ductus. Infants born prematurely have high levels of circulating PGE₂, which tend to maintain the patency of the ductus after delivery (Lott, 1998).

Clinical manifestations of PDA depend in part on the size of the ductus (mild PDA may be asymptomatic) and the PVR level. Clinical presentation may include the classic

continuous murmur (most commonly heard in the small premature infant) or a crescendo systolic murmur. Infants with severe PDA may demonstrate bounding peripheral pulses and widened pulse pressures and a hyperactive precordium. If the PDA persists, the infant may show signs of increasing congestive heart failure.

Indomethacin, administered intravenously, is used in the treatment of PDA in premature infants. If given early, indomethacin has been found effective in closing nearly 85% of PDAs (Flanagan & Fyler, 1994). Indomethacin acts to inhibit the production of PGE₂ and thereby promotes the closure of the ductus. Indomethacin is toxic to the kidneys and is contraindicated in infants with renal compromise, bleeding disorders, hyperbilirubinemia, and necrotizing enterocolitis. Surgical ligation of the PDA is indicated when treatment with indomethacin has not been successful or when such treatment is contraindicated.

Anticipatory Guidance for Prospective Parents of Preterm Neonates

Parents are often unprepared for emergency situations that occur during the birth of their infant. Because of the unanticipated nature of preterm births, parent counseling before delivery is often performed under less than ideal circumstances. However, every effort should be made to communicate effectively with the prospective parents. Medical terms, abbreviations, and percentages should be avoided as much as possible. Discuss with parents what to expect at delivery, possible complications, and the range of possible outcomes. The infant's chances for survival should also be discussed, and the uncertainties regarding the infant's outcome should be acknowledged. Most importantly, repetition may be necessary for parents to comprehend all this information, and an opportunity to review the information and ask questions should be provided. If neonatal intensive care unit (NICU) admission is anticipated, an opportunity to tour the NICU should be offered, if time permits (Gomella, Cunningham, Eyal, & Zenk, 1999).

RESUSCITATION AND STABILIZATION IN THE DELIVERY ROOM

The American Academy of Pediatrics and American Heart Association Neonatal Resuscitation Program sets the standard for the resuscitation and stabilization of babies who have cardiorespiratory depression at birth or who present with asphyxia (Kattwinkel, 2000). Key components of the program involve anticipating which infants may require resuscitation and having appropriately trained personnel

Client Education

Anticipatory Guidance for Expectant Parents of Premature Infants

Anticipatory guidance for prospective parents of preterm neonates should be geared toward brief explanations about the infant's probable condition, expected outcome, length of hospital stay, equipment, and policies and procedures of the NICU (Gomella, Cunningham, Eyal, and Zenk, 1999). Some points that may be discussed with parents of preterm infants include:

1. Most extremely preterm neonates have respiratory distress and require oxygen and ventilatory support to breathe effectively. Other problems commonly experienced by preterm neonates include metabolic problems, infection, necrotizing enterocolitis, patent ductus arteriosus, intraventricular hemorrhage, apnea, and bradycardia.
2. Chronic complications of prematurity include chronic lung disease, periventricular leukomalacia, intraparenchymal cysts, hydrocephalus, malnutrition, retinopathy of prematurity, and hearing impairment.
3. Although the risk of disability is higher in preterm infants than in the general population, the majority of preterm children do not develop a major disability. Learning disability, attention deficit disorder, minor neuromotor dysfunction, and behavior problems are more frequent in school-aged children who were preterm than in full-term controls.
4. The expected length of hospital stay for most preterm neonates is estimated to be 2 weeks before or after the baby's estimated due date.

and equipment available and ready to respond if the need arises. Generally, one trained caregiver should be available at every delivery in which a healthy newborn is expected, and two caregivers should be available if a problem is anticipated. A skilled resuscitation requires the combined efforts of two trained individuals who perform a coordinated series of steps based on an evaluation of the infant's condition and response.

After delivery of a healthy term infant, routine care should be provided, including warmth, clearing of the infant's airway, and drying to prevent heat loss. In addition,

Nursing Alert

UNIVERSAL PRECAUTIONS

When performing neonatal resuscitation in the delivery room, the infectious status of the mother and baby is often unknown and the risk of exposure to potentially harmful body fluids is relatively high. The Centers for Disease Control and Prevention recommends that all bodily fluids be treated as potentially infectious, including blood, urine, stool, saliva, vomitus, and, in the case at delivery, amniotic fluid. Masks and protective eyewear or face shields should be worn during procedures that are likely to generate droplets of blood or other bodily fluids, which are especially common during the birth process. Gloves and protective gowns should be worn during resuscitation and when handling the newborn immediately after delivery. Mechanical devices should be used when suctioning the baby's nose, mouth, and pharynx and when suctioning the infant for meconium. Bag-mask devices should be used instead of mouth-to-mouth resuscitation when positive pressure ventilation is required. Although relatively uncommon, endotracheal suctioning or umbilical catheter placement has at times produced potentially infectious splashes of sputum or blood, respectively, thus requiring caregivers to exercise extreme caution and proper precautions when performing these procedures on a newborn.

because of the concern about the transmission of communicable diseases through blood or body fluid contact, strict universal precautions should be followed for all infants.

Resuscitation of an infant should be provided if meconium is present, the infant is not breathing or crying, the infant lacks good muscle tone, the infant is cyanotic, or the infant is delivered prematurely. Initial steps in the resuscitation include thermal management, positioning, suctioning, and tactile stimulation. First, the infant should be placed under a preheated radiant warmer to prevent heat loss. The infant should be positioned on his or her back or side with the neck slightly extended to ensure an open airway. If meconium was present in the amniotic fluid and the baby is not vigorous at birth (defined by strong respiratory effort, good muscle tone, and a heart rate of more than 100 beats per minute), tracheal suctioning should be performed (Kattwinkel, 2000). The infant's mouth, and then the nose, should be gently suctioned, using either a bulb syringe or mechanical suction (Figure 31-7). The infant should then be dried and the wet linens removed.

Once the infant has been dried, suctioned, and positioned, resuscitative personnel should simultaneously evaluate the infant's respiratory effort, heart rate, and color

Figure 31-7 Bulb suction of post-term infant in delivery room.

(Kattwinkel, 2000). If central cyanosis is present but the infant is breathing spontaneously with a heart rate of more than 100 beats per minute, free-flow oxygen should be administered at 5 to 10 L/min, using either an oxygen mask or oxygen tubing held with a cupped hand over the infant's face (Kattwinkel, 2000) (Figure 31-8). If the infant remains cyanotic despite 100% free-flow oxygen, positive pressure ventilation should be initiated.

If the infant is not breathing or has inadequate respirations, tactile stimulation can be briefly provided by gently slapping the soles of the infant's feet or rubbing the infant's back. If the infant does not respond, mask-bag ventilation should be provided at a rate of 40 to 60 breaths per minute and continued until spontaneous respirations are established. The establishment of adequate alveolar ventilation is the cornerstone of the resuscitation process, because it promptly reverses many of the metabolic consequences of failure of the respiratory organ. Bag-mask

Figure 31-8 Newborn receiving free-flow oxygen in delivery room as therapy for central cyanosis.

Critical Thinking

Failure to Respond to Resuscitation Efforts

A 24-year-old primiparous woman is admitted to the obstetric unit in active labor at 41 weeks' gestation. No prenatal care was obtained during the pregnancy. Rupture of membranes occurred 2 hours ago, with thick, particulate meconium noted. Fetal monitoring discloses an abnormal fetal heart pattern that is unresponsive to maternal positioning and oxygen administration. A decision is made to perform an emergency cesarean section. At delivery, the baby is cyanotic, limp, and unresponsive, with a heart rate of 40 beats per minute.

1. What risk factors mean that this baby may require newborn resuscitation?
2. What personnel should be present at the delivery?
3. What equipment would you assemble in preparation for the delivery?
4. What are the steps you would take to resuscitate this infant?
5. If the infant's heart rate remains below 60 beats per minute despite ventilation, chest compressions, and medications, what assessment would you make to ensure that resuscitation efforts were being effectively delivered?
6. Complications of delivery and misdiagnosis or failure to diagnose in a timely fashion are indicative of a comparatively high rate of risk and litigation in perinatal health care. Given that you are certain that ventilation, chest compressions, and medications are being delivered appropriately, what other medical causes would you need to consider if the infant remains unresponsive to all resuscitative efforts?

ventilation should be given with enough pressure to provide an easy rise and fall of the chest and produce breath sounds. If bag-mask ventilation is performed for longer than a few minutes, an orogastric tube should be inserted and left in place, thereby preventing distention of the stomach and intestines and decreasing the risk of aspiration of gastric contents. If the infant is suspected of having a diaphragmatic hernia, prolonged positive pressure ventilation should be performed using a bag and endotracheal tube (Kattwinkel, 2000).

Positive pressure ventilation should also be performed any time that the heart rate is less than 100 beats per minute. If the heart rate is less than 60 beats per minute, despite 30 seconds of effective positive pressure ventilation with 100% oxygen, chest compressions should be initiated. The lower third of the infant's sternum, immediately above the xyphoid process, should be compressed to a depth of one-third the anterior-posterior diameter of the infant's chest and at a rate of 90/sec in conjunction with a ventilation rate of 30 breaths per minute (Kattwinkel, 2000). Chest compressions are the central tool in maintenance of circulatory function in the infant with persistent bradycardia during resuscitation. Maintenance of adequate circulatory function is a critical factor in determining survival and outcome. Because cardiac output and blood flow in the newborn are heart rate-related, resuscitation efforts should be made with great care to maintain the adequacy of circulatory function and minimize the devastating effects of tissue ischemia.

Positive response of the infant to resuscitative efforts is indicated by increasing heart rate, spontaneous respirations, and improving color. If the infant's condition continues to deteriorate or fails to improve despite assisted ventilation, the resuscitative team should check the adequacy of ventilation. If the chest movement is adequate and 100% oxygen is being administered, the infant may require endotracheal intubation to further stabilize his or her condition.

Although medications are rarely needed in newborn resuscitation, if the heart rate remains less than 60 beats per minute, despite 30 seconds of ventilation and another 30 seconds of coordinated chest compressions and ventilation, drugs may be indicated to improve the infant's circulatory status (Table 31-1). Although the umbilical vein is the preferred route of administration in the delivery room, epinephrine may also be administered by an endotracheal tube if an umbilical venous catheter or other intravenous catheter is not already in place.

Epinephrine (1:10,000) is currently used in resuscitation to increase heart rate, augment cardiac contractility, and increase PVR. Although sodium bicarbonate is not indicated during brief arrest, it may play a role if severe

Nursing Tip

POSITIVE PRESSURE VENTILATION

Since establishing effective ventilation is the key to nearly all successful newborn resuscitations, the caregiver must be prepared to troubleshoot if the infant is not responding to positive pressure ventilation (Kattwinkel, 2000). Assessment must be done to ensure that chest movement is adequate. Common reasons why the chest may not be rising with each squeeze of the bag include:

- Inadequate face-mask seal
- Airway blocked because of improper head position or secretions
- Not enough pressure being used to ventilate the infant

If this happens when you are attempting to provide positive pressure ventilation, try using the following techniques:

- Reapply the mask to the infant's face
- Reposition the infant's head
- Suction secretions from the infant's nose, mouth, or oropharynx
- Increase ventilation pressure until there is an easy rise and fall of the chest

Table 31-1 Medications for Neonatal Resuscitation

Medication	Dose	Route	Rate
Epinephrine (1:10,000)	0.1–0.3 mL/kg	Endotracheal tube Umbilical vein or other intravenous route	Rapid push
If hypovolemia, Normal saline or Ringer's lactate or O-negative blood	10 mL/kg	Umbilical vein or other intravenous route	Over 5–10 minutes
If severe metabolic acidosis, Sodium bicarbonate, 0.5 mEq/mL (4.2% solution)	2 mEq/kg	Umbilical vein or other intravenous route	Slowly; no faster than 1 mEq/kg/min

metabolic acidosis is suspected or proven by blood gas analysis. Sodium bicarbonate should not be used, however, until adequate ventilation has been established. If alveolar ventilation is inadequate, bicarbonate administration exacerbates acidosis and may be accompanied by a fall in cardiac output and increased lactic acid production by the gut.

Volume expanders are the third classification of drugs that are currently of proven value in newborn resuscitation, by means of increasing vascular volume and, subsequently, tissue perfusion. Volume expanders are indicated during resuscitation when there is evidence or suspicion of acute blood loss accompanied by signs of hypovolemia. A significant blood loss may be suspected if the infant has a pale color, weak pulse, persistently high or low heart rate, and if improvement in circulatory status is poor, despite resuscitation efforts (Kattwinkel, 2000). The recommended solution for acutely treating hypovolemia is normal saline, but other acceptable volume expanders include Ringer's lactate, O-negative blood that has been cross-matched with mother's blood, or emergency-release O-negative blood.

If the infant continues to deteriorate despite effective resuscitative efforts, other possible causes that should be

explored include depressed respiratory drive, airway malformations, congenital heart disease, and lung problems, such as pneumothorax or diaphragmatic hernia.

Web Activities

- What online resources are available to support the American Academy of Pediatrics and American Heart Association's Neonatal Resuscitation Program? (see <http://www.aap.org/prof/nrp/nrpm.htm>)
- What information can you locate on the Internet about transition to extrauterine life that both parents and nurses can use?
- What parent support groups can you locate on the Internet for families of full-term or preterm infants who require neonatal intensive care?

