Idiopathic hirsutism in women is the result of excessive androgenic activity and begins during puberty. There is a gradual development over 2 to 3 years followed by a period of stability. There is a familial tendency toward hirsutism. Women of eastern European or Mediterranean descent are likely to have increased terminal hair growth. Idiopathic hirsutism usually occurs in women aged 15 to 25 years without symptoms of virilization. It is usually mild and not accompanied by menstrual irregularities. Hirsutism may present in pregnancy owing to production of androgens by the placenta and corpus luteum. Postmenopausal women experience an increase in androgen production, with 75% experiencing noticeable facial hair growth.

Management

When the cause of hirsutism is determined to be of adrenal or ovarian origin, the patient is referred to an

endocrinologist for treatment. Discontinuing a drug that is determined to be the cause or substituting an alternative may stop the rapid progression of terminal hair growth.

Treatment of idiopathic hirsutism and hirsutism resulting from PCOS is dependent on the severity and treatment preferences of the patient. Hirsutism is often perceived as a loss of femininity and sexuality; women affected will need reassurance. Idiopathic hirsutism does not frequently interfere with fertility.

Weight reduction may assist patients. Obese women have increased androgen levels due to insulin-stimulated androgen production in thecal cells. Weight reduction may also improve menstrual function in these patients.

Mild cases of hirsutism can be managed by cosmetic therapy, including physical removal, chemical depilatories, and bleaching. Electrolysis and laser therapy are more permanent solutions but are costly. Androgen production may be reduced with weight loss if the woman is obese.

Pharmacological therapy may be indicated in women with more severe hirsutism, such as that caused by a tumor. After the tumor has been removed, oral contraceptives, either monophasic or triphasic, may be effective. Estrogen-dominant medications, such as the Ortho brands of contraceptives, are effective and will increase sex steroid–binding globulin. Progesterone-dominant medications, such as the Wyeth brands of contraceptives, will increase clearance of testosterone. Medroxyprogesterone (Depo-Provera) is also effective. Hormonal therapy will stop further hair growth but will not reverse the present hair growth, which must be treated cosmetically. It may take 6 to 24 months to see results of hormonal treatment, which may need to be lifelong. Spirolactone (Aldactone) has been studied and demonstrated to reduce hair growth (100 mg/day), but it may take 6 months of therapy to see a clinically significant effect. Eflornithine 13.9% (Vaniqa) cream has been approved by the U.S. Food and Drug Administration and has evidence of reducing hair growth on the upper lip, especially when combined with laser therapy (Level I; Wolf et al, 2007).

INCREASED NECK SIZE

The neck contains 75 lymph nodes, the trachea, larynx, pharynx, the submandibular and salivary glands, cervical vertebrae, and the parathyroid and thyroid glands. Pathology in one of these structures or in an area that is drained by one of the many lymph nodes may increase neck size.

A patient with increased neck size may present with complaints that shirt collars are tight. The patient should be evaluated immediately for difficulty swallowing or breathing problems. An immediate referral is indicated in the presence of either symptom. Some patients may complain of pain.

Differential Diagnosis

Increased neck size may be caused by a mass in any structure in the neck, including glands, lymph nodes, larynx, or pharynx. Cysts may also develop in the neck and increase the size of the neck. Blockage of the salivary glands produces neck enlargement. The most common cause of increased neck size is an enlarged thyroid gland. Other potential causes include trauma, masses, neoplasms, cysts, and lymph node enlargements.

The history can assist in diagnosing the cause of increased neck size. Patients reporting a recent fall, automobile accident, or injury may have sustained cervical trauma. History of a recent infection may cause lymph node enlargement. The patient should be questioned about a history of thyroid problems or recent surgeries, allergies, sinus problems, and any complaints of headaches. Symptoms of dysphagia, dyspnea, chest tenderness, cough, and hoarseness should be addressed. Complaints of pain should be investigated, including if the pain is aggravated by range-of-motion movements, breathing, swallowing, or chewing.

The physical exam should assess whether the swelling (enlargement) is focal or diffuse. One or more focal masses may be enlarged lymph nodes related to Hodgkin's disease, sarcoidosis, a thyroglossal cyst, thyroid adenoma, or carcinoma. If the swelling is diffuse, venous distention of congestive heart failure (CHF), Graves' disease, subacute thyroiditis, superior vena cava syndrome, or subcutaneous emphysema (which is usually accompanied by subcutaneous crepitus) is suspected. If the swelling is focal, it should be noted if the lesion is midline or lateral because midline masses can be indicative of thyroglossal cysts or adenoma of the thyroid; lateral masses are more likely related to Virchow's node, Hodgkin's lymphoma, bronchial cysts, a pharyngeal pouch, or a stone of Wharton's duct. Intermediate swelling suggests venous congestion of CHF, a bronchial cyst, a stone of Wharton's duct, or an aneurysm.

A technique for detecting thyromegaly is to have the patient sit upright for examination. During examination, the neck is exposed down to the sternal notch while the examiner stands directly in front of the patient with the thyroid gland at the examiner's eye level. The patient should take several sips of water while the examiner observes for an enlarged thyroid gland. After visual examination, the thyroid is palpated anteriorly and posteriorly.

Thyroid nodules can be palpated in about 5% of Americans. Women are more likely to have palpable thyroid nodules, and the frequency of nodules increases with age. Fewer than 10% of singular nodules are malignant. Thyroid-stimulating hormone and thyroxine (T_4) levels should be obtained on the patient with enlargement or any abnormalities in the thyroid.

A single enlarged lymph node is unlikely to result in a significant increase in neck size. Sudden complaints of a lymph node enlargement suggest an infectious process.

Patients who present with enlargement of a node over several months or multiple node involvement are more likely to have neoplastic disease. A hard, immobile mass is also suggestive of a neoplastic process. A referral is indicated for biopsy of the nodes. Laryngeal cancer produces cervical lymphadenopathy and increases neck size. Pain, dyspnea, dysphagia, hemoptysis, stridor, and hoarseness may also be present.

Management

Management of the patient with increased neck size due to endocrine (glandular) abnormalities is to treat the underlying cause.

POLYDIPSIA, POLYPHAGIA, AND POLYURIA

Polydipsia is excessive thirst; it is associated with several endocrine diseases and certain drugs. Polydipsia may accompany increased urine output (polyuria), which can be related to excessive loss of water and salt.

Polyphagia refers to excessive eating before satiety. This symptom can present as a persistent or intermittent condition, resulting from endocrine and psychological disorders. Certain drugs are also known to cause polyphagia. Elevated thyroxine (T_4) levels increase metabolism and thus the body's need for calories, often causing polyphagia.

Polyuria is a condition associated with increased urine production; it is defined as excretion of more than 3,000 mL (3 L) per day. Any condition that increases hyperosmolar states will increase urination as a consequence of osmotic diuresis. The patient with polyuria is at risk for fluid volume deficit that could result in hypovolemia.

Differential Diagnosis

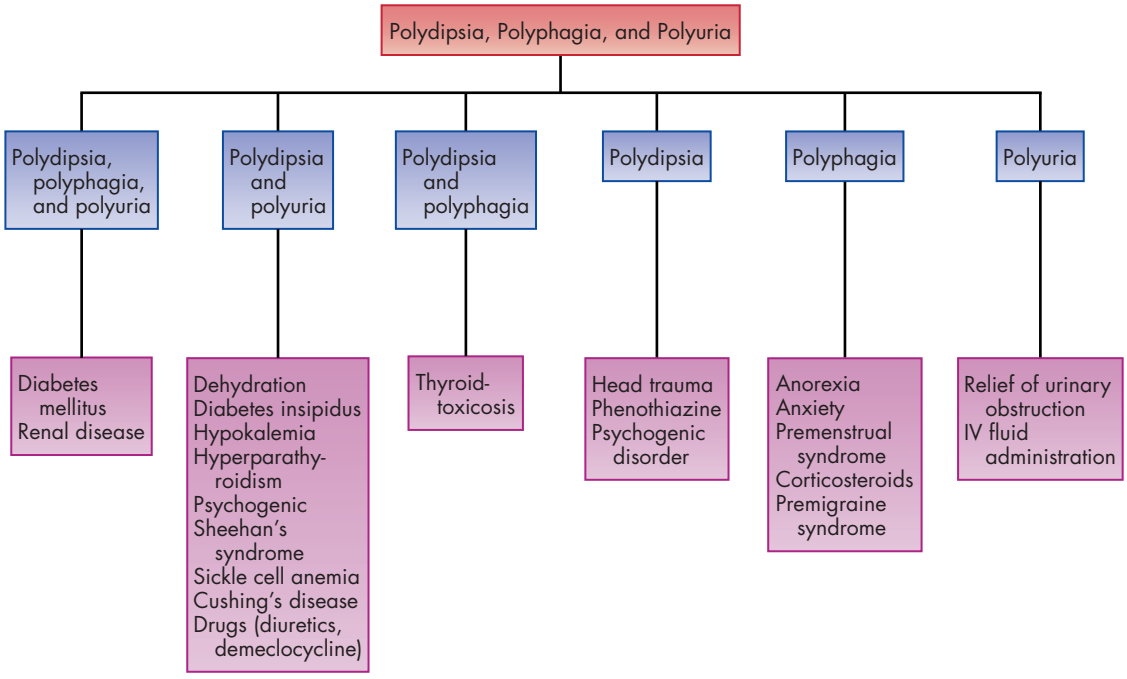
Differential diagnoses for the patient with symptoms of polyuria, polydipsia, or polyphagia include diabetes mellitus (DM), diabetes insipidus, diuretic abuse, head trauma, and psychiatric disorders. See Differential Diagnosis Flowchart 16.1 for other cause of these symptoms.

The patient should be questioned about any history of head trauma, weight changes, thyroid disease, hypertension, and family history of diabetes. The patient should also be questioned about any history of psychiatric illnesses or changes in mental status, for example, alertness or memory, as well as symptoms of fatigue. A detailed 48-hour history of intake and output should be obtained, including the type of fluid intake over 48 hours, as well as the characteristics of the urine output. Urine output is often difficult for patients to estimate and objective measurement may be needed. A weight history should be obtained.

The patient should be assessed for signs of dehydration and malnutrition. Weight and vital signs are assessed. Initial laboratory testing includes urinalysis, urine specific gravity, serum electrolytes, blood urea nitrogen, serum creatinine, complete blood count, fasting serum glucose level, and glycosylated hemoglobin percentage (A1C).

Polydipsia, polyphagia, and polyuria are the classic symptoms of DM. Blood glucose levels should be evaluated in patients who experience these three symptoms. An A1C equal to or greater than 6.5%, a fasting (following

Differential Diagnosis Flowchart 16.1



8 hours of no caloric intake) blood glucose level equal to or greater than 126 mg/dL, a 2-hour plasma glucose equal to or greater than 200 mg/dL following a 75-g oral glucose tolerance test (OGTT), or a random blood glucose level greater than 200 mg/dL in persons with classic symptoms of hyperglycemia (polyuria, polydipsia, polyphagia, weight loss) or hyperglycemic crisis confirm the diagnosis of DM. Additional symptoms indicating DM include weakness, fatigue, increased susceptibility to infections, and nocturia.

Management

Management of the patient with polydipsia, polyphagia, and/or polyuria is dependent on treating the underlying cause.

WEIGHT GAIN

Weight gain is a common complaint in clinical practice. It may be assessed as a risk factor, such as in coronary artery disease; as a symptom of another disorder, such as the edema seen with congestive heart failure (CHF); as a "sign of aging"; or it may indicate a problem such as hypothyroidism, Cushing's disease, or obesity.

Energy expenditure is composed of the resting energy expenditure, the thermic effect of food, and physical activity. Weight gain results from the ingestion of more calories than are expended. Most often, weight gain is a result of a combination of genetic and environmental factors. However, endocrine disorders, nephrotic syndromes, cardiovascular disease, and some drugs may be the cause of weight gain.

Differential Diagnosis

The history of weight gain, a 24- to 48-hour diet recall, and assessment of activity may provide insight into potential causes. Weight gain, when not associated with pathological disease, results from a complex combination of genetic and environmental factors. The incidence of weight gain increases with age. Several factors account for this weight gain, including a decrease in metabolic rate, decreasing muscle mass, and decreased physical activity. Weight gain results when there is no reduction in caloric intake.

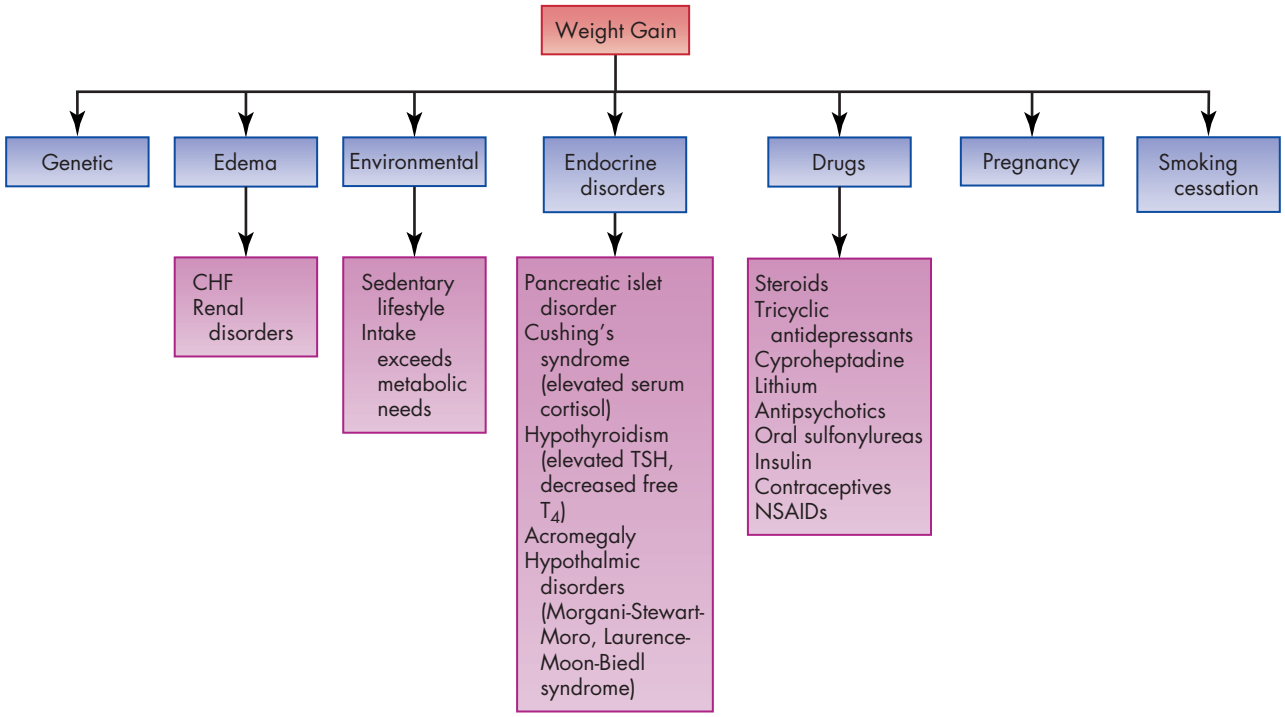
Multiple complex factors interacting simultaneously within the individual usually lead to weight gain. These include biological, genetic, metabolic, psychological, environmental, and social factors. Americans tend to have high-fat diets and put taste and convenience ahead of nutritional content. A sedentary lifestyle and a variety of psychological factors, including depression, anxiety, guilt, and seasonal affective disorder, all contribute to weight gain.

The major differential diagnoses that present with weight gain include hypothyroidism, Cushing's syndrome, renal or hepatic disease, CHF, premenstrual syndrome, pregnancy, medication use, depression, and excessive caloric intake (see Differential Diagnosis Flowchart 16.2).

The patient's history may reveal a family history of obesity, recent weight changes, precipitating psychosocial factors, or a past dieting experience. Food intake (including alcohol) and exercise behaviors should be examined, as well as tobacco and drug use.

A complete physical exam may be needed to evaluate potential pathological causes for weight gain. The weight is recorded and abdominal girth measured, as well as vital

Differential Diagnosis Flowchart 16.2



signs taken. Thyroid function tests (thyroid-stimulating hormone and thyroxine [T_4]), a serum blood glucose level, and a complete blood count are done in the initial evaluation of patients first presenting with weight gain. Serum cholesterol level, triglycerides, and a lipoprotein panel should be obtained to assess the patient's risk factors for cardiovascular disease.

In addition to the complaint of weight gain, patients may present with fatigue, inability to engage in physical activity, dyspnea on exertion, and pain in weight-bearing joints or in the spine. Patients may also present for the treatment of hypertension, diabetes, cholecystitis, or cardiovascular complaints.

Management

Treatment requires a variety of approaches and depends on the cause. Assessing the patient's motivation is crucial in assisting the patient to set realistic goals. The patient may require in-depth counseling and close follow-up. Many commercial and community programs exist to assist the individual with weight control. If an endocrine disorder is suspected, referral to an endocrinologist is indicated.

WEIGHT LOSS, UNINTENTIONAL

Unintentional weight loss of more than 5% of usual body weight within 6 to 12 months may reflect a physical or psychological illness, and a 10% loss of body weight in 1 to 2 months is predictive of a poor clinical outcome. Underweight is defined as being 15% to 20% or more below ideal body weight or a body mass index (BMI) of 18 kg/m^2 or less.

Unintentional weight loss is often a presenting symptom for many underlying pathologies. It may result from a decrease in intake, an increase in metabolic needs, or a combination of the two.

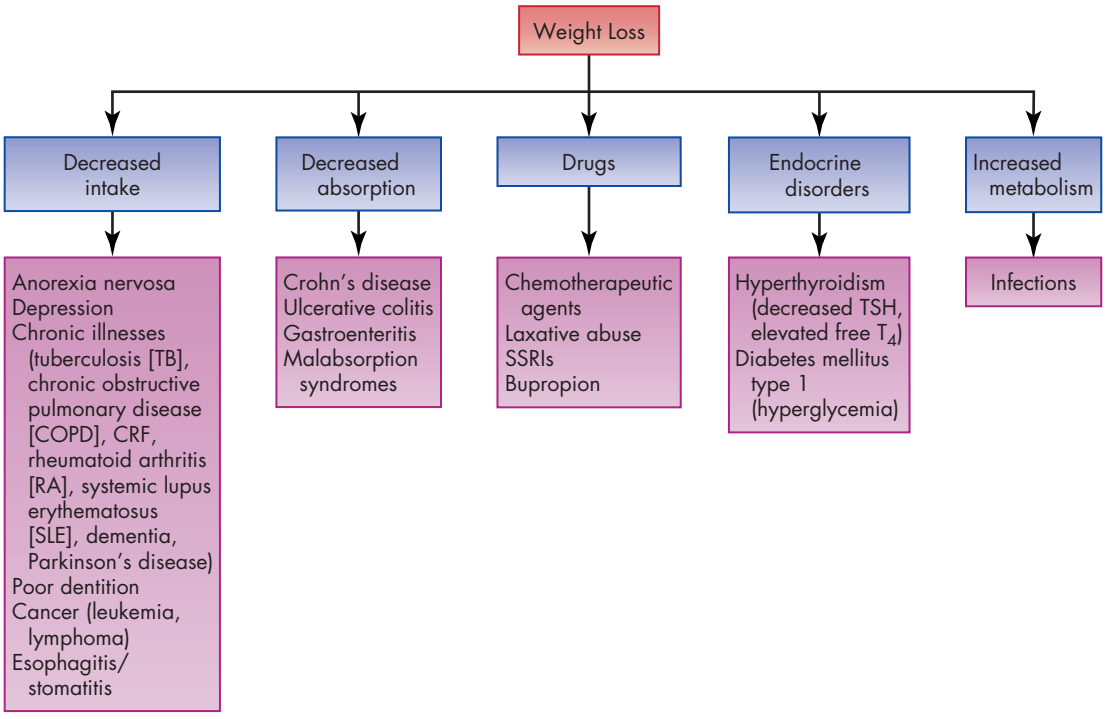
Differential Diagnosis

The history and physical exam may provide initial clues to the cause of the weight loss. The patient's height, weight, and BMI should be recorded, as well as the details about the onset and progression of the weight loss. Actual weight loss needs to be confirmed because it cannot be substantiated in up to 50% of all patients with this complaint. History should include a 3- to 5-day diet record; use of cigarettes, alcohol, or over-the-counter and street drug use; any active medical problems; prescribed medication use; and previous surgery.

Diagnostic testing should be based on the findings of the history and physical exam. Basic screening should include a complete blood count, comprehensive chemistry profile, thyroid function studies, urinalysis, chest x-ray film, and stool for occult blood.

A physical cause of weight loss can be found in about 65% of patients, psychiatric cause in 10%, and no identifiable cause in approximately 25% of cases. Physical causes of weight loss are almost always apparent after a brief evaluation or within 6 months of the first evaluation, even when the initial diagnosis is elusive. Many prescription medications, as well as poor dentition, oral lesions, irritation, and infection, have the potential to cause weight loss (see Differential Diagnosis Flowchart 16.3).

Differential Diagnosis Flowchart 16.3



Management

The underlying medical or psychiatric causes of weight loss should be treated. Neurological causes may respond to medications or rehabilitation. Nutritional deficiencies must be corrected with oral or parenteral supplements; an additional 500 to 1,000 calories per day may be indicated.

Megestrol (Megace) 800 mg/day is used as an appetite stimulant in patients with anorexia associated with HIV/AIDS. Tricyclic antidepressants (amitriptyline [Elavil], imipramine [Tofranil], doxepin [Adapin, Sinequan]) are effective in patients with weight loss associated with depression and stimulate appetite.

Follow-up is determined by underlying cause and plan of management. If no cause is found, the clinician should reevaluate the patient thoroughly in 2 to 3 months. The patient should be referred for systemic medical problems or for psychiatric evaluation. Referral to a nutritionist, a dentist for oral problems, or a social worker may also be indicated. The patient needs to understand the nature of the problem and participate in the development of the treatment plan.

COMMON ENDOCRINE PROBLEMS

HYPERTHYROIDISM

Hyperthyroidism, a common clinical condition, includes a heterogeneous group of conditions characterized by the excessive secretion and synthesis of one or both of the thyroid hormones: thyroxine (T_4) and triiodothyronine (T_3). Although many clinicians use the terms interchangeably, *thyrotoxicosis* is a larger term that encompasses hyperthyroidism, as well as exogenous thyroid hormone intake and subacute thyroiditis, in which acute inflammation of the thyroid gland results in the rapid excretion (rather than overproduction) of stored thyroid hormones.

The clinical manifestations of hyperthyroidism result from the effects of excessive thyroid hormone on body tissue, resulting in alterations in growth, metabolism, and development. These manifestations are sometimes mistaken for signs of psychiatric illnesses. The long-term effects of inadequately treated overt hyperthyroidism are heart disease, osteoporosis (in postmenopausal women), mental illness, and infertility.

Epidemiology and Causes

Hyperthyroidism occurs in 1.2% of the U.S. population. It may occur at any age but peaks in persons aged 20 to 40 years. Only 10% to 15% of hyperthyroidism is diagnosed in older adults. The prevalence of hyperthyroidism is 2% in women older than 70 years and 4% in women aged 40 to 60 years, with an overall prevalence of 1% to 3%. Hyperthyroidism is much more common in women than men (8:1).

National organizations differ in their recommendations for routine screening in asymptomatic patients. In 2004 the U.S. Preventive Services Task Force (USPSTF) concluded that there was insufficient evidence for or against routine screening for thyroid disease in adults without symptoms, and the USPSTF has not updated this recommendation. If the patient is symptomatic or in a high-risk category, such as having a family history of thyroid disease or previous history of thyroid disease or autoimmune disorders, screening is appropriate.

Hyperthyroidism often occurs spontaneously and can result from the excessive intake of thyroid hormones. Graves' disease is by far the most common cause of spontaneous hyperthyroidism in the United States. An autoimmune disorder characterized by autoreactive, agonistic antibodies to the thyroid-stimulating hormone (TSH) receptor, Graves' disease accounts for 80% to 90% of hyperthyroid cases, peaking in young adults aged 20 to 40 years. It is also the most common form of hyperthyroidism occurring in pregnancy.

Subacute thyroiditis is the most common cause of thyrotoxicosis, accounting for 15% to 20% of cases. Characterized by glandular inflammation and follicular cell destruction, it is thought to be of viral etiology, frequently occurring following an acute viral infection. More common in middle-aged adults between 40 and 50 years, subacute thyroiditis is more likely to develop in women than in men. Silent thyroiditis is a form of subacute thyroiditis in which the thyroid gland is moderately enlarged and nontender. It usually occurs in adults between 30 and 40 years and is also more common in women.

Toxic multinodular goiter (Plummer disease) is as common as subacute thyroiditis, accounting for 15% to 20% of thyrotoxicosis cases. This type of goiter is more common in older adults and is a complication of chronic, inactive nodular goiter. This condition is more common in other parts of the world where dietary iodine deficiency is prevalent. A single, toxic thyroid adenoma is the next most common cause of thyrotoxicosis, accounting for 3% to 5% of all cases.

The inappropriate use of thyroid replacement or treatment errors may also produce symptoms of hyperthyroidism. Thyrotoxicosis factitia is a form of thyrotoxicosis in which a patient takes excessive amounts of either thyroxine (T_4) or triiodothyronine (T_3). This condition should be considered in a patient with access to hormone supplements or with a psychiatric problem. An excess of dietary iodine may also precipitate symptoms of hyperthyroidism.

A tumor of the pituitary gland causing hypersecretion of TSH (thyrotropin) is a rare cause of hyperthyroidism. Other uncommon causes include metastatic follicular thyroid carcinoma; ingestion of iodine-containing drugs (e.g., certain expectorants, amiodarone, seaweed-containing health food supplements) or iodinated radiocontrast media; choriocarcinoma or hydatidiform molar pregnancy producing high amounts of human chorionic gonadotropin

(hCG), which is capable of weakly activating the receptor for TSH; struma ovarii (ectopic thyroid tissue), which is associated with dermoid tumors and ovarian teratomas; and testicular embryonal carcinoma (Table 16.1).

Pathophysiology

All types of hyperthyroidism are a result of overproduction and/or secretion of thyroid hormones, and the clinical manifestations of hyperthyroidism are a direct result of the effect of excessive thyroid hormones on essentially all organ systems and bodily tissues. Although thyroid hormones are required to regulate normal growth and development, excessive release of T_4 and T_3 from the thyroid into the circulation upregulates metabolism, leading to an increase in total body heat production, heart rate and contractility, and vasodilation. This explains the clinical manifestations of thyrotoxicosis, which include palpitations, diaphoresis, heat intolerance, and anxiety. T_3 is normally 20 to 100 times more biologically active than T_4, which is converted to T_3 in peripheral tissues. Interestingly, the degree of symptomatology does not consistently correlate with the extent of thyroid hormone overproduction. In general, younger patients tend to have symptoms more reflective of sympathetic activation (tremors, anxiety, and hyperactivity), whereas older patients manifest more cardiovascular symptoms, including atrial fibrillation and dyspnea, as well as weight loss.

Graves' disease is believed to result from an autoimmune response that may reflect a defect in suppressor T-cell function. Serum evaluation usually reveals the presence of antibodies to the thyroid-stimulating hormone receptor (TSH-R), known as thyroid-stimulating immunoglobulin (TSI). This antibody reacts with the TSH-R on thyroid follicular cells and allows release of thyroid hormones independent of the effects of pituitary TSH. Thyroid hormone levels are typically highest with this form of thyrotoxicosis. Excessive thyroid hormone levels result in thyroid growth (hypertrophy), hypermetabolism, and sympathetic overactivity. Circulating antithyroperoxidase (anti-TPO) is another common finding. A diffusely enlarged goiter involving both thyroid lobes, hyperthyroid ophthalmopathy (periorbital edema, conjunctival edema and injection known as chemosis, proptosis, lid lag, and even diplopia), and excessive uptake of radioactive iodine on diagnostic testing are all common characteristics. Graves' disease has a higher prevalence in people with human leukocyte antigen (HLA)–DRw3 and HLA-B89. It also strongly correlates with other autoimmune conditions including vitiligo, type 1 diabetes mellitus (DM), pernicious anemia, myasthenia gravis, or adrenal insufficiency.

In contrast, subacute thyroiditis produces symptoms of thyrotoxicosis via the release of preformed thyroid hormones, in response to an inflammatory response after an acute viral infection. Thus, unlike other common causes of thyrotoxicosis including toxic multinodular goiter and an isolated toxic adenoma that involve increased production and hypersecretion of thyroid hormones, subacute thyroiditis demonstrates a very low uptake of radioactive iodine on diagnostic testing. Subacute painful or granulomatous thyroiditis is associated with HLA-Bw35.

Toxic multinodular goiter typically arises in areas on dietary iodine deficiency. As scattered portions of the thyroid gland increase in activity in an attempt to compensate for insufficient iodine, hormonal excess develops slowly over time. In fact, this condition may be asymptomatic at the time of diagnosis, especially in older individuals in whom the classic symptoms of hyperthyroidism may be blunted (a condition termed *apathetic hyperthyroidism*).

Nuclear scintigraphy demonstrates scattered areas of both increased and decreased iodine uptake, which reflect the increased thyroidal activity that manifests in the setting of adequate dietary iodine. In contrast, a single

Table 16.1 Hyperthyroidism: Common and Rare Causes

	Disorder/Problem	Etiology
Common Causes	Graves' disease	Autoimmune disease
	Toxic nodular goiter	Unknown development of nodules that progress from nontoxic to toxic over time
	Subacute thyroiditis	Thought to be caused by viral infection
	Thyrotoxicosis factitia	Excessive ingestion of exogenous thyroid hormones
	Jod-Basedow phenomenon	Large intake of iodine in diet in a person with thyroid disease
Rare Causes	Pituitary adenoma	Rare tumor of the pituitary gland
	Struma ovarii	Rare secretion of thyroid hormones by thyroid tissue located in ovarian dermoid tumors
	Metastatic thyroid cancer	Very rare cause
	High-dose amiodarone	Excessive dosage of iodine-containing amiodarone
	Pregnancy and trophoblastic tumors	Very high serum levels of hCG

hyperfunctioning monoclonal follicular adenoma will demonstrate only a single focus of increased uptake on a radioactive thyroid scan. Such nodules tend to be functional only once they reach at least 2.5 cm in size. As pituitary TSH production is suppressed by the adenoma, the remaining glandular tissue becomes hypofunctional and actually demonstrates decreased uptake on nuclear scintigraphy.

Autoregulation of the thyroid normally prevents thyrotoxicosis in the face of dietary iodine excess, a phenomenon known as the Jod-Basedow effect. However, in the setting of a particularly concentrated iodine load (such as with iodinated radiocontrast media), patients with one or more autonomous thyroid nodules may lose this adaptive capability and be thrown into thyrotoxicosis (Jod-Basedow syndrome).

Clinical Presentation

The clinical presentation of hyperthyroidism depends on the duration and the amount of excessive thyroid hormone secretion. Symptoms are varied and depend on the cause and the multiple organ systems affected. Patients may be asymptomatic in the presence of mild elevations of thyroid hormones; they are more likely to remain asymptomatic at increasing levels if the increased secretion has been gradual.

Subjective

Because thyroid hormones have effects on most organ systems, a complete history and review of systems is indicated. Most patients with hyperthyroidism will complain of some combination of anxiety, nervousness, diaphoresis, fatigue, heat intolerance, palpitations, weight loss, and insomnia. In situations in which the thyroid tissue has become enlarged, the patient may complain of fullness or pressure in the neck. Additional symptoms include weakness, exercise intolerance, tremors, lower extremity edema, weight loss in the presence of an increased appetite, menstrual irregularities, frequent bowel movements or diarrhea, and exertional dyspnea.

Eye complaints include blurred vision, proptosis (downward displacement of the eyeball), photophobia, and double vision. Patients may also report that they are unable to concentrate, extremely irritable, and emotionally labile. Older patients may present with vague symptoms such as unexplained weight loss, apathy, worsening of angina, depression, change in bowel habits, and weakness. A summary of potential signs and symptoms of hyperthyroidism is presented in Table 16.2.

Patients should be questioned about current and prior endocrine diseases (in the patient and family), as well as a personal or family history of thyroid nodules, goiter, use of iodide-containing drugs, and thyroid neoplasms. Radiation to the head and neck increases the risk of thyroid cancer, which can produce hyperthyroidism. A weight history should be obtained, including recent and long-term weight patterns. If the patient is currently taking thyroid hormone replacement medication, how the medication is being taken should be assessed. Patients should also be questioned about any recent viral infections or the possibility of pregnancy, as well as use of other medications.

Objective

Signs of thyrotoxicosis on physical examination are associated with the various forms of hyperthyroidism and range from overt manifestations in young adults with an acute onset to a more subtle presentation in older adults. Often, an older adult will present with symptoms typically diagnosed as failure to thrive.

On physical examination, the thyroid may be enlarged, nodules may be palpable, and a bruit may be heard over the thyroid gland with the bell of a stethoscope. The neck should be examined for visual enlargement of the thyroid and palpated for lymphadenopathy. The thyroid must be palpated thoroughly, noting any nodules or enlargement, both anteriorly and posteriorly. Whereas the goiter of Graves' disease is often somewhat firm, the thyroid in toxic multinodular goiter may be softer, but with several palpable nodules. The neck should be moderately extended during examination, and water should be provided to the patient to aid swallowing. The thyroid gland moves with swallowing; however, a very large goiter or a large thyroid mass may prevent movement.

In subacute thyroiditis, the patient will present with a firm, painful, thyroid gland enlargement, fatigue, and possibly a low-grade fever. An enlarged painful thyroid gland is also consistent with degeneration or hemorrhage into a thyroid nodule, as well as either granulomatous or suppurative thyroiditis. In contrast, in silent thyroiditis or subacute lymphocytic thyroiditis, the gland is swollen but not usually tender.

Cardiovascular manifestations include tachycardia (resting heart rate greater than 90 beats per minute), irregular pulse, systolic murmurs, and widening of the pulse pressure. Although rare, an infiltrative dermopathy may be present in the lower extremities, which includes myxedema (deposition of glycosaminoglycan material in the dermis of the lower extremities causing nonpitting pretibial edema), erythema due to an inflammatory cell infiltrate, and skin thickening along the ankles and pretibial areas.

Visual acuity is tested, and the patient is assessed for lid lag. Lid lag is assessed by instructing the patient to slowly gaze up and down. As the patient gazes downward, the upper lid will lag behind the globe. Lid lag can also be detected by the globe lagging behind the lower lid as the patient gazes upward. Hyperthyroid ophthalmopathy occurs in 40% of patients with Graves' disease and is rare in patients with subacute thyroiditis. The conjunctiva may be inflamed, and visual acuity may be affected. Exophthalmos, excessive lacrimation, lid retraction, and lid lag may be present.

Table 16.2 Hyperthyroidism: Clinical Presentation

Body System	Subjective	Objective
General	Fatigue Weight loss Increased appetite	Muscle atrophy Tremors
Integumentary	Diaphoresis Heat intolerance	Warm, flushed, moist skin Onycholysis Hyperpigmentation Fine and silky hair Thinning hair Dermopathy of legs Pretibial myxedema urticaria Pruritus vitiligo
Gastrointestinal	Diarrhea Increased bowel movements Increased appetite	Increased liver function
Eye	Blurred vision Increased tearing Double vision Decreased visual acuity Photophobia Feelings of increased orbital pressure	Increased exophthalmos Lid lag and edema Corneal ulceration
Neurological	Tremors of hands	Hyperactive reflexes Tremor
Cardiopulmonary	Palpitations Exertional dyspnea	Sinus tachycardia Elevated blood pressure Symptoms of congestive heart failure Dysrhythmias (atrial fibrillation)
Genitourinary	Menstrual irregularities (decreased menstrual flow)	Gynecomastia
Head and neck	Pressure in neck Increased neck size	Enlarged thyroid gland
Psychosocial	Anxiety Nervousness Insomnia Irritability Emotional lability Restlessness	Increased pulse rate Increased respiratory rate Increased blood pressure
Musculoskeletal	Weakness	Proximal muscle weakness Loss of muscle tone Osteoporosis (postmenopausal women)
Hematological	Fatigue Breathlessness Palpitations	Normochromic normocytic anemia
Metabolic		Hypercalcemia Potassium wasting Increased alkaline phosphatase

The examiner should assess the skin for edema, general appearance, and signs of thinning hair. The skin may be moist and velvety to the touch, with increased pigmentation, spider angiomas, and vitiligo. Onycholysis (splitting and spooning of the nails) may be present.

Deep tendon reflexes may show a rapid relaxation of the reflex, and the most predominant hyperactive reflex is usually the Achilles tendon reflex. The patient may have decreased strength in the extremities and fine tremors, especially of the hands when the arms are fully outstretched. Lymphadenopathy and splenomegaly may also be present. A few patients may also have nonpitting pretibial edema.

Patients with long-standing hyperthyroidism may also have clubbing of the digits and signs of new bone growth in the hands, termed *thyroid acropachy*. Older adults with hyperthyroidism often appear apathetic. Physical examination may reveal atrial fibrillation (present in one-third of all older adults with hyperthyroidism), fine skin, brittle nails, and symptoms of congestive heart failure. The thyroid gland is often not enlarged in older adults.

Thyroid storm or crisis is a severe, sometimes fatal form of hyperthyroidism and requires immediate emergency medical care. Assessment, contributing factors, and treatment are listed in Table 16.3.

Diagnostic Reasoning

Diagnostic Tests

Initial Testing Laboratory examination is undertaken with the understanding that in many situations, levels of thyroid hormone often do not correlate reliably with the clinical presentation. The initial screening tests for suspected hyperthyroidism are measurement of the serum-sensitive TSH assay to detect suppressed levels in the setting of elevated thyroid hormones, T_4 and T_3. Laboratory protocols that add free thyroxine immunoassay (FT_4) and T_3 if the TSH is low can avoid additional blood draws and expense. If the protocol is not in place, an FT_4 and T_3 should be tested next. The sensitive TSH assay has a functional sensitivity of 0.02 mcg/dL or less, although units for this test are typically expressed as mIU/L or mcIU/mL.

In most cases of hyperthyroidism, a TSH level less than 0.35 mIU/L usually accompanies an elevated FT_4 measurement (above 12.5 mcg/dL). Measurement of

Table 16.3 Thyroid Storm/Crisis

Contributing Factors	Acute infection Trauma Stress in patient with hyperthyroidism Uncontrolled DM Severe drug reaction Following withdrawal of antithyroid medication or radioactive iodine therapy
Symptoms: Initial	Fever (usually initial symptom), often >100.4°F (38°C) Nausea, vomiting Abdominal pain
Symptoms: Progressive	Severe agitation, occasional psychosis Elevated temperature Diaphoresis Tachycardia, heart failure Dysrhythmia (atrial fibrillation of flutter) Confusion Cardiovascular collapse Malignant exophthalmos Elevated free thyroid hormone (T_4) levels but no more increased than hyperthyroidism; clinical diagnosis, not biochemical
Management	Hospitalization and aggressive reversal of thyrotoxins **1.** To block thyroid hormone synthesis, propylthiouracil (PTU) is given daily in two to four divided doses; methimazole is typically not used during thyroid storm because it does not prevent peripheral conversion of T_4 to T_3. **2.** To alleviate the beta-adrenergic symptoms, beta blockers are given (propranolol [Inderal] IV). **3.** To block conversion of T_4 to T_3, hydrocortisone is given IV. **4.** If radioactive iodine is prescribed but not given for a few days, potassium iodide oral solution (SSKI) or telepaque may be given. **5.** Supportive measures—decrease fever, treat underlying infection, give fluids and glucose.

FT_4 is generally preferred over total T_4 because it measures the level of T_4 unbound to carrier proteins, which is, therefore, biologically active. In turn, a significant number of medications may alter the laboratory results due to alterations in protein binding. These include anabolic steroids, androgens, estrogens, heparin, iodine-containing compounds, phenytoin (Dilantin), rifampin (Rimactane, Rifadin), and salicylates. In addition, in the setting of a low TSH, T_3 levels should be obtained because about 5% of hyperthyroid patients have normal T_4 levels but elevated T_3 levels. Normal levels for T_3 range from 100 to 200 ng/dL.

Subsequent Testing In Graves' disease, antithyroglobulin and antimicrosomal antibodies are elevated. A TSH receptor antibody test is usually elevated in Graves' disease and is part of subsequent testing. The diagnosis of thyrotoxicosis is considered in cases of hyperthyroidism when TSH levels are depressed and measurements of T_4 are normal. Subacute thyroiditis may also have laboratory abnormalities of elevated erythrocyte sedimentation rate and C-reactive protein. Mild anemia is also common.

Nuclear scintigraphy with radiolabeled iodine (^{123}I) or technetium (^{99}Tc) helps in assessing the functional status of the thyroid gland. A 24-hour radioactive iodine uptake (RAIU) test can differentiate Graves' disease from subacute thyroiditis and toxic nodular goiters, thereby refining treatment recommendations. It identifies areas of increased and decreased thyroid function, often termed *hot* and *cold* spots, within the gland. Patients with toxic nodular goiter and Graves' disease have a high RAIU, whereas in subacute thyroiditis, iodine uptake is low. Importantly, however, toxic adenoma and toxic multinodular goiter both present with areas of decreased isotope uptake as well, because the hyperfunctioning nodules lead to suppression of TSH via negative hormonal feedback. A thyroid scan is critical to determining functionality of any dominant thyroid nodule in a patient presenting with thyrotoxicosis, because cold nodules are highly suspicious for concomitant malignancy and must be evaluated further.

An ultrasound of the thyroid will assist in differentiating a cyst from a nodule. A pure thyroid cyst is less likely to be malignant than a nodule. A fine-needle biopsy is the preferred initial diagnostic technique for evaluation of thyroid masses, particularly solid masses, to rule out malignancy. Magnetic resonance imaging is the preferred test to assess for ophthalmopathy resulting from Graves' disease. It is especially beneficial in ruling out an orbital tumor.

Differential Diagnosis

Thyrotoxicosis, with high levels of TSH, is seen in a rare pituitary tumor. Excessive exogenous thyroid administration will produce the same symptoms seen in thyrotoxicosis. Thyroid cancer must be considered when the thyroid gland is hard and enlarged or when nodules are palpated.

T_4 levels may be elevated in acute illnesses such as hepatitis, in the presence of elevated estrogen levels, acute psychiatric problems, hyperemesis, familial thyroid hormone binding abnormalities, and autoimmunity. Dopamine (Intropin, Dopastat) and high dosages of glucocorticoids may decrease TSH levels. Drugs that may increase T_4 levels are amiodarone (Cordarone), amphetamines, clofibrate (Atromid-S), glucocorticoids in high doses, heparin administered during dialysis, heroin, levothyroxine (Synthroid), methadone (Dolophine), and perphenazine (Trilafon).

Management

Treatment of hyperthyroidism differs depending on the cause and patient characteristics. A euthyroid state is the goal of treatment, while minimizing the adverse effects of treatment and decreasing the incidence of hypothyroidism.

Emergency treatment is necessary if the patient presents in thyroid storm (see Table 16.3). The patient should be hospitalized for oral and IV hydration, if needed, and immediately begin thyroid-blocking medications, beta-adrenergic blockers, and corticosteroids if signs of ophthalmopathy are present. Iodine blocks the release of stored thyroid hormones, and glucocorticosteroids block the conversion of T_4 to T_3. Patients intolerant of beta blockers (asthmatics, patients with chronic obstructive pulmonary disease [COPD]) may be treated with calcium channel blockers as an alternate therapy. Supportive measures include treating any underlying infection; managing fever with antipyretics, hydration, and cooling blankets; and correcting any fluid and electrolyte imbalances. In critically ill patients, utilization of plasma pheresis or dialysis may reduce the circulating levels of T_3 and T_4.

Multinodular and uninodular goiters should be referred to an endocrinologist for evaluation of possible malignancy. Nonmalignant thyroid nodular disease with laboratory evaluations indicating hyperthyroidism is most often treated with radioactive iodine.

Management of Graves' Disease

The three treatment options for Graves' disease are antithyroid drugs, radioactive iodine, or surgery. None of these treatments alters the underlying autoimmune process of Graves' disease. The most successful treatment in achieving a permanent euthyroid state is surgery; however, it is rarely the preferred method of treatment unless the thyroid gland is extremely enlarged and is pressing on other structures in the neck. Many patients treated with radioactive iodine will experience a relapse and require a second treatment. Radioactive iodine also may worsen ophthalmopathy if present. Currently the majority of endocrinologists use an ablative dosing of radioactive iodine. This allows the resolution of hyperthyroidism, although patients then become hypothyroid and require thyroid replacement therapy for life.

Pharmacological Therapy Patients experiencing tachycardia, palpitations, or tremor benefit from the introduction of a beta blocker during initiation of therapy. Beta blockers provide effective, short-term relief of hyperadrenergic symptoms. Use of a beta blocker is contraindicated in patients with COPD, bronchospasm, or uncompensated heart failure. It is used cautiously in patients who take insulin for DM because it may block symptoms of hypoglycemia. Beta-adrenergic blockers often require higher and more frequent dosing because of the frequent resistance to usual doses. Once ablative treatment is completed, beta blockers will be tapered and discontinued. As stated previously, calcium channel blockers are an option in patients for whom beta blockers are contraindicated; however, this class of drug should also be avoided in patients with uncompensated heart failure, given their propensity to decrease inotropy (cardiac contractility).

Antithyroid medications work by inhibiting thyroid hormone synthesis at multiple steps. They are used as a primary treatment to reduce the level of hormone on initiation of radioactive iodine therapy, as well as before and after thyroid surgery. These drugs take time to achieve their peak effect, however, and hormone levels may not be significantly decreased for up to 2 to 8 weeks. These medications are not used as primary or sole treatment in the majority of patients.

Two antithyroid drugs are being used at present—propylthiouracil (PTU) and methimazole (MMI). These drugs are the treatment of choice for pregnant women, especially PTU, because it is less likely to cross the placenta than MMI. As a pregnancy progresses, the dose of PTU often decreases and can frequently be discontinued before delivery. It is important to remember that antithyroid drugs do cross the placental barrier, and overtreatment can have adverse effects on a fetus, thus the importance of having a clinical endocrinologist consulting on a pregnant woman's care. They are often used in persons awaiting surgical intervention and in patients of childbearing age. Antithyroid drug treatment is often the preferred treatment in patients without significant thyroid gland enlargement. PTU has an added therapeutic effect of inhibiting T_3 activity and preventing peripheral conversion of T_4 into T_3—the more biologically active of the two main thyroid hormones. Thus, it is useful in cases of thyrotoxicosis to rapidly reduce hyperthyroid symptoms.

PTU is usually started at doses of 50 to 150 mg PO two or three times per day (150–300 mg per day). MMI (Tapazole) is given at an initial dosage 10 to 40 mg orally or rectally daily. The dosage is titrated every 3 to 4 weeks based on thyroxine levels and TSH levels. TSH and T_4 levels are evaluated every visit, and a targeted history and physical is performed to monitor therapeutic response. (See Drugs Commonly Prescribed 16.1: Hyperthyroidism.)

Because of the amount of thyroid hormone stored in the thyroid gland, it may take 2 to 8 weeks to see a therapeutic response to antithyroid medication. These drugs are not indicated for long-term use because more than one-half of patients on these drugs alone experience resumption of symptoms. Once the patient has achieved a euthyroid state, the frequency of follow-up visits is extended to every 4 to 6 weeks for a period of 3 to 4 months. If the TSH and free T_4 remain stable during this time, the follow-up is extended to every 3 to 4 months. In patients taking antithyroid medication, a serum FT_4 level should be evaluated with TSH levels, because the TSH level may remain suppressed due to chronic hyperthyroidism long after T_4 levels are decreased.

Common adverse reactions to antithyroid medications include rash, urticaria, and arthralgias, which may occur in 1% to 5% of patients. Rare but serious adverse reactions include agranulocytosis, aplastic anemia, and hepatitis, which may occur in up to 0.5% of patients taking antithyroid medications. Except for agranulocytosis, which is more common with MMI, these reactions are more likely to occur with PTU. Thus, patients taking these drugs should be instructed to report immediately any signs of infection, especially a fever, sore throat, malaise, or mouth sores. The antithyroid medication must be discontinued immediately if any of these symptoms are

Drugs Commonly Prescribed 16.1 Hyperthyroidism

Drug	Indications	Adverse Reactions and Prescribing Considerations
propylthiouracil (PTU)	Hyperthyroidism	Common: Pruritus, drowsiness, allergic dermatitis, nausea, vomiting, arthralgia Rare: Agranulocytosis Note: Onset of drug action is 1 week, peaking in 4–10 weeks with a duration of 1–4 weeks.
methimazole (MM) (Tapazole)	Hyperthyroidism	Common: Pruritus, drowsiness, allergic dermatitis, nausea, parotitis, arthralgia Rare: Agranulocytosis Note: Onset of drug action is 1 week, peaking in 4–10 weeks with a duration of 36–72 hours.

experienced. The patient is often changed to a regimen of radioactive iodine to produce a euthyroid state. Agranulocytosis may take up to 10 to 14 days to resolve fully after the medication is stopped and may require concomitant administration of granulocyte colony-stimulating factor (filgrastim).

Before initiation of antithyroid therapy, a baseline complete blood count and liver function tests including hepatic aminotransferases (aspartate aminotransferase, alanine aminotransferase) should be obtained. During therapy, the white blood cell count is checked every 2 weeks during the first month and then every 4 to 6 months thereafter. Liver enzymes should be evaluated every 3 to 6 months.

Antithyroid drugs (see Drugs Commonly Prescribed 16.1: Hyperthyroidism) are used for 6 to 24 months after achievement of a euthyroid state. The dosage is then gradually decreased until the drug is withdrawn. The patient is followed every 1 to 2 months initially after cessation of therapy for a possible relapse. Many patients will experience a permanent remission after a 1- to 2-year course of antithyroid medications.

Radioactive Iodine Radioactive iodine–131 (^{131}I; Iodotope) is the treatment of choice for hyperthyroidism in the United States, especially in middle-aged or older adults. Typically, a 24-hour radioiodine uptake dose of 75 to 200 mcCi per gram of estimated thyroid tissue is administered orally, which concentrates in overactive thyroid cells, where it emits radiation, causing inflammation and the ultimate destruction of the pathological cells. It is less invasive than thyroidectomy, is a targeted therapy that is focused solely on the thyroid, and does not require hospitalization. Although response to this therapy is slower than with antithyroid drugs or surgical excision, radioablation is indicated in patients who have a poor response to antithyroid medication, as well as in cases of toxic multinodular goiter. Radioiodine is contraindicated in pregnancy and breastfeeding. The recurrence rates for hyperthyroidism are relatively low. For patients with Graves' disease, there is a 5% recurrence 1 year after treatment and that remains steady for 5 years as opposed to patients with uninodular or multinodular toxic goiter, which has a 6% to 7% recurrence rate and a 30% recurrence rate after 5 years (Level II; Bakos et al, 2013).

Women receiving radioactive iodine therapy should refrain from becoming pregnant for 4 months after therapy. T_4 levels need to be checked monthly for 3 months after the administration of radioactive iodine in patients receiving radioactive thyroid ablation therapy. Euthyroid patients should be assessed every 3 to 6 months for hypothyroidism by monitoring the FT_4 and sensitive TSH levels. Hypothyroidism may occur at any time, but is most likely to present during the first year. Some patients will fail treatment and require a second dose. First-time failure rates may be as high as 45%, but about 70% of patients receiving radioactive iodine therapy eventually develop hypothyroidism.

Hyperthyroid ophthalmopathy is often exacerbated with radioactive iodine treatment; however, research has found that the incidence of ophthalmopathy is reduced when prednisone (0.4 mg/kg) is given concurrently with radioactive iodine treatments. If ophthalmopathy occurs, the patient requires referral to an ophthalmologist. Treatment often includes diuretics and ophthalmic prednisone. Methylcellulose eyedrops (Tear Naturale) are useful to protect against excessive eye dryness.

A nonradioactive alternative to thyroid radioablation for severe Graves' disease or subacute thyroiditis involves administering a large quantity of concentrated iodine as a saturated solution of potassium iodide (SSKI, 35–50 mg iodide per drop, 1–2 gtts in water PO 2 times daily; Lugol solution, 8 mg iodide per drop, 3–5 gtts in water PO 3 times daily) or iopanoic acid (Telepaque, 1–3 g PO or 0.5 g PO 2 times daily). These concentrated iodine therapies effectively block the conversion of T_4 to T_3 and inhibit the release of thyroid hormones. SSKI and Lugol solution should not be used when autonomous thyroid nodules are present, however, such as in toxic multinodular goiter or toxic adenoma, because they may worsen thyrotoxicosis. In addition, these therapies are generally used only in severe cases of thyrotoxicosis because their use precludes definitive therapy with radioactive iodine for several months (the thyroid must first process out the iodine load).

Surgery Surgery (subtotal or total thyroidectomy) is required for patients with compressive symptoms of the neck such as hoarseness (from compression of the recurrent laryngeal nerve) or respiratory stridor, which indicates displacement of the trachea. It may also be considered for cosmetic reasons, for patients who have failed other treatment options, and for patients with refractory amiodarone-induced hyperthyroidism. Surgery is often recommended in a patient with a large gland, multinodular goiter, or when thyroid cancer is suspected. It is also indicated in individuals who cannot tolerate antithyroid medication; however, an antithyroid medication may be administered during the initiation of therapy to prevent excessive release of stored thyroid hormones. In addition, propranolol is typically used to decrease the resting heart rate to below 80 beats per minute, and SSKI may be administered (1–2 gtts PO 2 times daily) for 2 weeks before surgical resection. Before the development of these preoperative pharmacotherapies, thyroidectomy was one of the most common causes of thyroid storm. Today, important complications of surgery include permanent hypothyroidism, which will require lifelong thyroid hormone replacement, and laryngeal paralysis via damage to the recurrent laryngeal nerve. Hypoparathyroidism may also result if one or more of the parathyroid glands are inadvertently resected during surgery.

Management of Subacute Thyroiditis

Subacute thyroiditis is a self-limiting condition treated with beta-adrenergic blocking medications and NSAIDs.

If patients have moderate to severe symptoms or do not respond to beta blockers and NSAIDs, they are candidates for treatment with corticosteroids. Subacute thyroiditis often follows a viral illness. After the thyroiditis, some patients may experience a transient hypothyroid state. These patients will need thyroid hormone until they return to a euthyroid state. For the patient with severe pain, an NSAID may help. Short-term use of oral prednisone (Deltasone) may be indicated for severe inflammation and pain. Doses of 40 mg daily for 1 to 2 weeks with a gradual taper over 2 to 4 weeks are usually effective.

Management of Subclinical Hyperthyroidism

Subclinical hyperthyroidism is characterized by undetectable TSH levels and normal levels of T_4 and T_3. Treatment is only recommended for patients over 65 years of age or patients with cardiac disease or some evidence of symptoms related to hyperthyroidism. There is an increased risk of atrial fibrillation in hyperthyroid patients over age 65 years who have a TSH level between 0.1 and 0.5 mIU/L. Consultation with an endocrinologist is indicated for these patients. If treatment is not initiated, the patient should be monitored every 6 months for overt hyperthyroidism.

Patients experiencing symptoms of infiltrative ophthalmopathy will need to be followed by an ophthalmologist. Glucocorticoids, diuretics, and methylcellulose eyedrops may provide symptomatic relief. Radiation or surgical decompression may be initiated by the ophthalmologist in severe cases.

Follow-up and Referral

The complex nature of thyrotoxicosis requires collaboration and referral to an endocrinologist for effective management and close follow-up. Importantly, up to half of all patients with Graves' disease who go into remission after starting antithyroid pharmacotherapy without definitive thyroid ablation with have a second attack of thyrotoxicosis within 1 year. In addition, all patients with Graves' disease should be referred to an ophthalmologist for full evaluation, because up to half of these patients have some form of ophthalmopathy, which may present subclinically. In contrast, Graves' disease ophthalmopathy may present before the patient develops symptoms of full-blown thyrotoxicosis.

Specific time frames for follow-up are dependent on the treatment and patient response. TSH, FT_4, and T_3 levels should be monitored at each follow-up visit, as well as measurements of blood pressure, pulse, weight, and character of the thyroid gland. General guidelines include the following:

1. Monitor thyroid function tests at least twice a year.
2. Initial treatment should be evaluated at 1 month and at 6 months or more frequently if the patient is symptomatic.
3. Therapy with antithyroid medications should continue for 3 to 24 months.
4. After radioiodine therapy, thyroid function tests should be performed at 4 to 6 weeks, 12 weeks, 6 months, and annually thereafter, if stable.

Patient Education

After diagnosis, the patient with hyperthyroidism must be provided with the various treatment options available. The risks and benefits of each treatment must be explained. The importance of strict adherence to provider guidelines for follow-up must be stressed to each patient. If the treatment regimen has produced a state of hypothyroidism, the patient is informed that thyroid replacement therapy must continue for life.