Key Concepts

- Fetal circulation differs from that in the newborn in three major respects: minimal blood flow through the lungs, presence of placental circulation, and presence of anatomic shunts.
- Gas exchange in the placenta occurs by simple diffusion at the intervillous space. Two factors favoring oxygen diffusion from the mother to the fetus include oxygen pressure gradients across the placenta and higher concentrations of fetal hemoglobin.
- Three anatomic shunts divert oxygenated blood to organs performing life-sustaining functions. The ductus venosus connects the umbilical vein to the inferior vena cava and allows blood to bypass the liver; the foramen ovale allows blood entering the right atrium of the heart to go directly to the left atrium, left ventricle, and out the ascending aorta to immediately supply the brain; and the ductus arteriosus shunts blood from the pulmonary artery to the descending aorta, thus bypassing the lungs.
- Several changes at birth occur that switch the organ of respiration from the placenta to the lung, including the onset of ventilation with a concomitant decrease in pulmonary vascular resistance and increase in pulmonary blood flow, rise in blood oxygen content, and loss of placental circulation, resulting in an increase in systemic (peripheral) vascular resistance.
- Effective thermal management at the time of birth plays a significant role in promoting an optimal transition by the neonate to extrauterine life.
- Physiologic and behavioral transition to extrauterine life in the immediate newborn period occurs in three phases: initial period of reactivity, period of relative inactivity, and second period of reactivity.
- Conditions that may impede the newborn's smooth transition to extrauterine life include asphyxia, persistent pulmonary hypertension of the newborn, meconium staining, transient tachypnea of the newborn, hypoglycemia, and hypovolemia (shock).
- Asphyxia is a metabolic process that arises from failure of the respiratory organ in the fetus or neonate. This impaired gas exchange results in a complex combination of hypoxemia, hypercapnia, acidosis, and ischemia.
- The Apgar score neither establishes nor rules out the presence of asphyxia. Resuscitation should be immediately initiated when indicated and not delayed for assessment of 1-minute Apgar score.
- Major pathologies that may impede the newborn's smooth transition to extrauterine life include congenital heart defects, sepsis, and diaphragmatic hernia.

- Developmental immaturity of the pulmonary and cardiac systems may impede the preterm neonate's adaptation to extrauterine life.
- Nurses must partner with parents to ensure that hospital policies and practices facilitate the parent's right to be with their baby during the crisis period and to participate in their infant's care, as guided by parent preference and the clinical situation.

- The American Academy of Pediatrics and American Heart Association's Neonatal Resuscitation Program provides recommendations for resuscitation of infants, including thermal support, airway management, establishment of breathing and circulation, and medications as clinically indicated.

Review Questions and Activities

1. During normal transition from fetal to postnatal circulation, all of the following cardiopulmonary changes must occur in the neonate *except*:
 - a. The placenta is removed and SVR decreases
 - b. Lung expansion occurs and PVR falls
 - c. Ductal blood flow becomes left-to-right
 - d. Increased left atrial pressure

The correct answer is a.

2. An infant in primary apnea would exhibit which of the following signs?
 - a. Gasping before becoming pink
 - b. Heart rate around 50 beats per minute
 - c. Pulses poor or absent
 - d. No response to tactile stimuli

The correct answer is a.

3. Which of the following statements is true concerning asphyxia?
 - a. The Apgar score is a good indicator of the presence or absence of asphyxia
 - b. Poor perfusion accompanied by asphyxia is caused by volume depletion
 - c. The acidosis associated with asphyxia is primarily metabolic in origin
 - d. Ischemia has a more profound effect on tissue oxygenation than hypoxemia does

The correct answer is d.

4. In the delivery room, an infant presenting with no spontaneous respiratory effort and an Apgar score of 2 probably has:
 - a. Primary apnea
 - b. Secondary apnea
 - c. Narcotic depression
 - d. Retained fetal lung fluid

The correct answer is b.

5. Which of the following statements is *false* regarding the transition from a fetal to a postnatal circulatory pathway?
 - a. The major determinant of the direction of shunting through fetal circulatory pathways is the relationship between SVR and PVR

- b. Shunting of blood from right-to-left during transitional circulation may result in pulmonary congestion
- c. In fetal circulation, blood is ejected from both the right and left ventricle into systemic circulation
- d. A major determinant of the resistance to blood flow in the pulmonary circuit is alveolar hypoxia

The correct answer is b.

6. High PVR in utero is maintained by the presence of all of the following factors *except*:
 - a. Small pulmonary arteries, which contain little muscle mass
 - b. Absence of air-fluid interface in the alveoli
 - c. Absence of rhythmic distention of the lung
 - d. Low resting oxygen tension in utero

The correct answer is a.

7. A term infant develops severe respiratory distress within minutes after birth. On physical examination, the chest is hyperexpanded and the point of maximal impulse (PMI) is shifted to the right. Which of the following is the most likely cause for this infant's respiratory distress?
 - a. Diaphragmatic hernia
 - b. Congenital pneumonia
 - c. Right-sided pneumothorax
 - d. Meconium aspiration

The correct answer is a.

8. Which of the following statements is *true* concerning thermoregulation in the newborn?
 - a. The infant's core body temperature is an accurate assessment of neutral thermal environment
 - b. Hypoxia blunts the infant's metabolic response to cold stress
 - c. An infant in an incubator is in a neutral thermal environment when the randomly set air temperature maintains the infant's axillary temperature at 97.5°F to 99.5°F
 - d. The zone of thermal neutrality is wider in the infant with a very low birth weight

The correct answer is b.

9. The method of heat loss in which heat is lost to cool surfaces in direct contact with the infant is called:
 - a. Radiation
 - b. Convection
 - c. Conduction
 - d. Evaporation

The correct answer is c.

10. The neonate with an axillary temperature of 96.5°F is at increased risk of developing all of the following *except*:
 - a. Metabolic acidosis
 - b. Hypoglycemia
 - c. Hypotension
 - d. Hypoxemia

The correct answer is c.

Assessment and Care of the Normal Newborn

Nursing care of mothers and their newborn infants is often thought to be the most joyous and rewarding experience for the nurse because a brand new person is welcomed into the world. Although nursing care of the newborn after transition is focused on the health of the infant, the nurse has the opportunity to be involved with the parents of the infant and to interact with other family members to plan for the infant's future well-being within the family unit. Use the following questions to examine your personal feelings regarding nursing care of newborn infants:

- ❖ *How would I feel if I were the nurse caring for an infant who would not stop crying?*
- ❖ *How would I feel as a new mother if no one were to tell me whether my baby were doing well and when I might see him?*
- ❖ *How would I feel as a nurse if I were caring for an infant who was not feeding well?*
- ❖ *How would I feel if I were a new mother of a baby who was sick or had a physical abnormality?*
- ❖ *How would I feel if I were the nurse caring for a mother and her newborn and I overheard a family member say something to the mother that would affect the infant's health and safety at home?*

Key Terms

Acrocyanosis	Developmental dysplasia of the hip (DDH)	Meconium	Posterior fontanel
Anal wink reflex	Epispadias	Microcephaly	Postterm infant
Anterior fontanel	Erythema toxicum	Milia	Preterm infant
Caput succedaneum	Hypospadias	Mongolian spots	Pustular melanosis
Cephalhematoma	Imperforate anus	Mottling	Syndactyly
Chorioamnionitis	Lanugo	Patent ductus arteriosis (PDA)	Tachycardia
Coarctation of the aorta	Macrocephaly	Polydactyly	Tachypnea
Cyanosis			Term infant

Competencies

Upon completion of this chapter, the reader should be able to:

1. Perform a full physical examination and gestational age assessment on a newborn infant to provide an accurate account of the infant's status to its mother and father.
2. Describe the unique characteristics and behaviors of a newborn infant to its parents and other family members.
3. Demonstrate to all family members proper holding and positioning of infants for safety and to prevent injury.
4. Discuss factors with the parents and family that may place the infant at risk for illness, and suggest parental interventions for illness prevention.
5. Explain feeding and elimination schedules to parents to alleviate any concerns.
6. Anticipate parental anxieties related to caring for their new infant during the neonatal period and develop a teaching plan for parents to address these anxieties.
7. Incorporate family values and ethnic and religious perspectives in teaching plans for infant care and health maintenance visits.

Preparing for a healthy infant preoccupies a mother-to-be during the time that she is pregnant until the time of delivery, when the physiologic forces of contractions and the process of labor disrupt her fantasies and redirect her attentions. Her first glimpse of her infant reassures her that the journey from the womb to the world was accomplished safely (Rubin, 1984). As the mother holds her newborn for the first time, she celebrates this new life with the infant's father and other family members. The nurse in charge of the infant's care can safeguard this moment in family life by not intruding or interrupting the family's opportunity to be with their newest member.

After the parents and family members have the opportunity to touch, hold, and interact with their infant, the nurse can address any concerns related to the infant's condition or behavior. The interaction of the nurse with all family members at this time forms the basis for the nursing assessment of the family's ethnic or cultural perspectives

regarding the infant. This assessment is incorporated into the nurse's teaching plans for the parents and the family regarding caring for the infant at home.

Before the introduction of the infant to the parents and the family, the nurse uses assessment skills to determine the physical health of the infant and its physiologic stability after transition. This chapter describes the complete examination of the infant and the gestational age determination with size parameters that describes the physical condition of the infant. Findings that may place the infant at risk for injury or infection or that warrant further investigation alert the nurse to develop strategies for intervention. In addition, guidelines are presented for continued nursing assessments of the infant while the infant remains under the nurse's care. Finally, factors to consider in the determination of parental and family perspectives are delineated to provide a comprehensive assessment of the parental and family environment. The design of this chapter provides knowledge of the skills in newborn assess-

ment so that the nurse can intervene when necessary and implement infant care strategies that address parental concerns and family considerations.

ASSESSMENT AFTER TRANSITION

Nursing assessment of the newborn infant after transition continues to be a critical factor in determining the infant's adjustment to the extrauterine environment. Transition of the newborn immediately after delivery in the nursery or in another special care environment is conducted according to the institutional protocol. Time frames for this transitional period are adjusted for the individual infant's condition and accurate assessment of the infant's physiologic stability. Transition of newborn infants usually encompasses the first 4 to 6 hours of life (Seidel, Rosenstein, & Pathak, 2001). Nursing concerns after the transitional period are directed toward balancing the need for observation and assessment of the newborn infant with the needs of the mother and family to have their infant with them.

REFLECTIONS FROM A NURSERY NURSE

"I had gone to the mother's room to pick up her infant for the end of shift report. The mother was adamant that her infant was not going anywhere. She informed me that this was her baby, and if I touched her baby, she would call hospital security and accuse me of kidnapping. I was speechless. I didn't know what to do, so I left her infant in her room and made my report to the next shift. I went home and thought about what the mother had said, her rights as the mother of this infant, and hospital policies interfering with parental rights to their infants. I decided that my role as a nurse was to facilitate the opportunities for infants, mothers, and families to be together and that I needed to adjust my thinking and approach to accomplish this."

Figure 32-1 Knit caps and swaddling in a blanket help newborns maintain body heat.

Temperature

During the transitional period, the nurse determines that the infant is physiologically stable by skilled examination and assessment of the infant's thermoregulatory effort, cardiac system, and respiratory system. Infants received from the delivery room are usually swaddled in blankets with stocking caps to prevent chilling (Figure 32-1). To maintain body temperature, the infants are placed immediately in a temperature-controlled isolette or on a radiant warmer. Body temperature is assessed by recording axillary temperature or attaching the infant to a thermoprobe and recording monitor. Rectal temperatures are no longer routinely done on infants because the insertion of the rectal thermometer into the anus of an infant risks damage to the rectal lining and may break the thermometer. Anal patency is no longer confirmed by insertion of a thermometer. It is assessed by examination of the anus and visual confirmation of stool being excreted through the anal opening (Seidel et al., 2001). Axillary infant temperature should be maintained between 36.5°C to 37.6°C (97.7°F to 99.7°F) (Wong, Hockenberry-Eaton, Wilson, Winkelstein, Ahmann, & DiVito-Thomas, 1999).

Figure 32-2 Brown-fat distribution in the newborn.

The infant's ability to maintain body heat is related to controlling the factors that produce heat loss in the newborn infant. The organ system that occupies the largest surface area on an infant is the skin, placing the infant at risk for heat loss by evaporation to the environment. Placing the infant in a warm environment minimizes this risk. In spite of the rise in newborn birth weight, leading to larger infants, the subcutaneous fat layer is thin, offering no insulation against heat loss and no adequate energy source to raise body temperature. Warm environments coupled with decreased infant stimulation and energy expenditures assist the infant in maintaining body temperature. Infants who are chilled are not able to produce body heat through shivering but can produce body heat through an alternative mechanism. This alternative mechanism involves stimulating the metabolism of brown fat (Figure 32-2), a special adipose tissue in newborns, located between the scapulae, around the neck, in the axillae, behind the sternum, around the kidneys, and surrounding some of the major arteries (Wong et al., 1999). The location of brown fat in the axillae may cause a transient rise

in axillary temperature that the nurse may misinterpret as a rise in infant core body temperature. Assessments of infant temperature after transition provide the nurse ample opportunities for a determination of the infant's ability to control its temperature within the environment.

Cardiovascular System

Assessment of the cardiovascular system after the transitional period is directed to the infant's ability to convert fetal circulation to postnatal circulation. Fetal circulation during pregnancy was dependent on shunting blood flow through the foramen ovale, the ductus arteriosus, and the ductus venosus. As the infant breathes on his or her own, the inspired oxygen enters the pulmonary vasculature and pulmonary vascular resistance decreases, leading to an increase in pulmonary blood flow to the chambers on the left side of the heart. This, coupled with the increased systemic blood circulation from the placenta during cord clamping, leads to reversal of fetal blood flow because the heart now undergoes postnatal ventricular contraction (Wong et al., 1999). Reversing blood flow through the fetal shunts ultimately results in their closure, and backflow through the shunts results in heart murmurs that are often called "flow murmurs." The nurse monitors these events by carefully auscultating heart sounds, determining heart rate, checking peripheral pulses, and observing skin color changes indicative of improving cardiac perfusion to the extremities.

During the course of transition, the nurse would expect the infant's heart rate to decrease from highs of 150 to 160 beats per minute to a regular pattern and rate between 130 and 140 beats per minute. The infant heart adjusts to the increased blood flow through the ventricles and becomes more efficient at pumping blood through them. Peripheral perfusion is evaluated by the presence of peripheral pulses, capillary refill, and skin color. The nurse identifies the characteristics of peripheral pulses related to strength, rhythm, and bounding qualities; compares pulses bilaterally; and times capillary refill (rapid refill is 3 seconds or less). Skin color should remain pink or healthy and may appear "rosy" as capillary circulation improves.