Patients must be instructed that it takes 4 to 6 weeks after medication begins to notice an improvement in symptoms because of the amount of stored hormone in the thyroid gland. Patients who are unaware of this phenomenon may not comply with the treatment regimen. Patients need written instructions for the signs and symptoms of thyroid storm, as well as signs of hypothyroidism once treatment is initiated. The patient should be informed of all potential adverse reactions of all medications, particularly those of antithyroid preparations, and to discontinue the medication and to call the primary-care provider if a fever, sore throat, or malaise develops.

Persons receiving radioactive iodine therapy should avoid contact with infants, children, and pregnant women for 7 days after ingestion. Women who receive this treatment postpartum must not breastfeed for at least 3 to 6 months, because radioactive iodine is excreted in breast milk and can ablate the infant's thyroid.

The need for adequate rest and exercise should be stressed. Patients will need adequate sleep, as well as relaxation time, and should be taught methods to promote relaxation, such as biofeedback, music, or guided imagery. Patients should be encouraged to express their concerns regarding psychosocial implications of their disease, and the physiological basis for their symptoms should be reinforced.

Patients who complain of heat intolerance may benefit from wearing or sleeping on natural fabrics during the summer months and should remain adequately hydrated. Patients who have experienced significant weight loss may benefit from a high-carbohydrate, high-calorie diet. A patient with Graves' disease may benefit from dividing food intake into six smaller meals daily. If diarrhea is a problem, discourage foods that increase peristalsis such as highly seasoned foods and bulky or fibrous foods. The patient should check his or her weight daily and report any weight loss of more than 4 pounds in 1 day immediately. A consistent weight loss of 1 to 2 pounds daily should also be reported. A supplemental multivitamin, particularly with vitamin B complex, is needed to prevent deficiencies in times of severe hyperthyroidism because of a high level of vitamin consumption during states of elevated thyroid hormone levels.

Once treatment is initiated and the patient is euthyroid, caloric needs decrease but the patient may still have an increased appetite. A sensible diet low in fat and sugar with adequate protein may avoid a significant unwanted weight gain during this period. The patient should be instructed to check his or her weight frequently and to adjust intake to maintain an ideal weight. Stimulants such as caffeine should be avoided. A multivitamin is often indicated for patients who have sustained thyrotoxicity. Patients suspected of having long-standing hyperthyroidism may benefit from vitamin D and calcium supplementation because osteoporosis is a complication of elevated thyroid hormones.

Some patients may experience depression as the levels of thyroid hormones change, and this should be explained. The patient should be instructed to report any worsening of symptoms of depression. If the patient presents with signs or symptoms of depression or anxiety, he or she should be evaluated for depression or anxiety. If reassurance does not relieve anxiety, temporary symptomatic treatment may be indicated.

Patients with exophthalmos should wear dark lenses outdoors during the day. The use of artificial tears may relieve feelings of dryness and provide some corneal protection. Glasses or eye protection should be worn during any activity that may introduce dust or dirt into the eyes. A sleeping mask should be worn at night if the patient cannot close the eyes adequately. Elevating the head of the bed at night and restricting sodium intake may relieve edema.

Patients taking antithyroid medications should wear a medical identification bracelet.

HYPOTHYROIDISM

Hypothyroidism is a common, treatable disorder in which there is a slow progression of thyroid hypofunction, followed by signs and symptoms indicating thyroid failure. It is a disease of various causes that lead to inadequate amounts of thyroid hormone being produced and/or secreted, resulting in a slowing of many body functions and metabolic processes. Because hypothyroidism has an insidious onset and progresses slowly, the clinical manifestations may go unrecognized.

Thyroid hormone deficiency present at birth was historically called *cretinism* but is now known by the less pejorative term *congenital hypothyroidism.* Affecting 1 in 4,000 newborns, the causes of congenital hypothyroidism include developmental abnormalities of the thyroid gland, enzymatic defects, iodine deficiency, maternal antibodies to thyroid hormones, and excessive intake of goitrogens by the mother. In such instances, the mother may also suffer from thyroid deficiency. Thyroid hormone deficiency beginning in early infancy and childhood is characterized by growth retardation, mental deficiency, and delayed dentition. Adolescents with primary hypothyroidism may manifest an enlarged sella turcica and, rarely, precocious puberty, in addition to growth retardation. Growth retardation is treatable with hormone replacement therapy, but mental retardation persists.

Subclinical hypothyroidism is the presence of normal free thyroxine immunoassay (FT_4) with an elevated thyroid-stimulating hormone (TSH). As many as 15% of patients older than age 65 years have these levels, as do many other adults. However, few of these patients report symptoms, or their symptoms are nonspecific.

Epidemiology and Causes

The incidence of hypothyroidism varies with age, gender, and geographical and environmental factors. The incidence from numerous surveys ranges from 3 to 14 cases per 1,000 women, with significantly fewer cases reported in men. In fact, the incidence in women is 2 to 8 times greater than it is in men. It is estimated that as many as 4.6% of the U.S. population has an elevated TSH with a higher incidence in whites (5.1%) than in either Hispanics (4.1%) or African Americans (1.7%).

The most common worldwide cause of thyroid disorders is iodine deficiency, with a worldwide prevalence of 2% to 5%. In the United States, where iodine ingestion is usually adequate, autoimmune processes are the primary cause of thyroid disease. Hashimoto's thyroiditis, a type of primary hypothyroidism, is the most common form of autoimmune thyroid disease. This type of hypothyroidism occurs at least four times more often in women than in men, with the average age at onset from 30 to 60 years.

Iatrogenic hypothyroidism, which occurs after treatment with radioactive iodine (for hyperthyroidism) or surgery (for hyperthyroidism, thyroid nodules, or thyroid carcinoma), is the next most common cause of hypothyroidism, accounting for 30% to 40% of cases. Hypothyroidism also becomes increasingly common with age; in individuals older than age 50 years, up to 10% may have elevated TSH levels.

More than 95% of patients with hypothyroidism have primary or thyroidal hypothyroidism, involving dysfunction or atrophy of the thyroid gland. When the thyroid dysfunction is caused by failure of the pituitary gland, the hypothalamus, or both, it is known as central hypothyroidism. More specifically, secondary hypothyroidism refers to the failure of the pituitary gland to secrete adequate amounts of TSH. Tertiary hypothyroidism is a type of hypothyroidism resulting in inadequate secretion of thyrotropin-releasing hormone (TRH) by the hypothalamus or failure of TRH to activate its cognate receptors within the pituitary (peripheral resistance). Table 16.4 summarizes the causes of hypothyroidism.

Although one in five women will develop an alteration in thyroid function in her lifetime, recently published clinical guidelines do not recommend routine screening of asymptomatic women before age 50 years. Many clinicians, however, still use age 40 years as their criterion to begin screening. In 2004 the U.S. Preventive Services Task Force (USPSTF) found insufficient evidence to

Table 16.4 Causes of Hypothyroidism

Cause	Etiology
Loss of functional thyroid tissue	Idiopathic hypothyroidism: Atrophy (probably autoimmune), TSH receptor–blocking antibodies. Chronic autoimmune thyroiditis (Hashimoto's disease), subacute, postpartum, treatment with cytokines or amiodarone, external radiation. Status—post-radioiodine (^{131}I) treatment Status—post-thyroidectomy Infiltrating disorders: Malignancy, granulomatous disease Thyroid dysgenesis
Biosynthetic defects in thyroid hormone production	Inherited defects in hormone synthesis Iodine deficiency Antithyroid agents: Thioamides, lithium, iodide
Central hypothyroidism	TSH deficiency caused by pituitary disease: Postpartum infarction (Sheehan syndrome), tumors (e.g., craniopharyngioma, pituitary adenoma), granulomatous disease (sarcoidosis), irradiation, idiopathic TSH deficiency caused by hypothalamic disease: Tumors, irradiation, and transiently occurring nonthyroid illness Peripheral resistance to TSH by the pituitary
Transient hypothyroidism	Postpartum thyroiditis Subacute thyroiditis (usually viral) Withdrawal of thyroid hormone therapy in a euthyroid patient

recommend for or against routine screening for thyroid disease in adults. The American Thyroid Association recommends measuring thyroid function in all adults starting at age 35 years and then at least every 5 years. The American College of Physicians recommends TSH measurement in women older than 50 with one or more general symptoms that could be caused by thyroid disease. These organizations and many others have come to no clear recommendation for screening asymptomatic adults. All patients with a prior history of any medically or surgically treated thyroid disease should be screened with a serum TSH measurement yearly. In addition, patients with other autoimmune diseases and those with unexplained depression, diabetes mellitus (DM), cognitive dysfunction, prior external radiation to the head and neck, hypercholesterolemia, or other risk factors should be screened with TSH measurements. Women experiencing unexplained infertility should be screened for thyroid dysfunction, and postpartum women with vague complaints may benefit from screening.

Risk factors for thyroid failure include a family history of thyroid disease; personal history of thyroid disease; presence of antithyroid antibodies; radiation treatment to the head, neck, or chest; other autoimmune disease; old age; and use of lithium, amiodarone (Cordarone), or iodine.

Although production of T_4 decreases with age, serum T_4 and TSH levels remain stable, whereas T_3 levels may decrease in persons older than age 80 years. In many cases, hypothyroidism in the older adult is characterized by symptoms that may be subtle and similar to the normal signs of aging, thus making it easy to overlook. Common symptoms include hoarseness, deafness, confusion, frank psychosis, dementia, ataxia, depression, constipation, intolerance of cold temperatures, dry skin, or hair loss.

Pathophysiology

Normal thyroid function is required for every metabolic process in the human body. Growth and development, protein synthesis, and cell metabolism are all dependent on an adequate supply of thyroid hormone to the peripheral tissues. The thyroid plays an essential role in fetal development; oxygen consumption; heat production; sympathetic nervous system function; and cardiovascular, hematopoietic, pulmonary, and renal system function. Because of the multiple physiological effects of the thyroid gland, a deficiency of the T_4 hormone can lead to a complex array of clinical findings.

Localized thyroid disease is the most common cause of hypothyroidism in the United States, namely Hashimoto's autoimmune thyroiditis; worldwide, iodine deficiency is the primary etiology, because this element is a critical component of all thyroid hormones and incorporation of iodide molecules is a critical step in thyroid hormone synthesis. Under normal circumstances, the thyroid secretes 100 to 125 mcg of thyroxine (T_4) per day, but only minute amounts of triiodothyronine (T_3). T_4 is converted to T_3 in peripheral tissues, and T_3 is 20 to 100 times more biologically active than T_4.

When the production of T_4 is inadequate, the thyroid gland enlarges in response to increasing levels of pituitary TSH. This stimulates hypertrophy and hyperplasia of the thyroid gland, resulting in a *goiter*. In addition, deiodinase activity within the thyroid is increased, allowing for greater conversion of T_4 to T_3. Thus, the thyroid attempts to compensate by secreting increased amounts of T_3. However, in areas where the soil and water are deficient in iodine, inadequate substrate exists for these compensatory mechanisms, and endemic goiter results. Thus, a simple (nontoxic) goiter is the most common type of thyroid enlargement.

Hashimoto's thyroiditis is the most common etiology of hypothyroidism in the United States. This autoimmune form of hypothyroidism results when the body pathologically recognizes thyroid antigens as foreign, leading to a chronic immune response involving lymphocytic infiltration, vacuolization, and fibrosis of the parenchyma, which eventually leads to atrophy of the thyroid follicles. Autoantibodies may be undetectable early on in the disease process. However, over the course of the disease, up to 95% of these patients demonstrate serum antibodies to thyroid tissue, including antimicrosomal (antithyroperoxidase) antibodies (95% of patients) and antithyroglobulin antibodies (60% of patients). Over time, however, these autoantibodies usually become undetectable.

Inflammatory hypofunctioning thyroiditis may also result from other etiologies. Destructive thyroid inflammation may occur due to immune cross reactivity after viral infections, producing transient forms of hypothyroidism including de Quervain or painful thyroiditis, as well as subacute thyroiditis. In addition to a painful and tender thyroid gland, these patients are often significantly fatigued. Lymphocytic thyroiditis and transient hypothyroidism also occur in up to 10% of new mothers 2 to 10 months postpartum. This figure may rise as high as 25% in those with other autoimmune conditions such as type 1 DM. Although this condition is usually transient, lasting less than 4 months, and responds well to short courses of thyroid hormone replacement, postpartum thyroiditis predisposes these women to long-term hypothyroidism in the future.

Several iatrogenic causes of hypothyroidism have been recognized. Amiodarone (Cordarone), an iodine-containing antiarrhythmic, is one of the best known offenders because of its direct effects on the thyroid gland. However, both dopamine and lithium are associated with central (secondary or tertiary) hypothyroidism owing to their effects on the hypothalamic-pituitary axis and the secretion of TRH from the hypothalamus or TSH from the pituitary gland. Interferon-α, thalidomide, and the antiretroviral agent stavudine have also been associated with primary hypothyroidism.

Central hypothyroidism may also result from direct impingement by tumors on the pituitary gland (e.g., a pituitary adenoma that fails to produce TSH) or the hypothalamus. Brain irradiation has also been associated with subsequent defects along the hypothalamic-pituitary hormonal axis. However, by far the most common reason for iatrogenic hypothyroidism is the therapeutic result of previously treated hyperthyroidism (see previous section on hyperthyroidism in this chapter). Radioactive iodine treatment (^{131}I, Iodotope), concentrated iodine therapy (SSKI, Lugol solution), therapeutic surgical resection, or treatment for head and neck cancer involving external beam irradiation to the neck or surgical excision of a cancerous mass may all result in permanent hypothyroidism. Thus, these patients require close follow-up to detect clinical or biochemical evidence of hypothyroidism.

Low levels of thyroid hormones affect virtually every bodily system, resulting in an overall decrease in basal metabolic rate. An insufficient amount of thyroid hormone causes abnormalities in lipid metabolism, with an increase in total cholesterol, low-density lipoproteins, and triglycerides. These increases are associated with the development of atherosclerosis and cardiac disease in the hypothyroid patient. The gastrointestinal tract may be slowed in both gastric emptying and intestinal transit time, and gastric parietal cell dysfunction may result in achlorhydria and impaired digestion. Endocrine abnormalities of hypothyroidism include menstrual irregularities, infertility, delayed onset of puberty, and insulin resistance. Adequate amounts of thyroid hormone are also necessary for optimal erythropoiesis, and anemia is common in patients with hypothyroidism. Deficiencies in vitamin B_{12}, iron, and folate may also occur.

A characteristic pathophysiological change of hypothyroidism is the accumulation of hydrophilic proteoglycans within the interstitial space, which causes an increase in interstitial fluid. Pleural, cardiac, and peritoneal effusions are a common result of this process, as is the characteristic mucinous edema seen in long-standing hypothyroidism, known as myxedema. In a general sense, myxedema denotes infiltration of various bodily tissues with glycosaminoglycan substances, which may have widespread effects. In the heart, this infiltration decreases both chronotropy and inotropy, leading to cardiac hypertrophy as the body attempts to compensate for the decreased cardiac output.

Clinical Presentation

Subjective

The clinical presentation of the patient with hypothyroidism varies with the age at onset, duration of illness, and severity of disease. Regardless of the type or cause of hypothyroidism, the signs and symptoms are similar. Because this can be an insidious disease, the early symptoms are often subtle and nonspecific, increasing the risk of a missed diagnosis. The severity of symptoms may be related to the duration of hypothyroidism. A rapid onset of hypothyroidism is associated with more recognizable symptoms than is a gradual onset. The signs and symptoms are

directly related to the inadequate amount of thyroid hormone at the peripheral tissue level.

Early classic symptoms include fatigue, dry skin, slight weight gain, cold intolerance, constipation, and heavy menses. Myalgia, muscle cramps, headaches, and weakness may also be present. Later symptoms include very dry skin, coarse hair, loss of lateral eyebrows, alopecia, hoarseness, continued weight gain, slight impairment in mental ability, depression, decreased libido, and hypersomnia. Many of the symptoms are common complaints, which are not specific by themselves but together make up the manifestations of clinical hypothyroidism. Subclinical disease may be even more subtle or asymptomatic.

A complete review of systems is needed because symptoms are often subtle and may involve every body system. The presence of pain and swelling or enlargement in the neck, a history of radiation to the neck, and previous endocrine problems in the past medical history or family history should be elicited. It is also important to obtain a complete medication history, and for women, a complete menstrual history is essential, including the most recent date, characteristics, and duration of last menstrual period. Some findings are more specific for Hashimoto's thyroiditis including painless thyroid enlargement, neck pain, sore throat, feeling of fullness in the throat, low-grade fever, and exhaustion.

Patients with hypothyroidism often experience decreased motility of the gastrointestinal (GI) system, and constipation may be present. Although the exact mechanism of the effect of thyroid hormone on the GI tract is not fully understood, many patients experience atrophic gastritis and pernicious anemia.

Objective

The physical exam should begin with observation of the overall appearance of the patient, noting slow movements and dull facies. The blood pressure, resting pulse, respiratory rate, and weight should be compared with previous exams.

The hair may become coarse and thin, and thinning of eyebrows may occur. Patients with hypothyroidism frequently have a thickened tongue, evident by the indentation of the teeth around the edges. The thyroid may be enlarged and tender or not palpable. The consistency, size of thyroid, and nodules (focal or diffuse) should be noted, as well as any scars present on the neck. A visible goiter may also be present.

The heart may be hypertrophic, which may be assessed by identifying the point of maximal impulse. The patient is usually bradycardic and may have a pericardial effusion.

The lung exam may reveal a pleural effusion. Abdominal exam usually reveals diminished or hypoactive bowel sounds. On neurological exam, the patient may be hypotonic and hyporeflexic with a prolonged relaxation phase and/or ataxic.

The patient with hypothyroidism may have facial puffiness; periorbital edema; dry, coarse, thick skin and hair; brittle nails; slow speech; bradykinesia; hoarseness; large tongue; bradycardia; mild diastolic hypertension; psychological disorders; and pitting edema of the lower extremities. Myxedematous changes occur in the later stage with thickened, scaly, and "doughy" skin, enlarged tongue, muscle weakness, joint complaints, hearing impairments, and ascites. Table 16.5 summarizes the clinical presentation of hypothyroidism.

Diagnostic Reasoning

Diagnostic Tests

Initial Testing Although there are no universally accepted screening recommendations for hypothyroidism, the American Thyroid Association recommends a baseline screening at 35 years, with close attention to high-risk patients (pregnant women, women older than 60 years, persons with other autoimmune diseases). The American Association of Clinical Endocrinologists recommends checking the TSH in women of childbearing age even before pregnancy and then in the first trimester. The USPSTF does not recommend routine screening in adults without specific reasons. Congenital hypothyroidism is routinely screened for in neonates, as mandated in most states, because not treating hypothyroidism in this group has devastating effects (mental retardation). There is evidence to screen individuals with autoimmune disease, a first degree relative with autoimmune thyroid disease, pernicious anemia, a history of thyroid surgery or neck radiation, an abnormal thyroid exam, a psychiatric diagnosis, and patients taking amiodarone or lithium.

The diagnosis of hypothyroidism is made by measuring serum TSH. TSH and FT_4 should be used to follow treatment. When autoimmune thyroiditis is the suspected underlying cause, it is helpful to confirm this via antithyroid antibody titers, either antimicrosomal antibody (antithyroid peroxidase [TPO] antibody) or antithyroglobulin antibody. The antimicrosomal antibody test is more sensitive and specific. If the TSH is low, inappropriately normal, or insufficiently elevated in the presence of low T_4 values, central hypothyroidism caused by hypothalamic or pituitary disease should be excluded before starting thyroid replacement therapy.

The sensitive thyrotropin assay is the most specific test for diagnosing primary hypothyroidism. A rise in the TSH will precede any other abnormality of thyroid function as the first evidence of primary hypothyroidism. Hypothyroidism caused by primary thyroid failure can be confirmed by a concomitant finding of a decrease in serum FT_4. Patients in an early stage of hypothyroidism may present with an increase in serum TSH together with a normal or low-normal serum FT_4.

By radioimmunoassay, primary hypothyroidism is associated with low FT_4 with an elevated TSH level. The normal range of TSH is 0.35 to 2.5 mIU/L. However, an age adjustment may be needed, because the elderly may have normal values greater than 3 mIU/L. There is general

Table 16.5 Clinical Presentation: Hypothyroidism

Body System	Subjective	Objective
General	Fatigue Lethargy Mild weight gain Cold intolerance Mild depression Decreased libido Hypersomnia Muscle weakness and cramping	Slowing of mental processes Dull facial expression Periorbital puffiness Hypothermia Yellow skin (carotenemia) Facial pallor/swelling (myxedema)
Integumentary	Decreased sweating Hair loss Ankle swelling	Dry, cool, rough skin Alopecia Dry, coarse, thick hair Nonpitting edema
Gastrointestinal	Constipation Nausea	Hypoactive bowel sounds Large tongue Ascites
Neurological	Memory deficits Personality changes	Hyporeflexia Bradykinesia Delayed relaxation of reflexes Slowing of mental processes
Cardiopulmonary	Inability to exercise	Bradycardia Cardiac enlargement Pleural effusion
Genitourinary	Menorrhagia, irregular menses	Decrease in fertility
Head and neck	Enlargement of the neck	Enlarged tongue (late) Hoarseness

agreement that a TSH level above 10 mIU/L should be treated in patients with primary hypothyroidism. Levels of 4.5 to 10 mIU/L have varied recommendations. Absent cardiovascular disease, there are no outcome data to suggest that treatment for levels between 2.5 and 4.5 mIU/L is beneficial. An elevated TSH (up to 15–20 mIU/L) may be temporarily seen in euthyroid patients with a systemic illness. In this situation, the TSH and T_4 should be repeated in 2 to 3 weeks for confirmation. Patients with secondary or tertiary (central) hypothyroidism show a low, normal, or mildly elevated TSH level with low FT_4 and T_3 by radioimmunoassay. The laboratory values for patients with subclinical hypothyroidism show a mildly increased TSH (4.5–10 mIU/L) with a normal FT_4 level. Measurement of free T_4 is always preferred over total T_4, owing to alterations in hormone protein binding that may result in large fluctuations in total serum T_4 levels. Free thyroxine index (FTI), although not the test of choice, may be used because not all laboratories have the capacity to measure FT_4. FTI uses a T_3 resin uptake test to calculate the percentage of hormone binding sites available and multiplies this by the total T_4 level to give an estimation of the free T_4 level.

The antimicrosomal antibody (anti-TPO antibody) is diagnostic for Hashimoto's thyroiditis when found in high titers (1:400). The degree of elevation of this antibody correlates directly with clinical hypothyroidism. When hypothyroidism is present for a long period of time, the antibody titers fall. The antithyroglobulin antibody is also increased, but it is not as specific for Hashimoto's thyroiditis. If no antibodies are identified at the time of diagnosis, the condition is called *idiopathic hypothyroidism,* a form of autoimmune thyroiditis. The antimicrosomal antibody should also be evaluated in patients with repeat miscarriages.

Medications such as metoclopramide (Reglan) increase the TSH level. Dopamine (Intropin), glucocorticoids, NSAIDs, and somatostatin decrease the TSH level. Other medications, such as phenytoin (Dilantin), amiodarone (Cordarone), and lithium carbonate, can also affect thyroid function tests. Smoking (nicotine) can also affect thyroid hormone levels. There are many mechanisms by which medications affect thyroid function. The drug may bind with albumin and displace the thyroid hormones off the carrier proteins, or it may prevent albumin from binding with T_3 or T_4, in each case resulting in more active hormones in circulation. Some drugs may cause an upregulation in processing proteins (different cytochrome P oxidase isomers). These normally inactivate thyroid hormones, so

the upregulation can lead to more rapid processing of thyroid hormones, in turn, affecting TSH levels.

Subsequent Testing Once a diagnosis of hypothyroidism is confirmed, additional testing may be necessary to determine the effect of the disease on other body systems. Because T_3 is nonspecific and not sensitive, it is not routinely used as an initial diagnostic tool. In the early stages of hypothyroidism, T_3 levels may be normal because of TSH-induced hyperstimulation. T_3 levels may not fall until late in the disease. Because the T_3 level correlates well with clinical status, the patient will not be as severely hypothyroid clinically until the T_3 falls to significantly low levels. In addition, the T_3 level may be below normal or elevated in patients with chronic disease.

Because anemia is a frequent complication of hypothyroidism, a complete blood count should be done. A complete blood chemistry profile should be done to assess for alterations in electrolytes, blood urea nitrogen, creatinine, serum osmolarity, and glucose, because a decreased glomerular filtration rate (affecting renal function) can occur. A complete urinalysis should also be performed, with specific attention to the presence of protein (indicating possible renal impairment). Changes in the chemistries may be an indication of deteriorating thyroid function leading to myxedema.

Patients with mild to moderate hypothyroidism have a tendency to develop hypertension (especially diastolic hypertension); therefore, the blood pressure should be monitored. Interestingly, patients with long-standing or severe hypothyroidism tend to be normotensive or hypotensive. Depression of the biosynthesis of cholesterol causes a decreased rate of cholesterol catabolism and leads to hypercholesterolemia. These patients tend to have elevated triglycerides and elevated low-density lipoprotein cholesterol. The combination of hypertension and hyperlipidemia increases the risk of atherosclerotic heart disease in a hypothyroid patient. Thus, an annual lipid profile and an electrocardiogram (ECG) should be done. As the cardiac system continues to deteriorate, the ECG may show nonspecific ST- and T-wave changes or low-voltage QRS complexes.

Unless there is reason to suspect a nodule or to confirm multinodular goiter, radioactive iodine scans and uptake are not usually necessary. As part of the complete examination, patients should have an annual chest x-ray exam to rule out the complications of hypothyroidism, including cardiomegaly, congestive heart failure, and pleural effusion.

Ultrasound studies of the thyroid may be useful if a nodular thyroid is detected or if infiltrative disease is suspected (amyloidosis, sarcoidosis, or tuberculosis). Fine-needle aspiration is indicated for suspicious nodules, which may be found in patients with hypothyroidism, hyperthyroidism, or euthyroidism. In fact, 5% to 6% of isolated nodules are malignant, especially larger ones, and ultrasound may reveal suspicious findings such as irregular margins or microcalcifications.

Differential Diagnosis

Marked variations in TSH may occur in the setting of an acute illness or psychiatric disorder when the body's metabolic demands are altered. TSH levels normally peak in the evening and are at their lowest in the afternoon. Nonthyroid illness is often associated with decreased TSH, T_3, and free T_4 levels without clinical hypothyroidism, with a reduction in the conversion of T_3 from T_4. In addition, usually the TSH level is normal or mildly increased during recovery from nonthyroid illness.

In euthyroid hypothyroxinemia, the patient is euthyroid with a decreased T_4 level due to increased thyroid-binding globulin concentration caused by nephrotic syndrome, exogenous testosterone, or high-dose steroids. Also, drugs that inhibit T_4 binding, such as phenytoin, phenobarbital, and salicylates, may decrease the total T_4 level.

Management

The goal of thyroid hormone replacement in primary hypothyroidism is to normalize, not suppress, the TSH. Suppressed TSH, particularly in postmenopausal women or individuals with levothyroxine overreplacement, causes decreased bone mineral density after several years, leading to osteoporosis. The replacement goal in central hypothyroidism is to normalize the FT_4 because the TSH is not reliable. Hypothyroidism is typically treated medically; however, surgery may be indicated for particularly large, nonfunctional goiters that impair tracheoesophageal functioning.

Management of Hypothyroidism

The treatment for hypothyroidism is the daily administration of thyroid hormone to restore the patient to a euthyroid state (see Drugs Commonly Prescribed 16.2: Hypothyroidism). The usual medication is levothyroxine (Synthroid, Levothroid, Levoxyl), a synthetic preparation of T_4, which has generally replaced a desiccated thyroid preparation. Levothyroxine preparations are manufactured in numerous dosages, allowing for specific, precise titration to meet individual patient requirements.

According to the medical guidelines developed by the American Association of Clinical Endocrinologists, the usual dose is 1.6 mcg/kg per day for full replacement. Healthy patients younger than age 60 years may receive 50 to 100 mcg daily (full replacement dose). Patients who are older or have coronary artery disease should begin with one-half of the expected replacement dose or 25 to 50 mcg/day PO, increasing the dose gradually by 25 mcg/day once every 4 to 6 weeks. The TSH level should be measured every 4 to 8 weeks after initiating therapy and before each dosage increase. The common dosage is 75 to 150 mcg/day. Dosing is best done in the morning to avoid nighttime insomnia. Many other medications and mineral supplements interfere with GI absorption, including iron, calcium carbonate, aluminum hydroxide, sucralfate, and tube feedings. Thus, these medications require separation

Drugs Commonly Prescribed 16.2 Hypothyroidism: Lifelong Pharmaceutical Treatment

Drug	Indications	Adverse Reactions and Prescribing Considerations
Synthetic L-thyroxine* T_4 (Levothroid, Levoxyl, Synthroid)	Patients with increased TSH level, usually three times the upper limit of the assay. Overt hypothyroidism, lifelong pharmaceutical treatment. Goal: To give enough thyroid supplement orally to result in normal free T_4 and TSH levels.	Monitor antihyperglycemics, oral anticoagulants, and potential sympathomimetics. Wait 4–5 hours after cholestyramine ingestion. Not to be prescribed for obesity. Use with caution in patients with cardiovascular disease, diabetes, adrenal insufficiency. Increased sensitivity in myxedema and severe hypothyroidism. Start with the lowest dose and increase by 0.025 mg/day every 3–6 weeks to a maximum of 0.3 mg per day. Older adults require a beginning dose slightly lower.

*Synthetic T_3 supplements (Cytomel) are not recommended as a drug of choice.

of dosing in time, whereas patients receiving continuous tube feedings require IV thyroxine dosing.

Replacement with T_3 preparations (liothyronine [Cytomel, Triostat]) is usually not indicated; however, anecdotal reports exist that indicated combination T_3/T_4 therapy may be helpful in patients who do not respond adequately to T_4 replacement alone. Although T_3 is better absorbed via the GI tract than T_4, the appropriate ratio of triiodothyronine preparations versus thyroxine in combination therapy has not been well established, and such treatment decisions require expert input from an endocrinologist.

Another treatment of historical importance that is still used today in some settings owing to its relative lower cost is desiccated bovine thyroid (Armour Thyroid). Obtained from pooled thyroid extracts from cows, these preparations contain multiple foreign antigens, and the specific levels of active hormone are difficult to control. Some manufacturers standardize preparations based on bioassays, whereas others use iodine content as a surrogate measure of activity. T_3 and T_4 are both present, usually in a 1:4 ratio. Although some older patients who have been treated for many years with desiccated thyroid are wary of changing medications after decades of replacement therapy at stable doses, few clinicians in the United States will start new patients on these preparations. They should not be used for patients with underlying cardiac disease given the varied concentrations of highly active T_3, which poses a greater risk of overreplacement and iatrogenic thyrotoxicosis.

Regardless of choice of replacement therapy, all patients should be monitored for signs of thyrotoxicity, especially angina pectoris and arrhythmias, because optimizing thyroid replacement dosing can be difficult and time consuming. If significant adverse symptoms occur during levothyroxine replacement, the dose should be decreased and the patient should be referred to an endocrinologist for evaluation before reattempting replacement therapy at the original higher dose.

Concurrent severe illness or major surgery may alter dosing requirements in either direction in the hypothyroid patient. Pregnancy is also well known to increase replacement therapy requirements. Some clinicians suggest increasing replacement dosing by 30% on confirmation of pregnancy with subsequent adjustments per TSH levels, because untreated hypothyroidism in pregnancy is associated with preeclampsia, postpartum cardiac dysfunction, anemia, miscarriage, and low birth weight. The levothyroxine dose should be returned to the prepregnancy dose after delivery, and a serum TSH level should be obtained 6 to 8 weeks postpartum.

Untreated hypothyroidism may progress steadily for 10 to 15 years before resulting in *myxedema coma*—a life-threatening state of multiorgan failure, characterized by progressive respiratory depression, decreased cardiac output, and fluid and electrolyte abnormalities (including hyponatremia)—or even death. Box 16.1 presents the assessment and management of patients with myxedema coma.

Management of Subclinical Hypothyroidism

Treatment for subclinical hypothyroidism has varied recommendations. The American Thyroid Association and the American Association of Clinical Endocrinologists recommend treating subclinical disease when there is presence of antithyroid antibodies, when evidence of atherosclerotic cardiovascular disease exists, when heart failure exists, or if the patient is symptomatic at this TSH level.

Box 16.1 Assessment and Management of Myxedema Coma

Untreated hypothyroidism may progress steadily for 10–15 years before resulting in myxedema coma (a life-threatening condition characterized by progressive respiratory depression, decreased cardiac output, and fluid and electrolyte abnormalities) or death. Myxedema coma is severe hypothyroidism, most commonly seen in older adult women, presenting with altered mental status (profound lethargy or coma), hypothermia, bradycardia, hypoventilation, hypoglycemia, and adrenal insufficiency. It is usually triggered by a precipitating factor such as noncompliance with levothyroxine therapy, ingestion of narcotics or analgesics, sepsis, cerebrovascular accident (stroke), myocardial infarction, trauma, or severe stress. The mortality rate can be greater than 50% despite emergency medical intervention.

Assessment

The patient is usually pale with periorbital edema, dry skin, decreased temperature, macroglossia, distant heart sounds, bradycardia, and delayed deep tendon reflexes. The patient may have hyponatremia, seizures, and hypotension, with secondary respiratory acidosis, hypoxia, retention of CO_2. Clinical diagnosis, not laboratory diagnosis, is required; T_4 is usually low, and TSH is high.

Management

Give ventilatory support if indicated, treat hypothermia, and give levothyroxine (Synthroid, Levothroid) IV 300–500 mcg over 15 minutes; then IV 100 mcg every 24 hours to bring thyroxine concentrations back to normal quickly. Glucocorticoids should also be administered until coexistent adrenal insufficiency can be ruled out. Hydrocortisone hemisuccinate 100 mg IV bolus is initially given, followed by 50 mg IV every 12 hours or 25 mg IV every 6 hours until plasma cortisol level is confirmed as normal. Administer IV hydration to correct hypotension and hypoglycemia (if present). Avoid overhydration because clearance of free water is impaired in these patients. Rule out and treat precipitating factors (if septic, treat with antibiotics). Patients with myxedema coma need emergency medical intervention and should be treated by an endocrinologist in an intensive care setting.

Some patients with subclinical hypothyroidism feel better when treated with levothyroxine. Medication therapy has potentially dangerous adverse effects but may improve subtle abnormalities, prevent goiterous growth, and prevent the development of frank hypothyroidism. Therapy is advisable especially if thyroid autoantibodies are positive, because overt hypothyroidism frequently develops.

In young patients or patients with goiter, consider initiating levothyroxine therapy. If the decision is made not to treat these patients, they should be evaluated at 6- to 12-month intervals for evidence of more severe clinical and biological loss of thyroid function. A lower dose (0.5–1.0 mcg/kg) could be given in the treatment of subclinical hypothyroidism. If the diagnosis of hypothyroidism is uncertain in a patient who is already on levothyroxine, the dose can be reduced by one-half, and the FT_4 and TSH levels can be reassessed in 6 to 8 weeks. If the TSH level is increasing, the patient should resume the previous dose. If the TSH is normal, the patient should discontinue the levothyroxine, and the TSH level should be rechecked in 6 to 8 weeks for any increase.

Follow-up and Referral

After therapy has been initiated with levothyroxine, the practitioner should check the patient's levothyroxine levels in 4 to 8 weeks by evaluating the TSH level to determine whether adjustment of the levothyroxine dose is necessary. The target TSH level is 0.3 to 2.4 mIU/L. Increasing the levothyroxine dose more often than at 6-week intervals will probably lead to overreplacement. Once a stable dose of levothyroxine has been established, the TSH level in primary hypothyroidism or the FT_4 level in central hypothyroidism can be checked biannually or annually.

The patient should be examined annually for manifestations of thyrotoxicity (e.g., tachycardia, nervousness, or tremor) before increasing dosages. Laboratory values (FT_4 and TSH levels) within normal limits and a satisfactory clinical exam suggest that treatment is adequate. For maintenance treatment, the medication should be titrated to the lowest dosage required to maintain euthyroidism, with a normal TSH and a normal or slightly elevated T_4.

Undetectable TSH levels suggest overtreatment; medication should be decreased in these patients. TSH levels greater than 10 mIU/L indicate undertreatment, and medication should be increased.

Referral to an endocrinologist is necessary if the patient has cardiac disease, symptoms of myxedema, or central (secondary or tertiary) hypothyroidism. After starting hormone replacement therapy, if signs or symptoms of myxedema, chest pain, or thyrotoxicosis occur, the endocrinologist should be consulted. These patients are at high risk for serious complications related to hypothyroidism or its treatment. Hypothyroid patients with severe illness or those who present with unusual or confusing laboratory findings should be referred to an endocrinologist. Referral to an endocrinologist is indicated in patients younger than age 18 years, when there is evidence of pituitary disease, in pregnant and postpartum patients, and in those taking lithium or amiodarone (Cordarone).

For asymptomatic patients with subclinical hypothyroidism who (after consultation) are not being treated with medication, a TSH should be performed yearly, along with a focused history and physical exam.

Patient Education

During the follow-up visits, emphasis should be placed on compliance with lifelong thyroid replacement therapy (if indicated), reviewing the symptoms of hypothyroidism and hyperthyroidism, and stressing the importance of follow-up.

Instructions should be simple and repeated frequently with written information in the patient's primary language. An older adult or patient with decreased mental status or depression with hypothyroidism may need additional emotional support, reinforcement, and follow-up teaching. Support in the home setting may be necessary until the symptoms of slowed mental processes and depression abate. Initially, a family member may be needed to remind the patient to take his or her daily dose of medication.

Patients should be encouraged to wear an extra layer of clothing if they have cold intolerance and should be warned not to use a heating pad. Patients with diminished mental status and slowed responses may be at risk for burns. If psychomotor symptoms are present, the patient should be cautioned against operating dangerous machinery or driving a motor vehicle until the symptoms have resolved.

Because heredity is implicated in hypothyroidism, patients with children should be instructed to advise their child's primary-care provider of their diagnosis.

Patients who are at high risk for hypothyroidism (those who have had thyroid surgery, radioactive iodine treatments, history of thyroiditis, and postpartum women) should be taught the common symptoms of hypothyroidism (lethargy, fatigue, cold intolerance, constipation, weight gain, dry skin). The patient and family should also be instructed that hypothyroidism is a chronic, sometimes progressive disease requiring monitoring every 6 to 12 months. Patients and their families should be reassured that as the treatment progresses, the symptoms will resolve.

Practitioners are encouraged to write prescriptions that do not allow substitution and use the same brand for the patient throughout treatment. The same brand of thyroid preparation is recommended because the bioavailability, stability, and content of the medication may vary with the different brands. Patients should be given the rationale for treatment, adverse effects, and dosage for their medication. Emphasis should be on the fact that medication use is lifelong. The patient needs to understand that as the body ages or there are changes in body weight, the dosage of medication may need to be adjusted.

The patient should be taught the signs of hyperthyroidism (thyrotoxicity) in the event of thyroid replacement overdosage—for example, nervousness, palpitations, insomnia, and tremor. It is important to explain that it will take 1 to 2 weeks for the medication to be effective. During this time, patients may experience an increase in urination and a decrease in periorbital puffiness.

The Patient's Voice 16.1

One Patient's Story

I had pretty much a normal life. I was working in an administrative job, was in a bad relationship, and was perimenopausal. I would get home from work and it was a struggle to make dinner and clean up. I was exhausted all the time. I had trouble getting out of bed in the morning even after going to bed at 7:00 p.m.! On the weekends I would sleep for 14 hours a night and still wake up tired. At meetings, where I had once been quick with suggestions, I couldn't seem to think and put two sentences together. I had trouble finding the right words. I thought I was getting early Alzheimer's.

I was 50 years old, and I felt like 100! I was constipated, cold all the time, and in a mental fog every day. I saw my primary-care provider. She told me I was probably depressed because of my life situation and being perimenopausal and prescribed an antidepressant. After taking that for more than a month, I was not feeling any better and saw a different provider. That provider did a bunch of tests and a thyroid-stimulating hormone (TSH) assay was one of them. The results were through the roof. My thyroid was almost entirely shut down. If someone had just done the test earlier, I could have been spared a few years of total exhaustion.

The absorption of levothyroxine from the GI tract may be slowed by concurrent use of certain drugs, such as ferrous sulfate, sucralfate (Carafate), or antacids. The dose of thyroid hormone should be taken 2 hours before or 4 hours after ingestion of these medications. Because levothyroxine supplements may increase blood glucose levels, patients with DM should carefully monitor their blood sugar levels; their dose of insulin or oral hypoglycemic agents may need to be adjusted. Thyroid hormones may also affect the levels of phenytoin (Dilantin), lithium, tricyclic antidepressants, estrogen, digitalis, anticoagulants, and indomethacin (Indocin). The appropriate blood tests and screenings should be performed, and patients should be instructed on the important adverse reactions to report should they occur.

Because of increased sensitivity to certain medications in hypothyroid patients, patients should be cautioned against the use of analgesics and sedatives. Even in small dosages, these medications can cause severe somnolence and respiratory depression. Infrequently, a patient with normal TSH levels may continue to feel fatigued but should be discouraged from increasing the dose of medication, which some patients may be tempted to do. This symptom warrants further investigation as to the underlying cause and should be discussed during a clinic visit. In cases where patient compliance may be a problem, weekly dosages can be given, because the half-life of T_4 is approximately 1 week.

Patients should be taught to follow a healthy diet, with an emphasis on low-fat, high-fiber foods. Some patients may need to follow a diet that promotes weight loss once medication has been started. Because many patients with hypothyroidism experience constipation, they should increase their intake of raw fruits and vegetables and bran or high-fiber cereals and breads, and add unprocessed bran (two tablespoons/day) to cereal or liquids. A bulk-forming laxative containing psyllium may be taken on a daily basis. Increasing water intake to six to eight glasses a day is often beneficial in reducing constipation, as is increasing physical activity. A low-fat diet is recommended because there is a high incidence of atherosclerotic heart disease in patients with hypothyroidism.

Once therapy with levothyroxine is initiated, the patient should be able to resume all previous activities. Initially, rest periods with a gradual increase in exercise and activity, as tolerated, may be indicated. The patient must be instructed that if he or she develops any signs or symptoms of cardiac or respiratory difficulty, it is essential to seek immediate medical attention.

THYROID CANCER

Thyroid cancer is classified as differentiated (papillary and follicular) and undifferentiated (medullary and anaplastic). Most thyroid cancers (60%) are papillary, 20% are follicular, and the remaining tumors are medullary or anaplastic. Medullary thyroid cancer is more likely to be familial. Anaplastic tumors are the fastest growing of all thyroid neoplasms; they are more common in older adults and are associated with a high mortality rate. A rare type of thyroid cancer is non-Hodgkin's lymphoma, which should be considered in persons with a rapidly growing goiter. Hürthle cell carcinoma is a rare type of thyroid malignancy (2%–3% of thyroid cancers) that is often considered a variant of follicular carcinoma. Consisting almost exclusively of Hürthle cells (also called oxyphilic or oncocytic cells) that contain abundant granular acidophilic cytoplasm, these malignancies are highly aggressive, metastasize in more than half of cases, and are difficult to follow because they do not respond to TSH or take up radioiodine.

Epidemiology and Causes

Thyroid cancer is the most common endocrine-related cancer. The incidence of thyroid cancer in the United States is small, with only 0.4% of the population diagnosed with this type of cancer; however, 13% of people in the United States are found to have thyroid cancer on autopsy. Most thyroid cancers are small and slow growing. Thyroid cancer accounts for 0.5% of all cancer deaths per year. The incidence increases with age, and it is more common in adults aged 20 to 54 years, but it can occur at any age.

Thyroid cancer is more common in women than in men (3:1). Thyroid nodules found in persons younger than 20 years of age or initially found in adults older than age 60 years are more likely to be cancerous. Nodules are often found on routine physical examinations, by the patient, or during imaging for other purposes.

The major risk factor for development of thyroid cancer is exposure to ionizing radiation. Several historical incidents resulting in high-dose radiation exposure have been linked to an increased incidence of thyroid papillary malignancies in children, including the atomic bombings of the Japanese cities of Hiroshima and Nagasaki, military atomic testing near the Marshall Islands, and the nuclear power plant meltdown in the Russian city of Chernobyl. Moreover, until the 1950s, radiation treatments were given to children for an enlarged thymus, enlarged tonsils, and acne. It is estimated that 1 to 2 million individuals were exposed to this risk factor. Studies have estimated that one-third of patients who received radiation therapy to the head and neck will develop a thyroid nodule, and one-third of these patients will later develop a malignancy. It may be advisable for patients who received head and neck irradiation as children to have an ultrasound for screening purposes.

Importantly, low-dose radiation exposure associated with routine radiographic imaging studies has not been shown to be tumorigenic. Interestingly, ^{131}I radioablation therapy for thyrotoxicosis and high-dose external beam radiotherapy have also not been associated with papillary thyroid carcinoma, presumably because of the greater amount of cellular apoptosis associated with these doses of radiation.

There is also an increased incidence of follicular and anaplastic thyroid carcinoma in areas where iodine deficiency and goiter are more prevalent. Thyroid cancer is also more common in persons with autoimmune disease. Medullary carcinoma is an inherited form of thyroid cancer, with 90% of those inheriting the autosomal dominant gene ultimately developing cancer.

Metastatic cancer of the thyroid is less common, but renal cancer, breast cancer, lung cancer, and malignant melanoma may metastasize to the thyroid gland.

Pathophysiology

Though thyroid carcinomas are relatively rare in the United States, benign thyroid disease is significantly more common. An estimated 4% to 7% of the general population develops thyroid nodules; although the vast majority of these represent benign disease, it is estimated that 5% to 6% of isolated nodules are malignant. Thus, distinguishing malignant from nonmalignant cases requires careful clinical evaluation.

As with all types of cancer, thyroid cancer is believed to develop from a series of mutational events producing a cell that is genetically different from its source. This explains the strong association of thyroid cancer with radiation exposure, which increases the incidence of DNA mutation and transformation of normal thyroid cells into malignant clones. Similarly, germline mutations in the RET proto-oncogene have been associated with the

inherited cancer syndromes multiple endocrine neoplasia (MEN) 2A, MEN 2B, familial adenomatous polyposis, and familial medullary thyroid carcinoma (FMTC) syndrome—all of which are associated with medullary thyroid carcinoma.

Thyroid cancers range from those that are well differentiated and slow growing to those that are poorly differentiated and aggressive. As with other malignancies, poorly differentiated thyroid cancers have an unfavorable prognosis. Cancers of the thyroid gland are typically classified into primary and secondary (metastatic) tumors. Primary tumors include papillary (80% of cases), follicular (10% of cases), anaplastic (2% of cases), and medullary tumors (5%–10% of cases), and rarely primary thyroid lymphomas (2%–5% of cases) and sarcomas. Papillary, follicular, and anaplastic tumors derive from the endodermally derived thyroxine- and thyroglobulin-producing follicular epithelium, whereas medullary tumors arise from the neuroendocrine-derived parafollicular or C cells. Thyroid lymphomas arise from intrathyroid lymph tissue and are strongly associated with chronic lymphocytic thyroiditis (Hashimoto's autoimmune thyroiditis), whereas sarcomas are derived from the vascular and connective tissue interwoven throughout the thyroid gland.

Clinical Presentation

Subjective

The major symptom of thyroid cancer is a lump or nodule in the neck, which is usually painless. Patients may also complain of a tight or full feeling in the neck, difficulty breathing or swallowing, hoarseness, hemoptysis, and swollen lymph nodes. New onset of hoarseness with hemoptysis is strongly suggestive of a malignant growth. Progressive dysphagia and shortness of breath may indicate invasiveness. Pain in the neck is usually a late symptom. History may reveal exposure to radiation as a child.

Objective

From 4% to 7% of the U.S. population have a palpable thyroid nodule, making clinical examination of the thyroid an ineffective method of screening. Differentiated thyroid carcinomas most commonly present as a thyroid mass or nodule. Although malignant neoplasms are more likely to be fixed, nontender, firm, and irregular in shape, only a biopsy can rule in malignancy. The physical exam should include examination of the tongue, oropharynx, and cervical spine for swelling, nodules, or tenderness.

Diagnostic Reasoning

Although there are some typical presentations of benign versus malignant nodules of the thyroid, many malignant lesions have an atypical presentation. A biopsy is the only reliable method of differentiating a benign from a malignant lesion; therefore on palpation of a nodule, the patient should be referred for evaluation and probable biopsy. Early referral of patients with nodules to an endocrinologist for evaluation and treatment reduces costs, decreases patient hospital time, and increases the precision of the diagnosis.

Nodules that develop in men, in persons younger than age 20 years or older than age 60 years, in persons with a family history of thyroid cancer, or in those with a personal history of exposure to radiation are suggestive of malignancy. Malignant growths are more likely to be irregular in shape, fixed, firm, and nontender. Multiple nodules of the same consistency are more likely to be benign. Fewer than 5% of nodules are malignant. The prognosis is good for thyroid cancer that is found early, is less than 2 cm in diameter, is of a favorable histological type, and has not invaded locally or metastasized.

Diagnostic Tests

Initial Testing High-resolution ultrasonography is beneficial in identifying thyroid nodules but is not reliable in differentiating a benign from a malignant lesion. It is indicated when there is suspicion of multinodular disease or when the thyroid is difficult to evaluate clinically.

Subsequent Testing A fine-needle aspiration (FNA) biopsy is usually successful in differentiating a benign from cancerous lesion of the thyroid gland and has an 83% sensitivity and a 92% specificity. Thus, the FNA will not capture all cases, and repeat biopsy may be necessary. The sensitivity of FNA is increased when it is ultrasound guided. Nondiagnostic FNA biopsies may require surgical lobectomy to confirm that the nodule is not in fact malignant. Psammoma bodies are found in 50% of papillary carcinomas; they are circular, laminated bodies found in the stroma of the tumor.

Elevated serum calcitonin is a strong tumor marker of medullary thyroid carcinoma, but these cancers are somewhat rare overall, so this test is not usually used in the initial work-up. For the inherited cancer syndromes MEN 2A, MEN 2B, and FMTC, polymerase chain reaction assays are used to detect germline mutations in the *RET* oncogene. Radioiodine uptake testing is a means of determining functionality of a thyroid nodule.

Computed tomography and magnetic resonance imaging are used when the tumor is large or recurrent or when there is expected extrathyroidal extension of the tumor, but these are not helpful for evaluation of a simple, isolated nodule. However, they can be used to assess for distant metastases and regional lymph node involvement. Spread to lymph nodes is more common with papillary than with follicular carcinomas; if metastasis does occur, lung and bone are the most common sites. Interestingly, lymph node metastases are not an important prognostic factor, but distant metastasis is associated with a nearly 70-fold increase in death.

Thyroid neoplasms are often painless, and thyroid function tests may show levels within the normal range unless the patient has thyroiditis.

Differential Diagnosis

Differential diagnoses include lymphocytic thyroiditis, multinodular goiter, benign thyroid nodule, cystic nodules, and regional lymphadenopathy. Mass-related effects may be similar to those associated with laryngeal or other forms of neck cancer (e.g., dysphagia or hoarseness due to recurrent laryngeal nerve involvement with vocal cord paralysis, hemoptysis due to local invasion through the trachea).

If medullary thyroid carcinoma is diagnosed, it is critical to take a thorough family history to assess whether this presentation occurs as a component of several inherited cancer syndromes, including MEN 2A or Sipple syndrome (which may present with concurrent pheochromocytoma and hyperparathyroidism), MEN 2B (which may present with concurrent pheochromocytoma, tall and slender Marfanoid body habitus, and ganglioneuromas), and FMTC syndrome.

Management

Initial Management

Any swelling suggestive of malignancy should be referred for evaluation of the mass. A surgeon and an oncologist (possibly a radiation or medical oncologist) will be necessary for determination of the diagnosis and treatment plan. Thyroidectomy or near-total thyroidectomy is the treatment of choice. The decision is based on the type of tumor, the size, and whether the tumor is compressing other structures. A surgeon with expertise in thyroid surgery should perform the procedure because of the potential of damage to the laryngeal nerves and the parathyroid glands. For small, noninvasive tumors, some surgeons prefer to perform a lobectomy, a more conservative approach. However, if there is local invasion, there is a greater possibility of recurrence. Radical neck surgery may be indicated for tumors with extensive local invasion.

Subsequent Management

After a total thyroidectomy, patients are often treated with radioactive iodine therapy to ablate any remnant thyroid tissue. Thyroid replacement therapy is initiated to suppress TSH to a goal of 0.1 mIU/L, and patients are monitored closely for response to therapy. They are subsequently followed every 6 to 12 months by an endocrinologist. A thorough neck exam, a chest x-ray exam, and physical exam are performed with observations for thyrotoxicosis. Thyroglobulin levels may also be measured for well-differentiated carcinomas. The endocrinologist may perform a follow-up ^{131}I scan 6 to 12 months after a total thyroidectomy and may initiate further radioactive iodine ablation therapy if indicated. A follow-up ^{131}I scan is not useful in medullary cancer because medullary carcinoma does not take up the radioactive isotope.

Some forms of malignancy have unique treatments. In addition to thyroidectomy and postoperative radiation therapy, thyroid lymphomas may also require chemotherapy directed by a medical oncologist. Sarcomas are particularly aggressive and, after thyroidectomy, are poorly responsive to chemotherapy and carry a poor prognosis.

Long-term prognosis of thyroid malignancy depends on cell type of tumor, size of the primary growth, gender (men are twice as likely to die from thyroid cancer as women), age at diagnosis (death is more common in those diagnosed younger than 20 years or older than 40 years of age), and extent of metastasis at the time of excision. Fortunately, papillary thyroid cancer is rarely fatal.

Follow-up and Referral

Follow-up is directed by the knowledge that no single diagnostic tool is sufficient to evaluate for recurrent disease. The follow-up of patients who have been treated for thyroid cancer includes periodic clinical exams, serum thyroglobulin measurements, chest x-ray films, and ultrasound examination to assess for recurrence. The patient is followed more closely during the first 3 to 4 years after surgery because recurrence is more likely within this time.

The patient with a total thyroidectomy will require thyroid hormone replacement for life. See Management of Hypothyroidism for specific guidelines.

Patients with medullary carcinoma MEN2 should be offered RET (rearranged during transcription) proto-oncogene testing. Provided the mutation is identified, all first-degree relatives should be offered the RET mutation analysis as well.

Patient Education

Patients with a family history of thyroid cancer should be advised to perform a "neck check" monthly. Patients with a history of goiter or irradiation should also perform this screening technique. The check is performed at home with a glass of water and a handheld mirror. The patient should be instructed to hold the mirror to visualize the area between the Adam's apple and clavicle. Then the head should be tilted backward, enough to adequately visualize the area without producing coughing or choking. As a sip of water is taken and swallowed, the patient should observe the area for any bulging. The maneuver should be repeated several times. Any signs of bulging should be reported immediately. Free copies of the *Neck Check* can be obtained at www.thyca.org/download/document/287/NeckCheckCard.pdf.

CUSHING'S SYNDROME

Cushing's syndrome includes a myriad of symptoms and physical features produced by persistent inappropriate hypercortisolemia. The condition was named after Harvey Cushing, a physician who found pituitary adenomas in six of eight patients with symptoms of adrenocortical hyperfunctioning in 1932. Cushing's syndrome may be caused by cortisol hypersecretion by the adrenal cortex due to cortical hypertrophy or to a tumor of the adrenal

gland. However, the prolonged administration of large doses of exogenous glucocorticoid hormones will also cause this cluster of signs and symptoms and simulate disordered adrenal function. The term *Cushing's disease* refers specifically to pituitary adrenocorticotropic hormone (ACTH) excess caused by a pituitary tumor (adenoma), which, in turn, causes oversecretion of cortisol by the adrenal gland and is a form of Cushing's syndrome.

Epidemiology and Causes

Cushing's syndrome may be classified mechanistically as ACTH-dependent or ACTH-independent hypercortisolemic states. The former mechanism results in adrenocortical hyperplasia and is most frequently due to an ACTH-secreting pituitary adenoma (70% of cases). Known as Cushing's disease, this condition occurs more commonly in women. The tumors are usually small (microadenomas) and may not be recognizable on pituitary imaging, with some patients demonstrating only hyperplasia of pituitary corticotrophs. Fewer than 10% of affected patients have a tumor greater than 10 mm in diameter. The tumors are not encapsulated and present in the anterior pituitary gland. Spontaneous cases of Cushing's syndrome are rare, occurring in 2.6 persons per 1,000,000 per year. Malignant pituitary tumors are, fortunately, rare.

Nonpituitary tumors account for ectopic ACTH secretion in 10% to 15% of ACTH-dependent cases of Cushing's syndrome. In contrast, excessive administration of exogenous ACTH and ectopic secretion of corticotropin-releasing hormone (CRH) by nonhypothalamic tumors each account for less than 1% of ACTH-hypersecretion cases.

The majority of ACTH-independent cases of Cushing's syndrome are due to iatrogenic administration of glucocorticoid hormones for therapeutic purposes. However, tumors of the adrenal cortex account for up to 20% of ACTH-independent cases, and both micronodular and macronodular dysplasia of the adrenal gland have been observed, although these etiologies are both quite rare, accounting for fewer than 1% of cases.

Pathophysiology

A basic knowledge of the hypothalamic-pituitary-adrenal neurohormonal axis is required to properly understand the pathophysiology of Cushing's syndrome. Ultimately regulated by the central nervous system, CRH is first produced by the hypothalamus and released into the hypophyseal portal circulation, where it stimulates the production of proopiomelanocortin (POMC) by corticotrophs in the anterior pituitary gland, from which ACTH (also called corticotropin) is derived as a cleavage product. ACTH then acts directly on the adrenal cortex to stimulate the production of cortisol and other adrenal hormones that act at peripheral tissue sites as intranuclear transcription factors for steroid-responsive genes. Cortisol is then metabolized by the liver and kidneys, and its breakdown products are secreted in the urine as 17-hydroxycorticosteroids, 17-ketogenic steroids, and 17-ketosteroids.

A key regulatory mechanism of this neuroendocrine axis is the negative feedback exerted by each downstream product on its preceding hormone—namely, the inhibitory effects of ACTH on CRH secretion, as well as serum cortisol on the secretion of ACTH and CRH at the level of the pituitary and hypothalamus, respectively. The pituitary is also likely subject to other forms of positive feedback from additional secretagogues. For example, pituitary corticotrophs have been shown to express receptors for growth hormone–releasing peptide and increase ACTH production in response to GRP secretion.

The secretion of ACTH (and, hence, serum cortisol) is normally pulsatile in nature in terms of frequency and remains constant. However, with the extent of ACTH release with each pulse varies according to the body's circadian rhythms (sleep–wake cycles), which accounts for the variation in serum cortisol levels observed through serial measurements at different times of the day. Physical and emotional stressors that increase the body's metabolic demands also increase ACTH and cortisol secretion. In the normal diurnal sleep–wake cycle, levels are highest in the early morning on awakening and are lowest late in the evening and during the very early morning hours after midnight.

In patients with Cushing's disease, pituitary adenomas secrete excessive amounts of ACTH. The hypersecretion is random, is episodic, and does not follow the usual circadian rhythm of ACTH secretion in terms of amplitude and duration. ACTH stimulates the secretion of glucocorticoids, mineralocorticoids, and androgenic steroids from the adrenal cortex. As cortical hyperplasia increases, the adrenal glands secrete increasing amounts of cortisol in response to each incremental pulse of ACTH. Moreover, in the presence of an adenoma, the usual negative feedback mechanism of excessive glucocorticoid secretion does not suppress ACTH production to the same extent as in unaffected persons, possibly owing to a defect in the glucocorticoid receptor in adenomatous corticotrophs. In turn, these patients present with hypercortisolemia and elevated levels of ACTH—particularly those with macroadenomas.

Importantly, however, in contrast to the ACTH-producing cells of relatively rarer ectopic, nonpituitary adenomas that remain virtually unresponsive to negative feedback mechanisms, pituitary adenomatous corticotrophs appear to still retain a threshold level, albeit a higher one than in normal corticotrophs, for cortisol-mediated negative feedback. This allows a high-dose dexamethasone suppression test to differentiate between pituitary and nonpituitary sources of ACTH hypersecretion. With ectopic, nonpituitary ACTH secretion, both hypothalamic CRH secretion and pituitary ACTH secretion from normal corticotrophs are suppressed. A number of different tumor types have been implicated

with ectopic ACTH hypersecretion, most commonly small oat-cell carcinoma of the lung and carcinoid tumors of the thymus or pancreas, all of which arise from neuroendocrine cell precursors. Interestingly, most of these tumors secrete a greater proportion of POMC precursors than ACTH itself.

In patients with Cushing's syndrome, cortisol measurements taken at various times during a 24-hour period will demonstrate prolonged elevations of cortisol levels, even though some readings may be within the normal range. The normally tight regulatory relationship between ACTH and cortisol secretion is lost, with late evening levels being particularly high. This excessive production of cortisol over the entire 24-hour sleep–wake cycle results in the clinical signs and symptoms of Cushing's syndrome.

The most frequent cause of Cushing's syndrome, however, is prolonged administration of exogenous glucocorticoid hormones—an iatrogenic etiology that is considered ACTH independent. Thus, any medical problem requiring the prolonged use of corticosteroids predisposes the patient to develop this syndrome. Examples include autoimmune disorders, reactive airway disease, and chronic obstructive pulmonary disease—all of which may involve long-term systemic steroid use as maintenance therapy or for recurrent exacerbations. Rarely, megestrol acetate (Megace), which has intrinsic glucocorticoid activity, may also lead to Cushing's syndrome. Exogenous steroid administration leads to suppression of CRH and ACTH excretion, as well as steroid production by native adrenal tissue. This results in bilateral adrenocortical atrophy and low salivary and urinary levels of 17-hydroxycorticosteroid and cortisol, unless cortisol itself is the steroid being administered.

Primary adrenocortical disease including cortical tumors and both micronodular and macronodular hyperplasia is much less common. Adrenal tumors may be benign adenomas or malignant carcinomas. Both types of tumors demonstrate altered expression of genes involved in apoptosis and telomeric function, which appears to underlie clonal immortalization. However, a number of significant differences exist between benign and malignant tumors. Adrenal adenomas produce cortisol from cholesterol backbones very efficiently, secreting relatively low levels of the cortisol precursors dehydroepiandrosterone (DHEA-S) and 17-ketosteroids. Adenomatous cells have also been shown to respond to beta-adrenergic agonists and multiple cytokines, including interleukin-1 (IL-1), gastric inhibitory peptide, vasopressin, and serotonin.

In contrast, adrenal carcinomas are far less efficient at producing cortisol, secreting cortisol precursors at disproportionately higher concentrations. Adrenal carcinomas are still capable of leading to Cushing's syndrome, however, owing to their size and secretory cell mass. They are also more likely than adrenal adenomas to produce elevated levels of the aldosterone precursor corticosterone and its hydroxy and deoxy variants. Adrenal carcinomas also produce high levels of vascular endothelial growth factor–A (VEGF-A), insulin-like growth factor (IGF)–1, IGF-2, IGF-2 receptor, cell cyclins, cyclin-dependent kinase, and the chemokines IL-8 and epithelial neutrophil-activating protein–78. In contrast, levels of the antiangiogenic factor thrombospondin-1 are reduced.

With primary adrenocortical tumors, hypercortisolemia allows for negative feedback of both CRH and ACTH secretion. Thus, pituitary corticotrophs atrophy, as do the normal adrenal cells of the zona fasciculata and zona reticularis. In contrast, macronodular adrenal hyperplasia results in glands weighing 25 to 500 g or more, with multiple benign nodules greater than 5 mm in diameter and a hypertrophic (rather than atrophic) internodular cortex.

Clinical Presentation

Subjective

The clinical presentation of Cushing's disease is usually gradual, developing over months or years. Signs and symptoms of Cushing's disease are those of hypercortisolism and androgen excess.

The presentation of patients with Cushing's syndrome is similar. Common complaints include weight gain, back pain, headaches, skin changes (see later), and muscle weakness. Women may complain of menstrual irregularities and hirsutism, and men often report decreased libido and impotence. Patients may also complain of emotional lability, increased appetite and weight gain, increased irritability, anxiety, poor concentration and memory, and sleep disturbances.

Objective

Patients with Cushing's syndrome predominantly present with generalized or central obesity. In fact, obesity is the most common and often the first clinical manifestation of this disorder. Excessive accumulation of fat in the face leads to the typical "moon face" appearance. Facial plethora often accompanies the moon facies. The "buffalo hump" appearance is caused by excessive accumulation of fat in the supraclavicular and dorsocervical area.

Most patients will have readily recognizable skin changes. There is atrophy of the epidermis and connective tissue, producing a thinning of the skin and easy bruising. Additional skin changes include hirsutism, acne, and striae. Striae are typically red to purple and usually are present on the abdomen but may be present on the hips, buttocks, thighs, breast, and axilla. Hyperpigmentation, commonly found in some types of Cushing's syndrome, is rare in patients with Cushing's disease.

Fungal infections of the skin, nails, and oral mucosa are common. Skin wounds heal slowly in the presence of excessive cortisol.

Most patients have muscle weakness, which is more prominent proximally and in the lower extremities. The

extremities are usually thin, with muscle wasting. Osteoporosis is common in patients with prolonged elevated cortisol levels, and pathological fractures may be evident on radiographic examination.

Other manifestations include glaucoma, leukocytosis, granulocytosis, lymphopenia, and psychiatric symptoms. Less common clinical findings include renal calculi and edema. Hypokalemic alkalosis is rare in Cushing's disease but is often seen in Cushing's syndrome.

Hypertension is often present secondary to sodium and water retention. Glucose intolerance and hyperglycemia result because cortisol interferes with the transfer of insulin across the cell membrane.

Diagnostic Reasoning

Cushing's syndrome and disease is diagnosed via a combination of laboratory testing and radiographic examinations.

Diagnostic Tests

Initial Testing The Endocrine Society released diagnostic guidelines recommending that one of four tests be used in the initial testing for Cushing's syndrome: urine free cortisol (at least two measurements), late-night salivary cortisol (two measurements), 1-mg overnight dexamethasone suppression test, or longer low-dose dexamethasone suppression test (DST; 2 mg/day for 48 hours). Additional laboratory tests should include a complete blood count, blood glucose levels, and comprehensive metabolic panel. Hypercortisolemia impairs glucose tolerance and often produces hypokalemia and leukocytosis.

Initial tests to assess cortisol levels include serum cortisol levels and urinary cortisol. The overnight DST assists in the confirmation of hypercortisolemia. To do the overnight DST, the patient takes 1 mg of dexamethasone (Decadron) orally at 11:00 p.m., and the plasma cortisol level is measured at 8 a.m. the next morning. A normal finding is a value below 1.8 mcg/dL, because an elevated morning cortisol level would indicate that the patient's endogenous cortisol secretion is insensitive to the negative feedback imparted by the exogenous dexamethasone dose. False-positive results may occur in patients who are obese, depressed, or under extreme stress. Medications that may also produce high cortisol levels are estrogens, antiseizure medications, and rifampin. Phenytoin (Dilantin), phenobarbital (Luminal), and primidone (Mysoline) accelerate the metabolism of dexamethasone and can also produce a false-positive dexamethasone test.

A nighttime (11:00 p.m.) salivary cortisol level is normally below 4.2 nmol/L and when obtained on two samples within this range excludes the diagnosis of Cushing's syndrome. Levels twice this high are suggestive of Cushing's syndrome. Although this is a relatively easy test to perform (samples are stable at room temperature), it requires special sample collection tubes and a nighttime collection schedule but has a sensitivity of 93% to 100%.

A urinary free cortisol 24-hour collection test requires the patient to collect urine for 24 hours, which is often not a practical expectation, unless the collection is done in an inpatient setting. The majority of patients with Cushing's syndrome will have an elevated level; if it is fourfold the upper limit of normal, this result is considered diagnostic for Cushing's syndrome. However, mild Cushing's syndrome may still have normal levels; thus, normal urinary free cortisol levels (less than 50 mcg/24 hr) do not rule out Cushing's syndrome entirely. If the test result is positive for Cushing's syndrome, the patient should be referred to an endocrinologist, who will conduct further testing to determine the cause and subtype of Cushing's syndrome. If symptoms of Cushing's syndrome are present but tests do not confirm the diagnosis of hypercortisolism, a low-dose DST should be performed.

Subsequent Testing The low-dose DST involves administration of dexamethasone 0.5 mg PO every 6 hours for 48 hours. Urine is collected on day 2 of the test. Urinary free cortisol above 20 mcg/dL or a 17-hydroxycorticosteroid level above 4.5 mcg/dL confirms the diagnosis of hypercortisolism. Many medications, including corticosteroids, phenothiazines, phenytoin, diuretics, quinidine, penicillin G, oral contraceptives, lithium, acetylsalicylic acid, and monoamine oxidase inhibitors, may affect the accuracy of test results.

Baseline plasma ACTH levels should be assessed once hypercortisolism is confirmed. Levels are highest between 7:00 a.m. and 10:00 a.m (8–80 pg/mL) and lowest just before bedtime (less than 10 pg/mL). Generally, levels below 20 pg/mL indicate a possible adrenal tumor, and levels exceeding 20 pg/mL are indicative of a pituitary or ectopic secreting ACTH tumor.

After completion of hormonal studies, radiological studies are performed to localize the possible source of excess cortisol production. Most microadenomas of the pituitary gland are detected by imaging. An abdominal computed tomography (CT) scan of the adrenal glands is done to detect adrenal tumors. In Cushing's disease, the adrenal glands are enlarged. A CT scan of the chest and abdomen is also beneficial in detecting possible sites of ectopic secretion. Because the lung is the most likely source of ectopic secretion, special attention to the chest is indicated. If the source is determined to be the pituitary gland, magnetic resonance imaging is indicated.

Patients should also be assessed for other sequelae of Cushing's syndrome such as hypokalemia, anemia, metabolic alkalosis, hyperglycemia, and hypercholesterolemia. Except for initial testing, the diagnosis of Cushing's syndrome and the differentiation as to cause are best accomplished either by an endocrinologist or in collaboration with an endocrinologist.

Differential Diagnosis

Pregnancy, obesity, and excessive activity may produce elevated serum cortisol levels. Other conditions that may produce elevated cortisol levels are alcoholism, severe

depression, obesity, hypertension, DM, glucocorticoid therapy, estrogen replacement therapy, and oral contraceptives. There are also various familial (genetic) predispositions to hypercortisolemia. Type 1 multiple endocrine neoplasia (MEN 1) syndrome presents with pituitary corticotroph adenomas in 2% of cases, whereas Carney's syndrome is a rare autosomal dominant complex consisting of bilateral micronodular dysplasia, pigmented lentigines, and blue nevi on the head and trunk, as well as multiple endocrine and nonendocrine neoplasms.

Management

The goals of treatment are to reduce the cortisol levels to normal and treat the underlying cause. The initial clinical management of patients with Cushing's syndrome should be handled by an endocrinologist. Despite successful treatment, some patients may relapse, so the patient must be evaluated for recurrence of hypercortisolemia.

Initial Management

Transsphenoidal pituitary microsurgery is the treatment of choice for pituitary adenoma causing Cushing's disease. If surgery is unsuccessful, irradiation of the pituitary may be considered. Complications from surgery include transient diabetes insipidus, visual disturbances, cerebrospinal rhinorrhea, and meningitis. After microsurgery, 75% of patients will experience dramatic decreases in cortisol and will require exogenous glucocorticoid therapy for 6 to 36 months after surgery. For patients who fail to respond or who have a recurrence, treatment may include stereotactic pituitary radiosurgery (gamma knife) or laparoscopic bilateral adrenalectomy. Conventional pituitary irradiation therapy has a 23% cure rate. Failure rates with both types of treatment increase over time. Diagnostic errors (depression and lack of a pituitary adenoma) increased failure rates of patients treated with surgery.

After a transsphenoidal pituitary microsurgery, 25% of patients have persistent signs and symptoms. This is more likely to occur if the tumor was not completely removed and in patients with corticotrophic hyperplasia. These patients require a second pituitary operation, radiotherapy, or bilateral total adrenalectomy.

In younger patients who are not surgical candidates, mitotane (Lysodren) or alternatively ketoconazole (Nizoral) 200 mg every 6 hours may be used alone or in combination to reduce cortisol overproduction. Older adults who are not surgical candidates may tolerate the use of ketoconazole; however, liver enzymes may be elevated with this treatment and need to be monitored by an endocrinologist.

Subsequent Management

After resection of a pituitary adenoma, normal corticotrophins are suppressed; temporary cortisone replacement therapy is indicated for 9 to 12 months, but may be as long as 36 months. The drugs of choice for replacement therapy are hydrocortisone (Cortef), prednisone (Deltasone), and fludrocortisone (Florinef). Dexamethasone (Decadron) is an alternative. The lowest dose effective in maintaining hormone levels is recommended. Complications of untreated or inadequate treatment of Cushing's disease are increased susceptibility to infections, nephrolithiasis, hypertension, and osteoporosis. Inadequate treatment may also lead to psychosis or uncontrolled DM.

Medications for corticosteroid replacement are listed in Drugs Commonly Prescribed 16.3: Corticosteroid Replacement Therapy.

Follow-up and Referral

The follow-up for each patient depends on the therapy. The patient should be followed monthly for the first year and checked for signs of adrenal hypofunction, and then every 6 to 12 months thereafter. Excessive corticosteroid treatment should be avoided as much as possible. The patient may need education to cope with lifelong symptomatology (specifically information on the importance of early interventions for infections), a prevention of emotional lability mechanism to cope with overwhelming stress, use of potassium supplements, and maintenance of a high-protein diet.

The disorder is usually chronic, characterized by periods of cyclic exacerbation and rare remissions. Complications are osteoporosis, increased susceptibility to infection, hirsutism, and metastases of malignant tumors (depending on causality).

Referrals are suggested for surgical intervention for the following conditions associated with Cushing's syndrome:

1. *Primary hypersecretion of ACTH.* Transsphenoidal microsurgery is recommended and is often followed by radiation and sometimes by medication (adrenocortical inhibitors).
2. *Adrenocortical tumors.* Surgery is recommended, but prognosis is still poor. Replacement therapy is used but usually for only 3 to 12 months. The patient may need treatment with adrenocortical inhibitors if not treated with surgery, which should be managed by an endocrinologist.
3. *Ectopic ACTH production.* Surgery is recommended for removal of neoplastic tissue to manage symptoms, although surgical cure is unlikely. Sometimes a bilateral adrenalectomy is performed. Follow-up for these patients would depend on causality and recommended treatment.

Patient Education

Although patients with Cushing's syndrome will be managed initially by an endocrinologist, the primary-care clinician often manages other aspects of the patient's health. It is important to work collaboratively with the patient in managing symptoms successfully.

Patients need a thorough understanding of their medications and the warning signs of undertreatment or

Drugs Commonly Prescribed 16.3 Corticosteroid Replacement Therapy

Drug	Indication	Adverse Reactions and Prescribing Considerations
prednisone (Deltasone, Meticorten) Supplied PO	Adrenalectomy Pituitary resection	Glucocorticoid activity: Moderate Mineralocorticoid activity: Weak Use the lowest effective dose to prevent side effects such as DM, psychosis, osteoporosis, infections.
prednisolone (Delta-Cortef, Prelone)	Adrenalectomy Pituitary resection	Glucocorticoid activity: Moderate Mineralocorticoid activity: Weak Use the lowest effective dose to prevent side effects such as DM, psychosis, osteoporosis, infections.
methylprednisolone (Medrol, PO) or Depo-Medrol IM or IV	Adrenalectomy Pituitary resection	Glucocorticoid activity: Moderate Mineralocorticoid activity: None Use the lowest effective dose to prevent side effects such as DM, psychosis, osteoporosis, infections.
hydrocortisone (Cortef, Hydrocortone) Supplied in PO, IM, IV, topical, ophthalmic	Adrenalectomy Pituitary resection	Glucocorticoid activity: High Mineralocorticoid activity: Yes Use the lowest effective dose to prevent side effects such as DM, psychosis, osteoporosis, infections.
cortisone acetate (Cortone) Supplied PO and IM	Adrenalectomy Pituitary resection	Glucocorticoid activity: High Mineralocorticoid activity: Yes Use the lowest effective dose to prevent side effects such as DM, psychosis, osteoporosis, infections.
dexamethasone (long-acting) (Decadron) Supplied PO, IM, IV	Adrenalectomy Pituitary resection	Glucocorticoid activity: Very high Mineralocorticoid activity: Weak Use the lowest effective dose to prevent side effects such as DM, psychosis, osteoporosis, infections.
fludrocortisone (Florinef) Supplied PO	Adrenalectomy Pituitary resection	Glucocorticoid activity: None Mineralocorticoid activity: High Use the lowest effective dose to prevent side effects such as sodium and water retention, edema, hypertension, hypokalemia.

DM: diabetes mellitus

overtreatment with cortisone. Cortisone preparations should be taken with food. Patients need to be told that they should consult with the primary care clinician when initiating additional medications, both prescription and over the counter. Patients on high doses should wear a medical identification bracelet. Because these patients are prone to infections, they should be instructed on how to avoid common infections, both bacterial and fungal. Patients cannot rely on elevated temperature to indicate the seriousness of any infection; therefore, they need to report any initial signs of infection.

Nutritional counseling may be indicated, including information on avoidance of excessive sodium and on a well-balanced, low-fat diet. Many patients are obese, and the importance of weight loss must be addressed.

Patients should monitor their glucose levels at least weekly. During periods of stress or medication adjustment, glucose levels will need to be tested more frequently. Patients should assess their glucose levels daily during periods of medication adjustment. If levels are stable and within normal levels, they may continue testing glucose levels until at least 1 week after final dose adjustment. They should resume daily glucose testing in times of stress or if any signs of infection are present. If the morning glucose level at any time is above normal, more frequent testing is indicated. The patient should be given a log to record the glucose test results and instructed to bring the log to each primary-care visit.

Patients with Cushing's syndrome will need to have their blood pressure monitored weekly. As with glucose monitoring, the frequency will depend on their symptoms and coexisting cardiovascular disease. More frequent monitoring will be needed during times of stress. The patient should obtain a sphygmomanometer for home use and keep a log of his or her blood pressures so that the primary-care provider can see the pattern.

The patient should be instructed about fall prevention. Because of the potential for osteoporosis, the patient should avoid activities that are likely to cause falls. Simple environmental changes can be made in the home to increase safety, such as removing small rugs, placing rails around the bathtub, and using a shower chair.

Patients should also report any symptoms of gastrointestinal upset (nausea, bloating, vomiting) and monitor themselves for signs of gastrointestinal bleeding (vomiting blood, tarry stools, increasing fatigue).

Instructions on skin care are essential. Research indicates that older adults with a history of long-term corticosteroid use are more prone to pressure ulcers. Thin, easily traumatized skin must be protected. These individuals should avoid applying tape and adhesive bandages directly to their skin. They should wear protective clothing for outdoor activities such as gardening.

There is potential for failure of the surgical intervention. Instruct the patient to report any return of symptoms if he or she has been asymptomatic for a period after the operation.

ADRENAL INSUFFICIENCY

Low levels of cortisol secretion by the adrenal glands can result from inadequate stimulation of the adrenals by adrenocorticotropic hormone (ACTH) from the anterior pituitary or because the adrenals are unable to produce adrenocortical hormones. *Addison's disease,* also known as primary adrenal insufficiency, is relatively rare and results from a failure of the adrenals to produce hormones because of a problem in the gland rather than a problem with the pituitary (ACTH). Other types of adrenal insufficiency, or hypocortisolism, occur from secondary sources, such as a failure of the pituitary gland to produce adequate levels of the adrenal-stimulating hormone ACTH or the abrupt withdrawal of exogenously administered glucocorticoids, which previously suppressed endogenous adrenal hormone production.

Epidemiology and Causes

Addison's disease is primarily (80% of cases in the United States) caused by autoimmune destruction of the adrenal cortex. Although it can occur at any age, Addison's disease most often occurs in persons aged 30 to 60 years. Women are diagnosed slightly more often than men, with an overall incidence of 0.6 per 100,000 and a prevalence of 4 per 100,000. Risk factors for Addison's disease include having a first- or second-degree relative with the disease.

Other causes of (secondary) adrenal insufficiency are chronic corticosteroid use followed by a physiologically stressful event, such as severe infection, trauma, or surgical procedure, in which adrenal hormone levels are inadequate, due to the iatrogenic suppression of endogenous hormone production. TB infection is the most common infectious cause of adrenal insufficiency worldwide, whereas HIV is the most common infectious cause in the United States, resulting from direct effects on the adrenal glands themselves. Other causes include bilateral adrenal hemorrhage and infarction, tumors of the adrenal gland causing decreased function, drugs (ketoconazole [Nizoral], etomidate [Amidate]), sarcoidosis, hemochromatosis, amyloidosis, and congenital causes.

Pathophysiology

Idiopathic Addison's disease is an autoimmune disorder and can occur at any age. Adrenal-specific autoantibodies are present in 50% to 70% of cases and are more likely to be present in younger patients and those with other autoimmune diseases. These autoantibodies are specific for cells of the adrenal cortex and for the enzyme(s) responsible for the production of cortisol and aldosterone. A combination of autoantibodies and cell-mediated immune responses is responsible for this disease. Frequently, idiopathic Addison's disease appears with other autoimmune diseases, which are collectively termed *autoimmune polyendocrine syndrome* (APS). Type 1 APS is an inherited autosomal recessive disease and, along with Addison's disease, includes hypoparathyroidism and mucocutaneous candidiasis. Type 2 APS is the more common type, with a constellation of disorders that includes Addison's disease, diabetes mellitus, celiac disease, immune thyroid disease, and hypogonadism.

Secondary hypocortisolism is usually a result of low ACTH levels and subsequent adrenal atrophy. The resulting hypocortisolism causes clinical manifestations similar to Addison's disease. However, in this type of hypocortisolism, there is no hyperpigmentation, as typically seen in Addison's disease, and the renin-angiotensin system functions normally, resulting in normal aldosterone and potassium levels.

Clinical Presentation

Clinical manifestations of Addison's disease include fatigue, weakness, anorexia, weight loss, nausea, abdominal pain, diarrhea, hypoglycemia, and hypotension (particularly orthostatic hypotension), which are primarily the result of hypocortisolism and hypoaldosteronism. Patients with Addison's disease typically exhibit hyperpigmentation due to elevated levels of ACTH, which is derived from the precursor protein proopiomelanocortin (POMC) that also gives rise to melanocyte-stimulating hormone. In severe cases, when a patient has Addison's disease that is well managed but the patient subsequently experiences a physiological stressor of some kind (e.g., infection, surgery), the requirement for cortisol increases and the patient may experience an Addisonian crisis, manifesting as severe hypotension and vascular collapse. The decreased adrenal androgen secretion associated with Addison's disease results in the loss of secondary sex characteristics (loss of pubic and axillary hair) in women, but because the adrenals are not a major source of androgens in men, male patients do not experience any loss of secondary sex characteristics.

Diagnostic Reasoning

Diagnostic Tests

When Addison's disease or other forms of hypocortisolism are suspected, a plasma cortisol level should be obtained. A morning (8:00 a.m.) cortisol level of less than 3 mcg/dL is consistent with Addison's disease, especially if accompanied by a plasma ACTH level greater than 200 pg/mL. Diagnosis is confirmed by a cosyntropin stimulation test, in which a synthetic form of ACTH is given intramuscularly (IM) and a serum cortisol level is obtained 45 minutes later. In Addison's disease, the exogenous ACTH dose does not result in a corresponding increase in cortisol secretion, demonstrating primary failure of the adrenal glands to respond to ACTH. Small, noncalcified adrenal glands on CT scan are indicative of autoimmune Addison's disease.

Differential Diagnosis

Patients with Addison's disease generally have an elevated ACTH level, which is associated with hyperpigmentation of the skin. In contrast, if a patient has hypocortisolism that is a result of hypopituitarism resulting in a low ACTH level, he or she will have normal pigmentation. In any patient with unexplained hypotension, Addison's disease and other forms of hypocortisolism should be considered. Other nonspecific clinical manifestations that may be associated with Addison's disease but are also common in other conditions are nausea, unintentional weight loss, weakness, and anorexia. Hypocortisolism should be considered when other causes for the constitutional symptoms have been ruled out.

Management

Initial therapy for adrenal insufficiency consists of hydrocortisone 15 to 30 mg in two divided doses, with two-thirds of the dose given in the morning and one-third given in the early evening. Prednisone can be used if the patient does not respond well to hydrocortisone. The dose of prednisone is 2 to 4 mg in the morning and 1 to 2 mg in the evening. The dose is adjusted based on the clinical response.

Stress hormone supplementation is necessary for patients who experience significant physiological stressors, such as serious infection, trauma, or surgery. In cases of severe stress, hydrocortisone is given IV or IM every 6 hours at a maximum dose of 50 mg. Oral medication at lower doses can be prescribed if the stress is less severe and then reduced to normal when the stress subsides.

In addition to hydrocortisone (glucocorticoid), mineralocorticoids must be replaced, although not all patients require daily therapy. Fludrocortisone (Florinef) acetate is the drug of choice and has a potent sodium-retaining effect. The usual dosage is 0.05 to 0.2 mg PO daily, which should be determined in conjunction with an endocrinologist. Symptoms of fatigue, postural hypotension, hyponatremia, or hyperkalemia may indicate the need for a higher dosage. Of note, in contrast to glucocorticoid requirements, increased mineralocorticoid supplementation is not required during times of increased physiological stress.

Some patients require androgen therapy along with the medications mentioned above. Dehydroepiandrosterone (DHEA) 25 to 50 mg PO daily has been shown to improve sense of well-being, increase muscle mass, and reverse bone loss. When prescribed DHEA, older women should be monitored for masculinizing effects.

Follow-up and Referral

Patients with adrenal insufficiency require chronic glucocorticoid and mineralocorticoid supplementation and are prone to Addisonian crises, due to the inability to mount an appropriate stress hormone response with endogenous cortisol. Determination of an appropriate replacement dose and regimen requires periodic assessment for signs of both underdosing (weakness, dizziness, and headaches on waking) and overdosing (Cushingoid features).

Once chronic maintenance dosing is established in conjunction with an endocrinologist, the primary-care provider will be able to meet most of the patient's ongoing health-care needs but should also evaluate for iatrogenic complications of chronic corticosteroid use, including cataract formation (requiring annual ophthalmological examinations) and the development of osteopenia/osteoporosis (requiring periodic dual-energy x-ray absorptiometry [DEXA] scanning). Expert consultation with an endocrinologist should be sought if dose adjustments or a change in class of hormone replacement is indicated.

Patient Education

Any patient with Addison's disease or adrenal insufficiency needs to be well informed about this condition and the potential implications for Addisonian crisis if the patient should develop a serious infection or experience other physiological stressors. Given the significant risk from systemic illness, patients should be instructed to see their health-care provider during times of illness. In these instances, additional corticosteroid supplementation (stress hormones) may be required, for example, a doubling or tripling of the dose of hormone replacement therapy in the setting of an illness, surgery, or dental procedure. This may require parenteral (IM) dosing if oral supplementation is not possible (e.g., because of significant nausea and vomiting or diarrhea). Thus, if possible, patients should be trained to self-administer IM injections and may be given a reserve prescription for parenteral hydrocortisone or similar agent to be used in these situations.

DIABETES MELLITUS

Diabetes mellitus (DM) is a syndrome of disordered carbohydrate, fat, and protein metabolism and hyperglycemia resulting from deficits in insulin secretion, insulin action,

or a combination of both. There are two distinct types of DM, type 1 and type 2 (each with a distinct epidemiology and etiology), but impaired fasting glucose (IFG) and impaired glucose tolerance (IGT) are used to describe a fasting glucose between 100 and 125 mg/dL or a 2-hour postglucose load blood glucose of 140 to 199 mg/dL. Some sources state that IGT and gestational diabetes are now considered under the IFG category.

DM is the most common endocrine disorder, affecting 25.8 million people in the United States, up to 7 million of whom may be undiagnosed. In 2011, DM affected 8.3% of the adult population in the United States. The complications of DM include cardiovascular and peripheral vascular disease, decreased immune system functioning, renal failure, and retinopathy. Diabetic nephropathy is now the leading cause of end-stage renal disease. DM also is the leading cause of acquired blindness in the United States. Tight control of blood glucose levels reduces the morbidity and mortality rates associated with DM, but control is not without its costs. The costs of long-term management of diabetes have serious implications on the quality of life of those affected and their families.

DIABETES MELLITUS TYPE 1

Diabetes mellitus type 1 is a metabolic disorder characterized by a severe insulin deficiency resulting from beta-cell destruction and producing hyperglycemia. The lack of insulin alters lipid, carbohydrate, and protein metabolism. Chronic hyperglycemia of DM results in damage to various body organs, especially the eyes, kidneys, nerves, heart, and both small and large blood vessels. Loss of vision, renal failure, loss of a lower extremity, and chronic foot ulcers caused by peripheral neuropathy are common sequelae of long-term hyperglycemia. Chronic hyperglycemia affects all body systems and places significant social, economic, and psychological demands on patients and their families.

Diabetic retinopathy remains the leading cause of new-onset blindness among adults aged 20 to 74 years. After 20 years of type 1 DM, nearly all patients have some retinopathy. Impairment of growth, an increased susceptibility to infection, and autonomic neuropathy, resulting in gastrointestinal, genitourinary, and cardiovascular symptoms including sexual dysfunction, also occur. Persons with DM have an increased incidence of atherosclerotic heart disease, peripheral vascular disease, and cerebrovascular disease. Diabetic ketoacidosis (DKA) and hyperosmolar hyperglycemic syndrome (HHS) are both life-threatening sequelae of hyperglycemia. HHS is more commonly seen in type 2 DM, however. Tables 16.6 and 16.7 provide more information on these conditions.

Table 16.6 Diabetic Ketoacidosis (DKA)

Overview	Clinical Presentation	Management
DKA is an acute decompensation in diabetes and requires immediate medical attention. The cardinal features of DKA: **Hyperglycemia**—blood glucose >359 mg/dL **Ketonemia**—plasma ketone level >5 mmol/L **Acidosis**—plasma bicarbonate level <9 mEq/L **Causes:** Lack of insulin Stress (physical or emotional), even with continued insulin therapy • As insulin levels drop, concentrations of glucagon rise, which increases glucose levels • Epinephrine inhibits glucose transport in peripheral tissues, thereby stimulating the production of glucose in the liver and noncarbohydrates are used to produces glucose in the liver. • Free fatty acids from adipose stores are oxidized in the liver for energy, and this causes a release of ketones and resultant acidosis.	DKA begins with: • Anorexia • Increased thirst • Nausea/vomiting • Abdominal cramping • Increased urine formation Later signs: • Kussmaul respiration • Signs of dehydration (usual fluid deficit is 3–5 L) • Oliguria • Altered consciousness Left untreated: • Coma • Vascular collapse • Renal shutdown • Blood glucose increases from 300–800 mg/dL. Diagnostic tests: • Serum glucose • Sodium potassium • Phosphate • Bicarbonate • Beta-hydroxybutyrate • Osmolarity • pH • Calculated anion gap	Goals: • Correct dehydration. • Normalize electrolytes. • Correct acidosis. First line of treatment is insulin. • Continuous-dose insulin infusion: 0.1–0.2 units/kg per hour Correct dehydration and electrolyte imbalance: • Rapid infusion of normal saline or Ringer's lactate IV: 1–2 L • Potassium replacement 3–4 hours after initiation of insulin and fluid therapy • Bicarbonate therapy if pH is 7.0 or below After recovery, causes for the DKA should be explored. Patient teaching about the need for more insulin during periods of illness and stress.

Table 16.7 Hyperosmolar Hyperglycemic Syndrome (HHS)

Overview	Clinical Presentation	Management
HHS is characterized by: • Severe hyperglycemia—blood sugar >600 mg/dL • No ketosis • Hyperosmolality • Dehydration • High mortality rate Seen in: • Older diabetics who develop infection or other illness • Undiagnosed diabetics • Patients with diabetes diagnosed after a long period of hyperglycemia Precipitating factors: • Peritoneal dialysis • Hemodialysis • Tube feeding with high-protein formulas • Mannitol • Phenytoins (Dilantin) • Steroids • Immunosuppressive agents • Diuretics • Surgery • Myocardial infarction • Sepsis • Renal insufficiency • Congestive heart failure	Insidious onset with subtle initial symptoms. History may indicate decreased fluid intake. Patients may present with: • Polyuria • Polydipsia • Weakness • No ketoacidosis • Lethargy and confusion develop when serum osmolality >310 mOsm/kg • Coma Laboratory tests: • Severe hyperglycemia—blood glucose >600 mg/dL • Initial serum sodium is decreased. • Serum sodium increases as dehydration progresses. • Serum osmolality >400 mOsm/kg	Goals: • Correct dehydration. • Normalize electrolytes. Correct dehydration and electrolyte imbalance. • Rapid infusion of hypotonic saline (0.45% NaCl) • In cases of hypovolemia, then use normal saline • Fluid needs may be 4–6 L in 8–10 hours • Correct serum sodium with following equation: Corrected sodium = measured sodium + (0.8 × every 50 mg/dL increment of plasma glucose above 100 mg/dL). Once blood glucose is <250 mg/dL, fluid replacement should be 5% dextrose in 0.45% saline solution or normal saline. An important end point of fluid therapy is to return urine output to 50 mL/hr or more. Less potassium is needed than in DKA.

Epidemiology and Causes

Type 1 DM occurs in approximately 800,000 Americans and accounts for about 10% of all cases of diabetes mellitus in the Western world. It is more common in whites (1.5–2 times higher than in nonwhites), and 60% of patients are under age 18 years on first presentation. Although there is no gender predisposition, marked variations have been observed across ethnocultural groups, correlating with differential expression of human leukocyte antigen (HLA) haplotypes. Type 1 DM was previously known as insulin-dependent diabetes mellitus (IDDM) or juvenile-onset diabetes. However, cases may occur at any age with a fairly abrupt onset. It is uncommon in children younger than 1 year of age and in adults older than 30 years. In nonpediatric patients, this condition is sometimes known as latent autoimmune diabetes of adults (LADA; see later discussion).

Currently, the American Diabetes Association (ADA) does not recommend screening for type 1 DM in apparently healthy individuals who have no risk of type 1 DM. Current clinical trials are being conducted to evaluate prevention strategies to delay clinical disease, and the ADA is hopeful that effective preventive therapies will eventually be found.

Type 1 DM has two forms—immune-mediated DM and idiopathic DM. *Immune-mediated diabetes mellitus* accounts for 90% of type 1 DM and results from an autoimmune destruction of insulin-producing pancreatic beta islet cells. It typically occurs in childhood or adolescence but can arise at any age. Current thinking on the etiology of type 1 DM is that it results from an infection or toxic insult in persons with a genetic predisposition. It is believed that there is a cross-reactive autoimmune response against pancreatic beta-cell antigens, with the most commonly identified infectious agents being congenital rubella, cytomegalovirus, adenovirus, mumps virus, and coxsackie B4 virus. Sensitized immune cells may release destructive cytotoxins and antibodies that contribute to the development of type 1 DM. Patients with immune-mediated diabetes are rarely obese and are prone to other autoimmune diseases such as Graves' disease, Hashimoto's thyroiditis, Addison's disease, vitiligo, and pernicious anemia. *Idiopathic diabetes mellitus* has no known cause with no evidence of autoimmunity and accounts for less than 10% of type 1 DM cases. It is a rare form of DM, is inherited, and is more common in people of Asian or African origin. The need for insulin replacement therapy in these patients is variable.

Pathophysiology

Type 1 DM is characterized by a reduction or absence of functioning beta cells in the pancreatic islets of Langerhans. Although the exact process is not well understood, it is speculated that the sequence begins with a genetic susceptibility that has been mapped to the HLA region on chromosome 6p. Specifically, an increased risk of type 1 DM has been associated with polymorphisms in at least five genes (*HLA-DQα, HLA-DQβ, HLA-DR3, HLA-DR4, HLA-DR9*), as well as preproinsulin (the primary protein product of the insulin gene) and PTPN22 (a lymphocyte-specific tyrosine phosphatase involved in T-cell receptor signaling, which also confers susceptibility to other autoimmune disorders). Inheritance of type 1 DM appears to be polygenic, however, because expression of a particular HLA allele alone is insufficient to lead to autoimmune beta-cell destruction.

Although other genes located within major histocompatibility complex (MHC) genetic loci, as well as non-MHC genes such as cytotoxic T-lymphocyte–associated antigen 4 (*CTLA-4*), influence diabetes risk, class II HLA genes have the greatest effect. In fact, certain non-MHC genes confer an increased risk of type 1 DM only in the presence of particular HLA haplotypes, implying the importance of polygenic interactions.

Much of our understanding of the pathogenesis of autoimmune DM stems from studies in diabetogenic murine models, including nonobese diabetic (NOD) mice and biobreeding (BB) rats. Some triggering mechanism such as a viral infection or other environmental factor is believed to stimulate an inflammatory response and initiate autoimmune infiltration of the pancreatic beta cells within the islets of Langerhans—a process termed *insulitis.* Strongly associated with interleukin-18 (IL-18) (interferon-gamma–inducing factor [IGIF]) and IL-12 expression, as well as interferon-gamma–positive Th1 T cells in NOD mice, insulitis involves autologous beta cells being recognized as foreign by the body's immune system. Islet cell antigens are presented by macrophages and other antigen-presenting cells within the context of class II MHC proteins to autoreactive T cells that mediate much of the subsequent beta islet cell destruction. Alterations in just one or two amino acid positions within certain class II MHC proteins can markedly increase their capacity to present autoantigens to autoreactive T cells. In turn, more than 90% of patients with type 1 DM express *HLA-DR3, DQB1*0201* or *HLA-DR4, DQB1*0302,* and persons expressing both of these HLA haplotypes are most susceptible to developing this disease. By contrast, other HLA polymorphisms confer a protective effect against type 1 DM, presumably due to their decreased affinity for binding autoantigen.

It is known that type 1A DM is clearly associated with an increased incidence of other autoimmune disorders, including thyroid, adrenal, and gonadal insufficiency. The coexistence of all these conditions has been termed *polyglandular autoimmune disease type 2.* Other rare autoimmune syndromes that involve insulitis shed further light on the importance of genetic pathogenic mechanisms. Autoimmune polyendocrine syndrome type 1 results from a mutation in the *AIRE* gene, an autoimmune regulatory gene that controls the subsequent expression of multiple peripheral autoantigens within the thymus (including insulin itself), which is believed to mediate T-cell self-tolerance. The IPEX syndrome involves mutations in *foxp3,* which is considered a master control gene for regulatory T cells. T suppressor cells are subsequently reduced in activity, allowing for the development of autoimmune disease in affected infants, including DM and fulminant enteritis, which is often fatal.

Both Th1 and Th2 cells are capable of inducing beta-cell destruction, underscoring the importance of both cell-mediated and humoral immune processes in the pathogenesis of type 1 DM. Indeed, the presence of functional autoreactive B lymphocytes and islet cell–specific autoantibodies has been shown both to increase the incidence and shorten the time to progression of type 1 DM. Interestingly, however, autoantibodies are not absolutely required for the development of type 1 DM, as demonstrated by documented cases of the disease occurring in humorally immunodeficient persons with X-linked (Bruton's) agammaglobulinemia.

Nonetheless, islet cell–specific antibodies may be identified in 70% to 80% of prediabetic and newly diagnosed type 1 diabetic patients. Multiple species of autoantibodies have been identified, including immunoglobulins specific for the islet cell enzyme glutamic acid decarboxylase (GAD), the tyrosine phosphatase insulinoma-associated protein 2 (IA-2), and the insulin molecule itself. It has not been fully determined whether these antibodies are themselves pathogenic or simply formed as a consequence of immunological upregulation. For example, although anti-GAD antibodies are found in 70% of human patients with type 1 DM, they do not play a significant role in the pathogenesis of diabetes in NOD mice.

However, even before GAD-specific immunoglobulins form, anti-insulin antibodies may be detected. Studies in NOD mice and humans have confirmed the role of both pathogenic CD8+ and CD4+ T-cell clones that recognize peptide epitopes of the insulin B chain. IA-2-specific immunoglobulin is typically detected after antibodies to insulin and GAD. Identification of two of these three classes of autoantibodies is strongly predictive of progression to type 1A DM in genetically predisposed individuals.

Research continues on the genetic predispositions of type 1 DM and individualized treatments based on genotype. For example, the single gene *SIRT1* was demonstrated using mouse models to be involved in the development of type 1 DM, because a mutation in the *SIRT1* gene was destructive to pancreatic beta cells. Genetic predisposition alone, however, does not fully

account for disease pathogenesis. Identical (monozygotic) twin studies reveal only a 30% lifetime risk of developing type 1 DM in twin siblings of probands; however, this compares to only a 5% risk in nonidentical siblings. Moreover, twin studies also demonstrate that autoantibodies against beta islet cells may be present for years in the unaffected sibling of a proband before autoimmune diabetes develops in the second twin. Thus, destruction of a significant amount of beta-cell mass may take months to years but will eventually lead to a lack of insulin.

It is this lack of insulin that disturbs the regulatory mechanisms that control the metabolism of glucose in the body. Hyperglycemia typically develops once 80% to 90% of a patient's beta cells have been destroyed. However, there are animal (baboon) models of autoimmune DM that demonstrate insulin deficiency with as much as 50% of beta-cell mass still intact. Moreover, inflamed islet cells from NOD mice explanted to isolated cell cultures slowly regain their ability to secrete insulin after 1 week of incubation. Thus, external factors such as the inflammatory cytokine milieu are believed to play an important role in diabetic pathogenesis, despite the presence of adequate beta-cell mass. The treatment implication of this is that some patients with autoimmune DM may have a reversible component to their disease if the autoinflammatory process can be stopped early enough and an adequate number of beta cells salvaged. For example, insulin-like growth factor–1 (IGF-1) has been cited as a cytokine that plays an important role in preserving beta-cell function.

However, progressive beta-cell destruction with hyperglycemia remains the hallmark of type 1 DM. In turn, it is this hyperglycemia that leads to both microvascular and macrovascular complications, which underlie long-term diabetic damage. Vascular endothelial dysfunction and inflammation result in fibrosis and intimal thickening, leading to progressive narrowing of the vascular lumen. In turn, blood flow through the microvasculature is reduced, leading to tissue ischemia throughout the body, which results in functional impairment of multiple end organs. Several clinical trials have demonstrated that careful glycemic control reduces the development and delays the progression of microvascular manifestations of diabetes, including nephropathy and retinopathy. Thus, patients with type 1 DM universally require exogenous insulin to maintain glycemic homeostasis.

Identifying the triggering event or events that are capable of inducing the pathogenesis of autoimmune diabetes has been the subject of much research and debate. Molecular mimicry is often cited as the mechanism by which seemingly innocuous environmental (e.g., food-based epitopes) or infectious (e.g., viral) antigens that share homology with beta islet cell antigens initiate a destructive autoimmune process, with the development of cross-reactive antibodies (e.g., the association of coxsackie B viral infection with anti-GAD antibodies and the shared homology between the FC2 protein of the coxsackievirus B4 virus and human GAD). Another proposed mechanism of pathogenesis observed in BB rats involves delayed expression of islet cell antigens, which is thought to eliminate self-tolerance mechanisms associated with thymic T-cell education early in development, that is, negative thymic selection of autoreactive T lymphocytes. How this mechanism may relate to autoimmune diabetes in humans is less clear, however.

Some research has identified certain perinatal factors as increasing the risk of type 1 DM (e.g., maternal age greater than 25 years, preeclampsia, neonatal respiratory disease, neonatal jaundice secondary to ABO incompatibility). However, the increase in risk noted in this study was small. One systematic review of 12 studies involving 2,398,150 persons demonstrated that high birth weight (greater than 4,000 g) and increased weight gain in the first year of life were associated with an increased risk of type 1 DM. In contrast, a significant body of research has established viral antigens and certain dietary influences as having the strongest impact on the development of autoimmune DM. Direct viral infection of pancreatic beta islet cells may play a role, but evidence for this mechanism is lacking. However, acute immunoglobulin M (IgM) titers to coxsackie B virus are known to be elevated in the mothers of children with type 1 DM. In addition, enteroviral infections are also more common in type 1 diabetics compared with their nondiabetic siblings. Congenital rubella syndrome has also been associated with the development of type 1 DM and other autoimmune syndromes up to 5 to 20 years later, especially in individuals with the HLA-DR3 haplotype.

Contrary evidence also exists, however, that appears to exonerate viral infection as a triggering mechanism. Human immunization with either viral or bacterial antigens has never been shown to increase the risk of developing autoimmune diabetes. Moreover, when NOD mice and BB rats are raised in pathogen-free conditions with no viral contact, they display an increased incidence of autoimmune DM. In fact, infection of either of these animal strains by the lymphocytic choriomeningitis virus early on in development actually protects against type 1 DM. The precise mechanism is poorly understood, however.

The impact of dietary influences on the development of type 1 DM has been heavily studied. Although food epitopes may not mimic beta-cell antigens directly, similar proteins from other animal species are thought to trigger autoimmune reactions leading to type 1 DM. Epidemiological research from at least 10 countries has implicated key protein components of cow's milk including bovine serum albumin and beta-casein as the most likely triggers of these autoimmune responses. However, cross-sectional and prospective studies have not confirmed these associations. In fact, some work has even suggested that vitamin D confers protection against autoimmune DM. In contrast, one epidemiological study indicated that the risk of developing type 1 DM

was 30% higher in regions of the United Kingdom where drinking water contained high levels of nitrates (14.8 mg/L vs. 3.2 mg/L).

The timing of the introduction of gluten- and rice-containing cereals into an infant's diet has also been implicated in increasing type 1 DM risk, specifically, when cereals are introduced before 3 months or after 7 months of age. The early introduction of rice cereals before 3 months is also associated with the development of celiac disease. Fortunately, these parameters correspond with the current American Board of Pediatrics recommendation to begin rice cereals (ostensibly, for their iron content) at 4 to 6 months of age.

Finally, secondary causes of diabetes may mimic either type 1 or type 2 DM, depending on whether the primary disease mechanism is destruction of beta islet cells with subsequent insulin deficiency or, rather, peripheral insulin resistance in which the body still produces insulin but the peripheral tissues utilize it less efficiently. Nonimmune mechanisms of beta-cell destruction that produce a type 1B diabetes–like state include hemochromatosis, cystic fibrosis, and pancreatitis.

Clinical Presentation

Subjective

The manifestation of symptoms varies, but the majority of patients seek medical attention because of symptoms related to hyperglycemia. The diagnosis of DM type 1 is often made when a patient presents with DKA.

The classic symptoms of type 1 DM are polydipsia, polyuria, polyphagia, anorexia, and weight loss. Nocturnal enuresis is often a disturbing symptom reported by many patients. Visual changes, especially blurred vision, weakness, and fatigue, are frequently present.

Polyuria, or increased urination, results from osmotic diuresis secondary to sustained hyperglycemia. The loss of glucose, free water, and electrolytes induces a hyperosmolar state, which causes thirst (polydipsia). Blurred vision results from the lenses and retina being exposed to hyperosmolar fluids. There may be a decreased plasma volume, which causes dizziness. Weakness is due to the catabolism of muscle and potassium loss.

The patient may also complain of nausea or abdominal pain. Urinary tract infection and pyelonephritis should be ruled out, especially in patients with abdominal pain, because diabetics are more likely to experience serious complications of pyelonephritis including renal papillary necrosis, emphysematous (necrotizing) pyelonephritis, or progression to gram-negative sepsis.

Patients with DM have impaired immunity and may present with repeated infections, decreased wound healing, or infections that are uncommon in the general public, including staphylococcal and *Klebsiella pneumoniae* infections. Hyperglycemia worsens humoral immunity and leukocyte function. In fact, infections such as malignant (necrotizing) otitis externa (due to *Pseudomonas aeruginosa*) and rhinocerebral mucormycosis occur almost exclusively in patients with DM. Patients may present with complaints of pruritus caused by an infection such as vulvovaginitis. Patients with poorly controlled DM may have chronic pyogenic infections of the skin. Necrobiosis lipoidica diabeticorum is rarely seen in any patient without DM and consists of plaques with demarcated borders and a shining yellow surface occurring on the anterior surfaces of the legs or dorsal aspect of the ankles. Because most patients with DM also have microvascular and macrovascular complications that decrease the blood flow to the tissues, pathogens are able to multiply rapidly because the increased glucose in body fluids is a good source of energy for them.

Diabetic foot ulcers result from a combination of factors including decreased circulation, infection, decreased immune response, and peripheral neuropathy. Occasionally, the patient may present with a complaint of paresthesia, which is related to a temporary dysfunction of peripheral sensory nerves. The patient with peripheral neuropathy presents with a stocking-glove distribution of anesthesia, leading to missed foot ulcers or burns on the hands (from cooking or smoking).

Objective

Weight loss despite normal or increased appetite occurs as water, glycogen, and triglyceride stores are depleted. There is a reduced muscle mass as amino acids are used by the liver for gluconeogenesis with resultant ketone bodies formed. Signs of dehydration such as poor skin turgor and dry mucous membranes may be present. Genital or urinary tract infections may be present as a result of the hyperglycemic state. Ketoacidosis is usually present and may be mild to severe. Hyperosmolar hyperglycemic nonketotic acidosis is a second complication of prolonged hyperglycemia.

Patients with long-standing DM frequently develop diabetic retinopathy, which is a result of retinal ischemia. Five stages of retinopathy are evident on physical exam: (1) dilation of retinal venules and retinal capillary microaneurysms; (2) increased vascular permeability; (3) retinal ischemia due to vascular occlusion; (4) angiogenesis with proliferation of new retinal surface blood vessels; and (5) retinal hemorrhage with fibrovascular proliferation and contraction, which may lead to retinal detachment. These patients must be referred to an ophthalmologist for evaluation.

Physical exam also requires a detailed neurological exam because DM can have neurological complications. For example, diabetics may have third cranial nerve palsy, or the sixth (abducens) and fourth (trochlear) cranial nerves can also be affected in cranial neuropathy.

Diagnostic Reasoning

Immediate testing in the clinic setting can be accomplished by utilizing a portable monitor to test capillary blood glucose level. This test is referred to as a random

plasma glucose measurement and is given without regard to time of last meal. It is important to consider that certain drugs, including glucocorticoids, furosemide (Lasix), thiazide diuretics, estrogen-containing products, beta blockers, and nicotinic acid, can produce hyperglycemia. If the random plasma glucose level is elevated in the clinic, the urine should be tested for ketones and additional blood plasma glucose testing should be done.

Diagnostic Tests

Initial Testing Current guidelines for the diagnosis of diabetes include any one of the following:

- Glycosylated hemoglobin (A1C) of 6.5% or higher
- Symptoms of diabetes (e.g., polyuria, polydipsia, weight loss) plus a random plasma glucose level of 200 mg/dL or higher
- Fasting plasma glucose level of 126 mg/dL or higher (following 8 hours of no caloric intake)
- Two-hour plasma glucose level of 200 mg/dL or higher during an oral glucose tolerance test (OGTT) with a 75-g glucose load (not for routine use)

These criteria should be confirmed by repeat testing on a different day, except in the case of unequivocal hyperglycemia with acute metabolic decompensation.

Patients with latent autoimmune diabetes of adults (LADA) or patients at risk for developing type 1 DM can be tested for islet antibodies (IAs); however, this is not a current recommendation for all type 1 DM patients. This test will help differentiate type 2 DM from LADA. Instead of IAs, a clinical screening tool can be utilized first to assess for signs and symptoms of diabetes, and then the IA test may be performed, because patients with LADA will have positive serum IA. Another test that may be helpful in assessing beta-cell function in a patient with type 1 DM is the C-peptide level. Proinsulin is cleaved into insulin and C-peptide, the latter being biologically inactive. Therefore, C-peptide levels are found in amounts equal to endogenous insulin. However, exogenous insulin preparations do not include C-peptide. Thus, a patient with residual pancreatic beta-cell function will have decreased but nonetheless detectable levels of C-peptide, whereas if no insulin is being produced, the levels of C-peptide will be negligible (normal fasting level = 0.51–2.72 ng/mL or 0.17–0.90 mmol/L).

The International Expert Committee on Diabetes recommends that an A1C of 6.5% or greater can be used to diagnose diabetes with a repeat level for confirmation. The confirmation is not needed if a patient has the clinical symptoms of DM or the glucose level is greater than 200 mg/dL. This cannot be used for diagnosis in pregnancy, hemoglobinopathy, or abnormal erythrocyte turnover situations.

Subsequent Testing A1C determination gives valuable insight into the mean plasma glucose concentration over the preceding 2 to 3 months and is helpful in documenting the degree of glycemic control at the time of diagnosis and as part of continuing care. The ADA recommends that the treatment goal should be A1C below 7.0%. The A1C level roughly correlates to the mean plasma glucose: 6% = glucose of 135 mg/dL; 7% = 170 mg/dL; 8% = 205 mg/dL; 9% = 240 mg/dL; 10% = 275 mg/dL; 11% = 310 mg/dL; and 12% = 345 mg/dL.

Additional laboratory tests that are appropriate to the evaluation of the patient's general medical condition should be performed. They include fasting lipid profile (total cholesterol, high-density lipoprotein [HDL], low-density lipoprotein [LDL], and triglyceride levels), urinalysis, microalbuminuria, thyroid function tests, liver enzymes, and serum creatinine if protein is present. Urine cultures are obtained if indicated. A 12-lead electrocardiogram (ECG) should also be included in the diagnostic for adults at onset of diagnosis. Screening for other autoimmune diseases (vitamin B_{12} deficiency, celiac disease, and hypothyroidism/hyperthyroidism) should be considered as well.

Differential Diagnosis

With the classic symptoms of DM confirmed by blood plasma glucose testing, a diagnosis of DM can be made; however, other potential causes of hyperglycemia should be considered. Hyperglycemia and glucosuria are present in patients with Cushing's disease, pheochromocytoma, or acromegaly. Extreme stress or trauma, such as that seen in extensive burns, may produce transient hyperglycemia. Renal tubular disease may produce glycosuria without concurrent hyperglycemia. Several pharmacological agents can cause hyperglycemia, including glucocorticoids, sympathomimetic agents, and niacin.