Respiratory System

Nursing assessment of the infant's respiratory system after transition begins with observing the infant's respiratory effort, listening to the sounds made while the infant is breathing, and auscultating all lung fields. Air entering the infants' lungs after delivery competes with fluid remaining in the alveolar spaces. The majority of this fluid in the lungs and aveoli is removed by pulmonary capillaries, the lymphatic system, and the labor and delivery process. Surfactant reduces the surface tension of the fluid and allows air to enter the aveoli for gas exchange (Wong et al., 1999).

Nursing Tip

BROWN FAT

It is important to keep the neonate warm to avoid excess energy expenditure. Brown fat is the infant's last defense mechanism against hypothermia.

Nursing Alert

TACHYPNEA

Tachypnea is usually defined as a respiratory rate of 70 or more breaths per minute. Respiratory rates between 60 and 70 breaths per minute are called borderline tachypnea and the infant should be observed carefully. Any newborn infant with respiratory rates that are borderline or tachypneic beyond 24 hours of life should be evaluated immediately for infection.

Fluid remaining in the lungs may cause a condition called transient tachypnea of the newborn (TTN) characterized by a rapid respiratory rate (above 60 breaths per minute) with no other symptoms of respiratory distress, for example, intercostal or sternal retractions, nasal flaring, or grunting. Grunting is an audible sound made by the infant while undergoing inspiration and expiration. Normal breathing occurs quietly. TTN is characterized by fluid in the lung fissures and streaky parenchymal changes with hyperinflation of the lungs on a chest X-ray (Seidel et al., 2001). Normally, with no treatment other than careful observation, a repeat chest X-ray 24 hours later reveals a clearing of the fluid and a resolution of the hyperinflated lung state.

Observation of the infant in the supine position assists the nurse in the evaluation of the infant's respiratory effort. Symmetrical chest movements, use of accessory muscles, a labored or unlabored appearance, and intercostal or sternal retractions are noted. Infants breathe primarily through their nose, and visual inspection can confirm this. Those infants who have evidence of bubbles around the mouth or who appear to be blowing bubbles through their nares can be relieved by using a bulb syringe to clear the oropharynx or the nasal passages (Figure 32-3). Lung fields should be auscultated anteriorly and posteriorly while gently rolling the infant onto each side. Breath sounds are noisy, and the

Figure 32-3 Infants who blow bubbles through their mouth or nose should be suctioned with a bulb syringe.

sound radiates and echoes throughout the entire chest because of the thinness of the chest wall. Until respiratory and hemodynamic stability is achieved, at approximately 12 to 24 hours of life, it is difficult to determine the presence of rales or rhonchi in lung fields because of the echoing and radiation of the auscultated sounds.

Nasal patency can be confirmed by gently occluding one naris at a time with the infant's mouth closed and observing for a rise in the chest, indicative of the infant's ability to inhale air into the lungs through an intact nasal passageway. Infants who have difficulty with this maneuver may have choanal atresia, a malformation of the bucconasal membrane, leading to obstruction of the nasal passageway. Choanal atresia is confirmed by being unable to insert a small catheter (a No. 8 French feeding tube is preferred in newborns) into an infant's nares. Bilateral choanal atresia produces cyanosis when the infant's mouth is closed and disappears when the mouth is open or the infant is crying. Unilateral choanal atresia may not be identified until rhinorrhea (nasal discharge) occurs in early childhood, obstructing the naris that is patent (Seidel et al., 2001). Choanal atresia is a developmental anomaly occurring during gestation, and it may be accompanied by other defects. Positive findings of choanal atresia should be reported immediately, and the infant should be examined for other anomalies, the most common being CHARGE association (Box 32-1).

Nursing Tip

CLEARING AIR PASSAGES

Auscultation of the infant's nose and mouth may reveal noisy breath sounds indicative of obstruction of air flow through the nares or oropharynx. Suctioning with the bulb syringe may remove fluid and debris that clutters these passageways. The nurse should subsequently hear decreased noise on auscultation.

General Nursing Care

Once the nursing assessment of body temperature and the cardiac and respiratory systems is made and established as stable over time, the nurse notes whether the infant has received ophthalmic and vitamin K prophylaxis and a first bath.

Box 32-1 Characteristics of CHARGE Association in the Newborn

C = Coloboma, a malformation of the iris and pupil, which affects the retina and the optic nerve

H = Heart defect

A = Choanal atresia

R = Retardation, physical and mental

G = Genital hypoplasia

E = Ear anomalies

Infants with CHARGE association may need an emergency tracheostomy or surgical repair of the atresia. They experience difficulty in feeding and responding to light (vision problems) or sound stimulation (hearing problems) and have episodes of peripheral and central cyanosis. Additionally, these infants may have decreased kidney function because embryonic development of ears and kidneys occurs at the same time. Nursing care focuses on reducing environmental stressors that irritate or excite the infant because these infants may have compromised breathing patterns and circulatory problems.

Ophthalmic Prophylaxis

Ophthalmic prophylaxis is given according to institutional protocol in ointment or drop form to prevent gonococcal and chlamydial infection in neonates (Figure 32-4). Choices for ointments or drops include 0.5% erythromycin,

Figure 32-4 Ophthalmic prophylaxis prevents gonococcal and chlamydial infection in the newborn.

**Nursing Alert****EYE DISCHARGE**

Any eye irritation or discharge persisting for more than 24 hours should be reported immediately to rule out chemical conjunctivitis from eye prophylaxis.

1% silver nitrate solution, and 1% tetracycline, which are effective against infection. Silver nitrate solution stains the periorbital area black when the infant blinks and can be removed with a moist wipe. All three ointments or drops cause a chemical conjunctivitis of the eyes within the first 24 hours of life. The nurse observes a matting of the eyelashes and, possibly, a yellowish discharge that can be removed with a moist wipe. The discharge and irritation to the eyes ceases after 24 hours.

Vitamin K Prophylaxis

Prophylactic injection of vitamin K (0.5 to 1.0 mg phytonadione) is given by intramuscular injection into the infant's thigh during the first hour of life to stimulate production of vitamin K by the bacteria in the infant's intestine (Figure 32-5). At delivery, the intestine of the infant is considered to be sterile, or without normal bacteria. Once the **meco-nium** stool has passed, the intestinal lining and mucosal cells rapidly adjust to metabolize food and excrete food by-products. Bacterial formation stimulates production of vitamin K, a cofactor in the normal clotting process, from the infection given to the neonate. Infants may develop a

Figure 32-5 Administration of vitamin K.

REFLECTIONS FROM A NURSE

"I was the nurse caring for a mother and her newborn son in the rooming-in area of our postpartum unit. I remembered this mother because she was so upset that she delivered here instead of at home. All she wanted to do was go home. She didn't want anything done for the baby. I think she was worried about it costing more money. I brought her the consent form to sign for the vitamin K injection and the eye ointment and she refused. She said her baby didn't need it. I went back to the nurse practitioner in charge, who subsequently conferred with the physician. The nurse practitioner and I went back to see the mother and explain to her that she had the right not to sign the consent form but that she needed to be fully informed before she made that decision. The nurse practitioner told the mother that there was a 10% risk of intraventricular hemorrhage in her baby's head during the first year of life without prophylaxis vitamin K and also explained the importance of the eye ointment to protect her baby's corneas. Mom said she would think about it. Later that day, before she left with her infant, she asked for both the eye ointment and vitamin K for her baby. I thought to myself, 'I'm so glad she thought about what her baby needed, instead of her own frustration at being here.'"

vitamin K deficiency within 2 to 3 days following birth if the vitamin K prophylaxis is not given. Severe consequences may occur in infants not given vitamin K, because central nervous system hemorrhages commonly occur (Taeusch & Ballard, 1998).

First Bath

The first bath is given in warm water with a mild soap to remove amniotic fluid, blood, vaginal secretions, and other

Figure 32-6 A newborn's first bath.

residues on the skin (Figure 32-6). The nurse should anticipate any chilling effect from the circulating air or the bath and take precautions to ensure that the infant is kept warm and dried quickly. Institutional protocol may recommend painting of the umbilical cord with a bacteriostatic dye. Some institutions have discontinued this procedure because the dye does not hasten the drying process of the cord or prevent umbilical cord infections. If the painting is done, the nurse must inspect and record the number of cord vessels present before the painting. It is difficult to inspect the cord for the presence of vessels when it has dye on it or when the cord has partially dried.

After being bathed and swaddled in blankets, the infant is ready to be examined in more detail. Nurses

Nursing Tip

UMBILICAL CORD VESSELS

The infant should have an umbilical cord with three vessels, two arteries, and one vein. Two-vessel cords (one artery, one vein) must be reported immediately: they are associated with renal and cardiac anomalies. Ultrasound examinations and echocardiograms are recommended in these cases to confirm any abnormality that might be present. The most common renal abnormality characterized by a two-vessel cord is renal agenesis, which affects the infant's urinary output because a kidney, usually the left, fails to develop normally in utero.

Table 32-1 Critical Pathway for Timing of Newborn Assessment

Assessment	Age (hrs)

perform several different assessments on newborns after delivery. The first assessment is accomplished during the transition, the first 4 to 6 hours of the infant's life. The infant is monitored for temperature and cardiac and respiratory stability during transition. After transition, the nurse performs a full physical examination, including a general assessment, physical examination, and gestational age assessment. Once this examination has been completed, the infant is monitored for any changes through periodic nursing assessments done at each nursing shift, brief examinations two or three times during the shift, and interactional assessments with the mother, father, and other family members. The purpose of all these assessments is to ensure the infant's physical and biologic stability and assist the nurse in planning for the family's adaptation to and care for the infant (Table 32-1).

GENERAL ASSESSMENT

Visual inspection of the infant in the crib forms the basis for a general nursing assessment. From inspection, the nurse can determine the infant's body position, skin color,

respiratory effort, relative size and length, and state of mind (asleep, awake, quiet-alert, or alert) and evaluate security measures in place to guarantee the identity of the infant and protect it from abduction. Infants in the nursery have nurses who are charged with the care of infants who are not at mother's bedside. Infants rooming-in with mother are cared for by the mother with the assistance of the nursing staff when needed.

Position

A newborn's position leaves clues as to its innate position of comfort. Many infants adopt their in utero position after delivery to enhance their feelings of security after separating from mother during the birth process. The normal body position of the newborn is flexion of both upper and lower extremities. The flexion of the upper extremities allows infants to touch their face with their hands, suck their fingers, and explore their new environment.

Lower extremities may be extended, fixed in one position from delivery position, or flexed. Usually, positioning in newborn infants is symmetrical. Asymmetrical posi-

POSITIONING OF INFANTS

The American Academy of Pediatrics (2000) recommends that all infants be placed to sleep in a non-prone position to prevent Sudden Infant Death Syndrome (SIDS). Placing infants in the supine position offers the best protection against SIDS. When using the side-lying position, caretakers are advised to bring the dependent arm forward to lessen the likelihood of the infant rolling to the prone position.

tioning may suggest an initial nursing assessment of injury related to birth trauma and may warrant further investigation. Failure to move an extremity or diminished extremity movement, unilaterally or bilaterally, would be a cause for concern.

Skin Color

Skin color becomes a vital part of the general nursing assessment because the newly born infant may show signs of jaundice or cardiovascular instability in the first several days of life. Jaundice in the newborn is characterized by a gradual yellowing of the skin that develops from head to toe. Visual jaundice in a newborn infant less than 24 hours old is considered to be “pathologic jaundice” or “hemolytic jaundice” and most likely results from serious blood incompatibility between the mother and the infant. “Physiologic jaundice” or “non-hemolytic” jaundice is the gradual yellowing of the skin in newborn infants that occurs after 24 hours of life, which may have a non-hemolytic cause. The three most common of these causes are: 1) the failure to adequately process bilirubin through inadequate intake or elimination, 2) traumatic birth injuries, and 3) minor blood incompatibilities. The neonatal jaundice that occurs with breastfeeding is usually not seen in the early postpartum period; this type of jaundice becomes visible in newborns that are approximately 1 week old and may persist during the entire course of breastfeeding.

Nursing Alert

JAUNDICE

Visible jaundice in a newborn infant under 24 hours of age must be reported immediately. A rate of rise in bilirubin levels of more than 0.5 mg/dL per hour should be investigated.

Additionally, congenital heart defects may be initially detected by skin pallor that does not improve with time. Skin color in all infants should be pink, indicating successful cardiac perfusion to the extremities. **Acrocyanosis** is common in newborns, localized to the hands and feet (Figure 32-7). Central cyanosis in the newborn has been described as a blue tint of the lips, gums, tongue, fingertips, and toes, with pallor noted underneath the eyes and on the cheeks. This is an indication that the newborn has a circulatory problem and needs immediate attention and investigation into the suspected cause of the cyanosis. Stimulating the infant to cry, changing the infant's position to increase movement, or gently patting the soles of the feet should result in a rapid pinkening of the skin to a red color as the infant increases respiratory and heart rate. The length of time the infant takes to return to the previous skin color forms the basis for the visual nursing assessment of the infant's cardiovascular system.

While the development of jaundice and pallor are the most critical problems found during the nursing assessment of skin, neither jaundice nor pallor of the skin can be determined accurately without knowing the infant's normal skin color. Infants of color, particularly African American and Hispanic infants, may have skin colors that have yellow tones that may make it difficult for the nurse to determine normal skin color. Strategies to improve the accuracy of assessment of infant skin include using more than one light source, examining all skin surface areas of the infant, and palpating over bony prominences. Light sources in areas where infants are examined vary in intensity from overhead room lights and hallway lights to lights in radiant warmers and fluorescent lights. Nurses who examine infants using more than one light source can identify skin color more accurately. Examination of the entire skin surface of the infant, paying particular attention to the palms, soles of the feet, lips, and behind the ears, adds to the

Figure 32-7 This newborn's hands show acrocyanosis.