Management

Type 1 DM is a chronic illness that requires ongoing health care and education to prevent acute and chronic complications. The complexity and lifelong management regimens necessitate that the patient and clinician work as a team to develop and implement the treatment plan. The ADA recommends a team approach to care, including the primary-care provider, an endocrinologist periodically when indicated, a certified diabetes educator, a dietitian, the patient, and the patient's family. Essential to successful implementation of the treatment plan is the plan's fit with the patient's lifestyle to the extent possible. This is where a diabetes educator is of the most assistance. Children with type 1 DM will also need school personnel involved in the treatment team.

To be effective, the treatment program requires insulin regimens, frequent self-monitoring of blood glucose (SMBG), medical nutrition therapy, regular exercise, continuing education in the prevention and treatment of complications, and periodic assessment of treatment goals. The principles of assessment and management are summarized in Table 16.8.

A diagnosis of diabetes, as with any chronic illness, requires the incorporation of the diagnosis and ultimate

Table 16.8 Outpatient Assessment and Management of the Patient with Diabetes Mellitus Type 1

Assessment	Laboratory Monitoring	General Health Maintenance
Every visit: • Symptoms of hypoglycemia and hyperglycemia • Results of SMBG • Any self-adjustments based on SMBG or symptoms • Problems with adherence • Symptoms of complications • Any other medical illnesses • Medications (prescription and over the counter) • Height and weight • Blood pressure • Cardiovascular assessment • Thyroid exam • Ophthalmic exam (with an annual dilated retinal eye exam) • Peripheral vascular assessment • Feet and skin assessment • Neurological assessment • Oral exam	A1C every 3 months during the first year of initiation of insulin therapy and during periods of insulin dosage adjustment In patients who have met treatment goals, measure twice a year. Initially and annually: • Lipid profile • Urinalysis • Serum creatinine Microalbuminuria screening annually: • Method 1: measurement of albumin-to-creatinine ratio (can be performed in clinic; first morning void is preferred because of the diurnal variation in albumin excretion; >30 mcg/mg creatinine indicates microalbuminuria) • Method 2: 24-hour urine collection	• Pneumococcal vaccine • Influenza vaccine annually • Aspirin prophylaxis in patients older than 40 years of age Patient education: • Preconceptive or contraceptive counseling (initial and quarterly when applicable) • Smoking cessation recommendations if applicable

management into the patient's lifestyle. It may take a traumatic event or "turning point" in a patient's management to break the complacency of management to one that focuses on lifestyle changes.

Initial Management

Insulin Therapy The initial goal of treatment for type 1 DM is to normalize the blood glucose level. This is best accomplished by intensive insulin regimens to accomplish the following goals: plasma glucose levels at 80 to 120 mg/dL before meals, plasma glucose levels of 100 to 140 mg/dL at bedtime, and an A1C below 7%. The new type 1 diabetic patient often presents in crisis and requires hospitalization. These patients should be managed by or in close collaboration with an endocrinologist and a comprehensive health-care team. It is beyond the scope of primary care to manage this patient alone.

When patients present in acute hyperglycemia, it is essential not only to treat the hyperglycemia but also to determine its underlying cause (medication nonadherence, underlying infection [the most common cause of DKA], or dietary indiscretion). See Table 16.6 for the management of DKA.

The Diabetes Control and Complications Trial conclusively demonstrated that in patients with type 1 DM, the risk of development or progression of retinopathy, nephropathy, and neuropathy is reduced 50% to 75% by intensive insulin regimens compared with conventional treatment regimens. Individual treatment goals should, however, take into account the patient's capacity to understand and carry out the treatment, the risk for severe hypoglycemia, and any other factors that increase risk or decrease benefit. Tight glycemic control increases the chance of hypoglycemic episodes and may not be appropriate for many elderly diabetics, patients with coronary artery disease who may be prone to hypoglycemia, or those with diabetic neuropathy who may lack the early neurological (adrenergic) warning signs of hypoglycemia.

Some patients may experience early morning hyperglycemia due to complete absorption of the evening insulin dose before the early morning hours (dawn phenomenon), particularly if an intermediate-acting form of insulin is used, such as neutral protamine Hagedorn (NPH), which has a peak effect at 6 to 10 hours and a duration of action of 10 to 16 hours. In addition, humans have an increased insulin requirement in the morning because of early morning secretion of growth hormone and cortisol. Thus, increasing nighttime insulin may just lead to late evening hypoglycemia, in the absence of an adequate insulin effect in the early morning hours. In turn, if NPH is being used, the evening dose should be given later. Alternatively, it may be more efficient to prevent early morning hyperglycemia by switching the regimen from NPH to a longer-acting form of insulin, such as glargine (Lantus) or detemir (Levemir).

The initiation of insulin therapy in newly diagnosed type 1 DM patients should be managed by or in close

collaboration with an endocrinologist. The majority of insulin used today is made chemically identical to human insulin by recombinant DNA technology or by chemical modification of pork insulin; however, beef and pork insulins are still available. Insulin is available in rapid, short, intermediate, and long-acting forms. The optimum dosage is highly individual and can depend on site and depth of injection, skin temperature, and exercise. Human insulin is preferred for patients newly beginning insulin therapy, pregnant women, and persons with allergies.

In the United States, insulin is available in concentrations of 100 or 500 U/mL, but the higher-concentrated preparations are used only in rare cases of insulin resistance, when the patient requires large doses. The 2013 ADA Standards of Medical Care in Diabetes state that the majority of patients with type 1 DM should be treated with three to four injections of insulin per day (including an injection of long-acting [basal] insulin once daily and an injection of prandial fast-acting [regular or lispro] insulin before each meal) or a continuous subcutaneous insulin infusion pump. Both strategies require diligent and frequent blood glucose monitoring by the patient and should be chosen only if appropriate for the patient. Commercially mixed NPH and regular insulin preparations are available, or the patient can custom mix his or her own insulin. Dose amount and timing should be individualized for the patient according to his or her health needs and lifestyle (see Drugs Commonly Prescribed 16.4: Diabetes Mellitus Type 1).

Self-Monitoring of Blood Glucose Self-monitoring of blood glucose (SMBG) is the testing of capillary blood to determine the blood glucose level. Typically, plasma venous glucose measurements are within 15% of the results of whole blood capillary test results.

Drugs Commonly Prescribed 16.4 Diabetes Mellitus Type 1 Insulin Regimens

Single-Dose Therapy

Single Injection

- Intermediate or long-acting insulin with or without regular insulin in the morning *OR* Intermediate or long-acting insulin at bedtime
- Recommend minimal SMBG in the morning and at bedtime.

Conventional Split-Dose Therapy

Two Injections

- Mixture of NPH and regular insulin in the morning and evening
- Recommend minimal SMBG before each dosing and at bedtime.

Intensive Insulin Therapy

Three Injections

- NPH and regular insulin in the morning; regular insulin at dinner; NPH insulin at bedtime
- Monitor for increased risk of hypoglycemic episodes.

Four Injections

- Regular or lispro insulin before meals and long-acting insulin to maintain basal insulin levels
- Monitor for increased risk of hypoglycemic episodes.

Types of Insulin	Species	Onset, Peak, and Duration	Route
Lispro Insulin			
Humalog	Recombinant DNA technology (usually used in combination with other insulins)	>15 min, 30–60 min, 3–4 hr	SC
Regular Insulin			
Humulin R	Human	30–60 min, 2–6 hr, 6–8 hr	SC, IM, IV
Iletin II Regular	Pork	30–60 min, 2–6 hr, 6–8 hr	SC, IM, IV
Novolin R	Human	30–60 min, 2–6 hr, 6–8 hr	SC, IM, IV
Purified Pork Regular	Pork	30–60 min, 2–6 hr, 6–8 hr	SC, IM, IV
Velosulin	Human	30–60 min, 2–4 hr, 6–8 hr	SC, IM, IV

Drugs Commonly Prescribed 16.4 Diabetes Mellitus Type 1 Insulin Regimens—cont'd

Types of Insulin	Species	Onset, Peak, and Duration	Route
Insulin Isophane Suspension (NPH)			
Humulin N	Human	1–1.5 hr, 4–12 hr, 18–24 hr	SC
Iletin II NPH	Pork	1–1.5 hr, 4–12 hr, 18–24 hr	SC
Novolin N	Human	1–1.5 hr, 4–12 hr, 18–24 hr	SC
Purified Pork NPH	Pork	1–1.5 hr, 4–12 hr, 18–24 hr	SC
Insulin Isophane Suspension (NPH)/Regular Insulin			
Humulin 70/30	Human	30–60 min, 2–12 hr, 24 hr	SC
Humulin 50/50	Human	30–60 min, 3–5 hr, 24 hr	SC
Novolin 70/30	Human	30–60 min, 2–12 hr, 24 hr	SC
Insulin Glargine			
Lantus	Insulin analog	Slowly absorbed with gradual onset, peakless, lasting up to 24 hr	SC
Insulin Detemir			
Levemir	Insulin analog	Slowly absorbed with gradual onset, relative constant concentration with peak at 6–10 hr, lasting up to 24 hr	SC

SMBG: Self-monitoring of blood glucose

SMBG is recommended for patients with type 1 DM to evaluate the effectiveness of the insulin regimen, medical nutrition therapy, and exercise. Used properly, it is the most useful mechanism to maintain glucose levels as close to normal as possible and prevent the single most common complication of diabetes therapy, hypoglycemia.

The frequency and timing of monitoring are dependent on the needs and goals of the individual patient. Optimal monitoring for patients with type 1 DM is three to four times a day—before each meal and before bedtime. Barriers to frequent monitoring in all patients with type 1 DM are cost, inconvenience, and the discomfort produced by the finger pricks. The benefit versus cost ratio must be thoroughly explored with each patient as a treatment plan is developed and goals are established. Table 16.9 presents the goals of glucose management in the patient without symptoms of hypoglycemia.

Continuous Glucose Monitoring Continuous glucose monitoring (CGM) utilizes a device that measures interstitial glucose and can be utilized with intensive insulin therapy. This measurement correlates with SMBG. The device has been studied in adults older than 25 years of age and found to reduce the amount of time type 1 DM patients spent in hyperglycemic and hypoglycemic ranges. The measurement of CGM must be calibrated with SMBG, and SMBG should be utilized to make acute treatment decisions. Patients who have limited awareness of hypoglycemic episodes, or ones who have them frequently, may also benefit from CGM.

Table 16.9 Goals of Glucose Management*

Time	Goal
Before meals	80–120 mg/dL
Bedtime	100–140 mg/dL
Postprandial	<180 mg/dL

*Goals are for glucose management without symptoms of hypoglycemia.

There are many different types of blood glucose meters, and one should be selected that best fits the needs and resources of the patient. Many of the meters have the ability to download records into personal computers, which allows the clinician to view the data. This can provide helpful information on trends of blood glucose control. The patient should, nevertheless, be instructed to keep a log of results along with insulin doses so that adjustments can be made to the treatment plan. There are more than 1,100 smartphone apps available for helping to manage diabetes. The glucose meter, as well as the individual patient's testing technique, should be assessed at each visit for accuracy while the patient's ideal dose is being adjusted and then annually once the patient is stabilized.

Management of Hypoglycemia Hypoglycemia (plasma glucose less than 70 mg/dL) is a common occurrence in patients with type 1 DM. It can occur for a variety of reasons: excessive exogenous insulin, missed meals or inadequate food intake, exercise, alcohol ingestion, drug interactions, and a decrease in liver or kidney function.

Signs and symptoms include diaphoresis, tachycardia, hunger, shakiness, altered mentation (ranging from inability to concentrate to coma), slurred speech, and seizure. The signs and symptoms exhibited by the patient are highly individual and can vary from mild to severe.

The goal of treatment is to normalize the plasma glucose promptly. If the patient is conscious and able to swallow, this is best accomplished by the ingestion of 15 g of carbohydrate. Examples include one-half cup of any fruit juice (no additional sugar added), 6 ounces of regular soda (not diet), 1 cup of milk, or glucose tablets. Candy (no chocolate) can be used but is not recommended because the patient may eat it when it is not needed. Blood glucose should be checked 15 minutes after treatment, and additional carbohydrate should be given if the blood glucose results remain less than 60 mg/dL. For severe hypoglycemia and if the patient is unconscious or unable to swallow, 1 mg of glucagon can be given subcutaneously. Another treatment alternative is 50 mL of 50% dextrose solution given IV.

Nocturnal hypoglycemia can occur if the predinner, intermediate-acting insulin dose is too high or if the patient skips dinner or eats an inadequate amount. The patient may not awaken with symptoms but on arising may note an increased fasting glucose level. This is due to a compensatory mechanism in the liver, which responds in the event of sustained hypoglycemia. After hypoglycemia has been resolved, the possible causes should be reviewed with the patient and preventive measures discussed. The Somogyi effect, for example, is a unique combination of hypoglycemia during the night with rebound hyperglycemia in the morning. Although several studies failed to confirm the validity of this pathological process, many clinicians still feel the Somogyi effect exists and is most common in children with type 1 DM. This possibility should be investigated whenever fluctuations in blood sugar levels are serious.

Once the patient has been educated in insulin therapy, SMBG, and hypoglycemia, subsequent management should include education in meal planning and assistance in developing a regular exercise program. Most patients will benefit from a referral to a certified diabetic educator for a group program or individual counseling. A referral to a dietitian should be ordered for all patients.

Diet Meal planning or medical nutritional therapy is one of the most challenging aspects of diabetes management because achievement of treatment goals may require substantial lifestyle changes. The goals of nutritional therapy are to maintain normal blood glucose level, prevent hypoglycemia, maintain normal serum lipid levels, attain or maintain reasonable body weight, and promote healthy eating patterns. The meal plan should be based on the patient's food choices; exercise; medical history; weight; lifestyle; and cultural, ethnic, and financial factors. The first step of the nutritional consultation should be an initial assessment of the patient's nutritional status, including a diet history. Recommendations for change should not be made until the patient's current eating patterns are determined. Most patients with type 1 DM are lean, so weight loss is generally not a factor in meal planning. The following formulas can be used to determine the total number of kilocalories needed to maintain current weight:

For men: 66 + 13.7 (weight in kg) + 5 (height in cm) – 6.8 (age)

For women: 65 + 9.6 (weight in kg) + 1.7 (height in cm) – 4.7 (age)

Complementary Therapies 16.1

Problem and Therapy	Dosage	Comment
Diabetes Mellitus		
• Cinnamon *(Cinnamomum cassia)*	1–2 tsp daily	In one study, the ingestion of 1–6 g of cinnamon for 20 days reduced blood glucose, LDL cholesterol, triglycerides, and total cholesterol.
• Fenugreek *(Trigonella foenum-graecum)*	0.5 g of seeds in 150 mL of boiling water; steep for 3 hours and strain. Do not exceed 6 g/day.	Contains soluble fiber that decreases blood glucose. Has anti-inflammatory properties.
• Zinc	15 mg daily	May improve effectiveness of insulin.
• Niacin	500 mg 3 times daily	May slow the progression of type 1 diabetes mellitus and may prevent complications of the disease.
• Alpha-lipoic acid	200 mg 2 times daily	Used in Europe for decades for the treatment of diabetic neuropathy. Prevents nerve damage by toxic free radicals and may improve the action of insulin.
• Biofeedback-assisted relaxation for type 2 diabetes mellitus		Patients enrolled in a biofeedback relaxation therapy group were found to have significantly decreased blood glucose levels.

Multiply the result by 1.2 for a fairly active person and up to 1.5 for an ill person. Individuals on insulin should eat at consistent times that are synchronized with their insulin administration.

A nutritionally balanced meal plan is important for the patient with type 1 DM and should take into account the higher prevalence of atherosclerosis. The ADA guidelines recommend that the meal plan consists of the following:

- Protein: 10% to 20% of daily caloric intake from protein
- Fat: 10% to 20% of daily caloric intake from fat (less than 8%–9% saturated fat with no more than 300 mg of cholesterol)
- Carbohydrates: A minimum of 60% to 70% of daily caloric intake from carbohydrates (with 20–35 g of fiber)

Previously, it was a widely held belief that simple sugars should be avoided based on the assumption that sugars (simple carbohydrates) are more rapidly digested and absorbed than starches (complex carbohydrates) and can therefore aggravate hyperglycemia. There is very little scientific evidence to support this. Although various simple and complex carbohydrates do have different glycemic responses, the first priority should be given to the total amount of carbohydrate consumed rather than the source of the carbohydrate. This means that sucrose and sucrose-containing foods must be substituted for other carbohydrates gram for gram. Other nutritive sweeteners (such as fructose, dextrose, and maltose) and sugar alcohols (such as sorbitol, mannitol, and xylitol) do not have any significant advantage over sucrose in improving overall diabetes control, and sugar alcohols in excessive amounts may have a laxative effect. The calories and carbohydrate content of all these sweeteners should be taken into account in the meal plan. Nonnutritive sweeteners such as saccharin, aspartame, acesulfame potassium, sucralose, and the Latin American herb stevia are noncaloric and do not affect the blood glucose level. The majority of patients with type 1 DM can safely use them.

Although soluble fiber can inhibit the absorption of glucose from the small intestine, the amount contained in most foods will not have a significant effect on blood glucose levels. Fiber recommendations for individuals with diabetes, therefore, are the same as for the general population (20–35 g/day).

Vitamin and mineral supplementation is not generally recommended for persons whose dietary intake is adequate. Chromium replacements have no known benefit except for the patient who may be chromium deficient as a result of long-term parenteral nutrition. Magnesium and sodium replacement should be given only if medically warranted.

The same recommendations used for the general population concerning alcohol ingestion are appropriate for the patient with type 1 DM. Moderate consumption does not adversely affect blood glucose control if the patient has overall good control, but calories from alcohol should be included as part of the total calorie intake. Heavily sweetened drinks should be avoided, and alcohol should be taken with and in addition to the meal plan.

Exercise Before beginning an exercise program, the patient should be screened for the presence of macrovascular and microvascular complications that may be aggravated by exercise. These include coronary artery disease (CAD), peripheral arterial disease, retinopathy, nephropathy, and peripheral or autonomic neuropathy. The patient with type 1 DM can perform all levels of exercise as long as glycemic control is good and there is no evidence of the complications that would preclude exercise. The ADA recommends that patients with diagnosed CAD should undergo a supervised evaluation of exercise tolerance before beginning an exercise program.

Because the metabolic adjustments that occur to maintain blood glucose levels during exercise in a nondiabetic individual are absent in patients with type 1 DM, exercise can exacerbate hyperglycemia if the patient has too little insulin. Conversely, if there is too much insulin, hypoglycemia may occur. The patient must, therefore, use the following general guidelines regarding exercise to regulate the glycemic response:

- Check blood glucose before, every 30 to 60 minutes during, and after exercise.
- Avoid exercise if the fasting glucose is more than 250 mg/dL and ketosis is present or if the glucose level is more than 300 mg/dL, regardless of whether ketosis is present.
- Consume additional carbohydrate if the glucose is less than 100 mg/dL and as needed to avoid hypoglycemia.
- Identify when changes in insulin or food are necessary.

Any exercise prescription should be individualized to take into account the patient's interest, lifestyle, physical condition, and motivation. The program should include 150 minutes per week of moderate-intensity aerobic activity. Muscle-strengthening exercises can also be added. With careful instructions, the patient with type 1 DM can enjoy the benefits of an exercise program.

Urine Ketone Testing Urine ketone testing is recommended for patients with type 1 DM and should be performed when the patient is experiencing stress and when SMBG levels are greater than 300 mg/dL. During an acute illness, especially if the patient is nauseated and vomiting, urine ketones should be monitored. Because pregnancy is a stress on the diabetic patient, pregnant women should assess urine for ketones periodically. Ketonuria can reflect dehydration and the need for extra fluid, as well as an increased insulin requirement.

Follow-up and Referral

Continuing care is essential in the management of type 1 DM. Long-term surveillance for potential complications

of DM demands almost as much daily attention of the patient and office time of the provider as do the daily regimens needed to manage this disease effectively.

The frequency of patient visits depends on the degree to which blood glucose levels are controlled, changes in therapy, and the presence and degree of complications or other medical conditions. If the patient is performing SMBG, telephone consultations instead of clinic visits may be possible. Once regulated, the patient should be seen at least quarterly. These visits should include a discussion on results of SMBG; adjustments to therapy made by the patient; symptoms of medical illnesses; problems with adherence to the treatment plan; changes in lifestyle; medications; and frequency, causes, and severity of hyperglycemia or hypoglycemia.

The National Institutes of Health (NIH) has set up a multicenter program called Trialnet that accepts referral of relatives of patients with type 1 DM for screening with islet cell antibody measurements. It offers treatment with various agents that are being investigated as potentially preventing the development of the disease. The Web site is www.diabetestrialnet.org.

Complications

Risks of type 1 DM complications (retinopathy, nephropathy, and neuropathy) are significantly reduced when A1C levels are maintained below 7%. A1C determination should be performed at least twice a year in patients with good control and quarterly in patients whose therapy has changed or who are not meeting glycemic goals. The physical exam should include a comprehensive foot exam and a funduscopic exam.

Referral to a specialist for the following complications may be indicated:

- *Retinopathy:* The ADA reports that after 20 years, almost all patients will have some degree of retinopathy, documenting the need for annual ophthalmic evaluations. Comprehensive dilated eye and visual exams should be performed annually by an ophthalmologist who is knowledgeable and experienced in the management of diabetic retinopathy for all patients age 10 years and older who have had diabetes for 3 to 5 years, all patients diagnosed after age 30 years, and any patient with visual symptoms or abnormalities.
- *Hyperlipidemia:* Adults with type 1 DM should be retested annually for lipid disorders with a complete fasting lipid profile, because there is an increased risk in these individuals for coronary artery disease.
- *Nephropathy:* A routine urinalysis should be performed annually in adults with type 1 DM to monitor for developing nephropathy. Screening for microalbuminuria should begin with puberty and after 5 years' duration of the disease. Persistent microalbuminuria (greater than 30 mg/24 hr) has been shown to be the earliest stage of diabetic nephropathy. Overt nephropathy (albuminuria greater than or equal to 300 mg/24 hr) will develop over a period of 10 to 15 years in approximately 80% of patients who develop microalbuminuria, many of whom will also develop hypertension. Transient elevations of albumin excretion occur during acute febrile illnesses, marked hypertension, short-term hyperglycemia, exercise, urinary tract infections, and in heart failure. Angiotensin-converting enzyme (ACE) inhibitors have been found to postpone progression of microalbuminuria and ultimately nephropathy in patients. They have few adverse effects and are suggested as part of the initial therapy for diabetic patients with nephropathy. Their use is contraindicated in women who are pregnant, and they should be used with caution in women of childbearing age. ACE inhibitors may also exacerbate hyperkalemia in patients with advanced renal insufficiency or hyporeninemic hypoaldosteronism. Older adults with advanced renal disease and patients with renal artery stenosis may experience a decline in renal function with ACE inhibitors. If a patient does not tolerate the use of ACE inhibitors, angiotensin receptor blockers (ARBs) can be used. Some studies suggest that they be used together in all diabetic patients for the benefit in nephropathy, because the medications act by different mechanisms.
- *Hypertension:* In a patient with type 1 DM, hypertension is often a manifestation of nephropathy. Control of hypertension has been demonstrated to reduce the rate of progression of nephropathy and to reduce the complications of cardiovascular disease. ADA guidelines recommend that the goal for blood pressure control in nonpregnant adults is to maintain the systolic blood pressure less than 140 mm Hg and the diastolic less than 80 mm Hg. Studies have shown that the closer patients with DM get to the target blood pressure, the less likely they are to develop cardiac sequelae. The goal for patients with isolated systolic hypertension is the aforementioned target blood pressure, but a more realistic goal may be for a patient with a systolic blood pressure of 180 mm Hg or higher to decrease the systolic blood pressure to less than 140 to 160 mm Hg and for patients with isolated systolic blood pressure of 160 to 170 mm Hg to decrease by 20 to 30 mm Hg. Recommendations are that initial treatment for patients with hypertension should include lifestyle management and, if medication is required, an ACE inhibitor or ARB should be started, unless contraindicated. Patients with signs of congestive heart failure and a normal or higher than normal ejection fraction should be screened for diastolic dysfunction and treated to target accordingly.
- *Macrovascular disease:* Diabetic patients are at risk for developing macrovascular complications including stroke, peripheral vascular disease (PVD), and CAD/cardiovascular disease. Evidence of uncontrolled angina, carotid bruits, and ECG abnormalities may

require advanced intervention. Daily intake of aspirin has been shown to reduce cardiovascular events in patients with diabetes. Patients with disabling claudication or nonhealing ulcers require a vascular consultation for their PVD. All diabetic patients should be screened for these diseases, because symptoms may not be present until late in the course of the disease process.

- *Neuropathy:* Foot ulcers and related problems resulting from the decreased peripheral sensation in diabetic patients with significant neuropathy are a major cause of morbidity and mortality. Half of the patients with hyperglycemia extending over 15 years will develop some degree of neuropathy. Peripheral neuropathy may result in pain, loss of sensation, and muscle weakness. The feet and ankles are affected most often, but many patients also complain of pain in the knees and upper extremities. Severe pain from neuropathy can lead to sleep and mood disturbances. A thorough initial foot exam followed by annual foot exams are indicated in asymptomatic patients. A 10-g Semmes-Weinstein monofilament should be used to assess sensation at least annually. Abnormal findings indicate the need for a thorough vascular, neurological, musculoskeletal, and soft tissue evaluation. Many patients take several medications to control the pain or discomfort of neuropathy. Analgesics, narcotic analgesics, tricyclic antidepressants, antiarrhythmics, and local anesthetics are frequently prescribed. Tricyclic antidepressants are commonly prescribed for painful neuropathies and are often the first-line drug in patients for whom they are not contraindicated. Gabapentin (Neurontin) may be an alternative choice for patients who cannot take tricyclic antidepressants. Patients suffering from chronic pain syndromes may benefit from a referral to a chronic pain clinic. Patients with neuropathy require professional nail and callus care because most ulcers begin at the site of a callus. Supportive athletic shoes are recommended for all patients for walking. Extra-depth shoes and custom-molded shoe inserts are indicated for patients who are at high risk for foot ulcers.
  Patients at high risk include those with neuropathy; structural deformities of the feet, skin, or nails; or a history of previous ulcers. Charcot foot disorders occur in 9% of patients with neuropathy, and its symptoms may be confused with those of cellulitis. It leads to bony destruction, joint subluxation, and bony remodeling of the foot. Patients with abnormal findings on radiological exam should be referred to an orthopedist for initial evaluation.
- *Pregnancy:* Of the 10% of all pregnancies that are complicated by diabetes, 0.2% to 0.5% are women with type 1 DM. There is an increased risk for many complications such as preeclampsia, preterm delivery, intrauterine fetal demise, or cardiac and renal malformations, just to name a few. There should be preconception counseling and then frequent follow-up to stress the importance of extremely tight glucose control.
- *Other:* Autonomic involvement can affect gastrointestinal, cardiovascular, and genitourinary function. Sexual dysfunction, particularly impotence, may occur. The demands of glycemic control on lifestyle often lead to depression. Patients should be evaluated for depression initially and annually.

Patient Education

Insulin administration involves the use of subcutaneous syringes marked in insulin units. Regulations governing the purchase of syringes vary greatly from state to state. Although syringe manufacturers recommend that syringes be used only once, it appears safe and practical for the patient to reuse the syringe if needed, but it should be discarded if the needle integrity is compromised. Syringes should be recapped by the patient using a one-handed technique, and they should be discarded according to state requirements. Patients with visual or dexterity difficulties may benefit from prefilling syringes. Prefilled insulin syringes may be stored in a vertical position in the refrigerator for up to 30 days with the needle pointing upward.

Alternatives to syringes include jet injectors and penlike devices. Jet injectors are useful for patients who have needle phobias, but they are expensive. Penlike devices hold insulin cartridges and are useful if the patient is visually or neurologically impaired, and they help to increase the accuracy of insulin administration. Unlike older insulins, the new varieties do not require refrigeration, which makes them more convenient. Another alternative is the insulin pump, which is a small device (about the size of a pager) that is worn externally. Continuous subcutaneous insulin is delivered via tubing attached to the pump. Use of the insulin pump requires care by skilled professionals, careful selection of patients, frequent blood glucose monitoring, and comprehensive patient education.

Insulin should be injected at room temperature, and bottles not in use should be stored in the refrigerator. It should be injected into the subcutaneous tissue of the upper arm, anterior or lateral aspects of the thigh, the buttocks, or the abdomen. Rotation of the site within one area is recommended rather than rotating to a different site with each injection.

Foot care should be reviewed at each visit. Patients at high risk for foot ulcer development need continued education to follow through with professional foot care and daily foot hygiene. Patients at low risk should be encouraged to continue good hygiene; wear proper footwear; avoid trauma to the feet; stop smoking if they do; and report any blisters, macerated skin, or hemorrhage into a callus immediately and limit weight-bearing on the affected extremity.

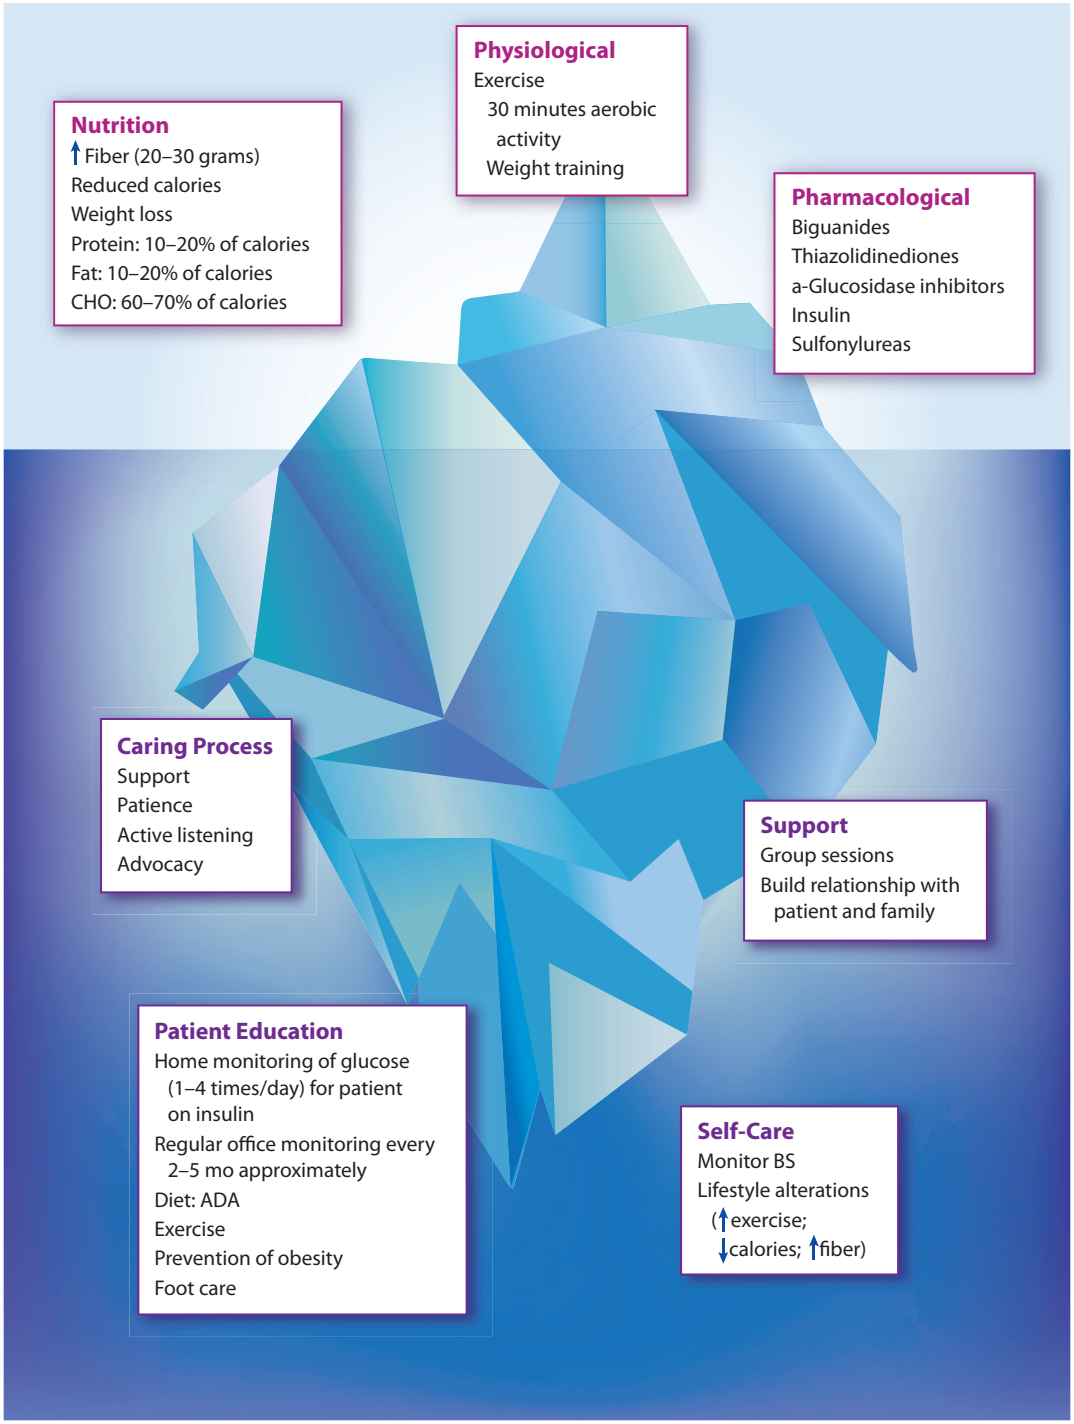
Any illness maximizes stress, and this is especially true for diabetics. When ill, all diabetics must continue to take their insulin and increase blood glucose monitoring to every 2 hours. Supplemental dosages of regular insulin may be needed to control blood glucose levels. If blood

sugar is higher than 240 mg/dL, the urine should be checked for ketones every 4 hours. A caloric intake of 50 g of carbohydrates every 4 hours should be maintained. A variety of clear fluids, including some with glucose, should be encouraged, as well as gelatin, ice pops, regular soda, soups, and toast, if tolerated. Patients should be encouraged to maintain an oral fluid intake of 6 to 9 oz/hr to avoid dehydration.

If vomiting or diarrhea persists over 2 hours, a fever of 101°F (38.33°C) or higher is present, or blood glucose is 240 mg/dL or higher and ketones continue to appear in the urine despite additional insulin, the patient should be instructed to seek medical attention immediately.

Signs of DKA to be alert for include extreme fatigue, abnormal cramping, and alterations in breathing pattern.

The Iceberg of Diabetes Mellitus



DIABETES MELLITUS TYPE 2

Type 2 DM is the fifth leading cause of death in the United States; however, it contributes to many other diseases, particularly heart disease, which is the leading cause of death. Type 2 DM is a group of heterogeneous forms characterized by insufficient circulating endogenous insulin, resistance to insulin action, and an inadequate compensatory insulin secretion response. Approximately 90% of all Americans diagnosed with diabetes have this type of DM. Type 2 DM reduces life expectancy because of complications, which are affected by the duration of diabetes, the degree of blood glucose control, and other cardiovascular risk factors such as smoking and hypertension.

Epidemiology and Causes

The prevalence of type 2 DM in the United States today is 6.6%. About 18 million Americans have type 2 DM, but nearly one-third of individuals are unaware that they have the disease. The disease is often asymptomatic in its early stages; as a result, individuals can remain undiagnosed for many years. The chronic hyperglycemia, however, is associated with long-term damage and dysfunction of various organs, including the kidneys, eyes, nerves, heart, and blood vessels. The comorbidities associated with type 2 DM are thus quite extensive, as reflected in the per capita health-care costs for diabetics in the United States, which are five times higher than those of nondiabetics.

Numerous risk factors are associated with the development of type 2 DM (see Risk Factors 16.1). At risk are those with a first-degree relative with type 2 DM, who demonstrate a 5- to 10-fold higher lifetime risk of developing the disease than age-matched controls with no family history. Moreover, nearly 40% of patients have at least one affected parent with the disease, and monozygotic twin studies further demonstrate between 60% and 90% concordance.

Risk Factors 16.1 Diabetes Mellitus Type 2

Family history (first-degree relative)
Age greater than 45 years
Impaired fasting glucose
Delivery of baby weighing more than 9 pounds
Hypertension
Hyperlipidemia (high-density lipoproteins <40 mg/dL in men and <50 mg/dL in women, triglycerides >250 mg/dL)
Obesity
Ethnicity/racial
- African American
- Hispanic American
- Native American
- Asian American
- Pacific Islander

Racial and ethnic variations also affect the prevalence of type 2 DM. A disproportionate number of African Americans, Hispanic Americans, Native Americans, Asian Americans, and Pacific Islanders have diabetes. The prevalence of type 2 DM in Native Americans and Alaskan natives is approximately two to six times that found in non-Hispanic whites. Pacific Islanders living traditionally have a prevalence of 2.9% whereas those who immigrate to the United States and adopt Western ways have a prevalence rate of 12%. Along with genetic differences, there are a host of factors that may underlie this disparity in disease prevalence, including socioeconomic factors, differential health-care practices, unequal access to health-care resources, and ethnocultural influences in diet and activity and the impact of institutionalized racism. However, the overall prevalence rate of type 2 DM appears to be increasing in the general population, as well as among specific ethnic minority groups.

The incidence of diabetes increases with age, especially in those 45 years of age and older. However, it is important to note that the condition may be diagnosed at any age. Paralleling the marked increase in childhood obesity over the last several decades, rates of newly diagnosed cases of type 2 DM among children are on the rise. Prevalence rates in adolescents and young adults are increasing faster than in any other age-group.

Those previously identified as having an elevated fasting glucose, impaired glucose tolerance, a history of gestational DM, or past delivery of an infant weighing more than 9 pounds are also at greater risk. Gestational DM is defined as any degree of pregnancy-associated glucose intolerance that affects 2% to 4% of all pregnancies in the United States. It is associated with significant fetal morbidity including macrosomia, congenital heart defects, hypoglycemia, hyperbilirubinemia, hypocalcemia, and sepsis. At the other end of the spectrum is polycystic ovary syndrome—a condition characterized by obesity, infertility, and insulin resistance in women, which is also a major risk factor for type 2 DM.

Several pharmacological agents are associated with iatrogenic hyperglycemia and the eventual development of overt DM. These include glucocorticoids, hormonal therapies such as oral contraceptives, the immunosuppressants tacrolimus and cyclosporine, nicotinic acid (niacin), antiviral HIV protease inhibitors (which also cause central fat redistribution known as lipodystrophy syndrome), several atypical antipsychotic agents including clozapine and olanzapine, and certain antihypertensives including beta blockers, calcium channel blockers, clonidine, and thiazide diuretics. In contrast, both angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs) appear to improve insulin sensitivity and reduce the development of type 2 DM in hypertensive nondiabetics.

Increasing evidence points to linkages among CAD, hyperlipidemia, obesity, and DM, as discussed extensively under Pathophysiology. Because early detection

and prompt treatment may reduce the complications of type 2 DM, screening for diabetes as part of routine medical care is appropriate under certain circumstances. Testing for diabetes should be considered in all individuals age 45 years and older and, if normal, should be repeated at 3-year intervals. Testing should be considered in younger individuals who are obese (more than 20% over desired body weight), have a first-degree relative with diabetes, are members of high-risk ethnic populations, have delivered a baby weighing more than 9 pounds, or have an impaired fasting glucose during pregnancy.

Pathophysiology

Type 2 DM is associated with two physiological abnormalities: insulin resistance and impaired insulin secretion. Insulin resistance is associated with acquired traits, such as obesity and aging.

Initially, as insulin resistance increases, insulin levels begin to rise, and the glucose level remains normal, causing a state of hyperinsulinemia. In turn, both fasting and postprandial hyperinsulinemia are predictors of future weight gain, which, in turn, predisposes the individual to hyperglycemia. Thus, this compensatory hyperinsulinemia fails to keep pace if blood glucose begins to rise as in a postprandial state. Moreover, hyperglycemia itself is toxic to pancreatic beta cells, possibly via decreased expression of the insulin gene. As a result, over time, this hyperinsulinemia actually progresses to relative hypoinsulinemia.

Unlike the pattern in type 1 DM, there is no autoimmune destruction of pancreatic beta cells. Rather, there is a decline in their endocrine function, with impaired insulin secretion in response to a glycemic load, which produces elevated plasma glucose levels. This appears to occur at the level of proinsulin, the secreted precursor form of insulin. In nondiabetic individuals, 10% to 15% of secreted insulin may be detected via immunoassays as proinsulin or one of its conversion intermediates. However, in diabetic patients, this value may be as high as 40%. Although the resultant hyperglycemia drives increased insulin secretion even further, obesity and insulin resistance alone do not appear to account for the increased fraction of proinsulin, thus implicating a potential defect in the conversion of proinsulin to insulin or the premature, dysregulated secretion of proinsulin.

Amylin, an islet cell–produced amyloid polypeptide, is also present in beta-cell secretory granules. Serum levels of amylin decrease in concert with those of insulin in type 2 diabetics, whereas pancreatic concentrations of the polypeptide are markedly increased in type 2 diabetics. These observations, along with amylin antagonist studies performed in rat models, have suggested that amylin may be a negative regulator of insulin secretion in type 2 DM; however, this hypothesis has yet to be confirmed in rigorous human studies.

Regardless, in conjunction with hyperinsulinemia, insulin resistance worsens, manifesting first as postprandial hyperglycemia and eventually as fasting hyperglycemia, once hepatic gluconeogenesis increases. The sequence of impaired insulin secretion preceding worsening insulin resistance has been documented in prospective studies. However, several other studies have indicated that these two pathophysiological mechanisms are independent risk factors for the development of type 2 DM and, in fact, occur in concert with one another, rather than in a sequential manner. Indeed, double-knockout mouse models lacking activity in both the glucokinase (involved in insulin secretion) and insulin-receptor substrate–1 (IRS-1) (involved in insulin sensitivity) genes develop DM, whereas single-knockout mouse strains lacking only one of these genes do not. Although insufficient to cause DM alone, insulin resistance appears to be the strongest predictor of type 2 DM development, an observation that is reinforced by the importance of insulin resistance as a component of the insulin-resistant metabolic syndrome (syndrome X).

There is a strong non-Mendelian genetic component to type 2 DM. Only about 5% of type 2 DM cases can be attributed to single-gene mutations that decrease insulin secretion or function, for example, glucokinase (a probable beta-cell glucose sensor), insulin promoter factor–1 (an insulin gene transcription factor), and beta-3-adrenergic receptor (a regulator of lipolysis). However, several other genetic defects have been associated with insulin resistance, including mutations in the genes encoding the protein components of the insulin receptor, which is a tetramer consisting of two extracellular alpha subunits and two transmembrane/intracellular beta subunits with inherent tyrosine kinase activity that initiates intracellular signaling on binding of the insulin molecule. In addition, genes not directly involved in insulin secretion or function, such as the hepatocyte nuclear factors 1-alpha, 1-beta, and 4-alpha, have each been associated with different forms of maturity-onset diabetes of the young—a rare form of type 2 DM that may first manifest in a patient's early 20s.

However, the most common forms of type 2 DM likely involve insulin resistance that is due to postreceptor genetic defects. Candidate genes that may play an important role include those for glycogen synthase (needed for hepatic glucose stores), IRS-2 (a cell-signaling mediator downstream of the insulin receptor), calpain-10 (a cysteine protease particularly important in diabetic Mexican Americans), and peroxisome-proliferator–activated receptor (PPAR) γ-2 (the target molecule of the thiazolidinedione class of antihyperglycemic drugs, which plays an important role in adipocyte differentiation).

Obesity is a major modifiable risk factor for developing type 2 DM, affecting up to 90% of type 2 diabetics. Moreover, patients who are not obese but have an increased percentage of body weight distributed in the abdominal area rather than the hips (also known as central obesity, upper body obesity, or male-type obesity) are also at greater risk. Although this mechanism has not been fully elucidated, obesity is known to contribute to

peripheral insulin resistance, both impairing glucose uptake and decreasing pancreatic beta-cell sensitivity to plasma glucose levels, thereby decreasing reactive insulin secretion. The aforementioned beta-3-adrenergic receptor and the c-Jun amino-terminal kinase (JNK) intracellular signaling pathways have both been implicated. Moreover, adipocyte-derived tumor necrosis factor–alpha (TNF-α) has been positively correlated with increasing insulin resistance, as has the adipocyte hormone resistin. In contrast, the adipocyte hormone adiponectin appears to be negatively correlated with insulin resistance. However, the bulk of the evidence for all these hormones comes primarily from rat and mouse studies, whereas human data are lacking. Whatever the case, physical exercise with a corresponding weight loss of just 10% to 20% of total body weight confers protection against the subsequent development of type 2 DM in overweight individuals, generating marked improvement in glucose tolerance.

Elevated plasma glucose levels may be well tolerated for many years by the diabetic patient, who may not seek treatment until chronic complications result. Eventually, however, insulin secretion will become insufficient to compensate for insulin resistance. Moreover, hyperinsulinemia and hyperglycemia increase lipid synthesis, raising the serum levels of fatty acids, triglycerides (greater than 150 mg/dL), and low-density lipoprotein (LDL) cholesterol, while lowering high-density lipoprotein (HDL) cholesterol. As a result, increased lipids are deposited on vessel walls more readily.

Hyperglycemia thus leads to both microvascular and macrovascular complications, which underlie long-term diabetic damage. Vascular endothelial dysfunction and inflammation result in fibrosis and intimal thickening, leading to progressive narrowing of the vascular lumen. In turn, blood flow through the microvasculature is reduced, leading to tissue ischemia throughout the body, which results in functional impairment of multiple end organs. This explains how DM can simultaneously reign as the leading cause of acquired blindness (due to retinopathy), end-stage renal disease (due to nephropathy), and nontraumatic lower extremity amputation (due to PVD and infection), as well as its major contribution to heart disease and stroke. In turn, several clinical trials have demonstrated that careful glycemic control reduces the development and delays the progression of microvascular manifestations of DM, including nephropathy and retinopathy.

Sympathetic tone and cardiac contractility are increased by hyperinsulinemia due to increases in the plasma catecholamines epinephrine and norepinephrine. With high levels of circulating glucose caused by cellular resistance to insulin, the distal nephron of the kidney absorbs increased amounts of sodium and water, expanding the intravascular volume and increasing the blood pressure. The triad of disturbed glucose metabolism, hypertension (greater than 140/90 mm Hg), and dyslipidemia with obesity is variably referred to as insulin resistance syndrome, syndrome X, obesity dyslipidemia syndrome, or the metabolic syndrome. This condition may exist in prediabetic, glucose-intolerant, or overtly diabetic states. Typically, this syndrome culminates in significant CAD and PVD and is strongly associated with the development of full-blown type 2 DM in prediabetics.

Clinical Presentation

Because the onset of diabetes may occur years before a diagnosis is made, individuals who are asymptomatic tend to be diagnosed during a routine physical exam or during treatment for another condition.

Subjective

Because the onset of type 2 DM is usually insidious, only a minority of patients are initially symptomatic. The patient may, however, present with pruritus or neuropathic complaints such as numbness and tingling. Some patients present with increased urination, nocturia, thirst, or polydipsia. In many cases, type 2 DM first presents as an infection, especially vaginitis (candidiasis) or a skin infection. Cardiovascular symptoms such as angina may prompt the patient to seek health care. The symptoms of type 1 and type 2 DM are basically the same. See the previous section on type 1 DM for a complete discussion.

Objective

There may be no dramatic change in objective findings, although the patient is often obese, with a history of dyslipidemia, hypertension, and CAD. Abnormal healing and an increased occurrence of infection, especially yeast infection, may be present.

Hyperosmolar hyperglycemic syndrome (HHS) is profound dehydration that results from prolonged hyperglycemia (see Table 16.7). Formerly known as hyperosmolar hyperglycemic nonketotic coma, HHS is associated with a high mortality rate and is seen in older adults who have developed an infection or other illness. It is commonly recognized in the older adult with pneumonia. Patients with undiagnosed DM may develop this condition because of prolonged hyperglycemia without treatment. Other risk factors for development include peritoneal dialysis; hemodialysis; tube feedings with high-protein formulas; and the use of mannitol, phenytoin, steroids, immunosuppressive agents, and diuretics. Symptoms are dramatic, including severe hyperglycemia (greater than 600 mg/dL), plasma or serum hyperosmolality (more than 340 mOsm), and profound dehydration. Ketosis may or may not be present, and neurological symptoms range from clouded sensorium to coma. The condition requires immediate referral for acute-care management.

Diagnostic Reasoning

Diagnostic Tests

Initial Testing Immediate testing in the clinical setting can be accomplished by using a portable monitor

to test capillary blood glucose level. This test is referred to as a random capillary glucose measurement and is given without regard to time of last meal. A result of 200 mg/dL or more should be evaluated by screening for blood glucose with whole blood. It is important to consider that certain drugs, including glucocorticoids, furosemide (Lasix), thiazides, phenytoin (Dilantin), estrogen-containing products, beta blockers, and nicotinic acid, can produce hyperglycemia. If the random plasma glucose level is elevated, the urine should be tested for ketones and additional blood glucose testing should be done. There are four ways to diagnose diabetes:

1. A glycosylated hemoglobin (A1C) level greater than or equal to 6.5% on two occasions.
2. Symptoms of DM plus random plasma glucose of 200 mg/dL or higher on two occasions.
3. Fasting plasma glucose of 126 mg/dL or higher on two occasions. *Fasting* is defined as no caloric intake for at least 8 hours.
4. Two-hour postload plasma glucose of 200 mg/dL or higher during an oral glucose tolerance test (OGTT) on two occasions. The test should be performed using a glucose load containing the equivalent of 75 g of anhydrous glucose dissolved in water. This test is not recommended for routine clinical use or in pregnancy.

Subsequent Testing An A1C determination gives valuable insight into the mean glycemia over the preceding 2 to 3 months and is helpful in documenting the degree of glycemic control at the time of diagnosis and as part of continuing care. An A1C value less than 7% indicates good control; however, a value less than 6% has been shown to significantly decrease the occurrence of complications.

Additional laboratory tests that are appropriate to the evaluation of the patient's general medical condition should be performed at the time of diagnosis and at least annually thereafter. These include a fasting lipid profile, serum creatinine, and urine albumin.

Correct classification of patients with diabetes can be difficult. A determination of the C-peptide level may be helpful in determining the extent to which exogenous insulin is being produced. Proinsulin, a precursor of insulin, is produced in the pancreas and is split into insulin and C-peptide. Unlike insulin, C-peptide is not metabolized in the liver; its serum concentration thus reflects insulin secretion. If the basal (fasting) C-peptide level is more than 0.5 nmol/L (greater than 1 ng/dL), the patient most likely has type 2 DM. In type 1 DM, the basal C-peptide level is less than 0.2 nmol/L.

Differential Diagnosis

Differential diagnosis includes type 1 DM, impaired fasting glucose, genetic defects in insulin action, diseases of exocrine pancreas, drug- or chemical-induced DM, immune-mediated infections, and neurological disorders that mimic diabetic neuropathy.

Management

Type 2 DM is a chronic illness that requires ongoing health care and education to prevent acute and chronic complications. To be effective, the treatment program requires frequent self-monitoring of blood glucose (SMBG), medical nutritional therapy with weight reduction when indicated, use of oral glucose-lowering agents and/or insulin, regular exercise, continuing education in the prevention and treatment of complications, and periodic assessment of treatment goals. Careful attention should be given to the control of cardiovascular risk factors, such as hypertension, smoking, and dyslipidemia. The lifestyle behavioral changes needed to improve glycemic control are best accomplished with frequent and concise direction. Diet and exercise therapy must be addressed with specific instructions.

Research confirms the benefits of improved glycemic control in the improvement of work and disability outcomes, quality of life, decreased symptomatology, and health-care cost savings. However, studies have also shown that although tighter intensive glycemic control in type 2 DM reduces microvascular complications, it does not improve quality of life or decrease mortality.

Although the primary-care provider's focus is often on glycemic control, the patient's focus is on the need to fit control into an acceptable lifestyle. Research has identified that dietary modifications, the need for frequent blood glucose monitoring, and subsequent follow-up with health-care providers place a financial and psychological burden on patients and families.

Initial Management

Diet and Weight Loss Meal planning or nutritional therapy is one of the most fundamental and challenging components of diabetes management. The goal of nutritional therapy is to achieve and maintain blood glucose level, lipid, and blood pressure goals. Most patients with type 2 DM are overweight, so weight loss is generally a significant factor in meal planning. Although hypocaloric diets and weight loss usually improve blood glucose control, traditional dietary strategies have not been very effective in achieving long-term weight loss. As research continues to explore why weight loss and maintenance is so difficult, the emphasis should be on controlling glucose and promoting healthy eating patterns. The meal plan should be based on the patient's food choices, exercise, medical history, and weight, as well as lifestyle, cultural, ethnic, and financial factors.

If weight loss is indicated, a moderate caloric restriction (250–500 calories less than average daily intake as calculated from food history) and a nutritionally adequate meal plan with a reduction of total fat (especially saturated and trans fats) is recommended. A hypocaloric diet, independent of weight loss, is associated with increased sensitivity to insulin and improvement in blood glucose levels. Moderate weight loss, irrespective of

starting weight, has significant benefits, especially in decreasing morbidity and mortality rates. In fact, weight loss is a primary intervention because it improves the serum lipid profile, reduces blood pressure, decreases insulin resistance, and ameliorates glucose intolerance.

Individuals on oral glucose-lowering agents and/or insulin should eat at consistent times that are synchronized with their medication administration. A nutritionally balanced meal plan is important for the patient with type 2 DM and should take into account the higher prevalence of atherosclerosis.

Specific diets for patients with diabetes are no longer recommended by the ADA; however, their recommendations for the composition of a healthy diet are 10% to 20% of daily intake from protein, 10% to 20% from fat (less than 7% being saturated fat), and 60% to 70% from carbohydrates.

Self-Monitoring of Blood Glucose The optimal frequency of SMBG in patients with type 2 DM has not been clearly established. The frequency, however, is dependent on the attainment of blood glucose goals. SMBG may be useful for guiding treatment decisions or patient self-management when being treated with oral medications or insulin and in patients who have not consistently achieved blood glucose treatment goals. The patient should, nevertheless, be instructed to keep a log of results for periodic review by his or her primary-care provider.

Urine glucose testing provides only a rough estimate of blood glucose levels and is infrequently recommended; however, in patients who cannot or will not implement SMBG, urine glucose testing is an alternative. Urine glucose testing does not reflect blood glucose levels until the renal threshold of 180 mg/dL of blood glucose is exceeded.

Exercise Exercise is an integral component of management of type 2 DM. Before beginning an exercise program, the patient should be screened for the presence of macrovascular and microvascular complications that may be worsened by exercise. These include coronary artery disease, peripheral arterial disease, retinopathy, nephropathy, and peripheral or autonomic neuropathy. The patient with type 2 DM can perform all levels of exercise as long as glycemic control is adequate and there is no evidence of complications that would preclude exercise. If the patient is taking oral antidiabetic agents or is on insulin, exercise can cause hypoglycemia. Thus, patients initiating an exercise regimen should be aware of the signs of hypoglycemia and be prepared to treat such an event.

Any exercise prescription should be individualized to take into account the patient's interest, lifestyle, physical condition, financial situation, and motivation. The program should include an aerobic activity, such as walking, for at least 150 minutes per week of moderately intense aerobic activity. Muscle-strengthening exercises can also be added. With careful instructions, the patient with type 2 DM can enjoy the benefits of an exercise program.

Subsequent Management

If fasting plasma glucose measurements are less than 200 mg/dL and presenting symptoms are not severe, a course of diet and exercise should be initiated to control hyperglycemia. The patient with type 2 DM will need frequent follow-up during the trial period. Symptomatic patients and patients with marked hyperglycemia (fasting plasma glucose 300 mg/dL or more) will show significant improvement in both with initiation of an oral agent.

Pharmacological Therapy Pharmacological therapy for type 2 DM is required when dietary modification and exercise do not result in blood glucose control. Drug therapy should always be considered an adjunct therapy to diet and exercise and not as a substitute. Oral medication is initiated when 3 months of nutritional therapy and exercise have not achieved and maintained fasting plasma glucose levels less than 120 mg/dL and an A1C of less than 7%. There is some suggestion that an A1C of 9% or more at time of diagnosis should be treated with medication in conjunction with lifestyle changes at the onset of care.

Current therapy for type 2 DM includes drugs that alter insulin action, stimulate insulin secretion, affect the absorption of glucose, mimic the effects of incretin, act as an insulin secretagogue, or suppress postprandial glucagon release, as well as insulin itself.

Metformin (Glucophage) is a biguanide that works by suppressing excessive hepatic glucose production and by increasing glucose utilization in peripheral tissues. Metformin reduces fasting and postprandial hyperglycemia and reduces hepatic gluconeogenesis. It may also improve glucose levels by reducing intestinal glucose absorption. Metformin does not stimulate endogenous insulin secretion but does lower triglyceride and LDL cholesterol levels while increasing HDL cholesterol.