REFLECTIONS FROM A NURSE

"It was two days before St. Patrick's Day and I had just finished the physical examination on a newborn girl with bright red hair and creamy white skin. I showed her off to everyone in the nursery, because you just don't see a lot of newborns with red hair. We (the nurses) joked that she came just in time for St. Patrick's Day. When I took her to her mother, I had to go in the room twice because I didn't see any Caucasian mothers in the room. I pulled her mother's chart and checked the ID bracelets just to make sure. I presented her to her mother, who was a very dark-skinned African American woman. She told me that all her babies had been born with red hair and this one looked like all of her other babies! I admitted my awkwardness and it gave me the opportunity to talk with this mother on a completely different level about her baby and her other children. I was so glad I had this experience. It totally changed my thinking about skin color in babies."

accuracy of the determination of normal skin color for the infant. Brief palpation of the infant's bony prominences, including the nose, sternum, sacrum, wrist, and ankle, by applying gentle pressure for 1 second yields the normal white color of blanching (first stage), followed by the "true skin color" (second stage), and ending with the skin color that reflects the ethnic heritage of the infant (third stage). Second-stage skin color (determined by using this method) that is not pink or pink-white and remains yellow or pale white is indicative of jaundice or pallor.

Body Size

Infant size is visually approximated for head-to-toe length and abdominal girth. The nurse's opinion as to whether the infant is small, medium, or large is later correlated with the graphed size classification. These physical parameters form the foundation for all future assessments of growth and development. The nurse also visually con-

firms that the head of the infant appears to be the largest body part.

Reactivity

The infant's reactions confirm the neuromuscular development of the infant. Is the infant asleep, awake, awake and quiet, or alert? Is the infant beginning to respond to the nurse by looking and moving extremities? Or is the infant actively alert, starting to fuss and cry? These are all discrete behavioral levels of awareness, or states (Brazelton, 1973), and require the infant to progress or regress from one to the other. The official behavioral state terms are deep sleep, light sleep, drowsy, quiet alert, considerable motor activity, and crying (Brazelton, 1973) (Figure 32-8). The implication of this assessment is that the term infant has developed a mature neuro-organizational system that eases the transition from one behavioral state to another (D'Apolito, 1991). Term infants exposed to cocaine in utero have lost the ability to change behavior levels in an orderly manner. Their behavior is erratic and disorganized, with excessive responses to stimuli and lengthy or absent transition periods between behaviors (Napiorkowski, Lester, Frier, Brunner, Dietz, Nadra, & Oh, 1996).

Observing the infant's response to the presence and voice of the nurse confirms the infant's responsiveness and behavioral organization levels. Infants who are irritable or who appear to be overreacting to voices, touch, or movement need comforting to assist them in calming their behavior. Swaddling in blankets, cuddling, rocking, and holding infants are interventions that the nurse can implement in the nursery. A complete physical examination should not be done on infants who are already irritated, because the examination leads to further disruption and disorganization of the infant's behavior.

Identification

All infants born in birthing centers, health care institutions, or hospitals are monitored to prevent misidentification, switching, or abduction. It is estimated that 12 to 18 infants are abducted by non-family members or strangers from health care facilities each year (Schuman, 1999). All nurses must become familiar with the infant security system used in their area of practice. Identification bracelets, "name-alert" cards for mothers with the identical last name, video cameras, door alarms, name badges to identify institutional personnel, and other sensing devices are often used to allay parental fears about the whereabouts and safety of their infant (Figure 32-9). Postpartum nursing units and nurseries traditionally receive many daily visitors because friends and family members want to welcome and see the new arrival. Increased traffic patterns between these two nursing units lead to crowding and increased opportunities for security violations. Nurses must also be alert to the

Figure 32-9 Matching identification bands are placed on infant, mother, and father; infant is footprinted.

Box 32-2 Preventing Infant Abductions

1. The identity of mothers of newborn infants is verified by their identification bracelet or other institutional device for identification.
2. Infants are identified by wearing two identification bracelets or one bracelet and another device (sensor or tag) (Figure 32-10). These security devices are placed on the infant in the delivery room. The nurse must verify that all identification devices, in addition to name cards, paperwork, charts, or anything else placed in proximity to an infant, belongs to that infant.
3. All identification devices of a mother and her infant are checked by the nursing staff before an infant is matched to its mother for visits or rooming-in. These devices are continuously re-checked by the nursing staff at the end and at the beginning of each nursing shift.
4. Transportation of infants from one unit to another or to another department for examination should be done only by authorized nursing staff, who should remain with the infant until the examination is complete and return the infant to its original location.
5. The infant should not be left by nursing staff with anyone but the birth mother, unless an official agency involved with parents and family has stipulated to the contrary. This includes persons claiming to be the mother's sister or spouse, father of the infant, grandmother, family relative, or adoptive mother.
6. When the birth mother is ill and is unable to take care of her infant, the father assumes responsibility for the infant and receives an identification bracelet to be matched with the infant's. In many hospitals, the father routinely receives an ID bracelet as well.
7. Family members or relatives may only see the infant while it is in the nursery. The mother's written permission is required for them to be able to hold or feed her infant in the nursery under nursing staff supervision.
8. The mother of the infant is instructed by the nursing staff never to give her permission to let someone that she does not know take or hold her infant.
9. All nursing staff are identified through their identification badges, not by the clothes that they wear. Nursing staff must continually reinforce their identity with mothers of newborns and be available to accompany them at all times for their security and safety.
10. All nursing staff should be aware of the institutional code for infant abduction and the procedures to follow should this event occur.

Figure 32-10 Application of a heel sensor.

location of the infant at all times and continually share this knowledge with the mother. Refer to Box 32-2.

PHYSICAL EXAMINATION

After the general nursing assessment is complete, the nurse begins the physical examination of the infant if the infant appears calm or resting. The manipulation and examination of the infant should not stress or irritate the infant.

Weight, Measurement, and Vital Signs

The infant's weight in grams and length in centimeters was determined in the delivery room and during the transitional period. Average weight for a term newborn infant is 3400 g (range, 2500 to 4300 g) and average length is 49.6 cm (range, 45 to 54 cm) (Fox, 1997). The frontal-occipital circumference (FOC) is measured in centimeters with a

Newborn Assessment

Once the infant enters the nursery, the nurse conducts a complete head-to-toe physical assessment to determine the infant's health status. The pictures in this story are arranged in order of priority, from most to least important. Each of these photos can be compared to the Ballard scale.

A general inspection is done first to identify abnormalities. A normal newborn assumes a flexed position.

Skin is inspected for color and texture. A full-term infant may display signs of skin dryness and cracking. Acrocyanosis may be present in the hands and feet but should diminish.

The newborn's heart is auscultated for rate and rhythm.

The lungs are auscultated to ensure expansion of both lungs and absence of rales or rhonchi.

Sometimes suctioning is required to remove residual fluid from the infant's mouth.

The newborn's first blood pressure measurement is taken.

The axillary body temperature is taken.

The newborn is weighed.

The infant's head-to-toe length is measured.

The infant's head circumference is measured.

The infant's chest circumference is measured.

The infant's abdominal circumference is measured.

The infant's head is inspected for molding and suture lines are palpated.

The face is inspected for symmetry, birth marks, milia, and nevi ("stork bites") over the forehead and eyelids.

The mouth is inspected for natal teeth and abnormalities of the hard and soft palate; the tongue should be at midline.

Femoral pulses are palpated.

Brachial pulses are palpated.

Ortolani's maneuver is done to check for hip dislocation.

Inspection of the genitalia. The nurse is palpating the scrotum to check for descent of the testes.

The spine and skin on the back are inspected for alignment, breaks in skin, moles, birth marks, or markers along the spinal column. This infant has a Mongolian spot near the base of the spine; this is a normal finding.

During the examination, the nurse will check certain reflexes. The presence of these reflexes suggests maturity of the neonatal neurological system.

This is the rooting reflex. The infant turns his head and opens his mouth when the perioral area is stimulated.

Sucking reflex is sometimes demonstrated spontaneously during the examination.

The tonic neck or fencing reflex—note the leg extension and the partial extension of the arm on the side the head is turned to, and the flexion of the arm and leg on the opposite side.

The grasp reflex is assessed.

The Moro reflex is assessed.

The head lag or traction reflex is assessed.

A

ssessment of Physical Maturity Using the Ballard Scale

Skin is assessed using the six parameters of the Ballard Scale. This post-term newborn shows skin cracking and peeling.

The amount of lanugo is estimated using the six parameters of the Ballard Scale.

The plantar surface of the foot is assessed for creases.

Maturity of nipple buds is estimated.

Nipples are measured.

The amount of cartilage in the ear is assessed.

The male genitalia are assessed to determine if the testes have descended and if rugae are present.

The female genitalia are assessed to determine maturity of development of the labia and clitoris.

*A*ssessment of Neuromuscular Maturity

Degree of flexion is determined.

Square window determination.

Popliteal angle.

Scarf sign in term infant.

Scarf sign in preterm infant.

Nursing Tip

CALCULATING POUNDS FROM GRAMS AND INCHES FROM CENTIMETERS

Infant weight is usually a whole number indicating how many grams the infant weighs. Divide this number by 1000: $1000 \text{ g} = 1 \text{ kg} = 2.2 \text{ lbs}$. Multiplication of the number of kilograms by 2.2 yields the number of pounds of infant weight. Less than 1 pound can be converted to ounces by remembering that 16 ounces = 1 pound. One can multiply the grams by 0.0022 to convert to pounds. To convert grams to ounces, divide the grams by 28.35. For example a 7 pound 8 oz baby would be 3402 grams. The length of the infant in centimeters is divided by 2.5 to convert centimeters to inches: $1 \text{ in.} = 2.5 \text{ cm}$.

measuring tape to determine head size. The measuring tape is gently placed around the infant's head at the largest part of the occipital area and gathered over the forehead, resting on top of the eyebrows. The largest of three attempts is recorded by the nurse. Normal head circumference for a term infant at birth ranges from 33 to 38 cm (Johnson & Oski, 1997). The weight, length, and head circumference measurements are plotted against the gestational age of the infant to determine the size category of the infant (Figure 32-11). Size categories are small for gestational age (SGA), appropriate for gestational age (AGA), and large for gestational age (LGA).

Vital signs are taken by the nurse and charted. Heart rate and respiratory rate are determined by auscultation. Temperature is recorded with an axillary thermometer or tympanic membrane thermometer. Blood pressure is checked on both the thigh and the arm of the infant. Systolic blood pressures range from 50 to 90 mm Hg and diastolic blood pressures range from 20 to 60 mm Hg (Fox, 1997). The systolic blood pressure of both the thigh and arm should be equal. A decrease of 10 mm Hg or more in the thigh in comparison to the arm may indicate **coarctation of the aorta**. This may also be indicated with a systolic blood pressure of more than 90 mm Hg (Fox, 1997).

Gestational Age Assessment

Since 1967, when the American Academy of Pediatrics recommended that all newborns be classified by birth weight and gestational age, the modification of the Dubowitz scoring system by Ballard, Khoury, Wedig, Wang, Eilers-Waisman, & Lipp (1991) remains the most popular method

for determining gestational age. This examination provides a score of neuromuscular and physical maturity that can be mathematically extrapolated onto a corresponding age scale to reveal the gestational age in weeks. Other gestational age examinations include fundal height before delivery, ultrasonography, and eye lens vascularity. Approximation of gestational age at delivery can be obtained by date of the mother's last menstrual cycle. This information is not as accurate as physical examination for gestational age. Gestational age assessments are often done by nurses on normal newborns and reported in the infant's chart.

The Ballard Gestational Age by Maturity Rating (Ballard et al., 1991) consists of two scoring systems: neuromuscular maturity and physical maturity of six characteristics each. Scores from each system are added together and mathematically extrapolated on the maturity rating scale to determine the gestational age by examination (Figure 32-12). The systems scored reflect the decreasing flexibility of muscles and joints in prematurity and the return to original positioning after movement indicative of a mature term infant. This examination is usually performed by the nurse within the first 12 hours of life and is more accurate when done on term infants between 10 and 36 hours of life (Gagliardi, 1993). It is not necessary to perform this examination in any order of categories to be assessed.

Maturity may occur at different rates among these categories. A score of 4 in one category does not mean that all subsequent categories must be scored as a 4. The examiner may strongly feel that a half-score is needed in one particular category because the infant exhibits a characteristic that falls between two scoring options. This is a valid choice, and half-scores are seen quite often in these assessments. These assessments are illustrated in the accompanying photo story.

Posture: Posture is the natural position that the infant assumes on its back. Both arm and leg positions are assessed in this category, and this is matched to the best picture of upper and lower extremities for scoring.

Square window: Wearing gloves, the examiner uses his or her thumb to gently press the infant's wrist and palm toward its forearm. Either the angle that the wrist and the third and fourth fingers make against the forearm or the angle that the wrist and thumb make against the forearm is used for scoring purposes.

Arm recoil: This category is scored by the lateral or inferior extension of both arms after flexing them at chest level. After release from extension, the amount of return to original position is observed by the nurse and scored. This assessment is often used to confirm brachial plexus injuries or fractured clavicles in the newborn when movements of the arms are observed to be unequal.

Figure 32-12 New Ballard score (Courtesy of Mead Johnson Nutritionals).

Popliteal angle: This is the assessment of the angle created when the knee is extended. The infant is assessed in the supine position with the pelvis flat and the thigh of one leg resting on the abdomen while the knee is extended by exerting upward pressure on the heel of the leg with the examiner's finger until resistance is met.

Scarf sign: This is placement of the infant's hand to the opposite shoulder. It is scored by observing where the elbow of the arm that was moved falls. The dotted line in the scoring category picture represents the sternal border or midline. In the supine position, the infant's hand is grasped between the thumb and first finger of the nurse's hand and, in one sweeping

movement, the nurse attempts to place the hand on the opposite shoulder. Using a finger, the nurse marks on the infant's chest where the elbow of the infant falls and scores this category accordingly.