Metformin can be used as a monotherapy or in combination with sulfonylureas or insulin. Metformin is the first-line medication recommended by the ADA and the European Association for the Study of Diabetes. It is also beneficial in persons with type 2 DM who have been taking sulfonylureas and remain hyperglycemic despite treatment, as well as in patients who are obese, because it has a neutral effect on weight. Metformin should be used only in patients with adequate renal function (serum creatine less than 1.4 or creatinine clearance greater than 50 mL/min). Because metformin can cause fatal lactic acidosis, albeit rarely, it should not be used in patients with liver impairment, in alcoholic patients, or in patients who may develop hypoxia due to cardiopulmonary insufficiency. The risk for lactic acidosis increases if contrast dyes for radiological procedures (which decrease kidney function) are used in patients taking metformin. In this case, and in the case of any surgical procedure (which also decreases kidney function), metformin should be discontinued 24 to 48 hours

before diagnostic and surgical procedures. Metformin administration should not be resumed for at least 6 hours after these procedures or until the patient is adequately hydrated. Initial dosing is 500 mg once or twice a day with breakfast and/or dinner (or 850 mg once per day) for 1 week, then twice daily with breakfast and dinner. The dosage should be titrated toward a maximum dose of 2,000 mg, although some studies have shown modest increased effectiveness up to 2,500 mg/day. Several weeks are needed to achieve the maximum effects of the dose. Common adverse reactions are diarrhea, nausea, anorexia, and abdominal discomfort, which usually resolve with a gradual increase of dosage. At the maximum dose, the monthly cost of metformin in the United States is about $4 on many generic formularies. A recent study examined the use of glimepiride (Amaryl) or canagliflozin (Invokana) as an add-on to metformin therapy in type 2 DM patients. The results indicated that canagliflozin reduced A1C and was better tolerated than glimepiride (Level I; Cafalu et al, 2013).

Sulfonylureas work by stimulating pancreatic insulin secretion, which then reduces hepatic glucose output and increases peripheral glucose metabolism. First generation sulfonylureas include acetohexamide (Dymelor), chlorpropamide (Diabinese), tolazamide (Tolinase), and tolbutamide (Orinase). Second generation sulfonylureas include glimepiride (Amaryl), glipizide (Glucotrol), and glyburide (DiaBeta, Glynase, Micronase). The benefits of second generation sulfonylureas are that they are more potent, tend to produce fewer adverse effects, and have fewer interactions with other drugs.

Sulfonylureas are not recommended for use during pregnancy or for women who are planning a pregnancy. Sulfonylureas are metabolized in the liver, and their use should be avoided in persons with significant hepatic dysfunction. Patients with severe insulin resistance may respond better to metformin or thiazolidinedione (Actos, Avandia) therapy than to the use of sulfonylureas (see Drugs Commonly Prescribed 16.5: Diabetes Mellitus Type 2).

Therapy with sulfonylureas should be initiated at the lowest possible dose and usually begins with a once-daily dose before breakfast, although twice-daily dosing is an option. The dose can be increased every 2 weeks until the desired response is achieved, the maximum dose is reached, or the side effects preclude any further increase. Common adverse reactions are mild gastrointestinal upset and skin rashes. Numerous drugs can interfere with sulfonylureas and can alter their effects.

Drugs Commonly Prescribed 16.5 Diabetes Mellitus Type 2

Drug	Indication	Adverse Reactions and Prescribing Considerations
First Generation Sulfonylureas		
• chlorpropamide (Diabinese) • tolazamide (Tolinase) • tolbutamide (Orinase)	For use as adjunct to diet and exercise in type 2 DM Contraindicated in ketoacidosis	*Applicable for all first generation sulfonylureas:* Reduce dose in older adults; potentiated by NSAIDs, alcohol, salicylates, sulfonamides, probenecid, monoamine oxidase inhibitors, tricyclics, beta blockers. Antagonized by diuretics, steroids, phenothiazines. NIH precautions: Monitor urine and blood glucose; discontinue if jaundice or persistent rash occurs. Secondary failure may occur with prolonged usage. Sulfonylureas are contraindicated in pregnancy and lactation.
Second Generation Sulfonylureas		
• glyburide (DiaBeta, Micronase) • glipizide (Glucotrol) • glimepiride (Amaryl)	For use as an adjunct to diet and exercise in type 2 DM	*Applicable for all second generation sulfonylureas:* Same as for first generation sulfonylureas
Biguanides		
metformin (Glucophage)	Monotherapy; may be used as an adjunct to diet in type 2 DM or with a sulfonylurea or insulin	Contraindicated in renal disease; check renal function before starting prescription. Monitor for hypoglycemia, especially in older adults. Adverse reactions: GI disturbances, metallic taste.

Drugs Commonly Prescribed 16.5 Diabetes Mellitus Type 2—cont'd

Drug	Indication	Adverse Reactions and Prescribing Considerations
Thiazolidinediones		
• rosiglitazone (Avandia) • pioglitazone (Actos)	Adjunct to diet and exercise in type 2 DM; used as monotherapy or added to metformin Not for use with type 1 DM or in ketoacidosis	*Applicable for all thiazolidinediones:* Insulin resistance reducer. Do not give to patients with liver disease or if ALT is greater than 2.5 × upper limit of normal. Monitor transaminases—obtain baseline and check every 2 months for first 12 months, then periodically. Discontinue drug if levels increase or jaundice occurs. May cause resumption of ovulation in an anovulatory patient (and thus may result in an unintended pregnancy). Side effects: Swelling of legs, fluid retention, weight gain (upper respiratory tract infections, headaches, muscle aches, toothaches, sore throat in fewer than 1%)
Alpha-Glucosidase Inhibitors		
• acarbose (Precose) • miglitol (Glyset)	Adjunct to diet and exercise in type 2 DM; used as monotherapy or with insulin, metformin, or a sulfonylurea	*Applicable to all drugs in this class:* Adverse reactions: Asthma, dizziness, hepatic injury Do not use if serum creatinine is greater than 2 mg/dL. Use glucose, not fructose, to treat hypoglycemia. Monitor serum transaminases. Adverse reactions: Occasional diarrhea, flatulence, abdominal pain—advise patient to take with first bite of main meal.
Meglitinides		
• repaglinide (Prandin)	Adjunct to diet and exercise in type 2 DM; used as monotherapy or in combination with metformin	This class stimulates the release of insulin from islet cells. Use with caution in older adults and patients with renal or hepatic dysfunction. Interacts with many drugs. Adverse reactions: Hypoglycemia, upper respiratory infection, headache, diarrhea, arthralgia
Phenylalanines		
• nateglinide (Starlix)	Adjunct to diet and exercise in type 2 DM	Resembles sulfonylurea agents. This agent has fewer side effects than biguanides or alpha-glucosidase inhibitors.
Incretin Mimetics		
• exenatide (Byetta) • pramlintide acetate (Symlin) (synthetic hormone) • sitagliptin (Januvia) • saxagliptin (Onglyza) • liraglutide (Victoza)	For use as adjunct to diet and exercise in type 2 DM Can be used with insulin for type 1 and 2 DM	Adverse reactions include severe pancreatitis. Action is to mimic incretin: Slows gastric emptying and mimics glucose-dependent insulin secretion. Suppresses postprandial glucagon release, gastric emptying, and appetite, thereby lowering postprandial glucose. If using with insulin, the insulin dose should be decreased by 50%.

Acarbose (Precose) and miglitol (Glyset) are alpha-glucosidase inhibitors that slow down the breakdown of complex carbohydrates into monosaccharides. This causes a delay in the absorption of glucose and reduces postprandial blood glucose levels. They do not stimulate insulin secretion, and if used as single therapy, they usually do not produce hypoglycemia. However, if used with insulin or sulfonylureas, the potential for hypoglycemia is present. The recommended initial dose of acarbose is 50 mg/day; it should be titrated slowly up to the maintenance dose of 50 to 100 mg 3 times daily with meals. Miglitol also delays absorption of carbohydrates, thereby lowering the postprandial glucose. Therapy is initiated with the lowest effective dose of 25 mg 3 times daily, but the maintenance dose is 50 mg 3 times daily. Both drugs have similar adverse effects—flatulence and diarrhea—which are thought to be caused by the osmotic effect of undigested carbohydrates in the distal bowel. The cost of monthly therapy with these medications is between $79 and $84.

Two thiazolidinediones, pioglitazone (Actos) and rosiglitazone (Avandia), constitute a newer class of antihyperglycemic agents. They work by sensitizing peripheral tissues to insulin and can be used either alone or in combination with sulfonylureas, metformin, or insulin. Neither of these agents should be used in any patient with liver disease or if the alanine aminotransferase (ALT) level is greater than 2.5 times the upper limit of normal. Liver enzymes should be monitored every 2 months for the first year of therapy and then periodically thereafter to monitor for liver failure, which has occurred with drugs of this category. If the ALT level is 1 to 2.5 times the upper limit of normal, the patient should be monitored closely or the drug should be discontinued.

Other categories of drugs for type 2 DM are incretin mimetics (glucagon-like peptide–1 [GLP-1] and glucose-dependent insulinotropic polypeptide [GIP] analogs) and dipeptidyl peptidase–4 (DPP-4) inhibitors. Exenatide (Byetta) is an incretin mimetic and has the same effects as the human incretin hormone GLP-1. It enhances glucose-dependent insulin secretion and slows gastric emptying, possibly leading to decreased food intake. Exenatide is given initially in a dose of 5 mcg two times daily subcutaneously and can be increased to 10 mcg after 1 month. The approximate monthly cost in the United States for an incretin mimetic is $270. Pramlintide acetate (Symlin) is an amylin (hormone secreted by beta cells) analog that suppresses postprandial glucagon release, gastric emptying, and appetite, thereby lowering postprandial glucose levels when given before meals. It can be used in both type 1 and type 2 DM and is used in conjunction with insulin. Pramlintide is given at a dose of 60 mcg subcutaneously initially just before each meal and then titrated up to 120 mcg. It is important to note that the dose of insulin should be reduced by 50% when given with pramlintide. DPP-4 is an enzyme that enhances glucose metabolism. Sitagliptin (Januvia) inhibitors enhance the effects of GLP-1 and GIP, thereby enhancing insulin secretion and suppressing glucagon secretion. DPP-4 inhibitors can be used as monotherapy but are more likely to be used in combination with metformin or thiazolidinediones. When used as monotherapy, the drug does not cause hypoglycemia and is weight neutral. The starting dose is also the maximal daily dose of 100 mg/day. Recently the FDA added a recommendation to monitor for acute pancreatitis for sitagliptin formulations with (Janumet) and without (Januvia) metformin. The approximate monthly cost in the United States for a DPP-4 inhibitor is $194.

The patient who fails to respond to the use of metformin or other agents should be evaluated for the possibility of type 1 DM. Although type 1 DM infrequently presents in older adults, it should be considered in patients with other autoimmune disorders, patients without a family history of type 2 DM, and patients of normal weight.

When nutritional therapy, exercise, and oral antidiabetic agents have failed to control blood glucose levels, the addition of insulin is recommended. The ADA recommends insulin as second-line therapy for type 2 DM or at the time of diagnosis in a newly identified patient with significant symptoms or high blood glucose or A1C levels. Relatively large doses of insulin may be required for type 2 DM patients, given their degree of insulin resistance, in comparison to patients with type 1 DM. Type 2 DM patients often require 1 U/kg or more. The recommendation is to start with bedtime intermediate-acting insulin or with a morning-dosed long-acting insulin and utilize SMBG to determine the amount of insulin dosing increases or decreases (see discussion in section on type 1 DM on insulin therapy). Metformin and thiazolidinediones can be used with insulin therapy, but sulfonylureas should be discontinued. Metformin and thiazolidinediones facilitate lower doses of insulin in maintaining glycemic control. Individual treatment goals should take into account the patient's capacity to understand and carry out the treatment, the risk for severe hypoglycemia, and any other factors that increase risk or decrease benefit.

Because several different types of oral antidiabetic agents can be used as monotherapy or in combination with each other or with insulin therapy treatment decisions can be complex. The following is a synopsis of treatment recommendations (each patient will require individualization dependent on starting A1C and specific lifestyle issues or comorbidities):

- Immediately on diagnosis of type 2 DM begin lifestyle therapy.
- If glycemic goals are not achieved within 3 months (or blood glucose levels and A1C are high), initiate monotherapy with metformin and/or consider basal insulin.
- If glycemic goals are still not met 3 months later, begin combined therapy with oral antidiabetic agents or consider intensive insulin therapy.

Monitoring for Hypoglycemia Hypoglycemia (plasma glucose less than 70 mg/dL) may occur in patients with type 2 DM for a variety of reasons: excessive exogenous insulin, excessive dosing of oral antidiabetic agents, missed meals or inadequate food intake, exercise, alcohol ingestion, drug interactions, and a decrease in liver or kidney function. When using two oral antidiabetic agents, the potential for hypoglycemic episodes is greater, and the patient and family should be aware of this. Signs and symptoms include diaphoresis, tachycardia, hunger, shakiness, altered mentation (ranging from an inability to concentrate to coma), slurred speech, and seizure. The signs and symptoms exhibited by the patient are highly individual and can vary from mild to severe. When the patient becomes ill, blood glucose will need closer monitoring; parenteral insulin may be necessary if oral agents cannot be tolerated.

Follow-up and Referral

On initial diagnosis, the patient should be referred to a dietitian and a certified diabetes educator. Because type 2 DM is a chronic disease, continuing care is essential, and the goal of treatment is to prevent or slow the chronic complications. The frequency of patient visits depends on the degree to which blood glucose levels are controlled, changes in therapy, and the presence and degree of complications or other medical conditions. If the patient is performing SMBG, telephone consultations may be possible instead of clinic visits. Once regulated, the patient should be seen at least quarterly. These visits should include a discussion on the results of SMBG; patient adjustments to therapy; symptoms of illnesses; problems with adherence to the treatment plan; changes in lifestyle; medications; and frequency, causes, and severity of hyperglycemia or hypoglycemia if the patient is on insulin or oral antidiabetic agents.

A1C determination should be performed at least twice a year in patients with good control and quarterly in patients whose therapy has changed or who are not meeting glycemic goals. The physical exam should include a comprehensive foot exam and a funduscopic exam.

Research indicates that patients are more successful in accomplishing lifestyle changes when there is regular contact with the health-care provider. This can be expensive and inconvenient. Community-based telemedicine programs can be helpful. (See Nursing Research–Based Practice Box 16.1.)

Nursing Research–Based Practice 16.1

New, N. Teaching so they hear: Using a co-created diabetes self-management education approach. *J Am Acad Nurse Pract* 22(6):316–325, 2010.

Diabetes self-management programs have been shown to be effective in lifestyle changes, including diet and exercise, with results of better blood sugar control. The purpose of this pilot study was to determine if a co-created diabetes self-management education (DSME) program improved diabetes self-care activities when compared to a typical DSME program. This study used a quasi-experimental design which consisted of 3 phases with a group of adults with type 2 DM. The first phase used a qualitative design to develop and evaluate a co-created DSME intervention. The second phase involved the intervention that was developed as a result of the first phase. This quasi-experimental design included pre- and post-intervention data collection. The data collected was about diabetes knowledge, self-management activities, and adaptation. The control group received the usual DSME education while the experimental group received the new intervention. Phase 3 involved measures of satisfaction with the program for both groups. There were 20 participants in each group. Both groups had improvements in the dependent measures, but only the intervention group showed a statistically significant increase in the Diabetes Self-Care Activities score. The intervention based on patient-perceived problems and needs was a community-based self-management educational program and resulted in improvements in self-care activities.

Complications

Referrals for the following complications are indicated:

- *Retinopathy:* Comprehensive dilated eye and visual exams should be performed annually by an ophthalmologist or optometrist who is knowledgeable and experienced in the management of diabetic retinopathy for all patients who are diagnosed with type 2 DM, because most individuals have had diabetes for several years before they are diagnosed. Type 2 DM is the leading cause of acquired blindness in adults aged 20 to 74 years, and up to 25% of newly diagnosed patients may present with retinopathy at the time of diagnosis.
- *Hyperlipidemia:* Adults with type 2 DM should be retested annually for lipid disorders with a fasting lipid profile including serum cholesterol, triglyceride, HDL, and calculated LDL cholesterol measurements. ADA guidelines suggest that emphasis in clinical management should be directed toward lowering of the LDL, increasing the HDL, and lowering elevated triglyceride levels. Aggressive therapy is indicated because it is suggested that it will lower the risk of CAD. LDL levels should be less than 100 mg/dL in a patient with no overt cardiovascular disease (CVD) and less than 70 mg/dL with overt CVD. In patients with diabetes without a history of coronary vascular disease, behavioral therapy is indicated when the LDL is 100 mg/dL or more. If behavioral and medical nutritional therapy is unsuccessful, the use of statins (HMG CoA-reductase inhibitor)

antihyperlipidemic therapy is indicated. Research indicates that intensive-dose statins increase the risk of diabetes compared with moderate-dose statin therapy (Level I; Preiss et al, 2011).

- *Nephropathy:* A routine serum creatinine and urinalysis should be performed annually for all patients. Screening for elevated serum creatinine and albuminuria in the patient with type 2 DM should begin at the time of diagnosis because it is not known how long the patient has had diabetes. Albuminuria is found in a high proportion of patients when first diagnosed with type 2 DM. The ADA recommends screening at the time of diagnosis of type 2 DM followed by annual screening because 20% to 40% of patients with type 2 DM will progress to overt hyperalbuminuria, and 15% to 20% will progress to renal disease. ACE inhibitors or ARBs are the recommended treatment for increased albuminuria.

Nephropathy has been associated with increased levels of plasma homocysteine. The Diabetic Intervention with Vitamins to Improve Nephropathy (DIVINe) trial was a randomized study examining the use of vitamin B therapy on adults with diabetic nephropathy. Although the therapy did reduce homocysteine levels, there was an increased risk of MI, stroke and all-cause mortality in addition to a detrimental effect on kidney function by reducing the mean glomerular filtration rate (Level II; House et al, 2010).

- *Hypertension:* In a patient with type 2 DM, hypertension is often a part of a syndrome that includes glucose intolerance, insulin resistance, obesity, dyslipidemia, and CAD. It is present in one-third of patients diagnosed with type 2 DM. Isolated systolic hypertension may occur with long duration of diabetes and is due in part to inelasticity of atherosclerotic large vessels. Control of hypertension has been demonstrated to reduce the rate of progression of nephropathy and to reduce the complications of cardiovascular disease. Systolic blood pressure should be less than 140 mm Hg and diastolic below 80 mm Hg. As with patients with type 1 DM, ACE inhibitors should be the initial treatment unless there are contraindications to their use.
- *Macrovascular disease.* Evidence of uncontrolled angina, carotid bruits, and electrocardiogram (ECG) abnormalities may require advanced intervention. An ECG is indicated in patients older than 40 years of age. Daily aspirin is recommended for cardiac prophylaxis in patients with a 10-year risk of CVD greater than 10% at a dose of 81 to 165 mg/day. Given the increased risk of bleeding due to its antiplatelet effects, aspirin is not recommended in low-risk patients with a 10-year CVD risk of less than 5%. Diabetic patients are at risk for developing macrovascular complications including stroke, PVD, and CAD/CVD. Patients with disabling claudication or nonhealing ulcers require a vascular consultation for their PVD. All diabetic patients should be screened for these diseases, because symptoms may not be present until late in the course of the disease process. Type 2 DM is the leading cause of nontraumatic lower extremity amputation due to PVD and peripheral neuropathy. Problems involving the feet may require care by a podiatrist, orthopedic surgeon, vascular surgeon, or rehabilitation specialist. Assessment guidelines are addressed in the section on type 1 DM.
- *Neuropathy:* Peripheral neuropathy may result in pain, loss of sensation, and muscle weakness. Its incidence increases over time in patients with type 2 DM, and it is more prevalent in patients with low serum insulin concentrations and poor glycemic control. Autonomic involvement can affect gastrointestinal, cardiovascular, and genitourinary function. Patients with significant urinary symptoms or impotence should be referred to a urologist. All patients should be screened for neuropathic symptoms at the time of diagnosis and then at least annually.
- *Pregnancy:* To reduce the risk of fetal malformation and maternal and fetal complications, every pregnancy in a woman with type 2 DM should be planned in advance. Pregnancy is contraindicated in women taking oral antidiabetic agents, and, if receiving this treatment, the patient must switch to insulin. The pregnant woman with type 2 DM requires excellent blood glucose control and should be monitored closely by a multidisciplinary team, which includes the obstetrician or certified nurse midwife.
- *Psychosocial:* The complex management of DM places stress on the patient and family. Research has shown that obese women with type 2 DM reported increased stress, anxiety, and guilt. The complex self-management skills required to manage DM and its impact on well-being may affect the quality of life and contribute to depression. Patients should be monitored for problems with treatment adherence and for depression.

Patient Education

Successful diabetes management involves a team effort to achieve mutually agreed on treatment goals. To achieve these goals, it is crucial that the patient and family or significant other be educated in all aspects of the treatment plan. The following list is a synopsis of the salient topics for patient education:

- *Introduction:* Definition of type 2 DM, causes of diabetes, and function of the pancreas and insulin
- *Regulation of blood glucose:* Role of diet, exercise, insulin; signs and symptoms of hyperglycemia; causes, treatment, and prevention of hyperglycemia; signs and symptoms of hypoglycemia; causes, treatment, and prevention of hypoglycemia; when to contact the practitioner

- *Blood glucose monitoring and urine testing:* How to perform SMBG, how often to test, recording and reporting results, and urine ketone testing
- *Medication and insulin administration:* Actions and adverse reactions of oral antidiabetic agents; actions of insulin; types of insulin, effects on blood glucose; storage of supplies; drawing, mixing, and injecting insulin; site selection and rotation; and needle disposal
- *Meal planning:* Types of nutrients (carbohydrates, proteins, fats), timing of meals, portions, use of sweeteners, eating out, use of alcohol, and sick-day management
- *Exercise:* Benefits, types of exercise, effects on blood glucose, planning and measuring exercise, snacks
- *Prevention of long-term complications:* Importance of blood glucose control, vision exams, foot care, prevention of infection, and signs and symptoms of complications

HYPOGLYCEMIA

Hypoglycemia is a clinical syndrome of subnormal plasma glucose concentration that may affect infants through the elderly, although the primary etiology of the disorder differs markedly among various age groups. Hypoglycemia in patients with diabetes mellitus (DM) has been discussed previously in this chapter. In this section, hypoglycemia in patients without diabetes will be explored. Adult hypoglycemia is characterized by blood glucose levels of less than 55 mg/dL of blood, whereas neonatal hypoglycemia is typically defined as a level below 30 mg/dL in the first 24 hours of life. There is no universal agreement about these thresholds, however, with some research supporting a level of less than 50 mg/dL for men, 45 mg/dL for women, and 40 mg/dL for infants and children as indicative of hypoglycemia. Clinical hypoglycemia occurs when the blood glucose level is low enough to cause signs and/or symptoms.

Hypoglycemia with diabetes is the most commonly occurring endocrine emergency; however, it is not common in patients without diabetes. There are three types of hypoglycemia: fasting, reactive, and induced. Fasting hypoglycemia is a low blood sugar level more than 5 hours after eating; it can be subacute or chronic, but blood glucose does not return to normal without glucose ingestion or administration. Reactive or postprandial hypoglycemia is less common and is most often acute in nature. Reactive hypoglycemia usually produces symptoms 2 to 4 hours after a meal rich in carbohydrates, and symptoms rarely occur in a fasting state. Within 5 to 6 hours after a meal, the blood glucose level will return to normal. Induced hypoglycemia is the most common form. Medications and alcohol are the most frequent causes of induced hypoglycemia.

Another option for classifying hypoglycemia in adults is to use the patient's clinical presentation: ill or seemingly well. The Endocrine Society suggests this alternative to assist guiding diagnostics and also in situations where patients typically present with one type of hypoglycemia but may also experience a second classification of hypoglycemia. For instance, patients with insulinomas typically present with fasting hypoglycemia, but they also frequently experience postprandial hypoglycemia, making a classification of their hypoglycemia difficult.

Epidemiology and Causes

Hypoglycemia as a separate disease entity is most common in the elderly and is more prevalent in women overall. About 1% of the nondiabetic population is affected. Although endocrine disorders are the most frequent cause of hypoglycemia, bariatric surgery, insulinomas, non–islet cell neoplasms, liver disease, pregnancy, medications, and alcohol consumption are also causes. Hypoglycemia in neonates is a unique phenomenon, largely related to the immature developmental stage of the neonatal endocrine system, as discussed under Pathophysiology.

Classic hypoglycemia denotes a low plasma glucose level in the setting of insulin-dependent DM. Inconsistent subcutaneous absorption of insulin, decreased food intake, missed meals, and increased insulin secretion during exercise produce hypoglycemia in patients with DM. Moreover, physical and emotional stress may alter the body's reaction to insulin. Sulfonylureas also can produce hypoglycemia in patients with type 2 DM, but it occurs less commonly than with type 1 DM.

The symptoms of fasting hypoglycemia occur when the patient has not eaten for 5 or more hours. The possible causes of fasting hypoglycemia include pancreatic beta-cell tumors, extrapancreatic tumors, hypopituitarism, myxedema, glycogen storage diseases, ethanol-induced hypoglycemia, severe malnutrition, septicemia, pregnancy, and renal failure which results in decreased clearance of insulin from the body. The list of drugs that can cause fasting hypoglycemia is lengthy: insulin and sulfonylureas, fluoroquinolones, propanolol (Inderal), salicylates, quinidine, pentamidine (Pentam 300, NebuPent), coumarin, sulfonamides, tricyclic antidepressants, disopyramide (Norpace), didanosine, ritodrine, chlorpromazine, isoniazid (INH), selective serotonin reuptake inhibitors, clofibrate, thiazide diuretics, lithium, and ACE inhibitors. Poisoning with organophosphate and carbamate-based pesticides also results in hypoglycemia. Illegal sexual-enhancement drugs have also been associated with severe hypoglycemia. In adrenocortical insufficiency, there is a decreased production of cortisol which is required for gluconeogenesis, thus leading to hypoglycemia. Liver diseases, including hepatitis, cirrhosis, hepatomas, and hepatic congestion, interfere with the uptake and release of glycogen from the liver and ultimately may lead to hypoglycemia.

Postprandial hypoglycemia, or reactive hypoglycemia, may be caused by gastrointestinal surgery or any other alimentary tract disorder that affects absorption; congenital deficiency of enzymes necessary for carbohydrate metabolism; and late insulin release caused by B-cell dysfunction. It is an early manifestation of DM and has

been seen with extreme exertion in untrained, physically unfit persons, as well as in patients with sepsis or heart failure. Idiopathic or functional postprandial hypoglycemia also exists that cannot be ascribed to any discrete cause.

Hypoglycemia may be factitious or self-induced by the excessive intake of sulfonylureas or insulin. Timing of these types of hypoglycemic events is not related to food intake. If this type is suspected in patients with known access to these drugs (health-care workers and caregivers of diabetic patients), serum and urine sulfonylurea levels should be obtained. A very low or nonexistent serum C-peptide level confirms that insulin is being injected exogenously.

Lifestyle patterns may contribute to hypoglycemia as well. The excessive consumption of simple sugars, an excessively refined and processed diet, excessive exercise, stress, irregular eating patterns, or missing meals may cause abnormal fluctuations of blood sugar levels. Nutrient deficiencies, food allergies, and poor digestion may also contribute to hypoglycemia. Cigarette smoking and high caffeine intake also produce instability in blood glucose levels. (Table 16.10 lists the causes of hypoglycemia.)

Table 16.10 Causes of Hypoglycemia

Type of Hypoglycemia	Causes
Fasting hypoglycemia	Renal failure (decreases rate at which insulin is secreted contributing to hypoglycemia) Hepatic disease Insulinomas Pancreatic tumors Autoimmune disease Hypopituitarism Extrapancreatic tumors Ethanol intake Septicemia
Reactive hypoglycemia	Postgastrectomy Gastric bypass surgery Hereditary fructose intolerance Congenital enzyme deficiency Pancreatic beta-cell dysfunction Meals high in carbohydrates Exercise Pregnancy
Drug-induced hypoglycemia	Exogenous insulin Sulfonylureas Propranolol Salicylates Quinine Pentamidine Disopyramide

Pathophysiology

To understand the clinical and biochemical phenomenon of hypoglycemia, it is important to grasp the mechanics behind the body's careful regulation of euglycemic plasma glucose levels between 80 and 90 mg/dL. After a carbohydrate-containing meal in which glucose is absorbed from the gut into the bloodstream, plasma glucose levels transiently increase to 120 to 140 mg/dL. Glucose subsequently enters pancreatic beta cells via the GLUT1 and GLUT2 cell membrane transporters, where the enzyme glucokinase phosphorylates it to glucose-6-phosphate, thereby acting as a glucose sensor and triggering the passive entry of calcium into beta cells, causing insulin secretion. Insulin lowers plasma glucose levels by decreasing hepatic glycolysis (glycogen breakdown) and gluconeogenesis (de novo glucose synthesis), driving glucose uptake by skeletal muscle and adipose tissue via the translocation of intracellular glucose transporter molecules to the cell membrane surface, and decreasing both proteolysis and lipolysis, which decreases the number of gluconeogenic precursors. In turn, plasma glucose levelstypically return to normal within several hours after a carbohydrate-containing meal.

Hypoglycemia is sensed by central nervous system receptors in the hypothalamus as well as peripheral receptors that act via afferent nerves to trigger an appropriate hormonal response to maintain glucose homeostasis. The body counters glucose levels below 80 mg/dL by decreasing pancreatic insulin production, eventually secreting several counterregulatory hormones at levels below 70 mg/dL, including glucagon from pancreatic alpha cells, which acts directly on the liver, and epinephrine from the adrenal medulla, which acts similar to glucagon via hepatic beta-adrenergic receptors, as well as mediating the autonomic (sympathetic, adrenergic) symptoms of hypoglycemia (e.g., diaphoresis, anxiety). Epinephrine also directly inhibits insulin secretion via alpha-2-adrenergic receptors. If hypoglycemia is severe (less than 60 mg/dL) or persists for several hours, additional counterregulatory hormones are mobilized, including cortisol from the adrenal cortex and growth hormone from the pituitary gland.

These counterregulatory hormones increase hepatic glucose production via a number of mechanisms, including glycogen breakdown into individual glucose monomers (glycogenolysis) and, once intrahepatic glycogen stores are depleted, de novo glucose synthesis from amino acid, pyruvate, glycerol, and free fatty acid precursors (gluconeogenesis). In turn, the body also metabolically shifts away from glucose utilization toward alternate sources of fuel to maintain euglycemia, for example, proteins and ketone bodies converted from fats. Increased lipolysis is thus reflected in increased plasma free fatty acids, and increased protein breakdown is reflected in higher concentrations of the amino acids alanine and glutamine.

The brain utilizes glucose almost exclusively as its fuel source; however, it is not capable of synthesizing or

storing it. Thus, the brain is particularly sensitive to dramatic changes in blood glucose concentration. Hypoglycemia, in which plasma glucose falls below 60 mg/dL, prevents the brain from receiving an adequate supply of blood glucose, thereby impairing function. Even asymptomatic hypoglycemia has been associated with neurocognitive impairment in infants and children. In adults, cognitive dysfunction can be detected in otherwise normal individuals at plasma glucose levels between 50 and 55 mg/dL; older men are particularly prone to this type of neurological impairment. At levels between 45 and 50 mg/dL, lethargy and obtundation follow, with coma occurring at levels below 30 mg/dL, followed by convulsions below 20 mg/dL and eventual death. Severe hypoglycemia has also been associated with cardiovascular dysfunction.

The histological structure of the pancreas is uniquely designed to prevent these events. Within the pancreas, each islet of Langerhans consists of several hundred cells, including a core of insulin-producing beta cells surrounded by glucagon-secreting alpha cells and an outer layer of somatostatin-producing delta cells and PP cells, which make pancreatic polypeptide. As arterial blood enters the islet core, the beta cells are the first to encounter plasma glucose concentrations. Thus, the function of alpha cells is determined largely by the normal activity of beta cells. For example, insulin directly inhibits glucagon secretion by pancreatic alpha cells.

In adults, reactive hypoglycemia occurs when these counterregulatory responses fail after the person consumes a carbohydrate load, causing blood glucose to fall 2 to 5 hours after eating. Patients with decreased glucagon and epinephrine responses to low blood glucose levels have up to a 25-fold greater risk of experiencing hypoglycemia, particularly during sleep, as sleep itself decreases counterregulatory hormonal responses.

Unfortunately, an initial hypoglycemic episode appears to contribute to a vicious cycle of hypoglycemia, as recurrent hypoglycemia has been associated with autonomic failure and a delay in the early warning signs associated with a subsequent hypoglycemic episode. This may relate to an increased production of cortisol, which decreases glucagon and epinephrine responses, as well as upregulation of glucose transport in the brain, which renders the central nervous system less sensitive to producing neuroglycopenic symptoms.

Hypoglycemia in infants has an extensive differential diagnosis of potential etiologies, because a number of congenital genetic defects exist that may initially present with neonatal hypoglycemia. These include disorders of glucose utilization related to hyperinsulinemic states (e.g., persistent hyperinsulinemic hypoglycemia of infancy, macrosomia associated with maternal diabetes, insulinoma), disorders of glucose metabolism (e.g., Krebs cycle or oxidative respiratory chain defects), genetic defects in the metabolism of alternate fuel sources (e.g., carnitine acyl transferase deficiency, long and medium chain acyl–coenzyme A dehydrogenase deficiency), and hypermetabolic states such as sepsis, severe burns, hyperthermia, polycythemia, or congenital hyperthyroidism. Persistent hyperinsulinemic hypoglycemia of infancy is the most common etiology of hyperinsulinemia during the first 3 months of life. This primary disorder of the pancreas is more commonly observed in infants who are small for gestational age and those born to mothers with toxemia (maternal sepsis).

Infants may also suffer from inadequate glucose stores (e.g., prematurity, malnutrition, intrauterine growth restriction), congenital hormonal deficiencies (e.g., growth hormone, cortisol, panhypopituitarism), or disordered gluconeogenesis (e.g., glucose-6-phosphatase deficiency, glycogen synthase deficiency, galactosemia, maple syrup urine disease, or any one of several glycogen storage diseases). Perinatal asphyxia potentiates hypoglycemia, worsening the resulting neurological impairment that is associated with sustained or recurrent hypoglycemia.

Clinical Presentation

The clinical presentation of hypoglycemia, especially subjective symptoms, varies depending on the physical status of the person. Older adults with neuropathy may lack awareness of its symptoms unless they are severe. In an accidental exposure to hypoglycemic agents, the symptoms are often not recognized or associated with this disease. Whipple's triad includes signs/symptoms, a low plasma glucose level, and resolution of the signs/symptoms after plasma glucose is back into the normal range.

Subjective

Symptoms of hypoglycemia may be present when the blood glucose level falls below 60 mg/dL. Brain function is often impaired when levels fall below 50 mg/dL. Some patients may exhibit symptoms with abnormal fluctuations of glucose and insulin. Symptoms vary from very mild to severe and are classified into adrenergic and neuroglycopenic.

Adrenergic symptoms include sweating, tremulousness, dizziness, confusion, anxiety, and palpitations. Neuroglycopenic symptoms include headaches, seizures, fatigue, weakness, drowsiness, syncope, diplopia and blurred vision, and personality changes. The neurological manifestations of hemiparesis, convulsions, confusion, and coma are more common in patients with DM. Symptoms are often relieved with ingestion of carbohydrates. Seizures and coma are severe complications.

The history should focus on eating habits, meal times, exercise habits, alcohol intake, and any history of liver or renal disease, as well as on family history of endocrine disorders, including DM and hypoglycemia.

Objective

Objective findings that accompany hypoglycemia may include tachycardia with or without premature ventricular contractions, diaphoresis, hypothermia or hyperthermia,

coma, seizures, trembling, Babinski's sign, aphasia, and hemiparesis.

A physical exam with special attention to objective signs of endocrine disease is indicated initially. Assessment for an enlarged liver and neurological indications of chronic alcohol abuse should also be performed. In patients unable to provide an adequate history, the skin should be examined for needle marks, which may reflect possible insulin injections.

Infants prone to hypoglycemia have a unique physical presentation. Hyperinsulinemic babies (e.g., those born to diabetic mothers or babies with insulin-producing tumors) have large body size because of the growth effects of insulin. In contrast, those with decreased body fat are more likely to suffer from insufficient glucose stores. Poor linear growth reflects growth hormone deficiency, whereas midline craniofacial defects may indicate more global pituitary hormone defects. Hepatomegaly is a common sign of glycogen storage diseases. In more general terms, neonatal hypoglycemia may present with jitteriness, hypotonia, lethargy, poor feeding, cyanosis, apnea, or hypothermia.

Diagnostic Reasoning

Diagnostic Tests

Plasma blood glucose levels are used to diagnose hypoglycemia. Hypoglycemia is suspected if the plasma blood glucose level is between 45 and 60 mg/dL or if an overnight fasting glucose level is less than 60 mg/dL. Hypoglycemia is present if the plasma blood glucose level is 45 mg/dL or less. Evaluation of the etiology, when not attributed to treatment of DM, requires subsequent laboratory evaluations.

Initial Testing Initial testing includes a blood glucose level. The best time to obtain a blood glucose level is when the patient is experiencing symptoms. If hypoglycemia and symptoms occur concurrently and if both are relieved with eating, the diagnosis of postprandial hypoglycemia is confirmed. However, finger-stick monitors are not very accurate at extremes of high and low glucose concentrations. They are a helpful tool in detecting high and low blood glucose, but the number itself may not be accurate. An oral glucose tolerance test may be done; however, overinterpretation of the glucose tolerance test may lead to an overdiagnosis of hypoglycemia. More than one-third of normal patients have hypoglycemia with or without symptoms during a 4-hour fasting test. For definitive diagnosis, the patient should have (1) documented occurrences of blood glucose levels, (2) symptoms that occur when the blood glucose level is low, (3) evidence that symptoms are relieved by sugar or other foods, and (4) identification of the particular type of hypoglycemia. It is important to remember that whole blood glucose levels are 10% to 15% lower than serum glucose levels, because red blood cells consume glucose. The most reliable method of diagnosing hypoglycemia is with a plasma glucose 72-hour fast. During this test, the patient is allowed calorie-free, caffeine-free fluids; and the patient fasts at least overnight, but it may be as long as 72 hours. Before and after the fast, a baseline serum glucose, insulin, proinsulin, and C-peptide measurement is obtained. Urine is tested for ketones throughout the test, and capillary glucose measurements are taken every 6 hours. The test is terminated when symptoms of hypoglycemia appear, and a blood glucose level is measured immediately. A positive test result for men is considered to be a blood glucose level less than 55 mg/dL and in women, less than 45 mg/dL. If after 72 hours of fasting and light exercise, hypoglycemia (less than 60 mg/dL) is not demonstrated, the test is negative. This test is performed in a hospital under close observation. Chronic hypoglycemia may be evident by a low glycohemoglobin level.

Subsequent Testing The following laboratory tests assist in the diagnostic reasoning during a hypoglycemic episode: plasma insulin level, insulin antibodies, plasma and urine sulfonylurea levels, and C-peptide. Other tests include a blood urea nitrogen, creatinine, alcohol levels, and liver function tests. To rule out endocrine pathology, if suspected as a possible cause, obtain cortisol and ACTH levels. The first void in the morning can be tested to detect ketones; a lack of them would imply a defect in the fatty acid oxidation pathway, because ketone bodies are not formed. In infants, urine may also be sent for organic acid analysis.

Fasting insulin levels range from 8.0 to 16.0 mcU/mL or 3.0 to 0.6 ng/mL. An abnormally elevated insulin level is seen in patients with insulinomas, exogenous insulin administration, insulin resistance syndrome, and reactive hypoglycemia in developing DM. An elevated insulin level in the absence of blood glucose variation is suggestive of insulinomas, exogenous insulin administration, insulin resistance syndrome, and reactive hypoglycemia in developing DM. Elevated insulin levels in response to glucose fluctuations suggests functional or reactive hypoglycemia.

C-peptide analysis is done with radioimmunoassay techniques and provides an index of beta cell function. Normal values range from 0.9 to 4.2 ng/mL. A low C-peptide level with an elevated insulin level confirms insulin administration. C-peptide levels are elevated in insulinomas. To differentiate insulinoma from factitious hypoglycemia, the ratio of insulin to C-peptide is determined. If the insulin:C-peptide ratio is less than 1.0, the hypoglycemia is a result of endogenous insulin secretion; if greater than 1.0, then exogenous insulin administration is confirmed.

Differential Diagnosis

Differential diagnoses include generalized anxiety disorder, panic attacks, hyperventilation, pheochromocytoma, drug or alcohol intoxication, transient ischemic attack, cerebrovascular accident, and psychosis. Causes of reactive

hypoglycemia include meals high in refined carbohydrates; certain nutrients such as fructose and galactose cause a burst of insulin secretion. Drugs (e.g., sulfonylureas, salicylates) can cause excess glucose utilization or deficient glucose production. Oral diabetic medications are especially prone to causing reactive hypoglycemia when used in combination therapy. Insulinoma (adenoma of islets of Langerhans), although rare, should be considered in an otherwise healthy adult who is found to have fasting hypoglycemia.

Management

The goal in management of hypoglycemia is to normalize the blood glucose levels and treat the underlying cause. The patient with pathology is referred to an endocrinologist for further evaluation and treatment. In cases of functional and idiopathic hypoglycemia, the initial management plan may be developed in consultation with an endocrinologist.

Initial Management

Treatment of acute hypoglycemia for alert patients is 6 to 12 ounces of orange juice or another fruit juice without additional sugar. One cup (8 oz) of milk can be substituted if juice is not available. Glucose tablets, if available, can be used. In acute care settings, glucose is provided emergently as standardized IV bolus preparations of dextrose diluted to various concentrations in water (e.g., D25% or D50%), as opposed to the standardized hypotonic saline solutions with lower amounts of dextrose that are used primarily for maintenance glucose requirements (e.g., D5% 0.45% NaCl). The blood glucose level should be monitored closely after bolus IV administration of dextrose and then periodically while the patient is on a dextrose-containing continuous IV drip. Glucagon hydrochloride (0.03–0.1 mg/kg per dose; 1–2 mg in adults; 1 mg in children older than 5 years or weighing more than 20 kg; 0.5 mg in children younger than 5 years or weighing less than 20 kg) may be given IM, SC, or IV if the patient is unresponsive. Doses may be repeated as needed every few hours in adults and even more frequently in children (up to every 20–30 minutes initially).

Hypoglycemia is a medical emergency because of the seriousness of the potential sequelae (e.g., seizures, coma, cardiovascular dysfunction, death). Even if euglycemia is readily restored, patients must be evaluated for potential hospital admission for inpatient care and close observation if there is any concern for symptom recurrence. Patients requiring admission include those with hypoglycemia without an obvious cause or severe or persistent neurological deficits.

Subsequent Management

Long-term management of hypoglycemia includes treatment of underlying causes and dietary modifications. If hypoglycemia is a result of pancreatic or extrapancreatic tumors, surgical excision is recommended. Although the treatment of choice for insulinoma is surgical resection, there is only an 85% success rate with an experienced surgeon. If the tumor is small, it may not be found on an exploratory laparotomy. When surgery is unsuccessful, an endocrinologist may initiate diazoxide (Hyperstat, Proglycem; 3–8 mg/kg per day PO in divided doses 3 times daily or 200 mg every 4 hours in adults) therapy to reduce insulin secretion. If hypoglycemia is caused by rapid gastric emptying following a gastrectomy, an anticholinergic drug may delay gastric emptying, decrease intestinal motility, and provide relief.

In patients with pseudohypoglycemia or idiopathic hypoglycemia, in which the cause cannot be identified, the treatment is primarily with dietary modifications. A high-protein, low-carbohydrate diet divided into six small daily feedings often relieves the symptoms. Caffeine, refined sugars, and alcohol should be restricted. If food allergies are suspected, allergy testing may be indicated to identify offending foods. If a medication is at fault, an alternative drug should be considered.

In a hyperinsulinemic infant, therapy may be only supportive with glucose infusions if the increased insulin levels are due primarily to maternal diabetes and are transient. However, if increased insulin levels are intrinsic to the infant, diazoxide is typically the first step in pharmacological treatment (15–20 mg/kg per day PO in divided doses 3 times daily). Octreotide (Sandostatin; 2–10 mcg/kg per day SC in divided doses every 4–6 hours), a long-acting analog of somatostatin, may be used as second-line therapy for short-term management of hypoglycemia. The dihydropyridine calcium channel blocker nifedipine (Adalat, Procardia; 10 mg PO 3 times daily initially and titrated up to 80 mg/day) has also been shown to be useful in hyperinsulinemic children, because it interferes with the calcium-dependent secretion of insulin (other calcium channel blockers have not been approved for this indication). There is no role for cortisol in acute treatment.

SMBG is the cornerstone of self-management. Patients may need to monitor blood glucose levels frequently during initiation of lifestyle changes to evaluate success. Monitoring glucose levels during exercise, eating at regularly scheduled intervals, and understanding the importance of SMBG may prevent severe hypoglycemic reactions. All patients with hypoglycemia will benefit from home blood glucose monitoring.

Infants younger than 3 months who have refractory hypoglycemia that cannot be treated pharmacologically may require pancreatic resection. Usually, a near-total resection of 85% to 90% of the pancreas is recommended, but development of diabetes is a subsequent risk. In infants between 3 and 6 months of age, frequent feedings may first be attempted for up to 1 month to see if this addresses a temporary phenomenon.

In patients with inoperable pancreatic tumors or patients in whom resection has been unsuccessful, small

frequent feedings that are high in carbohydrates (every 2–3 hours) may be effective in preventing acute hypoglycemic episodes. In patients with renal failure, small frequent high-carbohydrate meals may prevent episodes.

Follow-up and Referral

Patients with a history of hypoglycemic events need frequent follow-up and evaluation. On each visit, the record of hypoglycemic events should be reviewed. More frequent SMBG may be indicated, especially 12 to 24 hours after a hypoglycemic event. Patients who continue to experience hypoglycemic episodes despite intervention should be referred to an endocrinologist.

Patient Education

The importance of dietary modifications must be stressed. Nondiabetic patients with reactive, functional, and fasting hypoglycemia should eat five or six small meals daily to steady the release of glucose into the blood. The meals should be balanced with carbohydrates, protein, and some fat. Instruct the patient who experiences symptoms after a meal high in refined sugar, but not after a regular meal, to restrict refined sugars in the diet. Patients who cannot eat small meals throughout the day should be encouraged to carry raw seeds and nuts mixed with dried fruits.

Patients with diabetes should be instructed to maintain their glycemic goals, report any episodes of hypoglycemia, and monitor their blood glucose at bedtime and before, during, and after exercise. Alcohol, cigarette smoking, and caffeine should be avoided.

COMMON METABOLIC PROBLEMS

METABOLIC SYNDROME

Metabolic syndrome is a constellation of risk factors. There is a body of evidence recognizing a metabolic origin for patients with cardiovascular risk *and* prediabetes. The metabolic origin of this syndrome is not well understood, although the involvement of insulin resistance may be the linking factor. However, the importance of these two disease processes and the increased risk for some patients cannot be overlooked. The American Diabetes Association (ADA) has published a statement with five other groups, and the Endocrine Society has a practice guideline stressing the importance of recognizing these at risk patients.

The cluster of factors for metabolic syndrome include hypertension, hyperlipidemia, and insulin resistance. Patients with these characteristics are at twice the risk for cardiovascular disease (CVD) over 5 years, compared with those without these comorbidities, and have a fivefold increase in risk of type 2 DM. Patients with this presentation should have intense lifestyle modification education as well as treatment to reduce the lifetime CVD risk, including decreasing blood pressure and hyperlipidemia and reducing the prothrombotic state. There is also evidence that patients may delay the onset of diabetes with aggressive lifestyle changes and possibly using metformin or a thiazolidinedione agent. Both medications have been shown to delay the conversion of prediabetes to diabetes.

Patients with the constellation of factors for metabolic syndrome are at increased risk of lifetime CVD and diabetes. Primary-care providers are obligated to assist these patients with the modification to prevent these lifelong risks by recognizing the factors and starting lifestyle treatment early. For more information about metabolic syndrome, see Chapter 10.

OBESITY

Obesity is an excess of adipose tissue (body fat) and is manifested by body mass index (BMI) of 30 kg/m^2 or higher for adults and a BMI at or above the 95th percentile for children and adolescents. Published clinical guidelines on the identification, evaluation, and treatment of overweight and obesity cite that the complex etiology of overeating makes this chronic illness poorly understood and often intractable to medical management. The two major types of obesity are upper body (apple-shape) and lower body (pear-shape) obesity. Patients with central or upper body obesity have excessive body fat in the abdomen and flank areas and are at a greater risk for type 2 DM, coronary artery disease, stroke, and early death than those with lower body obesity. Patients with lower body obesity have excessive adipose tissue in the buttocks and thighs.

The direct and indirect costs of obesity are more than $152 billion per year in the United States, including the direct medical costs and the cost attributable to lost wages. Americans spend more than $40 billion a year on diets and dietary products. The psychological cost of obesity in those affected includes stigmatization and discrimination.

Epidemiology and Causes

Overweight and obesity are epidemic in the United States today. Thirty-five percent of men and 36% of women are obese. Another 30% of Americans are overweight with a BMI between 25 and 29 kg/m^2. African American women are more likely to be obese than are white women. The incidence of obesity is higher in those of lower socioeconomic status regardless of race. Central and upper body obesity is more common in men, whereas lower body obesity is more common in women.

Worldwide, obesity is more prevalent in industrialized countries, and the prevalence is increasing worldwide, including in developing countries. The World Health Organization (WHO) classifies obesity as one of the world's most neglected public health problems.

The causes of obesity are categorized as essential and secondary. Essential obesity is the most prevalent type and is a result of the intake of more calories than are expended. This type of obesity results from the multiple interactions of genetic and environmental factors (cultural, metabolic, social, and psychological factors). Numerous genes have been identified that affect control of appetite, and mutations in these genes, along with environmental factors and behavior, result in obesity.

Secondary obesity is rare; possible causes include Cushing's disease, polycystic ovary syndrome (PCOS), hypothalamic disease, hypothyroidism, and insulinoma. Some medications associated with weight gain include glucocorticoids, tricyclic antidepressants, and phenothiazines.

Risk factors for development of obesity include diet, lifestyle, environment, and the interaction among the aforementioned causes. A diet high in fat contributes to obesity because dietary fat has more than twice the calories of carbohydrates or proteins. A sedentary lifestyle or a sudden decrease in physical activity without a reduction in caloric intake may cause obesity. An environment that supports sedentary lifestyles and facilitates access to fatty foods, processed foods, and refined sugars contributes to the incidence of obesity today.

Obesity affects almost every body system and is associated with an increased risk of multiple diseases. The consequences of obesity are listed in Table 16.11. The different types of obesity are related more closely to specific complications. Central trunk obesity is closely related to diabetes mellitus (DM), coronary heart disease, stroke, and early death. The health risks associated with obesity are directly correlated with the severity of obesity and include metabolic, structural, and psychosocial changes. Mortality risk increases as complications of obesity develop and approaches 50% when weight is 30% to 40% above the ideal. Reduction in body weight by 5% to 20% significantly decreases these comorbid risk factors in obese individuals.

Table 16.11 Consequences of Obesity

- Coronary heart disease/congestive heart failure
- Hypertension
- Dyslipidemia/hyperlipidemia
- Type 2 diabetes mellitus/metabolic syndrome/insulin resistance
- Sleep apnea
- Restrictive lung disease
- Asthma
- Varicose veins and venous insufficiency
- Gout and hyperuricemia
- Osteoarthritis
- Reflux esophagitis
- Gallbladder disease
- Thromboembolic disease
- Cancers: Endometrial, breast, prostate, colon

Obesity is also associated with an increased risk of colon, rectal, and prostate cancer in males. In obese females, uterine, gallbladder, biliary tract, breast, and ovarian cancer are more prevalent. Persons who are obese have an increased surgical and obstetrical risk. Psychosocial disability is also related to obesity. This is often a result of the societal stigma attached to obesity. Pickwickian syndrome is associated with severe or morbid obesity. This syndrome includes hypersomnolence, congestive heart failure, and hypertension.

Pathophysiology

Obesity results when one's intake of calories exceeds metabolic needs. The control of appetite and the mechanisms that govern food intake are complex and incompletely understood. The hypothalamus controls certain aspects of appetite and appears to have a role in an individual's food preferences. Other important central nervous system sites include the tractus solitarius of the hindbrain, the arcuate and paraventricular nuclei, and the amygdala. Mediated by several neurotransmitters including norepinephrine, dynorphin, hypocretin, serotonin, neuropeptide Y, and ghrelin, to name just a few, both the central and peripheral nervous systems produce and integrate a complex array of neural inputs that regulate diet and weight. In contrast, other hormones such as cholecystokinin, enterostatin, leptin, and the gut hormone peptide YY 3-36 have all been shown to suppress food intake through appetite suppression and inducing feelings of satiety. Whether obesity can be significantly attributed to dysregulation in one or more of these neuroendocrine regulatory mechanisms remains to be seen.

There is, however, a well-documented genetic predisposition to the development of obesity. Twin studies have revealed high correlations in obesity prevalence between siblings raised apart in separate households as well as together by the same set of parents, whereas the BMIs of adoptees correlate more closely with those of their biological rather than adopted parents. Secondary causes of obesity due to medical conditions are rare, however, and include various endocrine and neurological diseases.

In many individuals, obesity, overweight, and overeating appear intrinsically tied to a fragile emotional state, poor self-esteem, and dissatisfaction with life circumstances. The stressors and psychological demands that underlie a patient's poor dietary choices may be powerful influences that are capable of defying the counterbalancing knowledge that overeating and obesity lead to ill health. Thus, an addictive behavioral component to overeating appears to be a driving factor in many obese individuals. The complex psychology of obesity has been the subject of extensive study, and the most effective obesity treatment programs typically involve some sort of psychiatric analysis or counseling as primary or adjunctive therapy.

Whereas most individuals tend to underestimate their food intake by 10% to 20%, obese individuals

underestimate caloric intake even further, by 30%. However, behavioral choices alone do not explain the entire pathophysiology of obesity.

The body is known to have neuroendocrine homeostatic feedback control mechanisms involving both the peripheral and central nervous systems, which seek to maintain nutrient intake and ideal weight. Examples include glycemic levels (hypoglycemia is a trigger to eat), serum leptin concentrations, glucocorticoids that act as appetite stimulants, sympathomimetic hormones that act as appetite suppressants, and the peptide ghrelin—a ligand for the growth hormone secretagogue receptor that increases appetite (ghrelin levels increase in anticipation of a meal and in response to diet-induced weight loss). Differences in fat-free body mass also correlate strongly with differences in energy expenditure among different individuals. In particular, weight gain is associated with increased metabolic demands and energy expenditure that retard further weight gain, whereas weight loss is associated with reductions in energy expenditure that counter further weight loss. Thus, a formerly obese individual who loses weight will experience a relative decrease in energy expenditure compared with a nonobese individual and will thus require 15% fewer calories to maintain his or her reduced weight. In turn, failing to reduce one's caloric intake appropriately may result in progressive weight gain.

On a molecular level, the bulk of our understanding of the pathophysiology and genetics of obesity stems from preclinical animal models—particularly that of the obese mouse, for which a number of genetically altered strains are available. Through genetically engineered knockout mice that lack one or more target genes, as well as transgenic models that overexpress either a functional or nonfunctional version of a target gene, researchers have identified several single gene defects that result in murine obesity. Some of these genetic findings have been further generalized to humans.

Expressed by adipose, intestinal, and placental cells, the leptin gene has been the subject of much controversy in human obesity. Serum leptin concentrations strongly correlate with body fat content, and leptin-deficient mice demonstrate insulin resistance, hyperinsulinemia, and hyperphagia. Leptin has been shown to reduce levels of neuropeptide Y, a potent stimulus for food intake produced in the brain's arcuate nucleus. Human obesity due to leptin deficiency has been identified in two consanguineous families, as has obesity due to leptin receptor deficiency. However, leptin overexpression has not been shown to reduce appetite or weight, and most obese patients express normal levels of this protein. Thus, decreased leptin levels appear to signal that fat stores are insufficient for growth and reproduction; however, the hormone itself is not a negative regulator of appetite or weight gain. Obese individuals appear to have decreased sensitivity to leptin.

Other single-gene defects associated with murine obesity include mutations in carboxypeptidase E, the enzyme responsible for the cleavage of proinsulin, and the *tub* gene, which is associated with neurological deficits, hypothalamic damage, and increased appetite. The *agouti* gene, which encodes an antagonist protein for the hypothalamic melanocortin-4 receptor, has also been associated with murine obesity and hyperphagia, as have deletions in the melanocortin-4 receptor. Mutations in multiple species of serotonin receptors are associated with murine obesity, a finding that appears to underlie the role of serotonergic pharmacotherapies that reduce appetite.