Heel-to-ear: This category assesses hip flexibility in infants. With the infant in the supine position, with the pelvis on a flat surface, one leg is gently extended and moved toward the infant's head on the corresponding side. When resistance is met, the visual distance between the ear on the infant's head and the great toe of the foot, along with the leg position, is scored. Infants who experienced breech positioning or who are suspected of having **developmental dysplasia of the hip (DDH)** may show a great amount of flexibility in this category.

Skin: Scoring in this category is based on palpation and visual inspection. Skin texture, transparency, relative thickness, and flaking and peeling of the epidermis are noted. Transparency, defined as skin through which veins can be seen, is evident in premature (preterm) infants and disappears with increasing maturity. Flaking of skin and peeling with wrinkles occurs in post-term infants.

Lanugo: Lanugo is the fine hair seen mostly on the backs and arms of premature infants. It eventually thins out in the lumbar region and disappears, leaving small traces on the shoulders. Stroking the infant's back while in the prone position will assist the nurse in identifying the lanugo that still exists apart from the infant's natural body hair. Mexican-American infants normally have thin, dark body hair that may cover their entire back and shoulders. This needs to be distinguished from real lanugo, which is lighter in color and softer and curls at the ends.

Plantar surface: Creases on the soles of both feet are scored according to the extent to which the creases cover the soles. The best way to visualize the extent of plantar creases is to gently curl the infant's toes toward the heel, and determine the score.

Breast: The amount of breast tissue is approximated by gently measuring the tissue present on the infant using a measuring tape in millimeters or by grasping the tissue between the examiner's thumb and forefinger. In addition, the bud and areola are inspected for size and stippling. Lastly, the area of breast tissue is palpated to determine its elevation from the chest wall.

Eye and ear: Eyelids should be open and should open easily in the mature infant. Ears are inspected for incurving of the pinna and palpated for a determination of the thickness of cartilage. The upper lobe recoil is performed bilaterally to validate the return to

the posterior upright position when moved anteriorly and inferiorly. As pinnal incurving occurs from the top of the lobe down toward the bottom of the lobe, some mature infants may only have the upper portion of the pinna on the ear lobe curved in, with the remainder flat. The nurse may want to look at the ears of the infant's parents and other family members before scoring this category.

Genitalia: Both male and female genitalia are assessed with the infant in the supine position and the legs abducted. At approximately 35 weeks gestational age, the testes descend into the scrotum from the inguinal canal and rugae start to appear as creases on the surface of the scrotum. Deep creases gradually develop as crevices on the scrotum as the infant becomes more mature. Visualization of a pendulous scrotum occurs in the supine position with the lower extremities abducted. In this same position, female infants can be assessed for the covering of the clitoris and the size of the labia majora. The distance between the edges of the labia majora and how much of the female genitalia is covered can also be visualized and scored.

Once the scoring is complete on the Ballard Newborn Maturity Rating, the scores from both the neuromuscular and physical maturity categories are totaled. This score is compared mathematically to the gestational age (in weeks) through a simple proportionate formula that equates the score range with the gestational age in weeks and calculates the exact position of the score within that range. Nurses should note that maturity scoring does not directly translate to gestational age in weeks. Often examiners make this mistake and estimate an infant's age at birth to be much younger than it is. An infant determined to be

HOW TO CALCULATE GESTATIONAL AGE

Your newborn's gestational age examination score of 34 falls between the scores 30 and 35 and occupies $\frac{4}{5}$ of the score range from 30 to 35. Correspondingly, the exact age in weeks must also occupy $\frac{4}{5}$ of the age score range of 2 between 36 and 38. Solving this simple ratio equation, you note that $\frac{4}{5}$ of 2 equals 1 $\frac{4}{5}$, which, multiplied by 7 (days in a week) and added to 36, reveals a gestational age of 37 $\frac{4}{5}$ weeks for a maturity score of 34.

less than 37 weeks' gestational age is called **preterm**, or premature. An infant whose score falls between 37 weeks' and 42 weeks' gestational age is called **term**, and the infant that is scored beyond 42 weeks' gestation is called **post-term**.

Systems Assessment

The nursing assessment of the newborn infant's physical characteristics begins after completion of the general assessment and the gestational age assessment. The examination is initiated by placing the infant in the supine position and usually proceeds from the assessment of the skin first, followed by a head-to-toe examination. This assessment follows the inspection, light palpation, deep palpation, and auscultation sequence of nursing assessments except when the abdomen of the infant is examined. Inspection, then auscultation, followed by light and deep palpation is the proper sequence to follow when examining the abdomen. The examination may be performed on a radiant warmer to preserve infant temperature stability, in the infant's crib in the nursery, or at the mother's bedside. Performing this examination at the mother's bedside allows the nurse to introduce the mother to her infant and display the unique characteristics of this infant to the mother. It also allows the nurse to begin the interactional assessment of the mother and infant by observing the mother's attention to her infant, talking to her infant, tone of voice used, and holding position.

Integumentary System

The skin and all the other elements of the integumentary system, i.e., hair and nails, are examined for color, texture, distribution, disruptions, eruptions, and distinguishing characteristics or birth marks. When performing the skin

assessment, the nurse should make sure that the room is well-lit and be willing to use extra light sources for accuracy. The color of a newborn's skin should be pink, indicating good peripheral cardiac perfusion. After blanching over bony prominences, the underlying skin color should be pink-white before it returns to its natural pigmentation. Skin color can also be assessed by a visual inspection of the infant's mouth, tongue, and gums. These areas should always display a healthy pink-red color, darkening to bright red when the infant is crying.

Common Variations

Wearing gloves, the nurse inspects and lightly palpates the scalp and body hair for texture and distribution. Mexican-American, Asian, and African American infants are often born with a full head of scalp hair and have some body hair on their back, shoulders, and buttocks. Hair is described as fine, thick, curly, or straight and the color and location are noted (Figure 32-13). Mexican-American and Asian newborns have dark, straight hair at birth. The hair on African American newborns is usually tightly curled and softer in texture. Eyelashes and brows are also inspected. Nail beds are examined on both fingers and toes for shape, length, and color. Many infants are born with long fingernails that may cause facial scratches as the infant feels and explores using fingers (Figure 32-14). Scratching by a newborn infant is controlled by placing mittens on the hands because newborn nails are very soft and flexible and difficult to trim with accuracy.

Infant skin should feel soft and smooth in term infants, and leathery with cracking and peeling in post-term infants. Breaks in the skin are noted to be either disruptions or eruptions. Disruptions include any break in skin integrity, including lacerations, electrode marks, and peeling layers. Forceps deliveries or vacuum extractions may

A.

B.

Figure 32-13 Newborn hair varies in texture, from straight (A) to curly (B).

Figure 32-14 This newborn has facial scratches from long fingernails.

break the skin on the scalp or face, leaving marks or bruises. Scalp electrode monitors leave small puncture sites in the infant's scalp that may not have a scab covering them at the time of the nursing assessment. Skin peeling is common in those infants classified as post-term. Frequently, infants are born with a condition called **pustular melanosis**, in which small pustules are formed before delivery. The pustule disintegrates, leaving behind a small residue (scale) in the shape of the pustule, which later develops into a small flat spot called a macule, 1 to 2 millimeters in diameter. These small macules are numerous, look brown similar to freckles, are located on the chest and extremities, and appear to be a rash (but are not). Pustular melanosis is more commonly seen on African American infants than on Caucasian infants.

Nursing Tip

NAIL LENGTH IN NEWBORNS

Nurses who are experienced in examining newborns report: "the longer the nails, the more mature the baby." They are basing this observation on the time of development of fingernails and toe nails, which occurs late in the third trimester of pregnancy.

A greenish color around the nail bed of a finger or toe may indicate **meconium** staining from in utero exposure to meconium before or during delivery. Two other places where the nurse would see meconium staining on a newborn infant are the umbilical cord and the ear canals.

Some of the skin eruptions that occur in the early neonatal period are classified as normal variations. Small, singular, white papules that appear to be tiny pimples may be seen on a newborn's face, particularly on the chin. This skin condition is called **milia** and is one form of a sebaceous cyst. One or two white, pinhead-sized inclusion cysts may be seen on the penis or the scrotum of male infants or on the areola of female infants. Separate from milia and inclusion cysts, the infant may have acne, a skin eruption that usually occurs with puberty but, in infancy, is related to excessive amounts of maternal hormones. Neonatal acne eventually disappear from the infant's cheeks and chest. The most common normal skin eruption seen in newborns is **erythema toxicum**, a rash that generally occurs on the face and chest first and spreads to the rest of the body. The cause of this rash is unknown, and it may persist on the infant for a month after delivery. It begins with small, irregular, flat patches of redness on the cheeks and progresses to singular, small, yellow pimples on an erythematous base, as it moves to the chest, abdomen, and extremities. This skin condition appears particularly disturbing and frustrating to parents because there is no treatment to speed up its departure. It appears, remains, and disappears on its own schedule.

Another skin eruption is a blister formation on the fingers, wrist, or upper lip of the infant from sucking before and after delivery. These are not cause for alarm, and parents need to be reassured that these blisters or calluses will go away.

Distinguishing characteristics of the newborn's skin are either normal variations in skin color, birth marks, or evidence of birth trauma from the delivery. Normal variations in skin color include the dark blue, grey, or purple diffuse color seen on the buttocks of infants called **Mongolian spots**, which also appear on their shoulders, forearms, wrists, and ankles (Figure 32-15). These spots will

Figure 32-15 Mongolian spots.

Figure 32-16 Mottling.

fade and disappear as the infant grows older. Some newborn skin shows a “cobblestone” appearance of pink-white areas outlined with a darker pink border (Figure 32-16). This **mottling** (called *cutis marmorata*) of the skin is common in newborns and results from the infant’s vasomotor response to a lowered environmental temperature outside the womb. As the newborn adjusts to extrauterine life, this mottling disappears. Additionally, maternal hormones during labor and delivery may cause a normal darkening of the skin in the genital areas of both male and female infants.

Birth marks on a newborn infant are different from other marks that are the result of trauma to the infant from the delivery process. Birth marks are usually small, flat areas of color that may be white, tan, brown, red, or blue. Borders may be irregular. The nurse documents the location and color of the birth mark (Figure 32-17). Any area of colored skin that contains hair or is located at the midline of the infant anteriorly or posteriorly should be investigated for underlying tissue involvement. A white or pale

Figure 32-17 Birth mark.

patch of skin usually represents an area of hypopigmentation and, by itself, is not an indicator for concern. However, numerous areas of hypopigmentation, including patches that have a leaf pattern, must be reported immediately. These patches may be found on the chest, back, extremities, and in the axilla. A neurologic condition, tuberous sclerosis, may be suspected in infants who have a hypopigmented skin patch that resembles a patterned leaf. Tan spots on the skin are often called *cafe-au-lait* marks and are very difficult to see on an African American infant. Many infants are born with these, and it is only a significant finding when the nurse counts six or more that are larger than 1 centimeter in diameter. Infants with these large *cafe-au-lait* spots at birth may be at risk for developing type I neurofibromatosis and need observation during infancy for any tumors that develop underneath the skin.

Brown skin marks or brown nevi (singular, nevus) are birth marks in which the color may vary from brown to intense black. Nevus have been thought to be an early form of a precancerous lesion (Seidel et al., 2001), and parents are taught by nurses to observe and report any change in color, shape, size, or elevation of these marks during the lifetime of their child.

A red birth mark, or *nevus flammeus*, is often seen at the nape of the neck (“stork bite”) and on the face between the eyebrows or on the eyelids, nose, or upper lip. Appearing pale red in color, the *nevus flammeus* often has an irregular border or “splash mark” appearance. Red birth marks often turn bright red when the infant is crying, and gradually fade as the infant gets older. Other red birth marks observed in infancy are capillary hemangiomas, which may appear as red, raised lesions anywhere on the infant’s body. They also contain areas of purple, blue, or white skin within the lesion. The nurse can address the parents’ concern about this lesion by explaining that it will grow larger, undergo a process of involution, and then gradually disappear during the first year of life. These lesions are not surgically removed unless they interfere with a vital system or are located on the face.

A blue nevus is a small, discrete blue or blue-black birth mark. It is usually found on the buttocks and hands and feet. This nevus is often mistaken for a Mongolian spot when located on the buttocks. It is differentiated from a Mongolian spot by its distinct borders and brighter color, which is different from the darker diffuse purple-blue-gray coloring over a general area characteristic of Mongolian spots. They are usually no larger than one centimeter in diameter.

Common Problems

Marks on an infant that are the result of birth trauma are usually characterized by the initial red imprint of the traumatizing instrument (e.g., forceps) and their color follows the normal progression of the skin color changes with a

bruise. Common areas to inspect for birth injuries are the scalp, face, shoulders, arms, legs, and feet. Marks from birth trauma are commonly seen in large infants when it is difficult to deliver the head or rotate the shoulders. Infants whose delivery position is breech or whose presenting parts are either the legs or feet can often show extensive bruising or edema from attempts to deliver the infant. In some cases, birth trauma may not be evident by a difference in skin color or edema at the injury site. These infants become extremely irritable when their position is changed or during simple extremity movements. Observation of infant behavior when the nurse examines the skin of the infant in the prone and supine position may lead the nurse to further investigate additional areas.

The presence of petechiae on the infant's skin that cannot be attributed to birth injury or trauma must be investigated further. Petechiae may represent an underlying infection, a hemorrhagic process, or congenital condition (congenital rubella). Petechiae should be reported immediately because many of the causes may be life-threatening to the infant if left untreated.

Purple or dark red marks that are extensive and differ from nevus flammeus are called port wine stains. Port wine stains are usually found on the head over the eyelid along the trigeminal nerve tract. These birth marks usually do not cross the midline and may be seen on the trunk or extremities. Neurologic assessments should be performed on all infants with port wine stains. Parents can be reassured that pulse-dye laser surgery can achieve cosmetic correction of the lesion at a later age (Seidel et al., 2001).