Mutations in prohormone convertase-I have been associated with human obesity in one family. In contrast, the role of the *agouti* gene in human obesity has not yet been confirmed. Other candidate genes involved in human obesity include the beta-3-adrenergic gene, which is involved in sympathetic autonomic responses that affect appetite, and peroxisome-proliferator–activated receptor (PPAR) γ-2, a gene involved in adipocyte differentiation. Genome scans have identified other potential DNA regulatory sites (e.g., chromosome 10p), but definitive gene products have yet to be identified.

Obesity is also a presenting feature of at least 24 different genetic syndromes, displaying an entire range of heritability patterns. These syndromes are relatively rare, but the most common are Prader-Willi syndrome, a neurodegenerative disorder resulting from genetic abnormalities in the long arm of chromosome 15q11 to 13, and the autosomal recessive Bardet-Biedl syndrome involving concurrent hypogenitalism, mental retardation, and renal abnormalities.

Clinical Presentation

Subjective

Patients will often present to their health-care provider with some or all of the following symptoms as a result of obesity: fatigue, decreased energy, weakness, joint pain, shortness of breath, increased daytime sleepiness, and depression. Most will seek help for another medical condition or present with one or more of the aforementioned complaints. When weight history is obtained, patients often report several attempts at weight loss.

Objective

The diagnosis of obesity is having a BMI of 30 kg/m^2 or greater (Table 16.12). In extremely muscular individuals, BMI is not an accurate gauge of obesity; in such cases, a body-fat analysis will yield more accurate information about body composition. In children, obesity is diagnosed as having a BMI in the 95th percentile or higher on age- and gender-specific pediatric growth charts.

Historically, ideal body weight was calculated by comparing actual body weight to population tables from the Metropolitan Life Insurance Company. Weights for the original and updated tables were calculated based on data from middle-class Americans seeking insurance, and

Table 16.12 Calculating Body Mass Index and Classifying Obesity

Calculating Body Mass Index

The most recent formula for calculating body mass index (BMI) was developed by a panel convened by the National Heart, Lung, and Blood Institute and the National Institute of Diabetes and Digestive and Kidney Diseases. The equation for BMI is weight (kg) divided by height (m) squared (kg/m^2).

Classifying Obesity

Classification	Relative Weight	BMI
Overweight	100%–120%	25–29.9 kg/m^2
Obesity	140%–200%	30–40 kg/m^2
Severe (morbid) obesity	>200%	>40 kg/m^2

as Americans grew heavier, the weights in the table increased.

Measurements of weight and height are used to calculate the BMI for the exact classification of obesity. BMI is calculated by taking the body weight in kilograms divided by the height in meters squared. Despite criticism, BMI remains the measurement most frequently used in research and clinical practice because it is easily calculated without laboratory equipment. In research, BMI correlates with percentage of body fat measurements taken with underwater weighing but is not as reliable in older adults.

Owing to differences in complications of different types of obesity, two methods can be used to assess for central obesity. The first is to do a waist measurement. Greater than 40 inches in men and greater than 35 inches in women signifies increased risk for central obesity. The second method is a waist-to-hip ratio, which is calculated using the following formula:

$$\text{Waist-to-hip ratio} = \frac{\text{Waist measurement at smallest part}}{\text{Hip measurement at largest circumference}}$$

A ratio of greater than 1.0 for males and greater than 0.8 for females indicates central truncal obesity.

Diagnostic Reasoning

Secondary causes of obesity must be ruled out before initiating a treatment plan with the patient. Cushing's syndrome, hypothalamic injury, and hypothyroidism should be considered as potential causes. A complete history and physical with anthropometric measurement are essential elements of the initial assessment. A comprehensive history includes a weight history and attempts at weight loss. Family history of obesity and cultural food preferences must be addressed in the assessment. The amount of control the patient maintains in food purchasing and preparation should be considered.

The patient should be questioned about any periods of rapid weight gain and environmental or psychosocial changes in lifestyle during these periods explored. An exercise history should also be obtained, with special emphasis on the relationship of any weight gain or loss periods to exercise. Specific questions to assess current or past eating disorders are essential.

A past medical history and complete medication profile are necessary, especially the intake of corticosteroids, laxatives, diuretics, and appetite suppressants. Although rarely the cause of obesity, a personal or family history of thyroid disease should be explored.

The complete physical exam with a focus on signs of a possible cause of obesity (Cushing's syndrome or thyroid disease), as well as complications of obesity, should be done.

Diagnostic Tests

Initial assessment of the patient who is obese should include the following laboratory tests: thyroid-stimulating hormone (TSH), complete blood count, fasting glucose, liver function tests, and a lipid profile. An electrocardiogram (ECG) should also be obtained.

Differential Diagnosis

The diagnosis of obesity is usually straightforward. Acute or chronic fluid retention should be distinguished from increased adiposity, because edematous states and water balance must be considered. The differential diagnosis of obesity is geared toward determining the underlying cause. Although the vast majority of cases are due to nonnutritive dietary choices and sedentary lifestyle, certain medical conditions such as hypothyroidism should be ruled out with simple lab tests (e.g., TSH). But in general, an extensive laboratory work-up is not necessary. Patients should be evaluated for other risk factors associated with obesity, however, especially those implicated in coronary artery disease (CAD), such as hyperlipidemia and insulin resistance associated with type 2 DM.

Management

Whether weight gain is related to exogenous factors or endogenous factors is an important difference. Clinical management of obesity requires the balancing of energy intake and expenditure. All of the current clinical evidence suggests that successful management must include a combination of diet, exercise, and behavioral interventions. Multidisciplinary approaches to weight loss have a higher success rate. It also appears that continued close contact with a healthcare provider is more important for long-term success than any particular diet program. Because of the chronicity of obesity, the patient must learn long-term management skills. Cognitive therapy in conjunction with education is effective in increasing self-esteem, improving depression, and decreasing patients' dissatisfaction with their bodies.

The management plan should focus on reducing comorbidity and reducing visceral obesity, not solely on improving cosmetic outcomes. In fact, dietary instructions are essentially the same for the obese individual as for a healthy nonobese person: low-fat, high-fiber, high–complex carbohydrate eating plan with emphasis on portion control. A management plan that is realistic, that can fit into the patient's lifestyle, and that includes gradual changes in diet and activity is more likely to be accepted.

Assisting the patient to identify reasons for overeating may benefit the patient in managing his or her behavior. Being tired, anxious, and angry are major triggers for overeating. Remember the acronym HALT: hungry, angry, lonely, and tired.

Counseling of patients should include the benefits of weight loss: reduction in blood pressure, serum triglycerides, and blood glucose levels and an increase in HDL cholesterol. Patients with type 2 DM may experience a decreased A1C level. Management should be directed toward an initial goal of decreasing the patient's weight by 10% over 6 months. Subsequent goals are made after achievement of the initial goal. Treatment guidelines include measuring BMI at each patient encounter. If a patient has a BMI of 25 kg/m^2 or more or a waist circumference greater than 35 inches in females or greater than 40 inches males, care should be taken to assess for risk factors. All patients, regardless of their BMI, should be counseled about healthy lifestyle behaviors, including diet and exercise. The weight-loss goals and plan should be made in consultation with the patient to devise a program that is "doable" for the patient. If on repeated visits the patient has failed to lose weight, the provider should explore possibilities with the patient.

Management of the patient will depend on the patient's motivation and the cause of the obesity. Research has shown that attempts to lose weight almost always follow a major life transition such as an acute life-threatening illness, divorce, or death of a loved one. Other recent research with overweight women found incongruities in women's beliefs about the causes of their being overweight and how they planned to lose weight. Although many women identified stress as a major factor for overeating, they believed that dieting, not stress reduction, was the key to weight management.

Cultural and socioeconomic factors affect not only the prevalence of obesity but also attitudes as to acceptable weight and its implications. For example, some cultures view being overweight as a sign of good health and prosperity. In many Western cultures, obesity is seen more as a cosmetic problem than a major health problem.

Dietary Management

Before dietary modifications are initiated, a 3- to 7-day diet history should be evaluated. The patient should keep a diary, recording all oral intake, including water and drinks. It is often beneficial for evaluation to have the patient record daily activity along with food intake. Clues as to lifestyle patterns and behavioral eating patterns can be assessed more adequately with both sets of data.

The overall goal of weight loss depends on a calorie deficit. To calculate the energy requirements of patients, the following formula can be used: Multiply body weight by 10 for women and 12 for men. This will provide the amount of calories needed to maintain the current weight. A weight-loss goal of 1 pound per week can be achieved by reducing caloric intake by 500 kcal daily, because 1 pound of fat accounts for about 3,500 kcal. The National Institutes of Health guidelines suggest that the ideal weekly weight-loss goal is 1 to 1.5 pounds. More weight loss can be expected during the first week of a calorie-restricted diet because of excessive loss of water.

The diet should be balanced, and the patient should follow current guidelines for a healthy diet. Total calories eaten should consist of 30% or less from fat, 15% from protein, and 55% or more from complex carbohydrates. Saturated fats should be avoided. Besides restriction of fat intake, dietary recommendations must take into consideration minimum daily requirements, the patient's food preferences, and the patient's lifestyle.

Usual calorie restrictions range from 1,200 to 1,800 kcal daily. A restriction of 1,000 to 1,500 kcal per day is classified as a low-calorie diet (LCD). This level of restriction is indicated in patients who are at least 40% over the ideal weight.

A very low calorie diet (VLCD) includes 800 kcal daily, or 6 to 19 kcal/kg of body weight. VLCDs have short-term effectiveness and usually do not produce long-term results if used alone. A VLCD should be reserved for patients who are more than 40% over ideal body weight and at high risk for serious health consequences. VLCDs are contraindicated in older adults, pregnant and lactating women, and individuals with cardiovascular disease, gout, DM, cancer, severe renal or hepatic disease, and hypertension. Most VLCDs are liquid protein preparations. The major advantage of protein-formula liquid diets is that they remove the patient from the food environment.

Patients on VLCDs will need fluid, mineral, and nutritional supplements and frequent laboratory evaluations of potassium, magnesium, and uric acid levels. An initial ECG is done to rule out cardiac arrhythmias. Patients with this level of dietary restriction will need weekly evaluations by a specialist skilled in weight-loss management. Most patients will average a 1.5 to 2.5 kg per week weight loss on this restriction. Men are more likely to respond to a VLCD. VLCDs, although initially very successful, often are not effective in producing long-term maintenance of the weight loss. Fifty percent of patients will gain the weight back within 1 year.

The patient on a VLCD must be monitored for hypomagnesemia, hypokalemia, hyperuricemia, ECG changes, and cardiac arrhythmias. The overall long-term

effectiveness of these diets remains controversial, and they should be reserved for patients who are extremely obese.

Exercise

Exercise is a significant part of a weight-loss and maintenance program. It is especially beneficial in the long-term management of weight loss, lowering blood pressure, increasing muscle mass, increasing insulin sensitivity, improving the lipid profile, and improving glucose metabolism. Unless specific contraindications exist, exercise should be prescribed for all patients. Including resistance exercises in the exercise prescription will help maintain lean body mass.

Slow, sustained exercise, 45 to 60 minutes daily, is more beneficial for weight loss than are high-impact exercise routines. Adults should engage in at least 30 minutes of moderate-intensity physical exercise on most days of the week. Moderately intense physical exertion is equal to a brisk walk of 3 to 4 miles per hour. Patients are more likely to continue low-intensity exercise than high-intensity exercise. A 20-minute walk is usually acceptable to most patients as a starting point.

Younger patients with obesity may begin an aerobic exercise program if physical examination results are within normal levels. Older, sedentary patients should begin with walking programs. Exercise tolerance testing may be indicated for older adults and adults at risk for CAD before beginning an exercise program.

Behavior Modification

Behavior modification is essential for initial weight loss and weight maintenance. Unless the patient can identify eating patterns and lifestyle patterns that have contributed to weight gain and change those within his or her control, long-term weight management will not be achieved.

Restrictive eating behavior control includes cognitive strategies for portion control and healthy food selections. The need to identify impulsive and binge eating is also important. Behavioral management is enhanced by avoiding high-risk environments or altering the environment to reduce triggers to overeating.

Stress has a significant impact on eating behavior. During times of stress, the patient may find it impossible to implement behavior modification techniques. Relaxation techniques can assist in managing stress. Relaxation techniques must be practiced frequently in times of low stress so they can be effectively used in times of excessive stress.

Pharmacological Management

Appetite suppressants are available over the counter (OTC) and by prescription and are classed as either catecholaminergic or serotonergic. Pharmacological therapy for obesity has received much press, especially because the combination of fenfluramine (Fen Phen) and dexfenfluramine (Redux) produced an increased incidence of cardiac valvular disease in some users. Both of these drugs were classed as serotonergic agents, and they have both been withdrawn from the market, raising significant concerns for this class of medications.

Catecholaminergic agents include amphetamines, but also non-amphetamine schedule IV appetite suppressants including phentermine (Fastin) and diethylpropion (Tenuate). These pharmacological agents typically reduce weight by 5% to 10% but must be administered continually or the weight is regained. The potential for adverse reactions, lack of evidence for long-term effectiveness, and potential for drug dependence make their use in the management of obesity debatable.

There are two other medications approved by the FDA for weight loss: orlistat (Alli and Xenical) and the combination of phentermine plus extended-release (ER) topiramate (Qsymia). Orlistat functions by blocking the absorption of fat in the gastrointestinal tract. Phentermine plus ER topiramate suppresses appetite and increases feelings of satiety.

Orlistat 60 mg is available OTC and is taken with each fat-containing meal and inhibits gastric and pancreatic lipases, reducing fat absorption. It is also available by prescription at a dose of 120 mg. Demonstrated results are a weight loss of 2 to 4 kg maintained for 2 years. Adverse effects of orlistat include diarrhea, gas, and abdominal cramping. Some studies suggest it may also inhibit the absorption of fat-soluble vitamins.

Phentermine plus ER topiramate has four dosing preparations to allow for titration of the medication when starting and stopping. The usual dose for weight loss is 7.5 mg/46 mg or 15 mg/92 mg. It is taken each morning to suppress the appetite (phentermine), increase satiety, decrease food appeal, and increase metabolic rate (topiramate). In studies, patients lost approximately 8% of their starting body weight using this combination medication. Adverse reactions include dry mouth, paresthesia, constipation, irritability, and seizures if abruptly discontinued.

Surgical Intervention

Surgical intervention for obesity should be reserved for those patients who have a BMI over 40 kg/m^2 or over 35 kg/m^2 with comorbid conditions. It is usually not considered until the obese patient has failed more conventional weight-loss methods. The incidence of bariatric surgery is booming in the United States today. The most common surgical procedures are the vertical-banded (Mason) gastroplasty and the roux-en-Y gastric bypass, which may both be done laparoscopically. Some studies have shown that surgery can produce up to a 50% loss of initial body weight. Complications may occur in up to 40% of patients after surgery and include peritonitis, abdominal wall hernia, dumping syndrome, infection, acute cholecystitis, hypoglycemia, pyloric outlet obstruction, chronic diarrhea, nausea, and vomiting. Patients should be counseled regarding these potential complications. They should also be informed of the possibility of

regaining much of the lost weight if lifestyle changes are not also undertaken and sustained.

Follow-up and Referral

Most weight-loss programs require close follow-up. The severity of the problem and the nature of the interventions should govern how frequently the health-care provider sees the patient, but clearly, patients are more successful in maintaining weight loss with frequent follow-up visits. Many patients will benefit from frequent clinician visits that provide medical guidance, goal setting, and emotional support throughout the weight-loss process. In addition, the importance of clinical follow-up once weight-loss goals have been achieved should be emphasized, because recurrent weight gain following periods of significant weight loss is common. The patient should be seen for a weigh-in, blood pressure measurement, and discussion of progress at least monthly, but once a week is often most beneficial until the patient has developed habituated lifestyle changes.

Patient Education

Patient education includes instruction on how to maintain a balance between intake and energy expenditure. Exercise, a low-fat diet, and lifestyle changes should be emphasized. Patients may benefit from a referral to a dietitian. Many patients are unaware of techniques to reduce fat in their diet by cooking methods alone. One suggestion that may help is to use nonstick cookware so that there is no need to use fat or grease in the pan. Other suggestions are to bake, broil, and braise rather than fry foods. Patients with obesity must be educated about the importance of a combination of therapies. They must be guided to set realistic goals. Most obese persons skip breakfast and eat more in the late afternoon and evening, which is not helpful.

Sustaining weight loss requires behavioral changes. Patients should plan out their weight-loss strategy in writing. The plan should include diet modifications, exercise routine, and behavioral strategies. A calendar should be developed outlining the schedule. If lapses in the plan are experienced, the patient should explore the reasons for the lapse. Health-care providers should review this outline on each visit.

Some patients will benefit from support groups. Support groups for weight loss and overeating are listed in the Resources section at the end of this chapter. Patients who feel "sabotaged" by family members will need to explore methods for support outside of the family. Finding a walking partner or walking right after work before going home are some strategies to suggest.

Challenges in Caring for Obese Patients

The increasing number of obese and morbidly obese patients brings a challenge to primary-care providers. Caring for patients who are obese certainly includes treating the obesity, but many of these patients will have diseases and illnesses that will bring them to the provider's office. The National Institute of Diabetes and Digestive and Kidney Diseases Weight-control Information Network (WIN) offers suggestions for health-care providers in the care of these individuals separate from the need to treat the obesity. Providers and staff need to receive education related to respect for patients, appropriate equipment in the clinic, and providing the same level of care for obese patients as nonobese patients. Table 16.13 provides details to guide providers in creating an accessible and comfortable clinic environment, including medical equipment that can accurately assess patients who are obese and ways to reduce patient fears about their weight.

GOUT

Gout is a metabolic disease that produces an inflammatory arthritis. Gout was identified in the days of Hippocrates and was often referred to as "the disease of kings" because of its prevalence in the wealthy, who were able to afford the rich foods that typically trigger this

Table 16.13 Provider's Guide to Caring for Obese Patients

Create an accessible and comfortable clinic environment.
- Provide sturdy, armless chairs and high, firm sofas in waiting rooms.
- Provide sturdy, wide examination tables that are bolted to the floor to prevent tipping.
- Provide a sturdy stool or step with handles to help patients get on the examination table.
- Provide extra-large examination gowns.
- Install a split lavatory seat and provide a specimen collector with a handle.

Use medical equipment that can accurately assess patients who are obese.
- Use large adult blood pressure cuffs or thigh cuffs on patients with an upper-arm circumference greater than 34 cm.
- Have extra-long phlebotomy needles, tourniquets, and large vaginal speculae on hand.
- Have a weight scale with adequate capacity (greater than 350 pounds) for obese patients.

Reduce patient fears about weight.
- Weigh patients only when medically appropriate.
- Weigh patients in a private area.
- Record weight without comments.
- Ask patients if they wish to discuss their weight or health.
- Avoid using the term *obesity*. Your patients may be more comfortable with phrases such as "difficulties with weight" or "being overweight." You may wish to ask your patients what terms they prefer when discussing their weight.

disorder. Once a disabling chronic disease, current medical diagnostics and treatment modalities have decreased its disabling effects.

An overproduction or underexcretion (or both) of uric acid with tissue deposition of monosodium urate crystals causes the metabolic disease underlying gout. Most individuals with gout (90%) have a problem with underexcretion of uric acid. The arthritis produced by gout is characterized by recurrent, painful attacks of monoarticular joint inflammation caused by the phagocytosis of urate crystals, which deposit in joints, soft tissue, and cartilage.

Epidemiology and Causes

Gout occurs rarely in children, premenopausal women, or men younger than 30 years of age. Seventy percent of people with gout are men, with a peak incidence between 40 and 50 years. Gout is more prevalent in black men, possibly because of the increased prevalence of hypertension in this group. The increased incidence in older adults has been associated with the increased use of diuretics.

Twenty percent of patients who present with gout have a family history of the disease. Persons from the United States, the Pacific Islands, and countries with abundant lifestyles have an increased incidence of gout. Gout affects 8.3 million adults in the United States.

Hyperuricemia (uric acid levels exceeding 7 mg/dL in men and 6 mg/dL in women) occurs in 5% to 10% of the United States population. Most of these adults, however, are asymptomatic. One in five persons with hyperuricemia will develop urate deposits in a joint, soft tissue, or cartilage.

The risk factors and predisposing factors for development of gout are listed in Risk Factors 16.2. Causes of primary gout include the idiopathic inborn error of purine metabolism, decreased renal clearance of uric acid, and specific enzyme defects such as Lesch-Nyhan syndrome and glycogen storage disease. Secondary causes of gout include other disease processes and medications that produce an overproduction or underexcretion of uric acid.

Patients with gout may experience an acute attack with rapid fluctuations of serum urate levels. Surgery, dehydration, binge alcohol consumption, emotional stress, infection, diuretics, and uricosuric drugs can cause rapid fluctuations.

Risk Factors 16.2 Gout

Primary Risk Factors
- Enzyme defects
- Decreased renal clearance of uric acid

Secondary Risk Factors
- Excessive daily intake of purine
- Obesity
- Starvation
- Alcohol abuse
- Medications: Thiazide diuretics, ethambutol, nicotinic acid, pyrazinamide, low-dose salicylates, cyclosporine
- Paget's disease
- Chronic hemolytic anemia
- Psoriasis
- Cytotoxic drugs
- Carcinoma and sarcoma
- Chronic renal disease
- Hypothyroidism
- Lead poisoning
- Hyperparathyroidism
- Diabetes insipidus
- Diabetic ketoacidosis

Pathophysiology

Gout is a direct result of hyperuricemia (high serum uric acid). Gout is characterized by an increased saturation of urate in the plasma and bodily fluids. Supersaturation of bodily fluids results in a precipitation of monosodium urate crystals out of body fluids into the joints, soft tissues, and cartilage. This leads to the symptoms and clinical findings of gout, because the deposition of urate in the joints and its crystallization trigger an inflammatory response. Several mechanisms may trigger an acute attack of gout, the most common being trauma or surgery. Gouty attacks may also be triggered by prophylactic or uricosuric agents, which are known to lower serum uric acid levels.

At the time of puberty, serum uric acid levels increase in men; however, most (90%–95%) remain asymptomatic throughout life. Estrogen is believed to protect women from hyperuricemia. Acute attacks are more likely to occur at lower serum uric acid levels in persons with alcoholism due to decreased urinary excretion. There is also an increased incidence of hypothyroidism in persons with confirmed crystal aspirates in synovial fluid. Although gout is frequently cited as a risk factor for the development of coronary artery disease, subsequent studies did not confirm previous findings of the Framingham Heart Study.

For unclear reasons, gouty arthritis has a predilection for the first metatarsophalangeal joint (the great toe)—a condition known as podagra. This may result from the relative coolness of this peripheral joint which allows for greater crystal deposition, the constant microtrauma to which this joint is subjected, and the differential impact weight-bearing alternating with recumbency has on the resorption of joint fluid and intra-articular urate. Gouty arthritis may extend to several joints and is classified into four stages based on timing and clinical presentation (Table 16.14).

In general, urate crystallization is more likely to occur at lower temperatures. Noninflamed synovial fluid in the knee is significantly cooler (90–91°F [32.2–32.78 °C]) than core body temperature. Thus, although a serum

Table 16.14 Stages of Gout

Stage	Subjective Findings	Objective Findings	Diagnostic Findings
I. Asymptomatic	None	None	Microtophaceous deposits of urates in joints and bursae
II. Acute phase (inflammatory phase)	Extremely painful monoarticular or polyarticular attack Pruritus and desquamation of the skin surrounding the joint as the inflammation subsides	Affected joints are red, warm, swollen Early acute attack subsides within a few days; may last up to 2 weeks; inflammation gradually subsides 10% of patients experience only one acute attack during their life span	Elevated WBC count Elevated temperature Elevated serum uric acid or normouricemia
III. Intercritical (the interval between acute attacks)	None; patient is asymptomatic	Intervals between attacks decrease as the disease progresses. If a second acute attack occurs, it usually presents within the first year after the initial attack	
IV. Chronic (chronic tophaceous gout phase; occurs as a result of recurrent attacks with multiple sites of urate deposits [tophi] in articular and periarticular tissue)	May restrict movement of affected joints Chronic pain, stiffness, decreased joint function, joint derangement, secondary degeneration	More than 50% of patients progress to this stage within 20 years of the initial attack if not properly managed Occasionally, tophus ulceration and erosion with chalk-textured drainage Uric acid kidney stones (5%–10% of patients)	Tophi

uric acid concentration of 7 mg/dL appears to be the threshold level above which gout is more likely to develop, crystallization may be more likely to occur at lower concentrations intra-articularly. Hyperuricemia alone is insufficient to lead to crystallization, however. As part of the inflammatory process, urate-specific immunoglobulin (Ig) molecules coat monosodium urate crystals in gouty synovial fluid, likely serving as a promoter of nucleation for urate crystals.

As gout progresses, crystals are deposited into multiple bodily tissues. In severe cases with repeated attacks, monosodium urate monohydrate crystals form into a nodular deposit known as a *tophus,* surrounded by granulomatous inflammation consisting of monocytes and giant cells. In addition to the skin and joints, *tophaceous* swellings may be found in a number of bodily tissues, including the heart valves, kidneys, and larynx, capable of leading to significant pathology. Microtophi, consisting of collections of urate crystals surrounded only by a thin fibrocytic ring, may also be present in gouty synovial fluid. Some researchers have suggested that these microtophi release their urate crystals into the joint fluid after the initiation of synovial inflammation in the early stages of a gouty attack.

Urate crystals induce intra-articular inflammation via a number of mechanisms. Synovial lining cells, monocytes, and endothelial cells have all been shown to phagocytose urate crystals in vitro and subsequently increase their production of inflammatory mediators via transcriptional upregulation and mRNA stabilization, including interleukin (IL)–1, IL-6, IL-8, and tumor necrosis factor (TNF). Blockade of IL-8 and TNF activity has been further shown to counter urate-induced inflammation.

However, neutrophilic migration into affected joints and their subsequent phagocytosis of urate crystals appears to play a central role in the pathogenesis of gouty arthritis. Neutrophils undergo an oxidative burst during this process, releasing lysosomal enzymes, superoxide anions, leukotriene B4, and IL-1, among other mediators. In fact, the complexities of neutrophilic chemotaxis and function within gouty joints have been a central focus of gout research. Studies have indicated tyrosine kinases, phospholipases, adhesion molecules such as E-selectin, and several chemotactic factors play key roles in neutrophilic recruitment and activation by urate crystals. This explains the efficacy of colchicine in treating acute attacks, because it inhibits neutrophil tyrosine kinase

activity in response to both gout and pseudogout crystals, as well as downregulates the activity of adhesion molecules on both neutrophils and endothelial cells.

A number of proteins interact with urate crystals to increase their pro-inflammatory properties. Immunoglobulins bound to urate crystals lead to a greater release of lysosomal and superoxide enzymes by neutrophils. In turn, neutrophil mediators have been shown to cleave Ig molecules from urate crystals to reduce their inflammatory nature. The inflammatory properties of tophaceous urate crystals are also reduced after protease treatment in vitro. In contrast, lipoproteins (specifically apolipoprotein B) reduce the inflammatory potential of urate crystals after binding, indicating that they may be involved in the self-limited resolution of acute attacks. The complement and kinin systems have also been implicated in urate crystal pathology, but they are not requisite for acute gouty inflammation.

The self-limited nature of an acute gouty attack involves several mechanisms. In addition to the deactivation and death of inflammatory cells and the inactivation of secreted pro-inflammatory mediators, leukocytes, monocytes, and macrophages have been shown in vitro to alter their cytokine transcriptional activity over time. In turn, they secrete several anti-inflammatory cytokines on resolution of an acute attack, including IL-1 receptor antagonist, transforming growth factor–β, and peroxisome-proliferator–activated receptor (PPAR) γ. Although acute attacks of gout typically resolve spontaneously within several weeks, if left untreated or if inadequately treated, gout leads to chronic arthritis and bony erosions within 5 to 10 years, producing joint deformities and ultimately restricting function.

Clinical Presentation

Subjective

A thorough evaluation of the onset, characteristics, and potential potentiating causes of the pain is completed on initial evaluation. The patient will present during an acute attack with pain, tenderness, erythema, and swelling. Usual presentation is monoarticular, and the joint most frequently affected is the first metatarsal joint; however, the midfoot, knees, fingers, wrists, and elbows may also be affected. The typical presentation is excruciating pain that awakens the patient at night. Patients often describe the pain as throbbing, crushing, and pulsating. The pain is not relieved by rest or position change. Pain prevents any weight-bearing on the affected limb. Often the patient cannot tolerate anything coming in contact with the affected part—even bed clothing touching the part is extremely painful. The patient may also report an episode of recent trauma to the affected joint, a recent drinking binge, or an eating binge before the acute attack. Patients may report a recent operation or severe illness, especially one producing a shift in fluid balance.

The patient's past medical history, including any joint or musculoskeletal trauma, should be reviewed, along with any family history of gout. Because gout is more prevalent in patients with hypertension, obesity, and hyperlipidemia, history taking should focus on these contributing factors. In addition, a drug history, specific for recent increased intake of aspirin or cyclosporine, should also be obtained.

Objective

Even though the patient initially presents with monoarticular complaints, a complete bilateral examination of all joints should be performed. Joints should be assessed for symmetry in appearance and range of motion. Asymmetrical presentation of joint inflammation, redness, tenderness, and limitations in range of motion are typical of gout.

The joint most frequently affected in the initial attack is the first metatarsophalangeal joint (podagra). Podagra is experienced by approximately 90% of patients with gout. Subsequent attacks may progress to include several joints (polyarticular). Other joints that are frequently affected include the instep of the ankle, the heels, knees, wrists, fingers, and elbows. Peripheral joints are more likely to be involved, because central joints are warmer and less conducive to crystal formations. In polyarticular episodes or if a large joint is involved, the patient may have an elevated temperature, tachycardia, anorexia, malaise, headache, and chills. On physical examination, the affected area is warm or hot to the touch. The patient will complain of pain on palpation, and range of motion will be limited. Skin overlying the affected area is often red and taut. Several days after an acute attack, desquamation over affected joints may be evident.

Patients who have progressed to the chronic tophaceous stage will have palpable tophi. *Tophi* are nodular deposits of monosodium urate monohydrate crystals that initiate an inflammatory process. Most tophi are firm and movable, whereas the overlying skin is thin and red. Tophi are most likely to develop on the pinnae, olecranon tips, and the distal joints of the hands and feet. Extensive tissue deposits of urate may also occur on the helix and antihelix of the ear, the eyelids, the sclera, and cornea.

Diagnostic Reasoning

Diagnostic Tests

Clinical presentation and history are often diagnostic of gout. Serum uric acid levels and radiographic imaging provide some confirmation; however, a definitive diagnosis is made only with identification of sodium urate crystals of aspirate.

Initial Testing Initial testing for gout includes a serum uric acid level. Most patients will have an elevated serum urate level in the absence of elevated blood urea nitrogen, because serum urate is above 7.5 mg/dL in up to

95% of persons with gout. However, some studies have suggested that serum urate levels may be normal in up to 15% of patients at the time of an acute gouty attack. In addition, elevated serum urate levels alone are not diagnostic of gout in the absence of characteristic joint signs and symptoms, and the clinician should look for other supportive laboratory findings. The erythrocyte sedimentation rate and white blood cell (WBC) count may also be elevated during an acute attack. The WBC count is typically greater than 10,000 cells/mcL, but values up to 100,000 cells/mcL may occasionally be observed.

The classic radiographic findings of gout are tophi, normal mineralization of bone, joint space preservation, asymmetrical polyarticular distribution, overhanging edge cortex, and punched-out erosions of bone. Radiographs of affected joints may show no changes in early stages. The only radiographic evidence in early stages may be asymmetrical soft tissue swelling. With recurrent attacks and progressive disease, however, radiolucent urate tophi and punched-out appearing areas are apparent in bone. Tophi appear as cloudlike increases in density, which may show signs of calcification. Urate crystals may also be seen in subcutaneous tissue, cartilage, joints, and other tissues. In the very late stages of gout, demineralization and loss of articular structures may be apparent on radiographic examination. Most changes are asymmetrical and occur predominantly in the feet, ankles, and knees. Patients with severe disease often have involvement of the hands and elbows.

Subsequent Testing The definitive test to confirm the diagnosis of acute gout is urate crystals in joint fluid aspirate. The synovial fluid will be turbid during an acute attack. The crystals are identified by compensated polariscopic examination of wet smears of the aspirate and are noted to be negatively birefringent (a diagnostic finding). Aspiration and subsequent examination of the fluid should provide evidence for the diagnosis. Patients who present with gout and comorbid symptoms of abdominal pain, peripheral neuropathy, and proteinuria should be assessed for lead exposure.

Differential Diagnosis

Differential diagnoses include septic arthritis, cellulitis, rheumatoid arthritis, bursitis, fracture, acute trauma, and reactive arthritis (previously known as Reiter syndrome).

Septic arthritis should be considered when a patient presents with joint pain, swelling, and erythema. Septic arthritis occasionally coexists with gout. It should also be strongly considered when a patient does not respond to initial management for gout. Septic arthritis more commonly occurs in larger joints. Gram stains and cultures of synovial fluids are positive for bacteria in septic arthritis. Patients often present with fever and chills. Radiographic examinations often reveal joint-space narrowing and erosions within 1 to 2 weeks of the onset.

The rheumatoid factor titer may help rule out rheumatoid arthritis. Rheumatoid arthritis may resemble gout, but it typically has a symmetrical subjective presentation and radiographic presentation. Joint-space narrowing is also typical of rheumatoid joint disease.

Psoriatic arthritis may resemble gout in its early stages; however, the initial joints affected are frequently the hand, feet, sacroiliac joint, and spine. Fusiform soft tissue swelling is typical of psoriatic arthritis, and early joint-space narrowing is common.

The development of an inflamed joint in a young man or woman following a gastrointestinal (GI) (*Campylobacter, Salmonella, Shigella*) or genitourinary (*Chlamydia trachomatis*) infection would raise suspicion for reactive arthritis. In its typical presentation, this form of autoimmune joint inflammation is accompanied by conjunctivitis and noninfectious urethritis, comprising the classic triad of reactive arthritis.

Pseudogout presents with many similar characteristics to gout. However, polarized microscopic examination of joint fluid aspirate reveals calcium pyrophosphate dihydrate crystals, rather than the negatively birefringent uric acid crystals associated with gout. Pseudogout usually presents at a later age, and the symptoms are characteristically less acute and severe. Pseudogout is usually polyarticular (in approximately 75% of patients) and typically affects the knees and larger joints. Pseudogout is associated with hyperthyroidism and hypothyroidism, hypomagnesemia, amyloidosis, hypercalcemia, hypophosphatemia, and hemosiderosis.

Management

The goals of clinical management are to terminate an acute attack, prevent future attacks, normalize hyperuricemia, and prevent potential complications of urate deposits. Management of gout includes pharmacological treatment of acute attacks and long-term medical and pharmacological treatment of hyperuricemia. Acute management of gout includes generalized rest, elevation and immobilization of affected joints, and pharmacological treatment. Prevention of disability due to gout is a reality today because of advances in pharmacological treatment; however, the patient must become an active participant in the long-term treatment plan (Table 16.15).

Initial Management

Pharmacological treatment for an acute attack includes NSAIDs, colchicine (if onset is less than 36 hours), and corticosteroids.

Nonsteroidal Anti-inflammatory Drugs The medication of choice initially is an NSAID. Traditionally, indomethacin (Indocin) has been the most commonly prescribed NSAID for an acute attack of gout, but the other NSAIDs are just as effective. Indomethacin 25 to 50 mg every 8 hours is given until symptoms subside, usually 5 to 10 days. A good alternative to indomethacin is naproxen (Naprosyn). The first dose of naproxen is 750 mg, followed by 250 mg every 8 hours for 5 to 10 days. NSAIDs are discontinued after the pain has dissipated. Contraindications

Table 16.15 Management of Gout

Acute attack	NSAIDs Colchicine Corticosteroids Rest
No further attacks	Avoid excessive alcohol Dietary modification to avoid purine-rich foods
Additional acute attack	NSAIDs Colchicine Corticosteroids Rest Avoid alcohol and binge eating Low-purine diet
Two or more additional attacks	Uric acid secretion <1,000 mg/24 hr: probenecid Uric acid secretion >1,000 mg/24 hr: allopurinol Dietary modification to avoid purine-rich foods Lifestyle modification Colchicine

to the use of NSAIDs are active peptic ulcer disease, impaired renal function, and allergic reactions to NSAIDs. Potential adverse reactions of NSAIDs include GI bleeding, nausea, rash, hypertension (especially in the elderly), hepatic impairment, fluid retention, and acute tubular necrosis with subsequent acute renal insufficiency (particularly at high doses or with chronic use).

Colchicine Colchicine is an effective medication to terminate an acute gout attack if administered within 36 hours of the initial onset of symptoms. If administered within this time frame, it is effective in 90% of all patients. Colchicine can be administered orally or IV. The IV route is rarely used due to its low benefit versus toxicity ratio. In acute attacks, administer 1 to 1.2 mg of oral colchicine at the first sign of attack, then 0.5 to 0.6 g every hour or 1 to 1.2 mg every 2 hours until pain is relieved. The cumulative dose of colchicine should not exceed 4 to 6 mg during one course of therapy for an acute attack.

Adverse reactions include nausea, vomiting, diarrhea, and abdominal pain and cramping. Colchicine usually provides relief within 18 hours; however, many patients will experience diarrhea or nausea within 24 hours of the first dose. In the past, colchicine was often intentionally dosed until patients experienced vomiting or diarrhea; however, this is no longer considered an appropriate gauge of dosing adequacy, because such GI complications are adverse (rather than expected) drug effects. In the Acute Gout Flare Receiving Colchicine Evaluation (AGREE) trial, patients were randomized to three groups: usual colchicine treatment, low-dose treatment (1.2 mg orally followed by 0.6 mg 1 hour later), and placebo group. Researchers found that the low-dose group had a 50% pain reduction without rescue medication compared with the placebo group. They also found that the low-dose group had fewer adverse events compared with the traditional therapy (Level II; Terkeltaub et al, 2010). Colchicine is contraindicated in patients with a hypersensitivity to colchicine; severe cardiovascular, renal, or GI disease; or blood dyscrasias. Patients with renal or hepatic disease require a decreased total dose. In addition, colchicine must be used with caution in older adults.

Corticosteroids Corticosteroids can provide dramatic systematic relief and can be administered orally, intramuscularly, or intra-articularly. In most cases, corticosteroids are reserved for refractory cases or cases where the use of colchicine and NSAIDs is contraindicated. Corticosteroids are contraindicated in septic conditions; therefore, they should not be administered before analysis of the synovial aspirate. For polyarticular gout, prednisone, 40 to 60 mg PO daily, usually produces a good response. The dose should be tapered quickly over 5 to 7 days. Patients with monoarticular disease who cannot tolerate oral corticosteroids or NSAIDs benefit from intra-articular steroid injection. Intra-articular injection is with triamcinolone 10 to 40 mg and depends on the size of the joint.

Subsequent Management

The long-term management of gout includes pharmacological agents, dietary modifications, activity evaluation, and education regarding the prevention of gout.

Pharmacological Management Pharmacological prophylaxis should be initiated after the second or third attack. In patients with hyperuricemia and a history of only one acute attack, modification of lifestyle may prevent further attacks. Alternatives to thiazide diuretics should be addressed. Pharmacological prophylaxis, however, should be considered in patients with polyarticular gout and patients with consistent hyperuricemia greater than 8 mg/dL. Colchicine and NSAIDs may be continued in lower doses up to 12 months following an acute attack.

Colchicine is often used to prevent further acute attacks triggered by changes in uric acid levels. Colchicine does not correct the underlying causes of an acute attack, however. Adverse reactions to long-term use of colchicine are bone marrow depression, peripheral neuritis, and GI symptoms, especially diarrhea. The dosage of colchicine for long-term preventive management ranges from 0.5 to 1.2 mg daily. Colchicine is often used to prevent an acute attack with the initiation of probenecid or allopurinol, because they may precipitate an acute attack by rapidly decreasing the urate serum level. Before scheduled surgery, colchicine 0.5 to 0.6 mg PO three times daily for 3 days before and 3 days after surgery may prevent an acute attack of gout.

Three agents are currently available to lower uric acid levels—probenecid (Benemid) is a uricosuric agent that blocks tubular reabsorption of filtered urate; allopurinol

(Zyloprim) and febuxostat (Uloric) are xanthine oxidase inhibitors that lower plasma urate and urinary uric acid concentrations. They should not be started during or within 1 month after an acute attack. Before initiation, a 24-hour urinary uric acid excretion test is performed to differentiate between patients who are hypersecretors from those who are hyposecretors, because pharmacological management of the two conditions differs.

Before initiation of probenecid therapy, a 24-hour uric acid excretion test should be performed. Uric acid excretions greater than 1,000 mg in 24 hours are abnormal, and levels between 800 and 1,000 mg in 24 hours are considered to be borderline. Probenecid is indicated in patients whose excretion of uric acid is below 700 to 800 mg in 24 hours.

Probenecid is the drug of choice in persons younger than 60 years of age without a history of blood dyscrasias, renal failure, or kidney stones. An initial dosage of 500 mg is recommended, increasing gradually to 1 to 2 g after 1 week. Dosage is increased based on uric acid levels, with a maximum dose of 2 g daily. Major adverse reactions of this drug include skin rash, uric acid stones, and GI upset. It may also precipitate an exacerbation of gout if it produces rapid shifts in uric acid levels. Probenecid inhibits the excretion of penicillin, indomethacin (Indocin), and acetazolamide (Diamox). Allopurinol (Zyloprim) is used to decrease uric acid production in patients who are unable to take probenecid. It is indicated in patients whose 24-hour uric acid secretion is greater than 1,000 mg. Adverse reactions include GI upset, headache, rash, bone marrow suppression, fever, liver or kidney failure, vasculitis, lymphadenopathy, hepatitis, alopecia, and dermatitis. It is contraindicated in persons with idiopathic hemochromatosis and renal and hepatic disease. Serious hypersensitivity reactions to allopurinol may occur but are rare. However, patients should still be cautioned to discontinue use and immediately report any rash or fever that occurs after starting the drug. Twenty percent of patients on both allopurinol and ampicillin develop a rash. The safety of its use in pregnant or lactating women has not been established. The initial dose is 100 to 200 mg daily, with the average daily dose ranging from 200 to 300 mg. Dosages of 400 to 600 mg daily are indicated only in severe gout. The maximum daily dose is 800 mg. The goal of therapy is to decrease the serum uric acid levels below 6 mg/dL. Dosage should be adjusted based on serum uric acid levels every 2 to 6 months.

Febuxostat (Uloric) is also used to lower serum uric acid levels by blocking uric acid production. The dosage is 40 to 80 mg daily. Serious adverse reactions may occur including hypersensitivity rhabdomyolysis, interstitial nephritis, stroke, and myocardial infarction.

Dietary Modifications

Dietary modifications include avoiding high-purine–containing foods, maintaining adequate fluid intake, and moderate alcohol intake. The complete restriction of purine in the diet has not proven effective; therefore, a moderation of purine in the diet is now recommended. Foods high in purine content are listed in Table 16.16. Fluid intake should be sufficient to maintain an output of 2,000 mL/day. Patients should force fluids to exceed 3,000 mL/day, especially if they are prescribed a uricosuric agent.

Table 16.16 Foods High in Purine

- All meats and seafoods (especially organ meats such as liver, kidneys, and sweetbreads)
- Meat extracts and gravies
- Yeast and yeast extracts (brewer's and baker's)
- Beer and alcoholic beverages
- Beans, peas, lentils, oatmeal, spinach, asparagus, cauliflower, and mushrooms

Lifestyle Modifications

Activity must be restricted during an acute attack, and bedrest should be maintained 24 hours following the acute attack. The joint should be immobilized; if a lower extremity is involved, no weight-bearing should be allowed during the acute attack. During intercritical periods, physical therapy may be indicated to maintain or improve function.

Hot compresses may promote comfort after an acute attack but should not be instituted until the acute pain subsides, usually 24 to 72 hours after initiation of therapy. Instruct the patient to apply heat for 20 minutes two to three times daily. Heat can be applied with moist heating pads, warm showers and baths, or moist towels heated in a microwave. Relief may also be obtained using ice packs during an acute attack. Patients should be instructed to apply packs only for 10 to 20 minutes sessions and to discontinue if pain is not relieved.

Long-term management includes dietary moderation (one to two servings of purine-rich foods per day), alcohol in moderation, weight maintenance, and maintenance of joint mobility.

Surgical Intervention

Patients with extensive or large tophi may benefit from surgical excision and should be referred to a surgeon.

Follow-up and Referral

The patient should be evaluated 1 to 2 weeks after an acute attack. If antihyperuricemia therapy is initiated, the patient needs to be followed every 4 to 6 weeks to adjust medications and review the goals of treatment.

Annual follow-up is recommended. Special attention is given to previously affected joints as to their range of motion and stability. Joints should be symmetrically evaluated for tophi. Annual serum uric acid levels are indicated in all patients, and evaluation of renal function

is indicated for patients on prophylactic antihyperuricemic therapy. An evaluation of the patient's diet (including specific questions about alcohol intake) and exercise regimen should be conducted during the annual exam. Reinforcement of previous education is essential to increase adherence to medication and physical regimens during intercritical periods. Patients who are overweight will need continued reinforcement to lose weight and reduce stress on weight-bearing joints. Patients younger than age 35 years, premenopausal women, patients with frequent acute attacks despite prophylactic treatment, and patients with renal insufficiency should be referred to a rheumatologist for an initial evaluation.

Patient Education

Patients need instructions on avoidance of triggers for acute attacks. Excessive exercise, trauma, and alcohol or eating binges may precipitate an acute attack. Patients need explicit information on the adverse reactions of medication and measures to allay some preventable adverse reactions.

Fluid intake should exceed 2,000 mL daily to prevent formation of uric acid kidney stones. Patients should avoid dehydration because it may precipitate an acute attack. Diet modifications must be reviewed with patients in detail and written information provided. Because both wine and spirits in excessive amounts impair the kidney's ability to excrete uric acid, they should be used in moderation. Patients must be aware that binge drinking may provoke an acute attack. If the patient is obese, weight loss should be encouraged because loss of excess body fat may normalize serum uric acid without pharmacological intervention. Weight loss will also decrease stress on weight-bearing joints. Caution as to severe, rapid weight loss should be given because secondary hyperuricemia may result. A very low calorie diet may precipitate an acute attack.

Patients may need to take colchicine before having elective surgery if they are not already taking it regularly. They should be instructed to avoid aspirin.

Good posture and protection of weight-bearing joints are essential. Because the feet are most frequently affected, the patient should wear supportive and properly fitting shoes. Some patients may benefit from a physical therapist's exercise prescription or a visit to a podiatrist for an evaluation. At the first signs of an acute attack, the patient should limit all activity, limit weight-bearing if appropriate, and contact the primary-care provider.

Chapter 17

Hematological and Immune Problems

Brian Oscar Porter, MD, PhD, MPH •
Jill E. Winland-Brown, EdD, APRN, FNP-BC

COMMON COMPLAINTS

BRUISING

A *bruise* (ecchymosis) is an integumentary manifestation of extravasated blood. Discoloration of the skin is attributed to a local interstitial pool of erythrocytes, which causes a light to dark blue skin color associated with red pigment. The bruise sets off a local inflammatory event that includes macrophage invasion and histamine release and may be associated with edema. Macrophages engulf red blood cells (RBCs) to clear the area.

Macrophages that contain the RBCs excrete hemosiderin and hematoidin. Hemosiderin is brown, and hematoidin is yellow. The release of these molecules from macrophages accounts for the characteristic color changes in bruises during their resolution. Hematomas (larger bruises) require lengthier periods of time to resolve than smaller bruises.

Bruising may result from blunt trauma or occur spontaneously in the absence of trauma. Thrombocytopenia (platelet counts below 50,000 cells/mL) predisposes an individual to bruise formation with minor trauma, given the integral role of platelets in the formation of blood clots. Spontaneous bruising may be seen with platelet counts below 30,000 cells/mL, particularly on the arms and legs. Spontaneous bruising may also be associated with the chronic use of corticosteroid or anticoagulant therapies. Steroids weaken the vascular walls, making them prone to release erythrocytes. Anticoagulants, when their levels exceed the therapeutic range, can permit microvascular ruptures to spill blood into interstitial spaces.

Anticoagulant therapy consists of warfarin (Coumadin) in oral dosages that are intended to keep the international normalized ratio (INR) between 2.0 and 3.0 for most disease-related prophylaxis, such as the prevention of valvular thrombus in atrial fibrillation. Initial dosing of warfarin is 2 to 5 mg per day for 3 days, followed by measurement of prothrombin time (PT) and INR. This initial loading dose starts the process of anticoagulation. Dosages thereafter range from 2 to 7.5 mg, on average, per day. Dosages can be higher than 10 mg if the INR dictates.

If the INR result is above the therapeutic range, several options can be followed depending on how far above range it is. First, the clinician should consider withholding one or more days of anticoagulant therapy. Second, therapy should be restarted at a lower dose after a hiatus of therapy. Finally, the PT and INR should be reevaluated within 3 to 5 days of the dosage adjustments.

Differential Diagnosis

The differential diagnoses of bruising include chronic use of steroid and anticoagulant therapies, thrombocytopenia, hemolytic anemia, domestic violence, self-inflicted injury or other blunt trauma, and hypersensitivity vasculitis. A thorough history and physical exam by the clinician should focus on the cause of the bruising.

FATIGUE

Fatigue presents as a complaint of tiredness that cannot be explained on the basis of exercise or other activity. It may be either acute or chronic, associated with a disease or independent of other pathophysiology.

Acute fatigue is most often associated with viral or bacterial infections and may serve as a harbinger of impending symptoms such as fever. Determining the etiology of chronic fatigue that may last for months is far more complex. A patient seeking relief from chronic fatigue may occupy the clinician's attention during many visits before the causes can be identified. The patient usually cannot explain the cause of chronic fatigue without the clinician asking appropriate assessment questions.

The clinical history of fatigue offers insights into the nature of the cause. Patient reports of fatigue that increases over the course of a day and abates after rest indicate an organic origin for fatigue. Functional fatigue, on the other hand, is characterized by fatigue on awakening that may actually improve after exercise. The close associations of depression and anxiety with fatigue make for a difficult task in distinguishing these functional causes of the fatigue from the fatigue itself. In addition, fatigue may reflect hematological abnormalities associated with other disease conditions, such as chronic anemia that results in decreased oxygen-carrying capacity, which makes

the patient less tolerant of physical exertion and may contribute to persistent fatigue.

Differential Diagnosis

Fatigue by itself presents a complicated differential. Fortunately, it seldom presents without other comorbidity.

Acute fatigue is perhaps the simplest type to diagnose and treat. For example, acute fatigue typically appears in a clinical history that is positive for viral or bacterial exposure, combined with examination findings of fever and other systemic abnormalities.

Chronic fatigue has many causes, including chronic anxiety or stress reactions, lack of restorative sleep due to poor sleep hygiene or sleep apnea, depression, infectious mononucleosis, hepatitis, tuberculosis, anemia, heart disease, lung disease, electrolyte disturbances, rheumatoid diseases, and cancer. Thus, a detailed history and physical examination are key to distinguishing these underlying conditions. For instance, in the case of anemia, a detailed history may reveal fatigue worsened with exertion, and physical examination may demonstrate findings of pale nailbeds, gingivae, and tongue, along with sinus tachycardia.

FEVER

Fever is defined as a temperature elevation above normal baseline in which pathology can be identified as the cause. On average, most individuals maintain a body temperature close to 98.6°F (37°C), which may normally fluctuate up to ± 0.9°F (± 0.5°C) throughout the day. Physical exertion can elevate body temperature temporarily, followed by a return to baseline after the activity ends. A persistent elevation in temperature is clearly pathological, however.

Fever may be either acute or chronic. If acute, body temperature tends to be greater than 101.3°F (38.5°C). Acute fever is associated with upper respiratory infections (URIs) that are either bacterial or viral in nature, drug reactions, gastroenteritis, or urinary tract infections. Physiologically, fever is associated with the release of inflammatory immune mediators (e.g., interleukin-6, tumor necrosis factor–alpha) that act as pyrogens, presumably to create an environment within the body that is not conducive to microbial growth and replication. The ability of the body to elevate the temperature in the event of infection diminishes with advancing age; therefore, acute fever in an older adult might not be comparable to that in a younger patient.

Chronic fevers tend to be low-grade temperature elevations. Temperatures rise to 100.4°F (38°C) in cases of hepatitis, infectious mononucleosis (especially in the third and fourth weeks after the onset of symptoms), cancer, sinusitis, dental abscess, prostatitis, and tuberculosis (TB).

The origin of a fever may not be apparent from the patient's history, physical examination, or laboratory testing. If the cause is not evident after a thorough work-up, a persistent fever should be classified as a *fever of unknown origin* (FUO). Specifically, FUO is defined as a fever of greater than 101.3°F (38.5°C) that occurs on at least three occasions over a 3-week period in an ambulatory patient. A hospitalized patient is diagnosed with FUO if the unexplainable fever persists for 1 week.

Differential Diagnosis

The magnitude of fever elevation may guide the clinician in differentiating its cause. Fevers can vary widely, however, based on the patient's age, history of pathogenic exposure, and many other factors. Fevers in excess of 104°F (40°C) tend to be associated with pancreatitis, pyelonephritis, and intracranial pathology. Fevers between 101.3°F (38.5°C) and 104°F (40°C) are associated with URIs and some acute viral syndromes. Fevers less than 101.3°F (38.5°C) are characteristic of hepatitis, some acute viral infections, and TB.

Differentiations in fever elevation guide the decision-making process of which laboratory evaluations to recommend. Correlated with history and physical examination findings, fever elevation determines the type of sampling of blood or other bodily fluids to be ordered. In addition, in the absence of definitive test results, knowledge of the categories of fever elevation may give the clinician more or less reason for alarm. For example, when a middle-aged woman with a 3-day fever of 102.2°F (39°C) presents with a nonproductive cough, chills, and inspiratory chest discomfort, and her lungs are clear but dull to percussion in the bases, the suspicion of a pulmonary consolidative process should cause the clinician to order a chest x-ray exam and complete blood count; however, the clinician may not order blood cultures because the fever is not high enough to suggest systemic infection, for which blood cultures would otherwise be indicated. Moreover, there are focal symptoms that explain the fever.

Environmental toxins may also cause fever. When this etiology is suspected, the history should focus on exposure to industrial chemicals, including pesticides and herbicides used in animal husbandry and agriculture. Fevers of environmental origin tend to follow an indolent course, often showing peaks and troughs. Physical signs may also be absent, thus adding to the indolence of the presentation.

LYMPHADENOPATHY

The term *lymphadenopathy* is used in clinical practice to designate any abnormality of lymph nodes and, in particular, enlarged lymph nodes. Perhaps the more exact term should be *lymphadenitis,* which suggests that inflammation is the cause of the lymph node enlargement. Lymph node enlargement may be regionally or systemically associated with inflammation. If the inflammation is regional, the lymph nodes that are proximal to a site of infection will show enlargement. If the disease process is systemic, lymph nodes in three or more sites that are dispersed across the body may become enlarged. An example of regional lymph node enlargement is cervical

lymphadenopathy associated with pharyngitis. An example of systemic lymphadenopathy is HIV infection, in which there may be lymphadenopathy in three or more extrainguinal lymphatic chains.

Lymphadenopathy follows the course of the disease. Thus, nodes may be acutely or chronically enlarged depending on the duration of the disease. Acute infection often leaves the regional nodes tender to touch. Chronically enlarged nodes, on the other hand, may be nontender.

Differential Diagnosis

The differential diagnosis for lymphadenopathy depends on the location of involvement and associated findings. Neck masses, for example, involve a differential that is based on node location in the neck, age of the patient, and associated morbidities, such as tobacco use. The clinician should distinguish between slow growth in nodes and rapid or acute onset of lymphadenopathy. Acute onset is characteristic of inflammation and acute infection, whereas slow-growing nodes in the neck suggest neoplasm, such as lymphoma. However, there are exceptions. For example, a young patient with no history of tobacco or ethanol use may present with slow-growing cervical lymphadenopathy, but the possibility of neoplasm is minimal in a patient of this age and with this history. Nonetheless, an adult older than age 70 years with even a remote history of tobacco use is likely to be diagnosed with lymphoma if there is slow-growing neck lymphadenopathy. Thus, the patient's age is an important consideration in the differential diagnosis of neck lymphadenopathy.

HIV-associated lymphadenopathy presents challenges to the differential diagnosis. The average HIV-infected patient is younger than age 50, has a history of alcohol and/or tobacco use, and may also be antibody-positive to other sexually transmitted diseases. Lymphadenopathy could occupy the neck, axillae, inguinal region, breasts, and thorax. Reactive lymphadenopathy is characteristic of early and middle stages of the disease attributable to HIV infection itself; later disease findings contributing to lymphadenopathy may include lymphoma or infection with cytomegalovirus, human papillomavirus, toxoplasmosis, or *Mycobacterium avium* complex. Persistent slow-growth enlargement, therefore, is reason to consider lymph node aspiration and cytological evaluation in this setting.

COMMON HEMATOLOGICAL PROBLEMS

MICROCYTIC ANEMIA

Anemia can mean any of several problems that involve suboptimal red blood cell (RBC) number or function (Table 17.1). The diagnosis suggests low hemoglobin (Hgb), low hematocrit (Hct), and/or a low number of RBCs. All of these problems involve a reduced amount of oxygen circulating in the body, because RBCs carry oxygen to tissues and cells. The World Health Organization (WHO) identifies *anemia* as an Hgb of less than 13.0 g/dL in men (less than 42% Hct) and less than 12.0 g/dL in women (less than 36% Hct). Slightly higher values of Hgb and Hct are considered standard in developed versus underdeveloped regions of the world.

As a rule of thumb, the estimated level of hematocrit is three times the value of the Hgb. For example, an Hgb value of 13.0 g/dL amounts to an estimated Hct of 39%.

Microcytic anemia is a category of anemia based on the small size (*micro-*) of the RBCs (*-cytic*). It has been linked to nutritional deficiencies, particularly a deficiency in dietary intake or uptake of iron. The small size of the RBCs is identified via one of the three indices of RBCs, the mean corpuscular volume (MCV). Microcytosis, therefore, is defined by an MCV value of less than 80 fL. In short, the clinician can make a diagnosis of microcytic anemia by identifying the presence of anemia combined with a low MCV.

Epidemiology and Causes

Microcytic anemia, as related to iron deficiency, is one of the most common anemias throughout the world. The incidence is high among women of childbearing age, with up to a third of pregnant women developing anemia in the third trimester. The ratio of incidence between women and men is 4:1. In the United States, 20% of adult women are affected by the condition compared with 3% of adult men. These statistics have remained constant for the past decade.

The causes of microcytic anemia include (1) an inadequate oral intake or gastrointestinal (GI) uptake of dietary iron, (2) anemia of chronic disease (ACD), (3) thalassemia, and (4) sideroblastic anemias.

The incidence of iron-deficiency anemia has been estimated to be 1:2.0 to 2.5 among pregnant women and 1:6 in persons older than age 75 years. Iron-deficiency anemia is often the easiest type to correct and remedy, unless it is caused by a GI malignancy. Iron deficiency is, therefore, less important in the differential even though it remains the most common cause of microcytic anemia.

Most adults in the United States ingest and absorb enough iron in their diets. It is estimated that the average dietary intake of iron in the United States is 10 to 15 mg per day, of which not more than 10% is absorbed in the stomach, duodenum, and jejunum. The average healthy adult, therefore, absorbs approximately 1 to 2 mg of iron per day. In addition, the same adult loses an amount of iron equal to that ingested and absorbed, thereby maintaining homeostasis.

ACD, unlike iron-deficiency anemia, presents a more complex diagnostic picture because of the many and

Table 17.1 Classification of Anemias

Anemia	Examples of Causes	Mean Corpuscular Volume (mm^3)	Mean Corpuscular Hemoglobin (pg)	Mean Corpuscular Hemoglobin Concentration (%)
Microcytic, hypochromic	Iron deficiency, lead poisoning, thalassemia, rheumatoid arthritis	50–80	12–25	25–30
Microcytic, normochromic	Renal disease, infection, liver disease, malignancies	<80	20–25	27
Normocytic, normochromic	Sepsis, hemorrhage, hemolysis, drug-induced aplastic anemia, radiation, hereditary spherocytosis	82–92	25–30	32–36
Macrocytic, normochromic	Vitamin B_{12} and folic acid deficiency, some drugs, pernicious anemia	95–150	30–50	32–36

Indications for Hemoglobin Electrophoresis

- Suspected thalassemia, especially in individuals with positive family history for the disorder
- Differentiation among the types of thalassemias
- Evaluation of a positive Sickledex test to differentiate sickle cell trait (20%–40% Hgb S) from sickle cell disease (>70% Hgb S)
- Diagnosis of Hgb C or sickle cell anemia (hemoglobin SC disease)
- Identification of the numerous types of abnormal Hgb, most of which do not produce clinical disease

Hemoglobin Electrophoresis	Percentage of Hgb	Comments
Hgb A_1 Infants	>95 10–30	Low: Alpha- and beta-thalassemia major and minor
Hgb A_2 Cord blood Birth–6 months >6 months	2–5 0–1.8 0–3.5 1.5–3.5	Elevated: Beta-thalassemia major and minor up to 9%
Hgb F Neonates 1 month 2 months 3 months 6 months–1 year	<10 70–80 70 50 25 3	Elevated: Beta-thalassemia minor up to 9% Elevated: Thalassemia major and minor (after 6 months)
Hgb C	Absent	Usually asymptomatic, but can cause red blood cells to sickle due to osmotic fragility; occurs in 2%–3% of blacks
Hgb D Hgb E	Absent Absent	Hgb D and E rarely occur alone but worsen disease when in combination with sickle cell anemia or thalassemia
Hgb H	Absent	Unstable tetramer of beta hemoglobin chains; 30% of hemoglobin in severe alpha-thalassemia with 3 of 4 mutated alpha genes (hemoglobin H disease)
Hgb M	Absent	Any of several mutated forms of hemoglobin that cannot be reduced to an oxygen-carrying state, resulting in congenital methemoglobinemia
Hgb S	Absent	Elevated—sickle cell anemia: <40% in sickle cell trait; 85%–95% in sickle cell disease. Most common beta Hgb variant: if both beta chain genes affected, then sickle cell anemia (1% of population); if only one gene affected, then sickle cell trait (8%–10% of population)

varied causes of inflammatory disorders in chronic disease, which include rheumatoid arthritis, malignancies, and serious infections. Given its complex diagnostic picture, ACD must always be considered in the differential for microcytic anemia, although despite its importance, the incidence and prevalence of ACD are unknown.

The thalassemias are a group of inherited diseases of alpha- or beta-globin chains. Microcytic anemia is caused by hemolysis that results from the suboptimal synthesis of alpha- or beta-globin chains, hence the categories of thalassemia known as alpha- and beta-thalassemia. Beta-thalassemia is associated with descendants of groups of individuals who originated in areas around the Mediterranean Sea. Alpha-thalassemia is far more widespread, occurring in individuals with ancestry from the Asian continent, including China and Southeast Asia. Prevalence has also been noted among persons living along the western coast of Africa.

Sideroblastic anemia reflects a disorder of heme synthesis, resulting in abnormal hemoglobin and disordered RBC function. It may be caused by chronic alcoholism or lead poisoning or may be a stage in the evolution of a generalized bone marrow disorder that may progress to acute leukemia.

Pathophysiology

Normal Hemoglobin Formation

The predominant normal adult hemoglobin (hemoglobin A; $\alpha_2\beta_2$) comprises one pair of alpha-globin chains and one pair of beta-globin chains, accounting for 90% to 95% of total adult hemoglobin. Each of these globin chains is linked to an individual heme group, which consists of a protoporphyrin IX molecule bound to a ferrous (Fe^{2+}) reduced iron ion. It is this heme unit that reversibly binds oxygen, allowing for transport of oxygen by the hemoglobin tetramer to the bodily tissues.

Several other forms of hemoglobin are formed during human development. At least three distinct forms of hemoglobin consisting of different combinations of zeta (ζ), epsilon (ϵ), gamma (γ), and alpha (α) chains present themselves throughout embryonic development in the following order: hemoglobin Gower I ($\zeta_2\epsilon_2$), hemoglobin Portland ($\zeta_2\gamma_2$), and hemoglobin Gower II ($\alpha_2\epsilon_2$). In contrast, the predominant normal hemoglobin form in infancy is hemoglobin F or fetal hemoglobin (approximately 80%), which has two gamma-globin chains substituted for the beta-chains ($\alpha_2\gamma_2$). Hemoglobin F has a stronger affinity for oxygen than hemoglobin A does, allowing for oxygen transport across the placenta from the mother to the developing fetus. As a newborn ages, this form of hemoglobin slowly clears from the circulation, accounting for less than 1% of hemoglobin by 6 months of age, with a corresponding increase in hemoglobin A. Finally, an additional form of adult hemoglobin known as hemoglobin A_2 also exists, which is present in far smaller amounts than hemoglobin A (about 2% to 5% of total adult hemoglobin). With a slightly higher oxygen affinity than hemoglobin A, hemoglobin A_2 has two delta (σ)-globin chains substituted for the beta-globin chains ($\alpha_2\sigma_2$).

Iron-Deficiency Anemia

Because the reduced ferrous (Fe^{2+}) ion is a critical component of the heme moiety in hemoglobin, sufficient iron stores are critical for adequate erythropoiesis in the bone marrow. In low-iron states, the production of hemoglobin is severely reduced, resulting in marked microcytosis. Iron deficiency remains the most common cause of microcytic anemia in the United States. Because most adults receive enough iron in their diets to prevent microcytosis (other than strict vegan vegetarians), the clinician's attention should turn to malabsorption or occult loss of blood as the primary causes of iron-deficiency anemia.

The majority of iron uptake occurs in the duodenum and upper jejunum. Thus, malabsorption of iron is linked to underlying GI problems such as celiac sprue; surgical resections involving the stomach, duodenum, or jejunum; inflammatory bowel disease such as Crohn's disease; rapid GI motility; gastroenteritis; and selected drugs such as the histamine receptor 2 (H_2) antagonist cimetidine (Tagamet). Decreased levels of iron can also occur as the result of molecular bonds between plasma iron stores and certain drugs. These bonds develop during the distribution phase of pharmacokinetics, sequestering iron ions and decreasing the plasma pool available for integration into heme molecules. For example, sulfonamide drugs such as sulfamethoxazole-trimethoprim (co-trimoxazole, Bactrim, Septra) can cause decreased plasma levels of iron.

Iron deficiency resulting from acute or chronic (occult) blood loss is perhaps the most prevalent cause of microcytic anemia. A net loss of blood depletes iron stores and impairs the bone marrow's ability to synthesize new RBCs, due to progressively decreased heme synthesis. Thus, RBCs are decreased not only in number but also in size, producing a characteristic microcytic anemia. Common sites of bleeding (which may be either painless or painful) include the GI tract (e.g., upper tract lesions such as peptic ulcers or gastritis; lower tract lesions such as colon cancer, ulcerative colitis, Crohn's disease, diverticulosis, ruptured hemorrhoids) and the genitourinary (GU) tract (e.g., heavy endometrial bleeding known as menorrhagia, hematuria from bladder cancer). In fact, microcytic anemia may be the first laboratory finding that initiates a line of investigation identifying underlying malignancy. For example, heme-positive stools or melena are strong indications for colonoscopic cancer screening in men and women older than 50 years or in younger individuals with a strong family history.

Anemia of Chronic Disease

Anemia of chronic disease (ACD) may cause microcytic or normocytic anemia. ACD as a cause of microcytic anemia results from mechanisms that involve inflammation, infection, and/or underlying malignancy. Inflammation may lead to occult and progressive blood loss, because microvascular eruptions may result from histamine-release and immune complexes that physically invade the involved region. When these eruptions occur in the GI tract, occult blood escapes through the intestines. Thus, of particular concern is the relationship of occult blood in the stool to GI malignancy. Alternatively, chronic use of NSAIDs, such as ibuprofen (Motrin, Advil) and aspirin, for chronic pain conditions must also be considered as a cause of occult blood loss. NSAIDs and aspirin are used in the routine management of both rheumatoid arthritis and osteoarthritis. Blood loss results from erosion of the protective mucosal lining of the stomach, in particular, due to decreased production of prostaglandin formed by the enzymes cyclooxygenase-1 and cyclooxygenase-2—the molecular targets inhibited by NSAIDs.

Thalassemias

The pathology of thalassemia is related either to depletion or mutation in the genes that code for the subunits of the protein component of adult hemoglobin—the alpha- and beta-globin chains. Alpha-thalassemia is caused by gene depletion that, in turn, creates a reduction of alpha-globin chain synthesis. Because two copies of the alpha-globin chain gene are inherited from each parent on chromosome 16, mutations or deletions may exist in one or more of these four genes, producing distinct clinical manifestations. Mutations or deletions in all four genes results in alpha (O)–thalassemia or alpha-thalassemia major. No hemoglobin A, A_2, or F can form in this disorder, which is incompatible with extrauterine life. Rather, there is an excess of Bart's hemoglobin, which consists of gamma chain tetramers (γ_4). Bart's hemoglobin has an oxygen affinity at least 10-fold greater than that of hemoglobin A and, thus, cannot effectively release oxygen to fetal tissues. This causes severe anemia with resultant congestive heart failure, widespread capillary leak, and anasarca known as hydrops fetalis (widespread edema of all fetal tissues), typically resulting in fetal demise by the third trimester of pregnancy.

Mutations in three of the four alpha genes results in hemoglobin H disease, characterized by the widespread formation of hemoglobin H, which consists of a tetramer of four beta-globin chains (β_4). This results in moderate to severe lifelong hemolytic anemia, which typically requires repeated blood transfusions. Mutations in only two of the four alpha genes is called alpha-thalassemia minor or alpha-thalassemia-1 trait. This results in a mild anemia with only minor clinical manifestations. Mutation in only one of the four alpha-globin genes is a silent carrier state called alpha-thalassemia minima or alpha-thalassemia-2 trait and can be diagnosed only through DNA analysis because it has no clinical manifestations.

In contrast, only one gene for the beta-globin chain is inherited from each parent. Mutation or deletion of one of these genes results in beta-thalassemia minor or beta-thalassemia trait, characterized by a mild anemia that is typically asymptomatic. Deletions or severe mutations in both beta-globin genes result in beta-thalassemia major (Cooley's anemia), characterized by a severe transfusion-dependent, lifelong anemia with skeletal abnormalities due to bone marrow expansion in the body's attempt to increase hematopoiesis. An intermediate form of the disorder known as beta-thalassemia intermedia also exists in which a patient inherits two mutated, albeit expressed, beta-globin genes, each with a different type of mutation (a compound heterozygote) that results in varied levels of expression or functionality. Clinical manifestations may be worsened by acute illness or infection that impairs erythropoiesis and exacerbates the anemia.

Sideroblastic Anemias

Sideroblastosis and its resulting microcytic anemia are caused by a host of molecular defects that affect the biosynthesis of the heme moiety of hemoglobin. Heme is normally formed first by the creation of 5-aminolevulinic acid (ALA) from glycine and succinyl-coenzyme A by the erythroid isoform of the mitochondrial enzyme ALA synthase, which requires vitamin B_6 (pyridoxine) as a cofactor. Although the underlying genetic defects in many forms of hereditary sideroblastic anemia have not been characterized, known mutations occur most commonly in the genes for the erythroid form of ALA synthase (located on the X chromosome), the mitochondrial transporter ABC7, pyridoxal 5-phosphate (a reversible form of the disease responsive to pyridoxine therapy), ferrochelatase, the copper-dependent enzyme cytochrome oxidase, and pseudouridine synthase–1.

In most forms of sideroblastic anemia, elemental iron is typically delivered appropriately to erythrocyte precursors. However, underlying enzymatic mutations prevent or reduce the ability of heme to incorporate into protoporphyrin IX. A reduced number of RBCs form from ring sideroblast precursors (a diagnostic hallmark) found in the bone marrow, because peripheral reticulocytosis is markedly diminished. Despite an increase in the RBC growth factor erythropoietin, anemia results from the destruction of the abnormal erythroid precursors in the bone marrow via apoptosis and intramedullary hemolysis.

Sideroblastic mutations result in excessive iron deposition in the mitochondria of affected erythrocytes (erythropoietic hemochromatosis) which, nonetheless, are hypochromic and microcytic because this form of mitochondrial ferritin cannot be utilized for cytoplasmic maturation in the developing erythrocyte. Intestinal

iron absorption is actually increased in sideroblastic anemia, owing to ineffective erythropoiesis, as is also observed in the thalassemias. Thus, iron overload occurs not only in erythroid cells but throughout the body, similar to genetic (familial) hemochromatosis, with predictable end-organ damage due to iron deposition (e.g., cirrhosis [liver], cardiomyopathy [heart], and endocrine defects [pancreas and adrenals]).

Acquired forms of sideroblastic anemia also exist. The most common causes include chronic alcoholism, which results in a multifactorial pathogenesis including many of the hypoproliferative mechanisms previously cited; iatrogenic associations with the antituberculous drug isoniazid and the antibiotic chloramphenicol; zinc toxicity, in which zinc ions preferentially bind to protoporphyrin in place of iron; and copper deficiency, which leads to decreased intestinal absorption of iron and diminished reduction of iron ions from the ferric (3+) state to the bioavailable ferrous (2+) form as a result of reduced cytochrome oxidase activity. Lead poisoning is also often cited as an acquired cause of sideroblastic anemia because lead inhibits ALA synthase. However, with lead toxicity true ring sideroblasts are typically not seen in the bone marrow, owing to the inhibitory effect of lead on the enzyme ferrochelatase, thereby preventing the integration of ferrous ions into heme. Idiopathic acquired sideroblastic anemia may also occur when a single erythroid progenitor cell develops a mutation affecting the heme synthesis pathway but is also conferred a survival advantage. As clonal proliferation of this precursor cell ensues, the bone marrow is largely replaced by this single sideroblastic lineage that is prone to apoptosis, which results in a myelodysplastic anemia.

Clinical Presentation

Subjective

Overall, patients with microcytic anemia present with subjective findings of tachycardia, fatigue, shortness of breath, dyspnea on exertion, palpitations, listlessness, poor concentration, anorexia, and dizziness or light-headedness. Because similar subjective findings are also associated with many additional diagnoses other than microcytic anemia, the history of patient complaints is unlikely to be conclusive.

Objective

As the Hgb drops below 10 g/dL (approximately 30% Hct), many patients present with a facial mask of fatigue, sallow-colored skin, pale mucous membranes, tachycardia, and tachypnea at rest. It is possible also to note a prolonged blanch response in the nailbeds (more than 3 seconds), although many patients may never present with this sign. Severe iron-deficiency anemia can cause progressive skin and mucosal changes, such as brittle nails, cheilosis (reddened appearance of lips with fissures formed at the angles of the mouth), and a smooth appearance to the tongue. In addition, pica is considered an objective finding associated with severe iron deficiency. *Pica* is identified as an eating disorder of craving for food substitutes, such as clay, dirt, ice chips, or cotton.

Diagnostic Reasoning

Diagnostic Tests

Initial diagnostic testing is focused on obtaining a complete blood count (CBC), from which an RBC count and RBC indices (MCV, mean corpuscular hemoglobin [MCH], and mean corpuscular hemoglobin concentration [MCHC]) are isolated. A low RBC count, Hgb level, and/or Hct identify anemia (see Table 17.1).

Secondary diagnostic testing for specific causes is described below.

Iron-Deficiency Anemia The diagnostic tests for iron-deficiency anemia are relatively simple to perform and are readily available. Serum ferritin is a reliable test of low stores of iron, provided the patient does not have advanced liver disease. A serum ferritin value of less than 30 mg/L is considered pathological. As the ferritin level falls, the total iron-binding capacity (TIBC) rises above the normal range. If the drop in ferritin and rise in TIBC continue untreated, the serum iron level will also fall (to less than 30 mg/L), as will the transferrin saturation (to less than 15%). In addition, secondary testing should focus on results of RBC morphology from the CBC. Findings such as anisocytosis (variable RBC size), poikilocytosis (variable RBC shape), and hypochromasia (pale-colored RBCs) may be revealed when samples severely deficient in iron are evaluated under the microscope.

Anemia of Chronic Disease Diagnostic tests for ACD focus on distinguishing ACD from iron-deficiency anemia. Unlike iron-deficiency anemia, ACD presents with a low serum iron level, along with a low TIBC. In addition, the serum transferrin level is either normal or increased in patients with ACD. Finally, the clinician should expect the transferrin saturation to be low, as it is in iron-deficiency anemia.

Thalassemias The thalassemias, both alpha- and beta-thalassemia, require a CBC and Hgb electrophoresis for diagnosis. The CBC is essential to determine the diagnosis of microcytic anemia, and the MCV is low for each group of the thalassemias. In alpha-thalassemia trait, the Hgb electrophoresis reveals no increase in hemoglobin A_2 or hemoglobin F. In addition, no hemoglobin H is present. Plasma iron parameters remain normal. The anemia of alpha-thalassemia is modest, as evidenced by Hct level between 27% to 40%.

Beta-thalassemia minor patients also have a modest anemia. In these patients, unlike those with alpha-thalassemia trait, Hgb electrophoresis reveals an elevated hemoglobin A_2 level and, in some cases, an elevated hemoglobin F. Neither Hgb elevation will typically be greater than 9%, however.

Patients with beta-thalassemia major present very differently from patients with other forms of thalassemia. Their anemia is severe. Left untreated, their Hct levels will fall to less than 10%. Electrophoresis results show little or no hemoglobin A, with variable amounts of hemoglobin A_2 present. The clinician should expect hemoglobin F to be the primary hemoglobin that is detectable in these patients. As with all of the thalassemias, findings in patients with beta-thalassemia will include abnormal RBC morphology such as poikilocytosis and anisocytosis.

Sideroblastic Anemia A diagnosis of sideroblastic anemia is confirmed by a Prussian blue stain of a bone marrow aspirate. The Prussian blue stain reveals tinged sideroblasts, which have iron deposits located in the mitochondria that surround the red blood cell's nucleus. In addition, erythroid hyperplasia is present in the aspirate from patients with sideroblastic anemia. A high level of serum iron and a high transferrin saturation should accompany these findings. Without a stain of the bone marrow aspirate, the laboratory profile could mimic iron-deficiency anemia, with a moderately low Hct of 20% to 30% and a low MCV.

Differential Diagnosis

The differential diagnosis depends on the blood work results. For microcytic anemia, it may be summarized by reference to its four predominant causes: iron-deficiency anemia, ACD, thalassemias, and sideroblastic anemia. The ultimate goal of the diagnostic evaluation is to identify the underlying cause of the microcytic anemia, such as GI malignancy, iron malabsorption, blood loss, menorrhagia, and so forth.

Management

The management of microcytic anemia focuses on treating and eradicating the cause of the anemia. If amelioration of the cause is not possible, symptomatic care is indicated.

The severity of the anemia will direct the intervention. The decision to transfuse a patient with red blood cells is a major clinical step that may be indicated if the Hct is 27% or less. The decision requires a thoughtful analysis of the overall clinical setting and hemodynamic status of the patient, which may not be severely compromised, even at low Hgb levels. Transfusing patients with comorbidities such as congestive heart failure (CHF) calls for great caution (given risks of fluid overload and high output heart failure). In addition, the risk of iron overload following repeated RBC transfusions must be carefully considered.

Iron-Deficiency Anemia

Iron-deficiency anemia is treated first with an increase in dietary iron and thereafter with supplemental iron. Foods rich in iron should be recommended, such as animal proteins, legumes, and dark green leafy vegetables, such as spinach. Diet alone may be sufficient in treating iron deficiency if the patient is either young or middle-aged or the cause of the anemia is short-lived. However, as the patient ages (particularly beyond age 65) and if the cause of the anemia is chronic, iron deficiency must be treated with either supplemental oral or parenteral iron.

Supplemental oral iron is best given as ferrous sulfate, 325 mg three times daily; 10 to 20 mg will be absorbed from the total daily regimen if the serum iron is moderately low. In more severe cases, however, the level of absorption will increase. The clinician should recheck the RBC indices and iron values 2 to 4 weeks after starting the regimen to ascertain the effectiveness of the oral regimen. The patient's adherence to the regimen could be complicated by the requirement that iron supplements be taken on an empty stomach to achieve maximal absorption. Therefore, if no measured improvement in anemia (Hct elevated by one-half of baseline), MCV, and iron stores appears after 1 month of therapy, the clinician should confirm adequate adherence to the regimen along with the underlying cause of the iron deficiency. The patient should continue to take supplemental iron for 3 to 6 months after normal levels in the blood and serum indices have been restored. Thereafter, the clinician should recheck laboratory values as indicated by the clinical assessment. If the patient does not respond to supplemental iron, then the clinician should doubt the initial diagnosis of iron-deficiency anemia. In particular, ACD should be suspected as the cause, or the clinician should reconsider whether the rate of GI blood loss might exceed stem-cell deployment from the bone marrow.

Supplemental iron by a parenteral route is indicated only when there is documented failure of therapy with oral iron supplements. The clinician should calculate the daily dose by subtracting the patient's measured MCV from the normal lower range value (which varies by age and gender). This value is considered the total number of milligrams of iron to add according to the MCV. In addition, the clinician must add 1,000 mg to the delivered dose to cover the storage of iron in the body. Overall, the daily dosage of supplemental parenteral iron is approximately 1,300 to 2,000 mg (1.3–2.0 g) of iron. The preferred route of administration is IV. Because anaphylaxis is possible with IV iron, the initial dose should be delivered over 4 to 6 hours to prevent adverse effects; some practitioners even advocate giving 50 mg over the first hour as a trial.

Anemia of Chronic Disease

ACD is treated symptomatically. Red blood cell transfusions may become necessary when the Hct falls below 27% to 30%. In most cases, however, the Hct will stay above 30%. Chronic ACD might require treatment with drugs that stimulate erythropoiesis given subcutaneously, including erythropoietin alfa and darbepoetin alfa. Typical ACD causes that require this are chronic renal failure and HIV infection or AIDS. The dosage varies according

to patient tolerance and hematological requirements. Erythropoietin alfa (Epogen, Procrit) is given three times weekly, then adjusted. Darbepoetin alfa (Aranesp) may be given weekly initially and then adjusted to dosing every 2 weeks. These medications can be administered IV in the hospital or clinical setting. In addition, patients can learn to self-inject these medications subcutaneously, just as diabetic patients learn to self-inject insulin.

Thalassemia

The thalassemias often require no treatment other than vigilance by the clinician concerning hematological markers. If a clinician diagnoses microcytosis with mild anemia, the patient should not be subjected to further checks for iron deficiency if there is a distinct thalassemic etiology. Clinical vigilance may be all that is required for microcytosis with mild anemia.

Patients with severe anemia, however, such as that associated with beta-thalassemia major and hemoglobin H disease, require regular transfusion with RBCs. In addition, these patients require folate supplementation and possibly oral iron chelation therapy to prevent hemosiderosis and hemochromatosis resulting from multiple transfusions. Hemosiderosis of chronic standing may also require referral for a splenectomy.

Sideroblastic Anemia

There are few options for the treatment of sideroblastosis. Depending on the severity of anemia, RBC transfusions may be required. Large doses (200 mg/day) of vitamin B_6 (pyridoxine, e.g., Beesix) have benefited some patients. Erythropoietin alfa (Epogen) has proven to be of little aid in supporting these patients.

Follow-up and Referral

Iron-deficiency anemia that is mild necessitates follow-up every 4 to 6 months. There should be no need to retest iron stores after the first follow-up visit following the initial diagnosis, unless indicated by patient complaints or physical examination findings. Thus, typical follow-up testing may consist only of serial CBCs. A referral to an appropriate specialist may be necessary if a thorough work-up identifies serious pathology that could account for iron-deficiency anemia, such as GI malignancy or other type of occult blood loss. These patients may require upper and/or lower endoscopy or other type of work-up to exclude serious pathology. Anyone 50 years or older with heme-positive stools or evidence of iron-deficiency anemia should be referred for a colonoscopy unless the risks of colonoscopy outweigh the potential benefits of catching a GI cancer early—such as in elderly patients in whom the risk of perforation is greater and could prove fatal.

In general, the plan of referral for microcytic anemia should facilitate isolating the cause of the anemia, initiating treatment in the primary care setting, and involving specialty care referral as needed. The primary care clinician, therefore, has the responsibility to perform all screening tests and to seek to diagnose the underlying cause. In turn, referral to a specialist for iron-deficiency anemia is almost never required unless it is complicated by concurrent diagnoses, including other causes of microcytic anemia. For example, iron-deficiency anemia secondary to menorrhagia would necessitate appropriate gynecological referral if procedural interventions such as uterine ablation or hysterectomy are indicated.

ACD follow-up can be more complicated than follow-up of iron-deficiency anemia. If the patient requires erythropoietin injections, then he or she should be maintained on a 30-day follow-up schedule for the first 6 months after initiating therapy. In most cases, only a CBC will be required to determine the effectiveness of this therapy. It is exceptional for patients with ACD to require transfusions. The clinician should refer patients with ACD to gastroenterologists, hepatologists, oncologists, rheumatologists, hematologists, or other specialists depending on the suspected underlying pathology. For example, if the clinician were to detect occult blood in the stool of a patient with microcytic anemia and the history did not reveal a likely cause, referral to a gastroenterologist would be warranted.

Patients diagnosed with one of the thalassemias may or may not require referral to a hematologist. Although patients with the more aggressive thalassemias (such as beta-thalassemia major or hemoglobin H disease) must be referred promptly to a hematologist, who will be entrusted with managing the plan of care, patients with alpha- or beta-thalassemia minor may be managed by the primary care clinician following initial diagnosis. In these patients, it may only be necessary to monitor serial CBCs every 3 to 4 months. More frequent observation and intervention is required, however, for the other types of thalassemias, which require transfusion therapy, and the plan of care established by the hematologist will dictate the follow-up schedule.

Because sideroblastosis is diagnosed by examination of a bone marrow aspirate, early referral to a hematologist is required for suspected sideroblastic anemia. The hematologist may also perform tests to determine lead exposure and resultant damage from lead toxicity. Follow-up evaluation will become the responsibility of the primary care clinician, however, and the CBCs of these patients should be monitored every 2 to 3 months.

Patient Education

Education should focus on self-care and primary care management of the underlying cause of microcytic anemia. Self-care encompasses topics such as adherence to the medication regimen, dietary changes, level of activity, self-monitoring for signs and symptoms of anemia, and adjustment to the requirements of new health-related practices. For example, patients with iron-deficiency anemia must be educated to perform the following self-care behaviors: (1) take ferrous sulfate (supplemental iron) on

an empty stomach or at the most with a small snack; (2) eat foods that are rich in iron, vitamin C, and B-complex vitamins, which are all necessary for RBC development; (3) remain as active as possible, and if fatigued, rest before resuming activity; (4) self-monitor for fatigue, shortness of breath, pale-colored stools (before initiating supplemental iron), and palpitations or tachycardia, which may all be associated with decreased oxygen-carrying capacity due to anemia; and (5) share information about iron deficiency so that friends and/or family can assist in adjustments that new health-related behaviors will require.

Additional patient education focuses on primary care management. Patients need to understand the importance of timely clinical laboratory evaluations, return visits, recognizing signs and symptoms of recurrent anemia that should be reported to the clinician, and proper techniques for administering or receiving drugs that must be delivered via a parenteral route, such as erythropoietin or IV iron supplements. Most important for patients with severe anemia is the necessity to remain vigilant in receiving blood transfusions and monitoring for the signs of potential iron overload, including liver dysfunction (nausea, loss of appetite, weight loss, yellowing of the skin, swelling of the lower legs).

NORMOCYTIC ANEMIA

Normocytic anemia is defined as an anemia associated with normally sized red blood cells (RBCs) (mean corpuscular volume [MCV] = 81–99 fL), although normal ranges vary with age. Many forms of normocytic anemia have normally shaped RBCs as well, although some conditions are recognized by typical abnormal morphological findings on peripheral blood smear. Most commonly, this type of anemia results from chronic disease states, but acute blood loss, hemolysis, and volume overload are other important etiologies of normocytic anemia.

Epidemiology and Causes

Normocytic anemias cover a broad range of diseases and conditions, each with its own epidemiology and prevalence rate. Nonetheless, it is possible to estimate the incidence of normocytic anemia of chronic disease (ACD) by recognizing that at least half of all patients with an underlying chronic disease will develop normocytic anemia over the course of their illness.

Pathophysiology

Most chronic diseases create mechanisms that reduce the life cycle of erythrocytes. In addition, chronic diseases may also be myelosuppressive. As discussed earlier, ACD may be microcytic. However, the combination of reduced cell life and impaired stem cell production (hypoproliferation) associated with chronic illness typically results in a normocytic, normochromic anemia. This may be related to a variety of different underlying conditions including infection, inflammation, autoimmune activation, malignancy (with or without marrow invasion), cardiac disease, diabetes mellitus, endocrine disorders (e.g., hypothyroidism, hypoadrenalism, hypopituitarism, hypogonadism), acute renal insufficiency (due to the accumulation of uremic metabolites that decrease RBC life span), and chronic renal insufficiency (due to impaired erythropoietin synthesis by the kidneys). Severe trauma, surgery, or major acute disease states such as sepsis and myocardial infarction may also result in normocytic anemia, possibly due to the significant tissue damage and inflammatory response associated with these events.

Hypoproliferation appears to be the major contributing factor to normocytic ACD, resulting primarily from iron sequestration in bone marrow macrophages, which effectively decreases the plasma iron pool available for integration into newly synthesized hemoglobin molecules. In addition, patients with ACD are less capable of adequate erythropoietin upregulation in response to their anemic state, compared with patients with non–iron-sequestering anemias (e.g., iron-deficiency anemia). Moreover, although absolute erythropoietin levels may be increased in ACD compared with nonanemic normal values, the bone marrow demonstrates a decreased erythropoietic response to this growth factor. Animal studies have shown that certain inflammatory cytokines including tumor necrosis factor, interferon (IFN)–βeta, and IFN-γamma may underlie these mechanisms of hypoproliferation in normocytic ACD. In addition, expression of the acute phase reactant protein hepcidin is also increased in ACD. Upregulated by the pro-inflammatory cytokine interleukin-6 (IL-6), hepcidin has been shown in animal models to directly inhibit iron absorption by the gut, resulting in decreased plasma iron levels.

Acquired aplastic anemia also results in a normocytic anemia. This may be a primary condition affecting only the erythroid lineage or it may encompass more than one cell line (e.g., white blood cells [WBCs] or platelets), which would indicate a proliferative defect in an earlier common progenitor cell that gives rise to more than one bone marrow lineage. Aplastic anemia may also be associated with certain types of viral infections in high-risk individuals, such as parvovirus B19 infection in patients with sickle cell disease or hereditary spherocytosis. A failure of erythropoietin production by the kidneys, as is also observed in chronic renal insufficiency, will similarly result in reduced RBC production and decreased reticulocytosis.

Normocytic anemia may also be caused by a relative increase in plasma volume, such as that which occurs in pregnancy or iatrogenic parenteral overhydration. This results in a dilutional drop in plasma hemoglobin, which may be physiological, as in pregnancy, or which may be reversible via pharmacological diuresis, as in the case of fluid overload.

Increased blood loss, such as from acute bleeding or hemolysis, is another major cause of normocytic anemia. As bleeding progresses and the marrow undergoes reticulocytosis, MCV may be transiently increased due to the relatively larger size of reticulocytes. However, once plasma

and bone marrow iron stores are exhausted, hemoglobin production decreases, and this anemia transitions to a normocytic state and then eventually into a microcytic anemia characteristic of iron-deficiency anemia.

If hemolysis occurs intravascularly, fragmented RBCs termed *schistocytes* are seen on peripheral blood smear. This type of anemia is most commonly associated with hemolytic uremic syndrome (HUS), thrombotic thrombocytopenic purpura (TTP), disseminated intravascular coagulation (DIC), or heart valve abnormalities that cause mechanical RBC shearing. Hemolysis may also occur extravascularly with clearance of RBCs by the reticuloendothelial system. This is characterized by rounded RBCs termed *spherocytes* on peripheral blood smear and occurs most commonly due to splenic removal of RBCs, as seen in hypersplenism or autoimmune hemolytic anemia (AIHA).

Immune-mediated hemolysis typically occurs when RBC-specific antibodies coat erythrocytes, rendering them prone to splenic removal or direct hemolysis by antibody-mediated complement fixation. RBC-specific antibodies may form as a consequence of antibody upregulation from viral infections such as mononucleosis, malignancies (especially chronic lymphocytic leukemia), or autoimmune disorders such as systemic lupus erythematosus. When these antibodies are primarily of the immunoglobulin G (IgG) class, they are known as warm agglutinins, because they result in RBC aggregation (agglutination) at warmer temperatures, due to the binding of two RBCs at a time (one to each of the IgG molecule's two antigen-binding sites). In contrast, IgM RBC-specific antibodies, such as those associated with *Mycoplasma* infection, are called cold agglutinins, because they are capable of causing RBC aggregation at relatively lower temperatures, by virtue of a greater number of antigen-binding and complement fixation sites that results from their tendency to cluster in pentamers (i.e., aggregates of 5 IgM molecules with a total of 10 antigen-specific binding sites).

Extravascular hemolysis may also result from a whole host of intrinsic RBC membrane defects, such as mutations in the membrane protein spectrin that cause hereditary spherocytosis. In addition, mutations in certain cytoplasmic enzymes render RBCs more prone to hemolysis. A prime example are disorders of glucose-6-phosphate dehydrogenase (G-6-PD), an enzyme critical to the production of glutathione, a powerful reducing agent and the RBC's main protective mechanism against highly oxidizing compounds such as naphthalene (the active chemical agent found in mothballs) or certain drugs such as trimethoprim-sulfamethoxazole (Bactrim), primaquine, and dapsone.

Clinical Presentation

Subjective

The patient presentation will depend on the severity of the anemia. Because normocytic anemia rarely presents with a moderate to severe anemia of less than 30% Hct, many patients with the diagnosis do not report subjective findings. On closer questioning, however, they might note malaise or fatigue.

Objective

The objective findings are the same as for microcytic anemia.

Diagnostic Reasoning

Diagnostic Tests

Initial testing begins with the CBC. The clinician should expect the finding of anemia not to be accompanied by an alteration in the RBC indices (MCV, mean corpuscular hemoglobin [MCH], mean corpuscular hemoglobin concentration [MCHC]), in order to establish a diagnosis of normocytic normochromic anemia, such as that associated with acute blood loss, sepsis, underlying malignancy, mechanical shearing from prosthetic heart valves, aplastic anemia, or ACD.

Subsequent testing begins with an absolute reticulocyte count (normal range for adults is 0.5%–2.5% of the total RBC count). Reticulocytes are the less mature type of RBCs. They acquire their name from their fine cytoplasmic network of ribosomal RNA used for hemoglobin synthesis, which is called a *reticulum;* this network appears when stained with certain dyes such as new methylene blue. The reticulum is lost as the RBC matures but is prominent in these less mature cells of the RBC lineage, which are larger than their mature RBC counterparts. Thus, the reticulocyte count is always higher than normal in any proliferative condition (proliferative normocytic anemia) and overall MCV may be elevated due to this abundance of immature reticulocytes. However, MCV may paradoxically be normal in a true microcytic anemia with a significant reticulocytosis, because the average (mean) RBC size may appear normal in the face of both small and large cells.

Proliferative microcytic anemia may be difficult to diagnose solely from laboratory testing. If the patient has a recent history of trauma, the diagnosis of proliferative microcytic anemia secondary to hemorrhage should be considered. However, when hemorrhage is not part of the clinical picture, attention should turn to evaluating the patient for hemolysis as a potential etiology.

Testing for hemolysis requires a peripheral smear, as RBC morphology is useful in determining the cause of the hemolysis. Possible morphological changes in RBC appearance include spherocytes, sickle cells, and schistocytes. Spherocytes are erythrocytes shaped like rounded spheres or globes, which are abnormal shapes for an erythrocyte. Sickle cells assume the shape of a quarter moon or the curved metal blade instrument known as a sickle, from which these erythrocytes take their name. Schistocytes, on the other hand, are classically called "fragmented" and appear as many varied shapes.

Further genetic testing may be required if these abnormal RBC morphologies are detected on the peripheral smear. The presence of sickle cells on the smear implies a sickle cell anemia diagnosis or one of its variants, such as sickle beta thalassemia, or sickle C disease. The presence of spherocytes necessitates obtaining a Coombs' test to detect anti-RBC antibodies, because a positive Coombs' test suggests hemolysis due to AIHA, whereas a negative test may suggest hereditary spherocytosis. Schistocytes require the clinician to order a prothrombin time (PT) and partial thromboplastin time (PTT), because elevated PT/PTT values may reflect disseminated intravascular coagulation (DIC) if there is also thrombocytopenia, given that platelet consumption from widespread thrombi/microthrombi is characteristic of this disorder. This results in bleeding and/or oozing, which may be refractory to treatment and ultimately prove fatal. Normal PT/PTT values in the presence of schistocytes suggests any one of several diagnoses, including severe hypertension; HUS/TTP; heart valve abnormalities (such as mitral valve stenosis); vasculitis; or hemolysis, elevated liver enzymes, and low platelet count (HELLP) syndrome. HELLP syndrome is typically associated with pregnancy, especially later-term pregnancies, and delivery of the baby is the primary intervention.

Although the peripheral smear typically reveals morphological changes in RBCs in the patient with hemolysis, RBC shape may be normal in some forms of hemolysis, such as with deficiency in the enzyme G-6-PD. A low level of G-6-PD in the absence of morphological changes in the peripheral blood smear of a patient with normocytic anemia strongly implicates the lack of this enzyme as the cause for the hemolysis. However, G-6-PD levels measured during an acute attack of hemolytic anemia may appear paradoxically elevated in patients with G-6-PD deficiency because of the relatively higher concentration of G-6-PD found in reticulocytes, which are upregulated during acute hemolysis as the bone marrow attempts to compensate for the increased hemolysis. Thus, serum levels are often normal during acute hemolytic attacks, and the diagnosis of G-6-PD deficiency must be confirmed by redrawing G-6-PD levels several weeks after the acute anemia has resolved.

Should the G-6-PD level be within normal limits in a patient who reports voiding dark red urine in the morning, then it is necessary to consider conducting the Ham acidified serum lysis test, as dark red urine raises suspicion that the diagnosis may be paroxysmal nocturnal hemoglobinuria (PNH). The traditional Ham acidified serum lysis test may provide a definitive diagnosis, although state-of-the-art diagnostic testing typically involves flow cytometric analysis, which directly evaluates RBCs for reduced or absent levels of the cell surface molecules CD55 and CD59 that result from the genetic defects underlying PNH.

In patients diagnosed with a hypoproliferative normocytic anemia with a normal MCV and low reticulocyte count, attention should turn to the white blood cell (WBC) count and platelet count. If both are low, the clinician should suspect pancytopenia affecting all the major bone marrow lineages. If the WBC and thrombocyte counts are high, however, then either ACD or renal disease is the likely cause of the normocytic anemia. Subsequent tests, therefore, involve renal function studies (e.g., blood urea nitrogen [BUN] and creatinine) and a careful review of the patient's medical history. Assessing endogenous erythropoietin levels is an important part of this work-up as well.

Differential Diagnosis

The differential for normocytic anemia includes mixed anemias of other classifications. Differentiation should be made between three major causative mechanisms*: deficiency* (iron, vitamin B_{12}, folic acid, pyridoxine [vitamin B_6]); *central*—caused by impaired bone marrow function (anemia of chronic disease, anemia of the elderly, malignant blood disorders); and *peripheral* (bleeding and hemolysis). Mixed anemias may appear normocytic because the MCV is within normal range even though iron-deficient RBCs may be small and vitamin B_{12}- or folate-deficient RBCs are megaloblastic. Moreover, because ACD is part of the differential for microcytic anemia as well as normocytic anemia, the clinician must distinguish between the RBC indices of the two in addition to focusing on the underlying chronic pathology.

Management

Management of normocytic anemia focuses on the cause of the disorder. Causes of normocytic anemia include ACD, renal disease, pancytopenia, hereditary spherocytosis, AIHA, sickle cell anemia, G-6-PD deficiency, paroxysmal nocturnal hemoglobinuria (PNH), DIC, heart valve abnormalities, HUS/TTP, vasculitis, severe hypertensive nephropathy, and HELLP syndrome. In the initial phase of management, treatment should be symptomatic, thereby alleviating the common downstream effects of anemia. Subsequent management consists of correcting, stabilizing, or preventing the cause for normocytic anemia. Correcting and/or stabilizing the underlying cause is limited to some cases of ACD, AIHA, heart valve abnormalities, vasculitis, severe hypertension, HELLP syndrome, and DIC.

Apart from appropriately treating the underlying disease pathology, management of ACD usually requires only watchful waiting; however, if the patient's Hct drops below 30%, the clinician may consider using erythropoietin alfa. Dosing with erythropoietin alfa for ACD is highly individualized and is dependent on the underlying causative disease pathology. In general, treatment should be targeted to increase hemoglobin to 11 to 12 g/dL, but not above 13 g/dL. Starting doses range from 50 to 150 U/kg SC three times per week, depending on the underlying pathology, and should only be initiated after carefully reviewing dosing guidelines in the specific product labeling. For the first 3 weeks of therapy, the clinician should check the Hct

twice weekly until the dosage level is stabilized. Two to 6 weeks may pass before the Hct undergoes an appreciable elevation.

Endogenous erythropoietin levels do not aid in determining the starting dose of exogenous erythropoietin alfa therapy. Moreover, the clinician may increase the dosage and frequency of administration until the Hct rises to an appropriate level. As the dosage level rises, however, it is possible that polycythemia (Hct greater than 60%–65%) may develop as a side effect of exogenous erythropoietin usage. Thus, if hemoglobin rises above 12 to 13 g/dL or the patient becomes frankly polycythemic, the drug should be discontinued. Within a week of discontinuing therapy, the Hct should start to decline. Otherwise, in rare cases, it may be necessary to phlebotomize the patient, removing enough volume to cause a drop in the Hct. After the clinician achieves and maintains a normal Hct, the dosage level may be reduced and/or the frequency of administration changed. Thus, the management of dosing of exogenous RBC growth factors such as erythropoietin alfa (Epogen, Procrit) darbepoetin-alfa (Aranesp) requires expert consultation with a hematologist or other appropriate specialist, given the significant risks of overdosage associated with polycythemia, including thrombosis, stroke, and myocardial infarction.

First-line treatment of AIHA consists of oral or intravenous corticosteroid therapy, such as prednisone 1 to 2 mg/kg per day in divided doses. Thus, an adult who weighs 70 kg would receive between 70 and 140 mg of prednisone in two or three divided doses each day. After an initial response is documented, the prednisone dose is decreased to 20 to 30 mg/day within several weeks, followed by a slow taper over several months to prevent recurrence of the condition. As for other patients on chronic corticosteroid therapy, supplementation with calcium, vitamin D, and folic acid may be initiated, along with bisphosphonate therapy, as prophylaxis against osteoporosis. If transfusion is required for severe anemia, the clinician should be aware that the risk of transfusion reaction is very high owing to crossmatching difficulties for these patients, given their Coombs' test positivity. The clinician should expect that the transfused cells will survive no better than the patient's own erythrocytes if the underlying AIHA is left untreated.

Surgical consultation is required for possible splenectomy should prednisone become ineffective or too toxic from chronic administration. In emergency situations, short-term hemolytic control of 1 to 3 weeks may be achieved with IV immune globulin (500 mg/kg per day for 1–4 days). In addition, off-label use of rituximab (Rituxan), an anti-CD20 B-cell–depleting monoclonal antibody therapy, has been used as second-line therapy for AIHA.

Heart valve abnormalities require an individualized plan of care developed with referral to an interventional cardiologist, which may include surgical correction of the abnormality. Many patients with heart valve abnormalities will have already started taking warfarin sodium (Coumadin) to prevent embolism formation. They should not stop taking anticoagulant therapy unless their platelet counts fall along with the Hct or active bleeding is present. Anticoagulation should also be stopped in the face of a rapidly falling Hgb, even in the setting of a normal platelet count.

Treatment of vasculitis consists of high-dose prednisone, and it may be necessary to raise the prednisone dose to 60 mg daily. The clinician should slowly taper the steroid dose as the lesions of vasculitis heal, fever declines, and other symptoms abate. Additional immunosuppressive therapy may also be required to augment the prednisone. Cyclophosphamide (Cytoxan) in a dosage range of 1 to 2 mg/kg per day may be added to the prednisone regimen. These drugs should be taken either along with or following a meal to avoid GI upset. If the dosage of cyclophosphamide exceeds 100 mg, the clinician can anticipate that only 75% of the dose will be absorbed via the GI tract. Therefore, for doses that exceed 100 mg, the dose should be split. Weekly or biweekly monitoring of the patient's complete blood count (CBC), liver and renal function tests, and uric acid level are necessary, given the potential toxicities of these agents.

Severe hypertension (greater than 180 mm Hg systolic and 110 mm Hg diastolic) can be treated with one antihypertensive agent or a combination of agents. Hemolysis that is secondary to severe hypertension may present in a patient that is known to the clinician, in which case drug therapy should be adjusted according to the history of treatment for the individual patient. (See the section on management of hypertension in Chapter 10.)

HELLP syndrome typically occurs during the third trimester of pregnancy. Because of its late onset in pregnancy, delivery of the infant is the treatment of choice. Most hematological indices return to baseline within 2 to 3 days after delivery; however, thrombocytopenia may persist for a week or more.

DIC requires treatment with heparin and platelet transfusions (replacement therapy). Platelet transfusion parameters run as low as greater than 20,000/mcL to minimize the risk of spontaneous bleeding, greater than 50,000/mcL in the setting of active bleeding, or higher in the anticipation of invasive procedures. Platelet transfusions, however, are often futile because of severe consumptive coagulopathy that quickly extracts platelets from the circulation.

Although the role of heparin is controversial, especially before or after surgery, heparin is mandated if thrombus is diagnosed in DIC. In addition, fresh frozen plasma (FFP) is an important therapy in DIC. It is often used empirically, rather than waiting for tests that specifically confirm deficits in certain clotting factors. Before symptoms are present, anticoagulation in the form of low molecular weight heparin (LMWH) such as enoxaparin (Lovenox) is an accepted therapy for patients at risk of postoperative deep vein thrombosis, provided

renal function is normal (because LMWH is renally cleared). There are also recombinant versions of certain human clotting factors such as factor VIII that are available for use in significant bleeding disorders.

Because patients who require heparin therapy for DIC require around-the-clock nursing care, they should be admitted to a hospital, where they can receive 500 to 750 U/hr of heparin, according to established weight-based dosing nomograms. Platelet transfusions should be used to maintain the thrombocyte count. In addition, cryoprecipitate should be given to raise the fibrinogen level to 150 mg/dL or more.

Prevention of hemolysis caused by low levels of G-6-PD by avoiding hemolytic triggers is preferred to treating hemolysis once an attack has initiated; however, the primary care clinician must understand both prevention and treatment strategies for hemolysis resulting from G-6-PD deficiency. Avoidance of oxidant drugs, such as dapsone (Avlosulfon), quinidine (Quinaglute Dura-tabs), and sulfonamide drugs (e.g., sulfamethoxazole/trimethoprim) and environmental triggers such as naphthalene (moth balls) is critical to prevent hemolysis in patients who are G-6-PD deficient. Treatment for acute hemolytic attacks consists of discontinuing all oxidant drugs, increasing oral and/or IV fluids, and administering RBC transfusions as indicated by the Hct level. Screening for G-6-PD among patients who may require one or more oxidant drugs has become standard in the management of patients with HIV/AIDS (sulfamethoxazole/trimethoprim treatment and prophylaxis for *Pneumocystis jiroveci* pneumonia) and patients such as elderly women who are susceptible to UTIs and may require frequent antibiotic treatment.

Follow-up and Referral

If normocytic anemia is not accompanied by an abnormal reticulocyte count, then follow-up every 6 months is sufficient for most patients. Follow-up should consist of a history and physical examination, along with obtaining a CBC and reticulocyte count. The patient's records should be constructed so that these values are readily retrievable. No referral is required for these patients.

If the peripheral smear is positive for spherocytes, sickle cells, or schistocytes, the clinician should refer the patient to a hematologist for further diagnostic evaluation and management. The hematologist will create a plan of care, which the primary care clinician can co-manage. Routine follow-up with the hematologist should occur every 3 to 6 months, depending on the severity and chronicity of the hemolysis.

If the reticulocyte count is low and the clinician discovers a low WBC and platelet count, the patient is diagnosed as being pancytopenic, and referral to a hematologist is indicated. If the evaluation of a bone marrow aspirate suggests the need for treatment, then the hematologist will determine the plan of care. Normal or high WBC and platelet counts suggest the need for referrals to specialists who can treat the underlying causes of ACD or renal disease. These referrals may include gastroenterologists, hepatologists, rheumatologists, infectious disease specialists, nephrologists, and cardiologists.

Patient Education

Education should follow the pattern outlined in the section on microcytic anemia; thus, patient education should address self-care regimens and primary care management.

Self-care of normocytic anemia is similar to that for other anemias. The patient should be instructed to remain as active as possible, and, if he or she becomes fatigued, to rest. In addition, the patient must remain vigilant for the signs and symptoms of a declining Hct—malaise, fatigue, shortness of breath, tachycardia, and palpitations. If a deficiency in G-6-PD is diagnosed, the patient should be made aware of this and of all the potential oxidant drugs that could serve as triggers of hemolysis and should, therefore, be avoided.

Patient education concerning primary care management should address topics including their respective cause of normocytic anemia. Because of the chronicity of several of these causes, patients must be instructed at every visit to adhere to their treatment regimens and follow-up plan, including pertinent laboratory testing. For example, sickle cell disease patients require frequent follow-up, infectious disease prophylaxis, and assistance from their families during sickle crises. Establishing a plan for the management of sickle cell crises is an important preparatory step in anticipation of an event and is discussed in greater detail later in this chapter in the section on sickle cell anemia.

MACROCYTIC ANEMIA

Macrocytic anemia is defined as anemia with a mean corpuscular volume (MCV) equal to or greater than 100 fL. These anemic states are typically normochromic and may be normoblastic or megaloblastic with large erythroid precursors. Macrocytic anemias result most commonly from defects in DNA metabolism or changes in red blood cell (RBC) membrane structure. Macrocytic anemia has four general categories of causes: (1) vitamin B_{12} deficiency, (2) folate deficiency, (3) antimetabolite drugs such as methotrexate, and (4) miscellaneous etiologies.

Epidemiology and Causes

Both sexes are equally affected by macrocytic anemia. Prevalence is greatest among people of northern European lineage and Caucasians. Incidence increases past age 60 years, but it has been observed in all age-groups. The most common cause of megaloblastic anemia is a hereditary autoimmune disorder called pernicious anemia, which results in vitamin B_{12} deficiency, a critical component to the RBC maturation pathway and effective erythropoiesis. In contrast to other forms of macrocytic anemia, pernicious anemia affects women over men at a rate of 5:1, and onset occurs in midlife, often after age 40 years.

Pathophysiology

Vitamin B_{12} Deficiency

Pernicious anemia is a macrocytic anemia caused by a hereditary autoimmune disorder in which destructive antibodies are directed against intrinsic factor, a 45-kDa protein produced by gastric parietal cells that binds to dietary vitamin B_{12} (cobalamin) during the digestion and absorption of nutrients and is critical to DNA synthesis and RBC maturation.

Under normal conditions, dietary vitamin B_{12} is cleaved from carrier proteins in the acidic environment of the stomach by the protease pepsin. However, it is then rapidly bound by cobalamin-binding factors known as R-proteins, which are found in gastric secretions and the saliva. As these complexes are not absorbable, they pass out of the stomach and into the duodenum. However, the alkaline environment produced by pancreatic proteases in the duodenum allows for the release of vitamin B_{12} from R-factor and its subsequent rapid, high-affinity binding to intrinsic factor. This newly formed vitamin B_{12}–intrinsic factor complex then binds to specific receptors for this complex (e.g., cubilin) in the ileum, where absorption into ileal enterocytes is mediated primarily by transcobalaminase II (complexes bound to transcobalaminase I and transcobalaminase III are metabolically inert).

Vitamin B_{12} is essential to the maturation of erythrocytes via the conversion of homocysteine into methionine and the demethylation of tetrahydrofolate. Demethylated tetrahydrofolate is a key component in the conversion of deoxyuridate to thymidylate and in purine synthesis involved in DNA metabolism. Anti-intrinsic factor antibodies are present in up to three-fourths of all patients with pernicious anemia and act either by blocking the binding of vitamin B_{12} to intrinsic factor or by blocking the binding of the cobalamin-intrinsic factor complex to ileal enterocyte receptors. In addition, autoantibodies produced against gastric parietal cells and pathogenic CD4+ T cells act in concert to destroy gastric parietal cells, producing a morphological change in the stomach lining known as atrophic gastritis.

A subsequent decrease in gastric acid production compounds vitamin B_{12} deficiency, as cobalamin cannot be freed from its carrier proteins in the less acidic stomach environment, thereby preventing its subsequent binding to intrinsic factor in the duodenum. Prolonged use of medications that counter gastric acid production such as histamine-2 blockers (e.g., ranitidine, famotidine, cimetidine) and proton pump inhibitors (e.g., esomeprazole, omeprazole, pantoprazole) have a similar effect. The widely used diabetic drug metformin (Glucophage) also decreases vitamin B_{12} absorption in up to one-third of patients taking this medication.

Thus, insufficient levels of vitamin B_{12} cause erythrocytes to expand in size compared with normal RBCs, thereby producing a characteristic megaloblastic anemia. In turn, pernicious anemia is characterized by a macrocytic anemia, a low serum level of vitamin B_{12}, atrophic gastritis, achlorhydria secondary to gastric atrophy, and a greater probability of other autoimmune diseases, such as hypothyroidism and vitiligo.