Colored skin lesions that contain two distinct areas of color, are extensive, cover a large amount of body surface, or contain hairs or a tuft of hair should be evaluated by a dermatologist. These skin lesions may indicate a defect in the underlying structures, and often ultrasound is indicated to evaluate the tissue underneath the skin. Skin nevi that contain hairs or a tuft of hair are called hairy nevi and, when present on the posterior surface midline in conjunction with the spinal column, may indicate a vertebral defect. The nurse should inspect and palpate the spinal column and sacrum for dimpling or depressions in the skin that may also be an indication of a vertebral defect. Spinal ultrasound examination of the spinal vertebrae is necessary to confirm any defects that would indicate the presence of spina bifida or spina bifida occulta.

Small crops of blisters or a single blister found on full examination may require further evaluation. Blisters that are not located on the thumb or hand (sucking blisters) or on the extremities in conjunction with other lesions indicative of pustular melanosis are a cause for concern. Groups or crops of blisters on a presenting part of the infant's body are caused by exposure to herpes as the infant passed through the birth canal. The most common location for these blisters is on the infant's scalp, near the hair-

line, or around the scalp electrode monitor site. Because this condition can be life-threatening to the infant, this finding must be reported immediately.

Newborn skin color that remains red or dark pink may be an indication of plethora. Plethora may be caused by polycythemia vera or hyperthermia. Polycythemia vera is a condition in which an increased number of red blood cells in the infant's bloodstream occurs as a result of backflow of maternal blood into the infant when the cord was cut. This diagnosis can be confirmed by a capillary hematocrit value of 65 or greater and a venous hematocrit of 60 or more (Seidel et al., 2001). Treatment of polycythemia vera includes admission to the intensive care unit for monitoring and a partial exchange transfusion.

Hair patterns may present a problem in infancy. Hair distribution is described in the nursing assessment, and the nurse notes the texture, color, and distribution. Visually, the nurse determines any disruptions to the distribution of hair or any areas that contain hair that is not uniformly distributed over the scalp with distinct hairlines. Hair that extends over the forehead, blurring the forehead and shortening the distance between the hairline and the eyebrows, raises a concern because of its association with congenital syndromes. Particular attention should be directed toward those areas of hair that are lighter in color, sections of hair colored very differently in comparison to the rest of the scalp hair, and hair patterns that appear to have a circular design (whorls). White hair patches in the midst of darker colored scalp hair and circular hair patterns may indicate a defect in underlying structures or be initial findings in congenital syndromes. These findings should be documented by the nurse and reported immediately for further evaluation.

Nursing Implications

An accurate assessment of the infant's skin allows the nurse the opportunity to prepare for conditions that might adversely affect the infant and to show common skin variations on the infant to the parents and any other family members that are present. New parents are especially concerned about "marks" or "spots" on their babies, and the nurse can address these concerns as well as remove any fears that the parents or family members may have voiced.

Head, Ears, Eyes, Nose, and Throat

The head, ears, eyes, nose, and throat (HEENT) of the infant are examined next, after the skin has been assessed. Visual inspection guides the nursing assessment of this system. The nurse inspects the face for symmetry and placement of eyes, nose, lips, mouth, and ears. The shape of the eyes, nose and mouth are also examined, and any

NEWBORN EXAMINATION

The nurse should wash her hands and don clean gloves before touching the newborn during the examination.

movements of the lips and eyelids are observed. Damage to cranial nerve VII (facial nerve) from trauma during the delivery process can result in one side of the mouth or tongue drooping, unequal cheek muscle movement or lack of appropriate eyelid movement. Ear shape, size, and position on the head can be examined from profile head positioning as well as the en-face position. Low-set ears bilaterally may indicate the need to examine the infant for other physical characteristics of syndromes. It is common for infants to be born with one ear set a little lower than the other. Eyes are described in terms of color and spacing on the forehead, and whether lids are open or closed. Nares should be open bilaterally, and the nasal bridge should not have a lateral deviation resulting from the delivery process. Upper and lower lip formations should be approximately the same size with the same color as the tongue and buccal mucosa inside the mouth. A chin should be visible and more prominent when the infant's head is placed in the profile position. A small jaw (micrognathia) viewed from the profile position may cause concern about proper tooth development, sucking, swallowing, and later tongue movement inside the mouth for speech.

Common Variations

Palpation begins with the head to determine the spaces between suture lines, the width of the fontanels, and the location and extent of edema from the delivery process. The sutures are felt as bony ridges, with spacing between them to indicate the distance between the borders (Figure 32-18). The **anterior fontanel** is a diamond-shaped open space formed by the anterior-posterior sagittal and frontal sutures and the lateral coronal suture. The area of the fontanel can be determined by feeling its borders and using the nurse's finger for measurements; 2.5 cm, or 1 inch, is the distance from the tip of the finger to the first finger joint). Some infants may have fairly large anterior fontanels (from 5 to 7 cm), and conversely, others may have small anterior fontanels (from 1 to 2 cm). The **posterior fontanel** is a small, triangular-shaped space formed by the sagittal suture and the posterior lateral suture and called the lambdoidal suture. This fontanel is usually 1 cm at its widest point and, on palpation, may be closed, with only a slight indentation

Figure 32-18 Sutures and fontanels.

at the initial examination. This is not an unusual finding. The anterior fontanel must be open to provide for the expansion of the bones of the skull for brain growth during the first year of life. Spaces between suture lines are reflective of the molding process necessary to deliver the head of the infant and may extend to all suture lines, including the frontal suture in the middle of the forehead. Fontanels should be palpated by the nurse for an assessment of intracranial pressure. Fullness without bulging, either palpated or visible, is a sign of normal intracranial pressure. Bulging fontanels in infants with large head circumferences are characteristic of increased intracranial pressures, most likely associated with hydrocephalus.

Soft-tissue edema or swelling from delivery may be palpated during the examination of the head (Figure 32-19). Edema that is fairly diffuse and crosses suture lines is called **caput succedaneum** and usually disappears during the first several days of life. Edema that appears to be localized, giving the infant's head the appearance of growing a horn on one side, is called a **cephalhematoma**. This represents a subperiosteal hemorrhage that does not cross suture lines. The skin in the area may or may not have a reddened color. As this material is slowly broken down and resorbed, the shape of the head may remain "lumpy" for a month after birth and the infant may show signs of jaundice from the metabolism of broken red blood cells from the hemorrhage.

The face, including eyes, nose, and ears, is palpated to confirm shape and size. Eyelids are opened manually to check color of the iris, sclera, and conjunctiva. Tiny pinpoint scleral hemorrhages may be noted in the inner or outer canthus of the eyes and are common after delivery. Small amounts of a yellowish discharge that appear to originate from the conjunctiva and stick to the eyelashes, along with swollen eyelids, indicate that the infant has received eye prophylaxis. Bilateral red reflexes are assessed with an ophthalmoscope and recorded.

Figure 32-19 A. Caput succedaneum; B. Cephalhematoma.

Gross vision in the infant may be evaluated by holding the examiner's face approximately 10 inches from the infant's face and determining the infant's ability to direct his or her gaze to the nurse's face and readjust the gaze when the nurse moves. The nasal bridge is palpated for symmetry and presence of any fracture that might have occurred during the delivery process. The mouth is opened and inspected and gums are palpated for the presence of neonatal teeth lying underneath the gum surface. Visible neonatal teeth should be assessed for looseness and may have to be removed to prevent aspiration (Figure 32-20). The uvula should be at midline. A bivalved or two-lobed uvula is an indication that there may be a cleft in the palate. During the mouth assessment, the infant's ability to suck can be tested by inserting a gloved finger into the mouth to feel the strength of the sucking motion. At the same time, the infant's hard and soft palate can be assessed for size, shape, and cleft formations. Cleft formations may be palpated as an actual opening or a notched ridge. High-arched palates may be an indication of difficulties in swallowing and may affect later speech development. The gag reflex should also be elicited and the back of the mouth,

ABSENCE OF RED REFLEX

Absence of a red reflex on physical examination of a newborn infant on one or both eyes constitutes an ophthalmic emergency because of the interference with the transmission of light to the retina. Appropriate nursing and medical personnel are notified immediately: early suppression of optic nerve function from obstructed light pathways may cause blindness.

throat, tongue, and uvula visualized. The throat is palpated externally to check for the presence of an enlarged thyroid gland and to ensure the trachea is at midline. Neck rotation is assessed through inspection of head movement and with gentle passive rotation by the examiner. Limitations to neck rotation may be a torticollis, which manifests as the head held to one side with the chin pointing to the other side, or a congenital defect in the cervical vertebrae. Since any limitation in neck movement has serious consequences for the infant, this must be reported immediately.

The ears are palpated to determine the thickness of the ear lobe and pinna, and irregular or unsymmetrical shapes are noted. Two common preauricular ear malformations are ear pits and ear tags. Ear pits are tiny pinholes located near the upper curved border of the pinna. These

Figure 32-20 Neonatal teeth (Courtesy of Mead Johnson).

may represent a small sinus tract between the skin and underlying structures. They result from the imperfect fusion of the tubercles of the first and second brachial arches during gestational development (Burns, Brady, Dunn, & Starr, 2000). The nurse should examine ear pits carefully to determine if there is a layer of skin covering the opening or the pit is open at its bottom. Ear pits that are draining fluid or appear to be at risk for infection require surgical repair. Ear tags are tags of skin shaped like bulbs that project from the surface of the skin. Removal by a plastic surgeon for cosmetic purposes is recommended because these areas often contain microcapillaries that bleed when severed. Ear canals are inspected for patency and gross hearing assessed by ringing a bell near each ear.

Common Problems

HEENT findings that necessitate further investigation are asymmetrical, unusual, or may be indicative of defects in underlying structures or congenital syndromes. The examination findings that are the most problematic for the infant are those that are immediately visible to the nurse examiner. Down syndrome is often identified in the early newborn period during the HEENT exam by the positive physical findings of a flattened (not round) occiput; a broad nasal bridge; upward slanted eyes with epicanthal folds; low-set ears; a prominent, enlarged tongue; a high, arched palate; and a small chin. In addition, the infant may exhibit Brushfield's spots, which are whitish spots on the iris of the eye. Cleft lip and cleft palate appear as open separations of the lip, mouth, nose, and hard or soft palate and are associated with a bivalved uvula. These clefts involve facial disfigurement, and the parents and family members are sensitive to other persons observing their infant. Malformations of the ears that involve missing lobes or lack of an ear canal also increase parental sensitivity unless they are covered by the infant's hair.

A careful nursing assessment of the eyes reveals several conditions that have the potential to adversely affect the infant's condition. In the visual inspection of the eye, any deviation from the normal white color of the sclera should be noted. Sclera that appear to have a bluish color may be indicative of a congenital condition called osteogenesis imperfecta, which affects the integrity of the structure of the bones. Infants with this condition may already have fractures from the trauma of delivery and must be handled carefully. Yellowing of the sclera appears last in the progression of jaundice in the newborn infant. The yellow color should alert the nurse to increased bilirubin levels in the newborn and the possible need for immediate intervention, including intravenous fluids and phototherapy. Examination of the iris of the eye may show a disruption, called a coloboma, that looks like a keyhole in the distinct circle of the iris and pupil that will affect vision in that eye. A yellow or white shad-

owy covering of the iris and pupil that occludes the red reflex may be a congenital cataract, which requires immediate referral. A red reflex that appears to be white in color, called *leukocoria* or "white eye," instead of the normal red or red-orange color may be caused by a neuroblastoma, which requires immediate medical attention. Congenital glaucoma manifests as eyes that appear to be protruding slightly from the periorbital area and feel hard and firm on palpation. This is an ophthalmic emergency because eye drops are required to decrease intraocular pressure to preserve vision.

A detailed examination of the eyes, nose, and upper lip may also reveal facial features characteristic of alcohol-related birth defects (ARBD). Short palpebral fissures, a small upturned nose, a flattened nasal bridge, and a thin upper lip with a wide, smooth philtrum are the most prominent features of ARBD (Jones, 1997). These infants demonstrate poor growth, a small head (**microcephaly**), small chins, and mental retardation (Taeusch & Ballard, 1998). Previously, these characteristics were referred to as fetal alcohol syndrome (FAS) or fetal alcohol effects (FAE) indicating the range of physical and mental effects that maternal alcohol consumption has on the developing fetus. The incidence of ARBD is 1 to 2 infants per 1000 live births and it may occur with the consumption of as little as three ounces of alcohol per day (Taeusch & Ballard, 1998). The incidence is much higher (1 in 50 live births) in Native American populations (Abel & Sokol, 1987). After delivery, these infants may exhibit jitteriness, irritability, and poor feeding that are related to their alcohol exposure. Nursing care of these infants is directed toward comforting mechanisms and decreasing environmental stimuli that would surprise or startle an infant prone to irritability.

Nursing Implications

The examination of the head, face, eyes, ears, nose, and throat is one of the most important examinations for nursing. The infant's head and face are the only body parts that are visible to the outside world when the infant is wrapped in or covered with blankets. The parents, family visitors, and strangers form their impression of the infant by viewing the head and face. Unfortunately, many congenital defects and syndromes affect parts of the head and face. Normal variations (for example, large or protruding ears, hair color, and birth marks) that often are the result of familial inheritance are also compared to other infants. Accurate assessments of the head and face will guide the nurse to address parental concerns.

Respiratory System

The infant's respiratory efforts are first assessed visually by the nurse noting the symmetry of chest movements. At this time, the chest is also inspected for placement and size of

Figure 32-21 Accessory nipple (Courtesy of Mead Johnson).

breast tissue. Maternal hormones crossing the placenta during labor and delivery may cause an enlargement of breast tissue even in male infants. Breast tissue and nipples should be aligned with the mid-clavicular line, which is an imaginary line that is one-half the distance from mid-line (the sternum) to the lateral border of the chest wall formed by the rib cage. Breast tissue that is placed between the mid-clavicular line and the lateral chest wall is called “wide-spaced nipples.” Wide-spaced nipples have been associated with several congenital syndromes, particularly Down syndrome. Additionally, the infant may have smaller extra nipples either above or below the primary nipples. The extra nipples, called accessory nipples, do not enlarge with puberty and may be removed at a later age for cosmetic reasons (Figure 32-21).

Common Variations

Relative ease of breathing can be determined by examining the infant lying in a supine position and observing the pattern of breathing, counting the respirations, and determining whether or not accessory muscles are needed for quiet breathing. The nurse may notice very slight sternal retractions during normal respirations in the infant. On palpation, the xiphoid process may be prominent or appear to protrude underneath the skin. Parents need reassurance that as the infant grows, this small piece of the sternum will not get bigger or pierce the skin. Infants are known to have irregular breathing rates with apneic spells that may last up to 15 seconds. Parents need to be warned by the nurse that infants do have apneic spells with normal breathing. Otherwise, they may become frightened that their infant is not breathing. Taking several respiratory rates during the physical examination may be required to get an accurate picture of the infant's respiratory effort. Respiratory rates under 60 breaths per minute in a term

newborn infant are considered normal. Rates between 60 and 70 breaths/min that are not caused by crying episodes and that persist need further examination.

Common Problems

Infants who appear to have marked sternal or intercostal retractions with breathing and look like they are expending energy (“working hard to breathe”) need a prompt respiratory assessment. Palpation of the anterior lung fields may reveal a birth injury, a fractured clavicle or rib, which may be causing an increased respiratory rate resulting from pain at the injury site. Rib injuries may also be visualized as asymmetrical respiratory movements of the chest wall. The shape of the chest may be inspected for deformities that might interfere with normal lung expansion. Funnel chest (pectus excavatum) and pigeon chest (pectus carinatum) result from an abnormal development of the ribs and sternum. Auscultation of all lung fields anteriorly and posteriorly can confirm the respiratory rate (instead of counting abdominal movements) as well as detect adventitious breath sounds from congestion. Upper airway congestion from mucus and residual amniotic fluid can be differentiated from lower airway congestion by auscultation of the infant's nose. Noisy breath sounds heard from the nose are usually indicators that the congestion exists in the nasal passages, throat, and upper bronchus rather than in the middle or lower lobes of the lungs. The nurse can use a bulb syringe to clear nasal and throat passages of fluid and mucus to ease breathing efforts by the infant. Retractions decrease as breathing becomes easier.

Retractions that do not disappear may be an indicator of respiratory distress in the infant. Respiratory distress is a symptom of many conditions in the newborn infant that should be investigated immediately. The infant may have a congenital respiratory condition, which is usually a narrowing of an airway; a congenital heart condition that interferes with the capacity of the lungs to supply oxygen to the blood for circulation; or an infection acquired from the mother. All of these conditions are life-threatening to the infant, and they require nursing and medical interventions.

Nursing Implications

Respiratory rates in newborns between 60 and 70 breaths per minute require continual observation by the nurse. The infant breathes faster when moving, irritated, or crying. The respiratory rate should be taken when the infant is calm or quiet. As with transient tachypnea of the newborn, a rapid respiratory rate in a quiet infant may be a temporary adjustment to extrauterine life. However, the nurse must be alert to the development of additional symptoms, i.e., nasal flaring, grunting, or intercostal

Figure 32-22 Silverman-Anderson index of respiratory distress. Reprinted with permission from Silverman WA, Anderson DH. Evaluation of respiratory status: Silverman and Anderson Index. *Pediatrics*. 1956;17:1.

retractions, that would indicate the development of a more serious condition (Figure 32-22). The nurse should monitor skin color and capillary refill of both upper and lower extremities to complete the nursing assessment of the efficiency of the respiratory system. The nurse must determine whether additional symptoms indicate a condition of respiratory distress in the infant or whether the absence of additional symptoms indicates that the infant is approaching respiratory stability.

Cardiovascular System

The cardiovascular system is best assessed by the nurse visually and by auscultation. Visual assessment includes skin color of the trunk of the infant and the skin color of the extremities. Color should be pink and increase to red when the infant cries or moves its extremities. Visual inspection of the lips, mouth, gums, and buccal mucosa is the best indicator of cardiac perfusion. The chest is palpated for any thrills, heaves, and the point of maximum impulse (PMI). In newborns, the PMI by auscultation occurs at the apex of the heart near the third or fourth left intercostal space. Heart rate is counted and heart rates above 160 beats/min are called **tachycardia**. The heart rate normally should fall in the range of between 120 and 150 beats/min. Capillary refill in fingers and toes is examined by pinching the end of the finger or toe and counting the seconds until the skin returns to its normal color. Normal refill times are less than 3 seconds. Refill times of more than 3 seconds may indicate a shunting of the circulation away from the periphery towards the trunk of the infant. All peripheral pulses are palpated for bilateral symmetry, strength, and rate. Pulses that continue to be strong and bounding as distance from the

heart increases may be an indication of a cardiovascular problem. Special attention is given to femoral pulses. These are checked one at a time and compared to the brachial pulses. Any decrease in the strength of the pulse between the brachial pulses and the femoral pulses may be an indication for a cardiac condition called coarctation of the aorta. Coarctation of the aorta is a narrowing of a portion of the aortic arch. The aorta is the main transport vessel for oxygenated blood to the upper and lower portions of the body. A narrowing of the aortic arch causes diminished blood flow patterns and may be suspected in infants with diminished or decreased femoral pulses.

Common Variations

All areas of the heart, i.e., the aortic, pulmonic, tricuspid, mitral, base, and apex, are examined by auscultation. Infant heart rates vary: they slow down with rest and speed up with activity or crying. Term infants usually maintain a heart rate of between 110 and 160 beats/min; rates lower than 100 beats/min are indicative of bradycardia and rates higher than 160 beats/min are considered to be tachycardia (Seidel et al., 2001). Either persistent bradycardia or tachycardia must be reported to the nursing staff responsible for the infant. Initially, infant heart rates are difficult to hear. The chest wall in infancy is thin and heart sound transmission has a tendency to be noisy and obscured by the infants' respirations. Patience and continued listening by the nurse are often necessary to determine the heart rate as well as any extra sounds or murmurs. Murmurs are often heard in newborns less than 24 hours old near the sternal border at the level of the left second or third intercostal space. A increasing amount of sound (crescendo)

Critical Thinking

The Newborn After Transition

You are performing a cardiac assessment on an infant who is 8 hours old. Auscultation of the heart reveals a soft heart murmur heard throughout systole and a heart rate of 170 beats/min. The infant appears large in size and has no visible congenital anomalies. Skin color is pale-pink with a capillary refill time of 3 seconds in both upper and lower extremities. Pulses are equal bilaterally, rhythm is regular, and you note that pedal pulses are especially strong, close to bounding.

- What do bounding pulses mean in a newborn infant?
 - Are your physical exam findings normal or abnormal at this time?
 - Which is the best nursing action to take next?
1. Continue observation of this infant and repeat your assessment in 30 minutes.
 2. Ask a nursing colleague to verify your physical examination findings.
 3. Report your findings to the medical staff immediately.
 4. Repeat your assessment to confirm your findings.

The best response is number three. Bounding pedal pulses, a heart rate increased above normal, and a soft systolic murmur indicate increased cardiac contractility in the presence of blood backflow through fetal shunts. This “increased workload” for the heart may lead to cardiac failure if not evaluated immediately. While confirmation of findings may be an appropriate action, examination findings can always be confirmed by the medical staff on duty. The nurse must learn to trust her own assessment skills and judgment in patient care situations that require immediate decisions. Signs of cardiac failure in newborns infants may be very subtle at first, and the nurse must be alert to any cardiac findings that are questionable.

occurring through systole is the usual sound pattern heard. The sound from an infant with **patent ductus arteriosus** (PDA) will gradually disappear when the ductus closes, within 2 to 3 days. Murmurs that persist beyond the second day of life and whose sound has changed to a more definitive whoosh pattern are not characteristic of an open ductus and require a cardiac evaluation.

Common Problems

The most common heart murmur in infancy is the ventricular septal defect (VSD) in which there is a small hole in the wall of the ventricle between the right and left chambers of the heart. The sound of the murmur is created by the heart pumping blood and the blood leaking through this hole. Small defects produce louder murmurs because of the buildup in pressure in the chambers from the blood leaking through with each contraction. Large defects produce softer murmurs as blood flow through the hole is greater, reducing the pressure buildup. The majority of ventral septal defects close without surgical correction as a result of the normal cardiac growth during the first year of life. Mothers of newborns with heart murmurs need to be reassured that most heart murmurs noted in infancy are not fatal nor do they require surgery, which are their biggest fears.

Cardiac insufficiency, leading to heart failure, occurs when the infant is unable to properly oxygenate and circulate blood. Nurses may suspect this condition in irritable infants with persistent pallor, rapid breathing, and cyanosis around the lips. Pulse oximetry readings of less than 94% oxygen saturation are cause for concern. An infant whose oxygen saturation falls below 90% must be placed on a cardiac and respiratory monitor in an intensive care unit. Infants who exhibit these symptoms may have heart defects with normal heart functions as long as the ductus remained open. As the ductus starts to close on day 2 or 3 of life, their cardiac condition becomes unstable and compromised. In these infants, a murmur develops on day 2 of life, which is the first indication of a cardiac problem. Infants who develop cardiac instability within the first 2 days of life are those infants who have a genetic karyotype of trisomy 13, 18, or 21 or tetralogy of Fallot. Tetralogy of Fallot consists of four specific cardiac anomalies: transposition of the aorta and pulmonary artery, right ventricular hypertrophy, pulmonary stenosis, and ventricular septal defect (Taeusch and Ballard, 1998). Newborns with tetralogy of Fallot are stable after birth, have no murmurs on auscultation, and maintain cardiac perfusion as long as their ductus arteriosus remains open. Medical and nursing staff refer to these infants as “pink tets.” When the ductus begins to close after 24 hours of life, severe cardiac instability occurs, with the development of central cyanosis. These infants are placed on a cardiac monitor in an intensive care unit, receive intravenous fluids with medication to preserve cardiac output, and undergo a full cardiac and surgical evaluation.

Nursing Implications

The accurate assessment of the heart and cardiovascular system in a newborn is necessary for the determination of present and future cardiac stability of the infant. Nurses who examine newborns develop the knowledge and

Critical Thinking

Newborn Heart Defect: What Do You Say?

You are reading an infant's chart and discover that the health care provider suspects a cardiac defect, has ordered an ECG, and has called a pediatric cardiologist to examine the infant. When you bring the infant to the mother, she tells you that she feels great, is ready to go home, and has called the father of the baby to come pick them up.

- What would you say to this mother?
- What might you say to the physician?

expertise to detect cardiac conditions often before the medical staff is aware of them. Nurses are also the key personnel that parents and family members contact who have concerns about the health of their infant. Cardiac problems in infancy cause severe anxiety in both parents. The major role of nurses beyond the cardiac assessment of newborns is to develop skills in communication to convey to parents and other family members the nature of the problem, the steps being taken, and the health and welfare of their infant.

Abdomen

The abdomen of a newborn infant in the supine position appears round, full, and bilaterally symmetrical. The umbilical cord should be clamped securely with no oozing of blood or it will need to be re-clamped. The cord should be examined for the presence of three vessels, two arteries, and one vein. Umbilical cords with fewer than three vessels should be reported to the charge nurse and medical staff. Large cords that have thickened areas of gelatinous material are referred to as having Wharton's jelly. Infants' abdomens may look distended from the presence of stool that has not yet been eliminated. After inspection of the relative size and shape of the abdomen, and watching abdominal breathing patterns, auscultation for bowel sounds in all four quadrants is begun. Several areas in each quadrant are assessed, because bowel obstruction in the newborn may present initially as a lack of bowel sounds in a small area of the bowel. Auscultation for the gastric bubble and the heart sounds of the abdominal aorta completes this part of the examination.

Common Variations

Light and deep palpation of the abdomen allows the nurse the opportunity to assess the integrity of the abdominal

REFLECTIONS FROM A NURSE

"It was late in my shift and I was rushing to deliver a newborn to the mother before shift change. The mother had indicated in the chart that she wanted to breastfeed her infant, and I was determined to get her baby to her to make that happen before the next shift came on duty. As I brought the baby to her bedside, the mother greeted me and told me she was so glad I was there, and she had been waiting for me to come. I was so surprised. She told me that I had taken care of her first baby who had something wrong with his heart. She said that she will always remember me sitting down with her and explaining to her about the heart, and how it worked. 'I've kept the drawing you gave me all these years,' she said. 'I've had all my babies at this hospital because I wanted you to take care of them,' she continued. I left her room with a big smile on my face. I never realized how much talking to mothers about their babies really meant to them."

contents of the infant. Light palpation begins with the end of the sternum and the xiphoid process, proceeding midline to the seat of the umbilicus on the abdomen. As palpation proceeds along the midline, a diastasis rectus, or a thinning of the abdominal wall along the midline may be palpated. A diastasis rectus can also be visualized as a "furrow" formation, or elongated lump, at midline when the infant is crying. Last, the circumference of the umbilicus can be palpated for hernias. The umbilical cord should be firmly seated in the abdominal wall, but there may be a separation between the cord and the abdominal wall, called a hernia. Hernias are measured by finger-tips to determine if they are large or small. Umbilical hernias are common in newborn infants, and small ones often close on their own when infants grow larger. Palpation is continued along the midline below the umbilicus to the symphysis pubis. Some umbilical hernias extend inferiorly and the size of the hernia may be misjudged.

Light palpation of the abdomen continues from midline to the costal margins (rib cage) to determine the pres-

ence of masses or enlarged organs. The small size of the newborn abdomen facilitates this examination as a result of the lack of space for enlarged organs or extra material (tumors or masses). Deep palpation is used to outline specific organs and their borders. The liver border, felt just below the right costal margin should be smooth and firm and not extend more than 2 centimeters below this margin. The spleen, tucked underneath the left costal margin, is only palpable at the tip of the organ, 1 centimeter below the costal margin. Positive palpation findings on a newborn's spleen are a cause for concern because organ enlargement must be present for the spleen to be palpated beyond its tip. Kidneys may be palpated at a right angle to the umbilicus at midline, located 1 to 2 centimeters above the umbilicus. However, they may be missed because of their small size. The bladder wall should be smooth and can be palpated at midline, inferior to the umbilicus.

Common Problems

Assessment findings that indicate a serious abdominal condition in the newborn are abdominal distention, absent bowel sounds, discharge from the umbilical cord or site, and palpation of an abdominal mass. Abdominal distention may appear to involve the entire abdominal surface or small areas of bulging. The nurse may notice enlarged abdominal veins in a distended abdomen. Light and deep palpation may reveal stool in the colon, which is not cause for alarm. Areas of abdominal bulging that shift when the infant is moved in the supine position may indicate the presence of fluid in the abdomen. Light pressure on the abdomen below the costal margin may generate a fluid wave to the opposite costal margin. This requires immediate attention by the medical staff to determine the source of the fluid in the abdomen.

Auscultatory sounds that are diminished or absent in the abdomen are indicators of potential circulatory problems. Auscultation of the abdominal aorta at midline above the umbilicus gives the listener an impression of circula-

tion to the abdominal organs and lower extremities. Diminished sounds may indicate decreased circulatory efforts, as in coarctation of the aorta. Decreased blood flow would affect the kidney's ability to filter blood and form urine, and the bowel's ability to digest nutrients and undergo peristalsis. Absent bowel sounds in an area of the abdomen would indicate a portion of the bowel that is not functioning and requires immediate attention. Necrotizing enterocolitis is a severe abdominal condition of newborns, resulting from inadequate circulation to the bowel, the destruction of the intestinal mucosa, and complete loss of bowel function. Loss of bowel function leads to intestinal obstruction and secretion of toxins from tissue that has been destroyed. This condition is life-threatening and requires immediate surgical intervention.

Inspection of the umbilicus and umbilical cord for discharge or leakage is done to detect signs of infection. Umbilical cords that have not been stained with the bacteriostatic dye are pale yellow. Green staining of umbilical cords occurs when the infant has passed meconium before delivery. The base of the umbilical cord should be clean and dry with no discharge or leakage of blood. The presence of a discharge must be reported immediately because it is an indicator of infection. Stool and urine from the diaper area should not leak out of the diaper and be in contact with the cord or the base of the cord. When this occurs, careful cleansing is required. An extra cord clamp can be applied if there is a blood leak. The abdominal wall surrounding the seat of the cord is inspected for redness. A circular area of redness around the base of the cord on the abdomen is a symptom of omphalitis, an infection of the base of the cord that requires antibiotic therapy.

Palpation of an abdominal mass or an enlarged abdominal organ in the newborn is facilitated by the infant's usually small abdominal girth. Masses or enlarged organs require immediate attention and investigation. The mass can be confirmed by an ultrasound examination, and medical management can be instituted at this time. In the newborn period, abdominal masses are usually a form of neuroblastoma, and the cause can be confirmed by biopsy. The most common enlarged abdominal organs are the liver, spleen, and kidneys. These findings can also be confirmed by ultrasound examination. The organs may be enlarged from an associated obstructive process or congenital malformation.

Nursing Alert

DISTENDED ABDOMEN

The essential tool for nursing assessment of the distended abdomen in a newborn is palpation. Abdomens that are distended can be palpated easily; they feel soft and pliable. A distended abdomen that the nurse is unable to palpate because of the rigidity of the abdominal wall is a medical emergency. This condition is often referred to as “acute abdomen,” and the infant is often inconsolable.

Nursing Implications

In addition to the cardiac and respiratory assessment, the assessment of the abdomen is vitally important in the newborn as the site of digestion and the beginning processes of elimination. The nurse develops auscultation and palpation skills to ensure the integrity of the abdominal organs and to detect any causes for concern. The nurse can anticipate the parental expectation that a round, full “tummy”

on their baby indicates a healthy baby, and teach the parents the signs and symptoms of abnormal conditions of the abdomen.

Genitalia and Anus

Both male and female genitalia are visualized and assessed with the infant in the supine position with its hips abducted. The scrotum of male infants in this position can be determined to be pendulous with descended testes. Flattened or depressed areas of the scrotal sac may indicate that a testis that has not descended. Testes are palpated in the scrotal sac by placing the nurse's second finger at the posterior midline of the scrotum and the thumb on the anterior midline. The index finger and thumb can easily palpate the left side of the scrotum for the presence of a testis, and the third finger and the thumb can likewise palpate for a testis on the right scrotum. Palpation in this manner ensures that one testis is not mistaken for two by being passed from side to side. This technique also allows for gently stroking of the inguinal canal with the respective finger and thumb if a testis is not felt in the scrotal sac. The nurse can bathe the inguinal canal with warm soapy water when a testis can not be located. Warm water has tendency to make a testis "pop up" in the canal and become more visible. One or both undescended testes that cannot be located in the inguinal canal in an infant older than 35 weeks' gestational age is an indication for an urologic evaluation of the infant.

Female genitalia are inspected with the hips of the infant abducted while lying in a supine position. The labia majora are visualized first and the extent to which they cover the remaining tissues of the female genitalia indicates the maturity of the infant. In most female infants at term, the borders of the labia majora meet and the clitoris is covered completely. In some term infants, the development of the genitalia may lag behind other systems and the nurse may see the labia minora and the clitoris uncovered.

Inspection of the anus and palpation of the anal opening occurs at the same time as the genitalia are assessed. Hopefully, the infant will have a stool during the nurse's examination, so that the nurse can validate that the anus is patent and that the stool does, indeed, come out of one and only one anal opening. Stool appearing in a female infant from the vaginal opening results from a rectovaginal fistula, an opening between the rectum and the vagina. The anus is palpated by spreading the tissue around the anal opening and feeling the musculature around the opening. At this time, any rectal tears from the passage of stool in the anal ring may be noted and the **anal wink reflex** elicited. While the infant is in the prone position, the buttocks are stroked from side to side with the index finger of the nurse. The buttocks draw together and "wink" at the point of the anal opening, validating the anatomic position. This reflex is used to evaluate anal openings in fe-

males that are closer than 1 centimeter from the vaginal opening. Anal openings too close to vaginal openings do not develop the appropriate muscle strength needed to assist in evacuating the rectum as the infant grows older. The "wink" reflex indicates where the normal anal opening should be positioned for future surgical correction.

Common Variations

In male infants, the nurse may discover that palpation of the scrotum for testes is impossible because the scrotal sac is swollen and distended, preventing accurate palpation. Fluid accumulation in the scrotal sac causes this and can be verified by transillumination of the scrotum. However, the nurse must first verify that the enlarged scrotum does not contain trapped bowel. Careful auscultation of the scrotum for bowel sounds will confirm this condition. If bowel sounds are present, it must be reported and confirmed immediately because this is a medical emergency for the infant. If bowel sounds are not present, the nurse can then proceed with transillumination of the scrotum. A penlight or an ophthalmoscope is used as the light source pressed against the scrotum to transilluminate it in a darkened room. Fluid appears as a yellow-orange reflection and, occasionally, a small, dark, round testis can be seen. The nurse must note that a scrotal or testicular mass does not transilluminate and report it immediately. Fluid in the scrotal sac is gradually reabsorbed over the infant's first several weeks of life, and the mother can be reassured that the scrotum will eventually have a more normal size and appearance.

Palpation continues in male infants to include the shaft of the penis in order to estimate penile length. Normal male infants are born at term with a penis that measures about 2 centimeters. The foreskin (prepuce) is lightly retracted to inspect the urethral opening and the location of the opening on the glans. The nurse may notice a cheesy coating called *smegma*, of the glans underneath the foreskin. Vertical urethral openings (urethral meatus) may be seen instead of round openings and are a symptom of **hypospadias** when they are not centered on the glans and are located instead on the ventral surface (Figure 32-23). Hypospadias repair when indicated is accomplished by using the excess foreskin to re-fashion the meatus. All newborn males suspected of having hypospadias are not to be circumcised. **Epispadias** is the condition in which a vertical urethral opening is located on the dorsal surface of the penis instead of the glans.

Many female infants have a white, thick cheesy substance, called vernix caseosa, between the labia; this is not a cause for concern. A small, triangular-shaped piece of tissue may be visualized between the labia. This is a *hymenal tag* and decreases in size as the infant grows larger. Gentle palpation of the labia majora and labia minora allows for visualization of the hymenal area. It is not unusual at this time to see a white mucoid discharge in the vaginal area as well as a small amount of blood. Maternal

hormones crossing the placenta create this discharge and bleeding that mimics a period in female infants. This is normal, and parents need to know how to clean the genitalia of their infants and not to be frightened when they see small amounts of blood. It usually takes about a week for a female infant to eliminate the influence of maternal hormones. Females may also have a smegma discharge between the labia.

Common Problems

The nursing assessment of the male genitalia is focused on the determination of whether they are normal. Swelling or

edema from the delivery process may impede this assessment. Bruising of the scrotum can occur with breech presentations, and palpation must be done carefully. Infants of color, particularly African American infants, have dark-skinned scrotums. Examination of the scrotal sac should reveal two testes. Undescended testes may be located in the inguinal canal and become problematic when they do not descend into the scrotal sac. Inguinal hernias are difficult to palpate in infancy. They are usually discovered when a loop of the infant's bowel becomes trapped in the scrotal sac. The scrotum enlarges, does not transilluminate, and exhibits characteristic bowel sounds when auscultated. This condition must be reported immediately, because surgical repair is necessary to save the bowel. A darkened area of the scrotum surrounding one testis with edema may be testicular torsion, in which the spermatic cord and tunica vaginalis twist before attachment of the tunica vaginalis to the scrotum (Juretschke, 2000). This condition in infancy is extremely rare, carries a high risk of testicular loss, and requires immediate surgical intervention (Juretschke, 2000).

Inspection and palpation of the penis determines penile length and completes the assessment of normal male genitalia. A penis less than 2 centimeters long indicates *micropenis* and may be associated with a pituitary tumor or insufficiency. Structures that resemble a penis in a female or ridges that mimic labia on a male require immediate investigation as ambiguous genitalia. In cases in which definite genitalia of either sex cannot be determined, genetic studies are performed in addition to testing for adrenal insufficiencies. Labeling of the infant as a “boy” or a “girl” prematurely leads the parents to treat the infant according to the label already given, which may be contrary to the genetic evidence.

The two most prominent concerns in the assessment of the female genitalia are an enlarged clitoral hood and imperforate hymen. Hormones crossing the placenta may cause the clitoris to be slightly enlarged. A large clitoris that appears hood-shaped and elongated, resembling a penis, may be the result of excess androgen stimulation. This is one symptom of congenital adrenal hyperplasia. Testing for precursors of adrenal corticosteroids and electrolytes for normal kidney function need to be initiated immediately. Edema from the birthing process may interfere with the examination of the labia majora and labia minora. Careful separation of the labia should reveal the urethral opening and an intact vaginal introitus. An imperforate hymen is a muscle wall that obstructs the vaginal opening. This condition will need surgical correction for future release of menses during normal menstrual cycles.

Inspection of the anal opening in both male and female newborns may reveal skin tags on the anal ring or an anal ring without an opening. The skin tags or other hemorrhoid-like tissues may cause discomfort or bleeding in the diaper when the infant is stooling. The lack of either

BLOOD IN THE DIAPER

Blood in the diaper of a newborn can be a concern for the nurse and frightening for the parents. The location of the blood can indicate the source of the bleeding. Blood that appears near the top of the diaper is most likely oozing from the umbilical cord. Blood that appears in the middle of the diaper in female infants is most likely bleeding that mimics a period from maternal hormones. Blood in the middle of a diaper on a male infant may be the result of a urine stream through a bruised penis from delivery or indicate a more serious problem to be investigated.

Critical Thinking

Ambiguous Genitalia

You are the nurse taking care of twins in the nursery. The twins are the fifth and sixth children of a young couple who desperately wanted to have a boy, since all their previous children were girls. The twins were born weighing 2200 g and 2250 g and appear to be normal boys. They have been in the nursery for the last 3 weeks, steadily gaining weight before discharge. As you read through the chart, you notice that one of the nurses palpated a high-arched palate on one twin and described a low-set ear. The medical team ordered chromosomal studies, which were reported last week. There was no evidence of trisomy, however, both of the twins had female karyotypes. Abdominal ultrasound tests revealed the presence of ovaries and a uterus in both infants. Nursing staff conversations with the parents revealed their intentions to raise the infants as boys. What is the best approach for you to take when you talk with the parents today?

- Do you think that the parents are ignoring the test results?
 - Do you think the parents will ever accept the test results?
 - Which of the following do you think is the best response?
1. "Do you have any questions for me about the care of your babies?"
 2. "I would like to talk with you about the test results and what they mean for your babies."
 3. "I have made an appointment for you to see the genetics counselor this afternoon about your babies."
 4. "I have asked the genetics counselor to meet with us and help me talk to you about your babies."

The best response is 4. The first response ignores the issue. The second response is repeating the same information the parents have heard before. They are not ready to listen to or hear what the test results mean. The third response takes control away from the parents and places them in a situation that they did not request. The fourth response offers the parents an opportunity to express their feelings and identifies any misunderstandings that they might have.

an anal ring or an opening in the anal ring is a condition called imperforate anus. This condition in the newborn is a surgical emergency because the newborn is unable to evacuate stool from the rectum. In 50% of newborns who have imperforate anus, this condition occurs as an isolated event and is not associated with other congenital malformations or syndromes (Taeusch & Ballard, 1998). A common congenital syndrome associated with anal malformations is VATER association. Three or more of the major abnormalities must be present to make the diagnosis, and prognosis for normal development is enhanced after surgical correction (Taeusch & Ballard, 1998). Characteristics of VATER association in the newborn include:

V = vertebral abnormalities

A = anal abnormalities (imperforate anus)

T = tracheal abnormalities

E = esophageal abnormalities (tracheal-esophageal fistulas)

R = renal and radial abnormalities

Nursing care of newborns with VATER association is directed toward proper newborn positioning for arm and spinal defects as well as promotion of breathing efforts through a partially compromised trachea. Additionally, nursing efforts to ensure nutritional intake and elimination are emphasized.

Nursing Implications