Normally, the complex of vitamin B_{12} and intrinsic factor is absorbed through the terminal ileum and then travels to the liver where it is stored. Studies have estimated that the liver may store up to 5000 mcg/day of vitamin B_{12}. Because the body requires no more than 10 mcg/day, liver stores of vitamin B_{12} typically last for several years before anemia ensues. Therefore, megaloblastic anemia is insidious in onset. In patients with HIV disease and liver dysfunction, both the depletion of liver stores of vitamin B_{12} and the destruction of storage sites within the liver have been identified as underlying causes of megaloblastic anemia.

Dietary deficiency of vitamin B_{12} in the typical American diet is rare because of its rich supply in animal proteins. However, because meats and dairy products are the only dietary source, vegetarians and particularly vegans (who completely avoid all meat and dairy products) may consume inadequate amounts of vitamin B_{12}. Other reasons for poor absorption include a number of mechanical causes, such as those associated with surgical GI resections (e.g., partial or total gastrectomy, resections of the terminal jejunum or proximal ileum) and Crohn's disease, which can destroy sections of the small intestine where absorption of vitamin B_{12} might otherwise occur.

Folic Acid Deficiency

Folic acid is a critical nutrient that acts in concert with vitamin B_{12} to further nuclear maturation in erythrocytes. Folate deficiency leads to decreased levels of tetrahydrofolate, an important building block of DNA. As with vitamin B_{12} deficiency, abnormal erythroid precursors deficient in folate are prone to intramedullary hemolysis within the bone marrow, leading to a characteristic anemia clinically indistinguishable from that of vitamin B_{12} deficiency. Animal models have also demonstrated that RBC precursors in folate deficiency are more prone to apoptosis or programmed cell death, although human studies are less definitive. However, in contrast to vitamin B_{12} deficiency, folic acid deficiency does not produce neurological sequelae.

Macrocytic anemia due to folate deficiency presents with a low serum folate level and a normal level of vitamin B_{12}. It is almost always related to inadequate dietary intake, although folic acid is found in citrus fruits, dark green leafy vegetables, and animal proteins. Adequate dietary intake is 50 to 100 mcg/day, except in pregnant women who need 800 mcg/day. Even in developed countries such as the United States, pregnant patients may not consume adequate amounts of folate in their diets, and folic acid deficiency increases in incidence in multigravid patients and with multigestational pregnancies.

Less common causes of folic acid deficiency are impaired metabolism and storage of folate. The liver typically stores enough folic acid as N^5-methyltetrahydrofolic acid (approximately 5,000 mcg) to serve the body's needs for several months, given the body's use of 50 to 100 mcg/day, as long as hemolysis and increased erythrocyte production are not issues, as in sickle cell anemia. There are many causes of impaired folate metabolism and hepatic storage, including chronic alcohol use resulting in decreased enterohepatic cycling and drugs such as phenytoin (Dilantin), sulfamethoxazole/trimethoprim (Bactrim), methotrexate, and oral contraceptives, which contribute to folic acid deficiency via a variety of mechanisms.

Impaired absorption of folic acid is another cause of folic acid deficiency. Tropical sprue, GI resections, Crohn's disease, and a few intestinal parasitic infections are the primary causes of impaired folic acid absorption. Unlike vitamin B_{12}, however, folic acid can be absorbed along the entire GI tract.

Antimetabolite Drugs

Any chemical that serves as a potential inhibitor of DNA or RNA synthesis is a potential cause of macrocytic anemia. Drugs such as hydroxyurea (an inhibitor of ribonucleotide reductase), the antiviral zidovudine, and the chemotherapies methotrexate, azathioprine, and 6-mercaptopurine can all cause macrocytosis, with methotrexate being best known for leading to anemia. Methotrexate interrupts purine metabolism in the liver by preventing molecular binding with dihydrofolate reductase, an enzyme required for the storage of folic acid. Thus, less folic acid can be stored, thereby leading to a reduction in serum folate levels.

Miscellaneous Etiologies

Various unrelated causes for macrocytic anemia include thiamine- or pyridoxine-responsive anemias and Lesch-Nyhan syndrome. Macrocytic anemia may also be caused by chronic alcoholism (ingestion of at least 80 g of alcohol per day), possibly via changes in RBC membranes caused by the alcohol breakdown product acetaldehyde. In addition, liver disease may lead to macrocytic anemia, possibly via increased lipid deposition in RBC membranes, and myelodysplasia, which causes a normoblastic (albeit macrocytic) anemia.

Clinical Presentation

Subjective

Patients with macrocytic anemia typically complain of stomatitis, glossitis, nausea and anorexia, diarrhea, peripheral neuropathies, and malaise if they are deficient in vitamin B_{12}. Macrocytic anemia caused by folate deficiency, drug toxicity, impaired folate storage in the liver, and miscellaneous etiologies will cause similar symptoms as vitamin B_{12} deficiency, with the exception of peripheral neuropathy, which does not occur in folate deficiency but is part of the symptom constellation associated with chronic vitamin B_{12} deficiency.

Objective

The clinician may note any of the following findings: pale or icteric mucosa, a dry and cracked oropharynx, a thickened and smooth-surfaced tongue, tachycardia, a systolic ejection murmur, tachypnea, and diffuse abdominal tenderness without organomegaly. Long-standing vitamin B_{12} deficiency may also result in a variety of neurological signs and pathological manifestations, including peripheral neuropathy in a glove and stocking distribution on the distal extremities, increased or decreased deep tendon reflexes, impaired position sense, diminished vibratory sensation in the lower extremities, a positive Romberg sign, a variable Babinski sign, and pronounced irritability or other mental status changes, including even frank dementia in severe cases. Of the megaloblastic anemias, neurological signs related to myelin defects in the dorsal and lateral spinal columns present only in vitamin B_{12} deficiency and not with isolated folic acid deficiency.

Diagnostic Reasoning

Diagnostic Tests

Initial testing involves confirmation of a megaloblastic macrocytic anemia on the peripheral blood smear. Expected findings include anemia and an elevated MCV (greater than 100 fL). The MCHC should be within normal limits, as the anemia is usually normocytic. It is important to note that the pathological processes that underlie macrocytic anemia may occur simultaneously with causes of microcytic or normocytic anemia, such as iron deficiency and thalassemia (microcytic) or anemia of chronic disease (normocytic). In these mixed anemias, MCV may actually be within a normal range, and the RBC indices are difficult to predict, typically requiring referral to a hematologist.

Reticulocytes may be either low or normal in number, depending on the cause of the anemia. If the cause of macrocytosis is a deficiency in vitamin B_{12}, then the serum level should be less than 0.1 mcg/mL and hypersegmented neutrophils will be present on the peripheral smear. Macroovalocytes will also be evident. In the case of folic acid deficiency, the serum folate level will typically be less than 3 ng/mL, although levels may vary in patients with chronic deficiency. Even one meal can normalize folate levels in a person with true deficiency. However, homocysteine and methylmalonic acid levels can distinguish between these two etiologies, with both values being elevated in vitamin B_{12} deficiency, whereas only homocysteine levels are elevated in folic acid deficiency. Common to both etiologies is a high serum iron level and findings consistent with mild hemolysis including low haptoglobin, elevated LDH, and mildly increased unconjugated bilirubinemia.

The Schilling test is rarely performed today but was classically used to diagnose GI malabsorption as a common etiology of vitamin B_{12} deficiency. The Schilling test uses orally administered radiolabeled vitamin B_{12} to measure the ability of the small intestine to absorb vitamin B_{12}, which is subsequently secreted in the urine. It involves a two-stage 24-hour urine collection that needs to be done before any radioactive scans are performed, as the material used in these scans may confound measurements of the radiolabeled vitamin B_{12}.

When diagnosing iatrogenic etiologies of macrocytic anemia, it is important to recognize that blood levels of specific drugs such as the antimetabolite methotrexate may vary according to individual laboratory standards. Additional tests may be indicated to assess for changes in liver function that may also be impaired by drugs, as reflected in elevations of hepatic transaminases (alanine aminotransferase [ALT] and aspartate aminotransferase [AST]), bilirubin, and lactate dehydrogenase (LDH). Urobilinogen may also be identified in the urinalysis.

Differential Diagnosis

The differential diagnoses for macrocytic anemia include all of the causes identified in this section: vitamin B_{12} deficiency, folate deficiency, antimetabolite drugs, and miscellaneous causes. In addition, the differential diagnosis includes anemia of chronic liver disease and myelodysplasia.

A thorough patient history often leads the clinician to the cause of the anemia even when diagnostic laboratory results might be equivocal. For example, if the patient is pregnant, then the clinician should suspect folate deficiency over vitamin B_{12} deficiency. In addition, megaloblastic anemia due to vitamin B_{12} or folate deficiency is also often characterized by thrombocytopenia and neutropenia due to defects in megakaryocyte and myeloid precursors. This same pancytopenia is also commonly seen in the various types of myelodysplasia.

Management

A general approach to the patient with macrocytic anemia should address the cause of the anemia, as well as the downstream effects of anemia itself. Thus, the goal is to correct or ameliorate the underlying cause while addressing clinically significant sequelae of the anemia. For example, it might be appropriate to deliver supplemental vitamin B_{12} or folate while providing RBC transfusions as needed. Transfusion is rarely indicated for macrocytic anemia, other than in severe cases, and the clinician must consider that these patients are often elderly and unable to handle large-volume transfusions, due to the risk of fluid overload.

If the cause of vitamin B_{12} deficiency anemia is not pernicious anemia (malabsorption), then the clinician may follow these guidelines for oral supplementation: prescribe up to 1,000 mcg/day of oral cobalamin until normal serum levels of vitamin B_{12} are achieved (usually 6–12 weeks after initiation of therapy). High doses such as these may even be effective in some cases of pernicious anemia, despite the lack of intrinsic factor, given the presence of an additional lower-efficiency GI absorption system that works independently of intrinsic factor and does not require a functional terminal ileum. Daily oral therapy, however, requires a high degree of patient commitment and compliance.

Thus, in most cases of pernicious anemia, and especially if neurological symptoms are present, more aggressive therapy is warranted. In these cases, the preferred route of administration is parenteral with 1,000 mcg of vitamin B_{12} intramuscularly (IM) daily for the first 7 days, then weekly for 1 month, followed by once monthly for life. Lower parenteral doses of 100 mcg have been advocated, although toxicity related to vitamin B_{12} overtreatment is not typically observed, as excess vitamin B_{12} is excreted in the urine. After depleted stores are replaced, patients may transition to oral, sublingual, or nasal preparations of vitamin B_{12} for ease of administration; however, serum levels of vitamin B_{12} and methylmalonic acid should still be followed periodically to ensure compliance with these medication regimens.

For folic acid deficiency, the clinician should prescribe 1 mg/day of supplemental folic acid. The effects of therapy should be reassessed after 2 to 3 months. It is critical to understand that treatment of folic acid deficiency will reverse many of the hematological defects shared with vitamin B_{12} deficiency; however, the neurological manifestations of cobalamin deficiency will progress and may be devastating if treated inappropriately with folic acid supplementation alone. Thus, it is important to rule out vitamin B_{12} deficiency before starting a folate replacement regimen, and if empiric therapy must be started before testing is available, patients should be treated with both folic acid and vitamin B_{12} supplements. Patients suspected of having either condition who do not respond with a significant reticulocytosis after 1 week of therapy should be evaluated further for a mixed anemic process originally masked by the megaloblastic manifestations.

It is also important to evaluate serum potassium levels in profoundly anemic patients once they start treatment, as increased erythropoiesis will markedly increase potassium utilization. As a result, as the anemia corrects, these patients may become significantly hypokalemic, requiring oral potassium repletion.

If the cause of the macrocytic anemia is an antimetabolite drug or other iatrogenic drug toxicity, the patient should discontinue all suspected drugs. Laboratory tests for elevated drug levels should be ordered; the liver transaminases (AST, ALT) should also be monitored for evidence of liver dysfunction, as well as coagulation times (PT/INR and PTT) as an indication of hepatic synthetic function. For patients with macrocytic anemia from miscellaneous causes, the individual etiologies and underlying disorders must be addressed.

Follow-up and Referral

Follow-up of the patient with vitamin B_{12} deficiency involves assessing the severity of the anemia. Serial CBCs and monitoring of vitamin B_{12} levels are required on a monthly basis after starting oral cobalamin therapy. If parenteral therapy is initiated, more frequent testing is required, such as once every 2 weeks. Additional testing includes liver function tests (LFTs). If LFTs reveal elevated transaminase levels before cobalamin replacement is started, then their course should be evaluated every 2 to 4 weeks. If liver enzyme levels rise after the start of therapy, more frequent testing might be required, as well as additional diagnostic testing for evolving hepatotoxicity.

Referral for vitamin B_{12} deficiency is often not required unless the diagnosis is pernicious anemia or the patient suffers from a particularly difficult to diagnose mixed anemic process. A hematologist and gastroenterologist should be consulted in the event of pernicious anemia, as these patients are at greater risk for gastric cancer, carcinoid tumors, and colorectal carcinoma. Thus, stool should be monitored periodically for occult blood as a trigger for colonoscopy. In addition, the hyperhomocysteinemia that accompanies vitamin B_{12} or folic acid deficiency is a risk factor for atherosclerosis and venous thromboembolism and should be addressed as an independent risk factor.

Follow-up of the patient with folic acid deficiency consists of a CBC and serum folate level drawn 2 to 3 months after starting therapy. The problem should be corrected by this point if the patient has adhered to the daily regimen of folic acid replacement. No referrals are indicated unless the anemia does not resolve.

Patient Education

Patients need to learn how to enrich their diets with folic acid and vitamin B_{12}. Increasing dark green leafy vegetables in one or two meals daily can support supplements and other therapies. In addition, patients should be educated about the basic signs and symptoms of macrocytic anemia so that they can self-monitor the effectiveness of therapy and possible recurrence of the anemia.

SICKLE CELL ANEMIA

Sickle cell anemia is an autosomal recessive disorder. The disease is caused by a point mutation in the DNA sequence of the gene for the beta-hemoglobin chain (termed the *hemoglobin S gene*), resulting in a marked hemoglobinopathy in which intracellular hemoglobin molecules form abnormal polymers that cause gross sickling of RBCs under hypoxic conditions. It is therefore diagnosed by the detection of sickled (scythe-shaped) cells on peripheral blood smear, a positive familial history, recurrent painful episodes of vaso-occlusive pain, and a pattern demonstrating mutated hemoglobin S on a hemoglobin gel electrophoresis profile.

Epidemiology and Causes

Sickle cell anemia and sickle cell trait are inherited conditions that occur most commonly in people of West African descent. The disease has also been identified in persons of European or Middle Eastern ancestry, although these cases are extremely rare. The disease is not prevalent among persons of Asian or Pacific Island descent.

Initial symptoms appear within the first year of life for those born with sickle cell anemia. Given the perinatal manifestations and associated comorbidities, prenatal screening is now available for at-risk couples, consisting of DNA analysis from fetal cells. The procedure should be offered to these couples as part of their prenatal counseling. If both the father and mother have sickle cell trait and each carry one copy of the mutated hemoglobin S gene, their offspring have a one in four chance of developing true homozygous sickle cell anemia. In more than 40 states, newborns undergo universal neonatal screening for hemoglobinopathies, including Hgb protein electrophoresis screening for sickle cell disease, the thalassemias, and other variant hemoglobinopathies.

Autosomal recessive genes for hemoglobin S are distributed equally between both sexes. Individuals who are homozygous for the hemoglobin S gene will develop sickle cell anemia and experience recurrent sickle cell crises throughout their lives. In addition, overall life expectancy is typically reduced to between 40 and 50 years of age. Those who are heterozygous for the hemoglobin S gene are said to carry the sickle cell trait, which is asymptomatic because hemoglobin A accounts for more than half of their hemoglobin. About 8% to 10% of persons of West African descent in the United States carry the sickle cell trait. One in 400 to 500 West African descendants suffers from sickle cell anemia, whereas up to 2% of all African Americans are affected.

Pathophysiology

The cause of sickle cell anemia is a point mutation in the genetic sequence of the beta chain gene of hemoglobin which results in the replacement of glutamic acid by valine at the N-terminal amino acid position 6 of this protein chain. The substitution of valine leads to the production of hemoglobin S, which is poorly soluble and prone to rigid polymerization when in its deoxygenated state. This typically occurs under conditions of physiological stress, such as physical overexertion, muscle tissue ischemia causing lactic acidosis, dehydration, infection, or exposure to cold environmental temperatures. However, the majority of acute sickling events have no identifiable cause.

Polymerized deoxyhemoglobin S takes on a rope-like form, aligning itself with other polymerized strands and transforming erythrocytes into a rigid, sickled, crescent-like shape. In turn, these sickled erythrocytes regularly become lodged in the microvasculature of various organs and bodily tissues, causing small but highly symptomatic infarcts throughout the body. Sickled cells adhere rigidly

to the inner membranes lining small blood vessels, inducing intimal hyperplasia that contributes to the obstruction of free blood flow in the smaller capillaries, as well as inducing RBC hemolysis due to this adherence to the inner vessel wall. RBCs in patients with sickle cell disease have an average life span of 17 days, versus the normal length of 100 days.

Sickled cells become lodged in the microvasculature as small thrombi. Once the thrombi are situated against the vascular membrane, they attract plasma proteins, leukocytes, and platelets, creating an occlusion to blood flow. This inflammatory process escalates, as ischemia to the surrounding tissue unfolds. Ischemic injury and infarcts cause pain as perimeter tissue is increasingly starved for oxygen and other nutrients. The rate of sickling increases as tissues become more hypoxic and acidotic. Erythrocytes, with or without hemoglobin S, that are lodged in and around the microthrombi lose intracellular water, which results either in hemolysis occurring before RBC sickling or in escalated sickle cell formation and plasma hyperviscosity. As hypoxia and acidosis increase, more erythrocytes begin to sickle, and nearly all sickled cells in the area of the thrombus will eventually hemolyze.

The body attempts to compensate for this resultant anemia (which is typically normocytic, unless also associated with iron deficiency or a form of thalassemia) with expansion and upregulation of the bone marrow. This has several pathological implications. Chronically elevated white blood cell (WBC) counts result in the production of inflammatory cytokines, which further complicates vaso-occlusive crises. The additional blood flow also leads to cardiomegaly and eventual high-output congestive heart failure. This results in greater metabolic and caloric requirements as the affected individual ages, leading to stunted growth and lower than average adult weight if the condition is poorly controlled and nutritional requirements are not met with dietary supplements.

Anemia is also worsened by impaired production of the RBC growth factor erythropoietin (which is normally produced in the kidney), owing to the presence of progressive renal disease from microinfarction of the vasa recta capillaries in the renal medulla. Hemolysis results in hyperbilirubinemia, which predisposes to the development of pigmented cholelithiasis (gallstones). In turn, cholecystectomy is the most common surgical procedure in patients with sickle cell anemia.

The formation of microthrombi occurs in many parts of the body but is especially prone to occur in the chest, vertebrae, and long bones of the legs. In pediatric patients, swelling, tenderness, and inflammation of the hands and feet (especially the fingers and toes, termed *dactylitis*), known as hand–foot syndrome, is a common manifestation before age 2 years. Leg ulcers are also common, typically affecting the skin over the lateral and medial malleoli and subject to infection by *Staphylococcus aureus, Pseudomonas, Streptococcus* species, or *Bacteroides.* Bone manifestations also occur. As ischemia progresses due to vaso-occlusion, the affected bone eventually infarcts and becomes susceptible to osteomyelitis by *Salmonella* species and, less commonly, *Staphylococcus aureus.* Severely debilitating noninfectious aseptic necrosis of the hip or shoulder joints may also occur due to vaso-occlusion of the arterial supply to the femoral or humeral heads, resulting in eventual loss of the entire joint.

Organs including the heart, liver, penis, and kidney also tend to be affected by vaso-occlusive crises, particularly during childhood and adolescent years. Priapism (painful and sustained penile erection often lasting several hours) is an emergent condition requiring inpatient treatment with hydration, transfusion, and in some cases surgical intervention to release engorged blood, as ischemia of the penis may lead to tissue necrosis. Retinopathy and its associated complications caused by microvascular ischemia increase in prevalence with age as well, including proliferative retinopathy, retinal hemorrhage and detachment, as well as retinal artery occlusion. Such changes may begin in childhood, and in turn, many patients with sickle cell anemia become blind before age 40 years.

Splenic sequestration results when large numbers of sickled erythrocytes become lodged in an engorged, functional spleen during early childhood, resulting in severe anemia and potentially fatal hypovolemic shock, carrying a mortality rate of 10% to 15%. Because this condition tends to be recurrent, splenectomy is often performed after the first episode. Later in adult life, vaso-occlusive episodes in the spleen lead to autoinfarction, with replacement of splenic parenchyma by fibrotic tissue, resulting in functional asplenia. Although this obviates the occurrence of splenic sequestration syndrome, splenic autoinfarction results in increased susceptibility to infection by encapsulated organisms, such as *Streptococcus pneumoniae* and *Haemophilus influenzae.*

In addition to splenic sequestration, severe anemia may also result from aplastic crises, in which patients experience extreme suppression of bone marrow erythropoiesis. This is often a postinfectious phenomenon that may follow infection with Epstein-Barr virus, *Streptococcus pneumoniae, Salmonella,* and especially parvovirus B19, seen classically in pediatric patients, which directly infects erythroid progenitors. The bone marrow is also susceptible to infarction, which may further exacerbate the chronic anemia.

Sickle cell disease patients are at risk for other life-threatening conditions, as well. In acute chest syndrome, bilateral pulmonary infiltrates occur with fever and significant pleuritic chest pain, resulting in a "splinting" pattern of respirations that consists of shallow breaths of suboptimal volume, which leads to progressive atelectasis and hypoxia. This condition may be triggered by vaso-occlusion, pulmonic infection, in situ thrombus formation with pulmonary infarction, or pulmonary emboli associated with bone marrow infarction (including fat emboli). Respiratory failure may eventually occur if the condition is not treated aggressively with IV hydration, RBC transfusion, pain management to relieve respiratory

splinting, supplemental oxygen, and antibiotics for documented infection (e.g., community-acquired pneumonia or less commonly bacteremia).

Another serious complication of sickle cell disease is the tendency for cerebrovascular accidents (e.g., strokes, transient ischemic attacks). In fact, a significant percentage of these patients will experience strokes before reaching adulthood, some repeatedly, but with the first episode most commonly occurring between 2 and 8 years of age. Myocardial infarction may also occur in the presence or absence of documented coronary artery disease, believed to be due either to occlusion or to severe hypoxemia resulting from the reduced oxygen-carrying capacity of the blood.

Clinical Presentation

Subjective

Subjective findings are associated with the severity of the anemia and with pain. Pain is evident only when there is a crisis, but the subjective findings of anemia may be apparent without concurrent crisis. In brief, the subjective findings of sickle cell anemia are similar to those of other types of anemia.

The cardinal subjective symptom of a sickle cell crisis is pain. Pain appears suddenly in the back, chest, abdomen, or extremities, which patients typically characterize as excruciating. It may last for several hours or several days and is unrelieved by rest or change in body position. Massaging the site is of little value in relieving pain. Other subjective findings may include nausea, anorexia, light-headedness, significant anxiety or panic, heart palpitations, and shortness of breath.

Objective

The patient may present with a low-grade fever (less than 101.3°F [38.5°C]) during and preceding a sickle cell crisis. Additional symptoms may include point tenderness and guarding at the sites of pain, pinpoint pupils, inability to follow commands, photophobia, tachycardia and systolic murmur, tachypnea, diminished respiratory excursion, hepatomegaly, a nonpalpable spleen (due to infarction and fibrosis), and pretibial ulcers.

Outside of a sickle cell crisis, the clinician may note characteristic physical findings resulting from chronic bone marrow expansion including a lengthened tower-shaped skull, frontal bossing of the forehead, and fish-mouth deformities of the vertebrae. During the objective examination, the clinician may note chronic effects of hemolysis, such as jaundice or a sallow color to the skin. The patient may appear older than his or her stated years. Personality traits characteristic of patients who have lived with a chronic debilitating disease may also be present.

Diagnostic Reasoning

Diagnostic Tests

Initial testing involves a CBC and a peripheral blood smear. It should be clear, however, that adults with sickle cell disease do not present de novo. They are typically diagnosed soon after birth and learn to cope with sickle cell crises even as they face delayed physical and psychological maturation. Postnatal infant screening in the United States, therefore, typically includes a CBC and peripheral blood smear.

Sickled cells will constitute 5% to 10% of the peripheral blood smear in most patients. The elevated reticulocyte count (greater than 10% of the total erythrocyte count) is characteristically accompanied by the presence of Howell-Jolly bodies, which are small remnants of nuclear material from hemolyzed erythrocytes that reflect hyposplenia from autoinfarction, and target cells, which are erythrocytes with a deeply stained core surrounded by a lighter-stained margin that resemble a target with a bull's eye. The clinician should also expect the WBC count to be elevated to 12,000 cells/mcL or greater, especially during and soon after a sickle cell crisis.

Further testing may include an indirect bilirubin level, which will be elevated after a sickle cell crisis due to hemolysis. Conversely, haptoglobin, a glycoprotein that binds free hemoglobin released from hemolyzed erythrocytes, will be significantly decreased, as it cannot be replaced quickly enough after a severe hemolytic episode.

Differential Diagnosis

The differential diagnosis for sickle cell anemia includes anemia resulting from other causes, sickle thalassemia, hemoglobin C disorders, nonspecific abdominal pain, UTI, poisoning, and diabetes mellitus. Each of these mimics some or all of the subjective and objective findings from the history and physical examination.

Sickle cell anemia is differentiated from sickle thalassemia by the MCV. The MCV should be low if there is any combination of sickle cell anemia and beta-thalassemia (a microcytic anemia) and normal if only sickle cell anemia is present. A combination of sickle cell anemia with alpha-thalassemia may cause a slower rate of sickling due to a reduced MCHC in the erythrocytes caused by the alpha-thalassemia. Therefore, the sickle cell crises in these patients are typically less damaging and possibly less painful than those in patients without this combination.

Hemoglobin C disorders are differentiated by a much milder onset and course of anemia than sickle cell anemia. Indeed, some patients with hemoglobin C disorders may pass their lives without any crises caused by the disorder. The underlying pathology is differentiated by the substitution of lysine for valine at amino acid position 6 of the beta-globin chain. Definitive differentiation between these disorders comes with a peripheral blood smear, which reveals rectangular crystals of hemoglobin C. With sickle cell/hemoglobin C disease (sickle C disease or SC disease), adult patients may still be prone to splenic sequestration crises, as their spleens typically do not autoinfarct and fibrose. Sickle beta-thalassemia may also be a milder, but nonetheless significantly morbid, condition compared

with homozygous sickle cell disease. It is usually microcytic. If there is no other production from the other beta-globin gene (*sickle beta thal*^{0}), these patients will be the most symptomatic. Alternatively, reduced production from the other beta chain gene (*sickle beta thal*$^+$) gives a milder condition, as there is still some functional hemoglobin A present. There are also rarer forms of doubly heterozygous hemoglobinopathies when hemoglobin S is combined with hemoglobins A, G, or O.

Nonspecific abdominal pain that mimics sickle cell anemia will have none of the characteristic laboratory markers of sickle cell anemia, other than possibly an elevated WBC count or a low Hct. Sickle cell anemia in crisis usually also manifests with extra-abdominal pain.

Urinary tract infection is linked to sickle cell anemia as these patients experience UTIs more frequently than other individuals. A UTI can present with excruciating abdominal pain and referred pain to the back and chest. The WBC count is typically elevated, and there could be a low-grade fever with either frank or microscopic blood present in the urine. Thus, the distinguishing differences between isolated cases of UTI and those associated with sickle cell anemia include the history and laboratory markers of sickle cell anemia.

Poisoning with certain agents may present with hypoxemia and acidosis that are similar to what is observed in a sickle cell crisis. For example, ingestion of strong alkalines, such as those contained in household cleaning compounds, causes nausea, vomiting, acute abdominal pain, and dyspnea. The history and CBC should aid in the rapid and almost certain differentiation of poisoning from sickle cell anemia.

Finally, diabetes is in the differential because of the similarities in blood chemistries, such as renal and hepatic function tests, an acidic blood pH, urinalysis, and physical examination. Again, as is the case with the other differential diagnoses, the history, CBC, and peripheral blood smear should readily differentiate these etiologies, even in an emergent situation.

Management

Initial Management

Folic acid (Folvate) supplementation of 1 mg/day by mouth is indicated, along with a diet that is rich in the complex B vitamins and vitamin C. Significant rehydration is needed as a part of management and is a key to reversing sickle cell crises. It aids in keeping the blood pH normal, thereby preventing acidosis with the sequela of sickling. Hydroxyurea, a chemotherapeutic agent, is a common treatment to increase hemoglobin F levels, an infant hemoglobin form with a higher affinity for oxygen than hemoglobin A or S, which allows for less hypoxemia and less sickling of RBCs. In turn, it reduces the frequency of painful crises.

Although packed RBC transfusions may be indicated in sickle cell anemia treatment to decrease the fraction of hemoglobin S prone to polymerization, especially in children, they are less commonly used in adults and must always be weighed against the risks of infection (especially with hepatitis C), transfusion reactions, and iron overload. Anemia with Hgb of less than 7 has been associated with a greater risk of stroke, severe vaso-occlusive episodes, acute chest, and death in children. Chronic transfusions, however, lead to iron overload and iatrogenic hemochromatosis, which can destroy solid organs such as the liver and adrenal glands. Exchange transfusion may be used when the clinical manifestations of sickle cell anemia (e.g., acute chest, priapism) are severe and refractory to initial treatment, in order to decrease hemoglobin S to less that 50% of total hemoglobin. If osteomyelitis is confirmed with magnetic resonance imaging (MRI), which is the diagnostic imaging test of choice, then antibiotic therapy is required. *Salmonella* predominates in osteomyelitis of sickle cell patients over *Staphylococcus aureus,* which is seen more commonly in non–sickle cell patients. Dactylitis (painful swelling of the feet and hands during the first several years of life in children with sickle cell anemia) requires urgent treatment, as do aseptic necrosis of the hip and priapism.

Subsequent Management

Management of sickle cell crises often requires hospitalization. General goals include symptomatic control of pain with opioid-type drugs, IV rehydration, oxygen supplementation to reestablish normal or near-normal oxygen tension and to prevent or control acidosis, and vigilance against possible damage to vital organs such as the heart, liver, and kidneys.

Given the increased risk of infection by encapsulated organisms (*Streptococcus pneumoniae, Haemophilus influenzae*) in sickle cell anemia patients, prophylactic penicillin should be used in children 2 months to 5 years of age and lifelong in children who have had splenectomies secondary to splenic sequestration crises. In addition, patients should receive all age-appropriate immunizations, including antipneumococcal vaccines (7-, 13-, and 23-valent forms are available), Hib vaccine, influenza vaccine, and meningococcal vaccine. Parents or other family members should also be taught how to assess for splenic size so that they can recognize the early signs of splenic sequestration syndrome in affected individuals.

Given the chronicity of sickle cell anemia and the propensity for recurrent sickle cell crises, there is a phenomenon of learned helplessness, narcotic addiction, and drug-seeking behavior that may develop in sickle cell disease patients who are afflicted with chronic pain. These are critical conditions that must be considered when developing a treatment plan for the management of sickle cell anemia, because they can significantly affect the patient's capacity for effective self-care.

Follow-up and Referral

Follow-up visits with sickle cell anemia patients should occur every 3 months during periods of stability when

they have not been in crisis for 6 months or more; however, the frequency and duration of crises may increase the required frequency of follow-up examinations with appropriate laboratory evaluations. Routine clinical markers to be assessed include a CBC, fasting blood sugar, electrolytes, renal and liver function studies, and urinalysis. Annual or biannual 12-lead electrocardiograms (ECGs) are also necessary to rule out cardiac pathology.

Every patient with sickle cell anemia should be evaluated at least twice per year by a hematologist. In addition, retinal examinations should be performed by an ophthalmologist on an annual basis. Retinal photographs may be required once retinopathies have been diagnosed. Other referrals become evident as organs start to fail; therefore, cardiologists, gastroenterologists, nephrologists, orthopedic surgeons, and general surgeons may be enlisted as necessary.

Patient Education

Education should focus on the patient's maturation and personality development, within the context of living with this chronic disease. Secondary gains (in the form of extra attention) that the patient received due to the illness early in life may result in the patient regressing to childish behaviors and coping mechanisms during sickle cell crises. In turn, these patients often present with poor coping skills. Patients who exhibit such regressive behaviors should understand that friends, acquaintances, and particularly prospective life partners and spouses may be offended by these behaviors. The patient, therefore, should be educated in ways that provide anticipatory guidance to others who witness such events.

Self-care behaviors that may prevent sickle cell crises should be reinforced regularly. These include adequate hydration, folic acid supplementation, avoidance of situations that tax the patient's physical and emotional stamina, and adequate sleep and rest as part of everyday activities. Additional self-care actions include participation in peer support groups, pregnancy prevention unless the patient is prepared for the possibility of additional sickle cell crises during pregnancy and lactation, involvement in prenatal counseling and testing of the fetus for DNA evidence of sickle cell disease, and avoidance of alcohol and adrenergic dietary elements, such as caffeine, that can cause diuresis and dehydrate the body.

Self-care also involves the patient's own spiritual practices. Spiritual beliefs and practices provide a unique contribution to the course of disease adaptation. In light of the early death of sickle cell anemia patients compared with the general population, spiritual practices may enhance personal acceptance of the disease. In addition, spiritual practices can marshal inner resources to resolve feelings of hopelessness and helplessness during sickle cell crises.

Because sickle cell disease is a lifelong condition, problems unique to children and adolescents with chronic disease are abundant. There is an important transition period in which the specialty care of these patients typically transitions from a pediatric to an internal medicine setting. Thus, these patients are often shocked to find that they are treated differently in an adult medicine setting, with more stringent requirements for adhering to a chronic treatment plan—especially regarding patient compliance and its relationship to the emergent treatment of chronic pain exacerbations. Peer support groups can be particularly helpful for these patients.

POLYCYTHEMIA

Polycythemia involves an increase in erythrocyte volume, which results in an increase in blood viscosity. The disorder may be either relative or absolute. A hematocrit (Hct) greater than 51% in women and 54% in men is characteristic. The term *polycythemia* is somewhat misleading. It means too many cell lines (*poly* = "many"; *cythemia* = "cell lines"), in general, and not just too many erythrocytes, in particular. Nevertheless, the name is associated with erythrocytes only.

Epidemiology and Causes

The incidence of polycythemia increases with age. It remains more prevalent in older men (older than age 70 years) than in women of similar age by a 2:1 ratio. On average, the incidence is 1.9:100,000. These statistics have remained stable for the past 60 years, according to three retrospective analyses. The incidence and prevalence of polycythemia increase among persons who reside at high altitudes, given the body's compensation for the relatively lower environmental oxygen tension through the upregulation of erythropoiesis.

Causes of relative polycythemia include decreased fluid intake, increased fluid loss, and extravasation of fluids. Absolute polycythemia, on the other hand, may be caused by either primary or secondary mechanisms. Primary polycythemia involves the proliferation of stem cells independent of erythropoietin and is termed *polycythemia vera.* In contrast, causes of secondary absolute polycythemia include Cushing's syndrome, erythropoietin-secreting tumors, and chronic hypoxia, such as that associated with residence at high altitudes and carboxyhemoglobinemia.

Pathophysiology

Relative Polycythemia

Relative polycythemia is a condition in which there is a decrease in plasma volume while the total number of circulating erythrocytes remains the same. The underlying pathology is almost always dehydration, which may be either acute or chronic. Acute dehydration is associated with vomiting, burns, crush-type injuries, and fevers, whereas chronic dehydration is an outcome of long-term use of diuretics, such as furosemide. Another chronic cause of dehydration is decreased oral fluid intake, a

condition frequently encountered in older adults. Cigarette smoking, though an important cause of absolute polycythemia, is also known to decrease plasma volume. Interestingly, this reduction reverses on cessation of smoking (with a reduction in Hct of 4 or more percentage points in just a matter of days). Terms such as *pseudo-* or *spurious polycythemia, stress erythrocytosis,* and *Gaisböck's disease* have all been used to label chronic states in which plasma volume is reduced while Hct and hemoglobin (Hgb) are elevated.

Absolute Polycythemia

Absolute polycythemia is a condition in which the actual numbers of circulating erythrocytes are increased with a corresponding increase in measured red blood cell (RBC) mass. (One exception is *inapparent polycythemia* in which the increase in RBC numbers is counterbalanced by an increase in plasma volume, often masking the polycythemia on standard blood tests.)

Absolute polycythemia may be divided into primary and secondary categories. Many diagnosticians consider primary disease to be polycythemia vera, which is a chronic myeloproliferative disorder caused by an abnormally dividing pluripotential stem cell that leads to a clonal erythrocytosis that is erythropoietin independent, as well as a variable leukocytosis (increased myelocytes) and thrombocytosis. The molecular defect underlying polycythemia vera has yet to be fully characterized, but aberrant cell signaling pathways involving tyrosine kinases, tyrosine phosphatases, insulin-like growth factor–1, and transcriptional dysregulation have all been suggested. Interestingly, however, the defect does not appear to be in the erythropoietin–erythropoietin receptor pathway, because erythropoietin levels are typically low in these patients.

Physiologically, erythropoietin has many functions: (1) stimulating mitogenicity (cell division) of progenitor cells, (2) protecting progenitor cells from apoptosis, and (3) inducing specific proteins involved in the differentiation and terminal maturation of erythrocytes, such as ankyrin and spectrin (structural membrane proteins) and the oxygen-binding globin chains. In turn, primary polycythemia may result from congenital or acquired mutations in erythroid progenitor cells that affect the erythropoietin–erythropoietin receptor pathway. For example, primary familial and congenital polycythemia (PFCP or benign erythrocytosis) is an autosomal dominant disorder thought to result from mutations in the erythropoietin receptor that lead to increased responsiveness of erythrocytes to this growth factor. However, the specific molecular defect remains undefined in many patients.

There are several causes of secondary absolute polycythemia—chronic hypoxia, carboxyhemoglobinemia, Cushing's syndrome, chronic corticosteroid use, erythropoietin-secreting tumors, and cardiopulmonary diseases (the most common cause of secondary polycythemia), which decrease oxygen saturation or diminish renal blood flow. Acquired forms include polycythemia due to the chronic hypoxia associated with prolonged high-altitude living, where the partial pressure of ambient oxygen is decreased. Carboxyhemoglobinemia is a condition associated with tobacco use, in which carbon monoxide–containing cigarette smoke increases carboxyhemoglobin (hemoglobin bound stably to carbon monoxide) levels, preventing the binding of oxygen to hemoglobin molecules and resulting in a leftward shift in the hemoglobin dissociation curve. This shift reflects a decrease in oxygen delivery to the tissues and, in turn, is compensated by polycythemia. Cushing's syndrome (abnormal corticosteroid production arising from the pituitary gland [ACTH overproduction], adrenals, or a hormonally active tumor [cortisol overproduction]) and chronic exogenous steroid use (either corticosteroids or anabolic steroids) are erythrogenic and, when left unchecked, may lead to polycythemia. In addition, the act of blood doping, in which RBC infusions are administered before sporting events by some athletes to increase oxygen-carrying capacity, is an important iatrogenic source of polycythemia. Finally, erythropoietin-secreting tumors tend to be located in the kidneys (e.g., renal cell carcinoma), liver (e.g., hepatocellular carcinoma, hepatoma), uterus (e.g., leiomyomata or fibroids), or central nervous system vasculature (e.g., hemangioblastoma).

Although these congenital forms are quite rare, secondary polycythemia may also be congenital, caused by inborn mutations that alter the oxygen affinity of hemoglobin, leading to decreased oxygen delivery to peripheral tissues with resultant hypoxemia. These include mutations in the alpha- and beta-globin genes that cause a marked increase in oxygen affinity with compensatory polycythemia, congenital methemoglobinemia in which the iron moiety in hemoglobin is trapped in the oxidized ferric form and therefore unable to bind oxygen (mutations in cytochrome b5 reductase prevent reduction of ferric ions back to the oxygen-binding ferrous form), and mutations that lower levels of 2,3-bisphosphoglycerate, a key molecule involved in oxygen delivery to peripheral tissues.

Several other erythroid growth factors have also been shown to exist. Stem cell factor (SCF), granulocyte-macrophage colony-stimulating factor (GM-CSF), and interleukin-3 (IL-3) are responsible for the growth of early pluripotent stem cells that give rise to the erythroid lineage. In addition, insulin-like growth factor–1 (IGF-1) also stimulates erythropoiesis in early progenitors and appears particularly important in patients with end-stage renal disease who no longer produce adequate amounts of erythropoietin due to parenchymal kidney damage. Type 1 receptors for angiotensin II have also been identified on erythroid progenitor cells, and both angiotensin-converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs) have been shown to counteract erythrocytosis in renal transplant patients. Thus, secondary polycythemia may result from

any number of mutations that affect these different growth factors, although these molecular lesions tend to be rare, many of which have only been identified in familial cohorts. Along this same line, iatrogenic polycythemia secondary to excessive use of exogenous RBC growth factors such as erythropoeitin-alpha and darbepoetin alfa should always be considered in patients on medications of this class.

Clinical Presentation

Subjective

Many subjective complaints do not arise until the Hct is greater than 60%. Because cardiopulmonary disease is the most common cause of polycythemia, the clinician should elicit an effective history of pulmonary symptoms such as chronic cough, cyanosis, hypersomnolence, or shortness of breath and dyspnea on exertion.

Common complaints include headache, blurred vision, weakness, fatigue, irritability, dizziness, and, on occasion, tinnitus. Epistaxis, however, may be the complaint of clinical presentation. Epistaxis is due to mucosal engorgement in the nares and irregularities in clotting. After a warm bath or shower, patients may complain of generalized pruritus, which is caused by the release of histamine from basophils that become released from the vasculature or pool along dilated vascular walls.

Eliciting a detailed smoking history is also crucial. The constellation of symptoms that reflect chronic carbon monoxide exposure should also be assessed in patients with high-risk occupations, such as taxi and bus drivers, toll booth operators, and underground tunnel or parking garage attendants.

Objective

The clinician should assess for erythromelalgia (burning pain in the hands and feet pathognomonic for polycythemia vera), as well as the tendency toward venous and arterial thrombosis or hemorrhage in this condition due to hyperviscosity and thrombocytosis. Gastrointestinal manifestations are also common, including peptic ulcer disease and gastroduodenal erosions. These are believed to be from hyperviscosity and increased histamine release. On an ocular examination, the clinician may note new vessel growth on the retinae as well as vascular engorgement. Splenomegaly is almost always present. Tenderness may be elicited from palpation of both upper abdominal quadrants. The left quadrant may be tender because of gastric ulceration and the right quadrant because of duodenal ulcers or, infrequently, due to hepatomegaly.

The skin (especially on the face) and mucous membranes have a dark, flushed (plethoric) appearance. The skin appears purplish or cyanotic as a result of inadequate tissue oxygenation, and a ruddy cyanosis may be apparent on the fingers and toes. Finally, Cushingoid features may be present if Cushing's syndrome or chronic corticosteroid use is the cause of secondary absolute polycythemia.

Diagnostic Reasoning

Diagnostic Tests

Polycythemia tends to be suspected when Hct is greater than 48% or Hgb is greater than 16.5 g/dL in women or Hct is greater than 52% or Hgb is greater than 18.5 g/dL in men. These levels should always be age-adjusted. Thus, initial testing always includes a complete blood count (CBC), which starts the process of differentiating absolute from relative polycythemia. If the patient has polycythemia vera or one of the other absolute polycythemias, the Hct is typically greater than 55% for women and 60% for men. In fact, if the Hct is not greater than these percentages, Cushing's disease and overuse of steroids should be ruled out, as both cause milder degrees of polycythemia. By definition, there is an elevated RBC count in absolute polycythemia, but RBC morphology is classically normal on the peripheral blood smear.

In the absence of concurrent infection, the white blood cell (WBC) count in absolute polycythemia typically ranges between 10,000 and 20,000 cells/mcL. The differential is usually unremarkable except for occasional basophilia. The clinician should expect the platelet count to be elevated and to vary—at times exceeding 1 million cells/mcL.

Secondary tests aid in the differentiation of primary versus secondary causes of absolute polycythemia. Diagnosis of polycythemia vera is based on detecting splenomegaly in combination with an elevated Hct and platelet count. However, a definitive diagnosis of polycythemia vera may call for bone marrow biopsy if other biochemical studies are inconclusive. Erythropoietin levels are usually low in polycythemia vera, and a normal or elevated erythropoietin level necessitates a search for other causes.

Secondary testing is directed by the suspected underlying pathology. Pulse oximetry should be measured after minimal exertion as an important part of the diagnostic work-up. In addition, an arterial blood gas (ABG) drawn to measure the partial pressure of oxygen in arterial blood (PaO_2) and co-oximetry to assess for the effects of carbon monoxide exposure (carboxyhemoglobin) or oxygen-poor methemoglobin may be indicated. Carboxyhemoglobin levels greater than 5% suggest CO poisoning.

If the patient has relative polycythemia, the CBC will reveal an elevated RBC mass, but the Hct will often not be as high as 55% to 60%. Plasma volume may also be measured to help distinguish relative versus absolute polycythemia, but values are not always predictable. In addition, the WBC and platelet counts are lower for relative polycythemia compared with absolute polycythemia.

Differential Diagnosis

The differential diagnoses for polycythemia vera include chronic myeloid leukemia, myelofibrosis, and essential thrombocytosis. Chronic myeloid leukemia would have

an extremely elevated WBC count (30,000/mcL). Myelofibrosis would have a normal or decreased Hct and abnormal RBC morphology. Essential thrombocytosis would have a normal Hct with a markedly elevated platelet count. Spurious polycythemia, in which there is a contracted plasma volume rather than a true increase in RBC mass, may be due to diuretic therapy.

Management

In general, the principles of polycythemia management concern the difference between relative and absolute causes. This section, therefore, presents management of polycythemia according to underlying pathology.

Initial Management

Relative Polycythemia Relative polycythemia is associated with dehydration; therefore, the clinician's objective is to rehydrate the patient. Rehydration in the primary care setting generally consists of oral hydration and medication adjustment if the cause of dehydration is related to a pharmaceutical agent, such as diuretics. Thus, the clinician must decide whether the patient is able to adhere to instructions regarding oral fluids and changes in drug regimens. Should IV rehydration be required, other factors must also be considered, such as the patient's age, associated comorbidities (e.g., cardiopulmonary disease such as congestive heart failure), ability to adhere to self-care instructions following discharge, and the availability of outpatient nursing care. Because of the complexity of care required for IV rehydration, acute-care or in-hospital nursing management is often the preferred setting for IV fluid therapy. Central to the decision to initiate oral versus IV hydration is the capacity of family or other caregivers to assist in the patient's rehydration.

Absolute Polycythemia Absolute polycythemia management begins with progressive phlebotomies if the Hct is greater than 55% to 60%. Phlebotomy is required to prevent thrombus formation, which can lead to a fatal embolic event, cerebrovascular accident, or myocardial infarction in a polycythemic patient. The goal of phlebotomy is to decrease Hct to 45% or lower. This goal can be achieved by the weekly removal of 500 mL of whole blood. For example, if the starting Hct is 65% and 3% to 4% Hct is lost with each 500 mL of blood, the goal of a 45% Hct can be reached after six phlebotomies. Maintenance of an Hct at or below 45% will require subsequent phlebotomies. Iron deficiency will develop after repeated phlebotomy.

Patients will report abatement of symptoms as the Hct falls. Should iron deficiency ensue, iron supplementation should not be started because supplements can stymie therapeutic gains achieved by phlebotomy. Despite potential iron deficiency, the fatigue associated with polycythemia should not recur once a Hct of 45% or less has been achieved.

Initial management of all absolute polycythemias follows the path of phlebotomy outlined above. Additional guidelines for initial management are specific to the underlying cause, for example, Cushing's disease, corticosteroid use, erythropoietin-secreting tumor, hypoxia, and carboxyhemoglobinemia. Surgical resection of the pituitary gland may be indicated for Cushing's syndrome depending on the source of the excess corticosteroids—the pituitary gland, the adrenal glands, and so forth. Tapering of steroids, if possible, is the management of steroid-induced polycythemia. Tumor excision or reduction is the management for erythropoietin-secreting tumors. Oxygen supplementation may be the initial management for chronic hypoxia (if PaO_2 is less than 60 mm Hg). Cessation of smoking is the management for carboxyhemoglobinemia due to tobacco use.

Given the significant risk of clot formation, hydroxyurea (Hydrea) is particularly useful in patients at risk for thrombosis, and low-dose aspirin should be started in all patients (especially those with thrombocytosis) unless contraindicated by another condition. IFN-α is useful in patients refractory to other treatments or in those with significant refractory pruritus although it may cause troublesome side effects, including flu-like symptoms and depression. Antihistamines may be helpful in treating the pruritus associated with polycythemia vera, although some patients may experience significant sedation with these medications. Anagrelide (Agrylin) is an antiplatelet agent that reduces platelet count and can be useful in patients with thrombocytosis although it should be used in caution in patients with coronary artery disease. Allopurinol should be used in patients with significantly elevated uric acid levels due to high RBC turnover, provided any acute gout attack has already been treated with colchicine, because allopurinol may precipitate uric acid deposition in the joints.

Subsequent Management

Subsequent management follows the steps taken in initial management. Patients with polycythemia vera will require repeated phlebotomies. Nonalkylating agents may be employed to suppress stem-cell formation, such as hydroxyurea (Hydrea) 60 to 80 mg/kg three times per week. Alkylating agents such as busulfan (Myleran) may also be used (1–3 mg/day as maintenance, with higher doses for induction), but these medications carrying a greater risk of long-term leukemia development. The risks of myelosuppression, such as systemic infection, must be considered with all of these agents, particularly if used at higher doses.

Secondary maintenance of patients with absolute polycythemia may also include antiplatelet aggregation therapy with aspirin although this treatment is controversial because the risk of thrombosis is also decreased with phlebotomy alone. If aspirin is used, a dose in the range of 81 to 325 mg/day should be sufficient although there is no consensus among hematologists and oncologists regarding the effectiveness of aspirin or the most appropriate dose in this population.

Follow-up and Referral

Relative Polycythemia

After dehydration has been treated, usually no long-term follow-up or referral is required, provided the underlying cause of the dehydration has been addressed. However, follow-up of patients who receive diuretics should be based on the need to monitor electrolytes and the therapeutic aims of diuretic therapy (e.g., follow-up of cardiac function). In turn, evaluating for normal potassium and sodium levels is an important goal of follow-up visits typically scheduled at 3-month intervals for patients maintained on chronic diuretic therapy.

Absolute Polycythemia

Because weekly phlebotomies are required to achieve and maintain an Hct of 45% or less, weekly assessments of the CBC and brief office visits are also necessitated. An initial referral to a hematologist is also required to confirm the diagnosis and establish the plan of care. If secondary management strategies such as myelosuppression are required, the clinician should rely on the hematologist for recommendations and comanagement. Specialty referral is also important because polycythemia vera carries a significant risk of transforming over time into myelofibrosis with myeloid metaplasia or acute myeloid leukemia.

Referrals to surgeons are required for tumor excision or pituitary resection, if indicated. A positive finding from computed tomography of the abdomen or magnetic resonance imaging of the brain should involve an immediate surgical consultation. A pulmonary referral may become necessary if the clinician does not detect lower carboxyhemoglobin levels as expected after a patient stops smoking.

Patient Education

Patients should learn that absolute polycythemia reduces life span. On average, patients live for less than 15 years after this diagnosis because of the risks of thrombosis. In spite of this grim prognosis, however, they should be reassured that active participation in their care may extend the quality of their lives and may increase longevity.

Increased quality of life is associated with improvement in the subjective presentation of the disease. Points to address in patient education include adherence to fluid intake requirements, drug regimens, exercise recommendations, laboratory evaluations, and adherence to follow-up visit schedules with the clinician and all specialty referrals.

Fluid intake requirements may fluctuate according to the stage and duration of treatment. As the disease progresses and phlebotomies occur repeatedly, the daily fluid intake should average 2 L for a 70-kg adult. Earlier in the treatment before blood volume is reduced, the necessary fluid intake is likely to be less—on average, 1 to 1.5 L/day. Drug regimen adherence may require learning how to self-medicate with a parenteral agent such as IFN-α. Therefore, teaching the patient and/or loved one how to deliver the drug is essential to the educational plan.

Instruction regarding exercise is dependent on the patient's level of tolerance for physical activity. The goal, however, should remain clear that increasing the level of activity can reduce thrombosis formation. Simplest among exercise plans for persons older than age 60 years is regular walking. The clinician should recommend that the patient walk with a friend in a safe place, such as an indoor shopping mall. An alternative is walking from side to side in a pool of waist-high water. This form of aquatic exercise can be helpful for patients with joint- and bone-related immobilities who otherwise experience increased pain when walking out of water.

Adherence to laboratory evaluations may diminish over time as the patient copes with this chronic and indolently fatal disease. Drawing the family and other loved ones into the circle of education and social support may enhance the patient's adherence to follow-up regimens. Call-back schedules for laboratory evaluations that fit with the individual's daily activities and provide rhythm to the patient's life are more likely to generate improved adherence.

Finally, visits to the clinician and specialists are times when patient education should be reinforced. Importantly, addressing and treating depression—an anticipated outcome of absolute polycythemia—can enhance adherence to all other elements of patient education. Therefore, teaching the patient and loved ones to recognize and report depression is a critical component of the educational plan.

LEUKEMIA

Leukemia is a neoplastic disease of malignant hematopoietic stem cells that differentiate and proliferate according to specific lineage trajectories that distinguish the types of leukemia as either acute or chronic. Further classification of leukemia specifies the stage of development and type of white blood cell (WBC) (immunophenotype) that is involved in the malignant transformation (see Table 17.2). The involved leukocytes proliferate and occupy space previously filled by nonmalignant cell lines. Thus, one significant outcome of the malignancy is the suppression of nonmalignant blood cells.

Epidemiology and Causes

The incidence of leukemias varies according to childhood and adult age groups. Overall, there is a slight predominance of male to female cases. Acute lymphoblastic leukemia (ALL) is the predominant form in children between 2 and 15 years of age, with higher prevalence seen among children younger than 5 years.

Other types of leukemia more commonly strike adults. Acute granulocytic leukemia (AGL) and acute myelocytic leukemia (AML) may be seen in adults of all ages, but their incidence increases after age 40 years. The

Table 17.2 Types of Leukemia and Treatment

	Age at Onset	Treatment—Combination Chemotherapy*	Treatment*—Other
Acute Leukemia			
Acute lymphocytic/ lymphoblastic leukemia (ALL)	2–15 years, rarely in adults	*Induction:* 4-drug regimen daunorubicin (Cerubidine) vincristine (Oncovin) prednisone (Deltasone) asparaginase (DVP L-asp) *Consolidation:* daunorubicin (Cerubidine) cytarabine (Ara-C) *Maintenance:* 4-drug regimen	CNS intrathecal methotrexate and cranial irradiation Allogeneic BMT in high-risk patients in first remission
Acute nonlymphocytic leukemia (ANLL) or acute myelogenous leukemia (AML) and acute granulocytic leukemia (AGL)	All adults but more prominent >40 years	daunorubicin (Cerubidine) OR idarubicin (Idamycin) OR mitoxantrone PLUS cytarabine (Ara-C)	Autologous or allogeneic BMT for high-risk patients in first remission
Chronic Leukemia			
Chronic granulocytic leukemia (CGL) or chronic myelogenous leukemia (CML)	All patients, but more prominent >60 years Median age 42 years	imatinib (Gleevec) PLUS hydroxyurea (Hydrea)	Allogeneic BMT in chronic phase (greater success in younger patients)
Chronic lymphocytic leukemia (CLL)	>60 years	cladribine OR fludarabine (Fludara) OR chlorambucil (Leukeran) PLUS cyclophosphamide May be used in combination with rituximab (Rituxan) or alemtuzumab (Campath)	Allogeneic BMT

*For all leukemias, the need for epoetin (Epogen, Procrit), darbepoetin (Aranesp), and/or pegfilgrastim (Neulasta) must be assessed.

incidence of acute lymphocytic leukemia increases in adults older than age 60 years. Chronic lymphocytic leukemia (CLL) and chronic granulocytic leukemia (CGL) are more prevalent among adults older than age 60 years; however, they may appear in persons of any age. CLL is the most common leukemia in developed Western countries, with a median age of onset of 70 years. Chronic myelocytic or myelogenous leukemia (CML) strikes middle-aged persons, with a median age of 42 years.

The etiology of leukemia is complex and not fully understood. Researchers have linked leukemia to environmental toxins such as chemical solvents, petroleum products, and insecticides, as well as heredity, although familial leukemias are rare. It is unclear whether the incidence of leukemia is higher among adult identical twins than among other adults; however, CLL in particular appears to have a familial predisposition.

The complications of mutagenic pharmacotherapies used to treat lymphoma, rheumatoid arthritis, or to maintain immunosuppression post-transplantation have provided insight into disease etiology. For example, alkylating agents, such as melphalan (Alkeran) and cisplatin (Platinol), have been implicated in a 5% to 10% increased incidence of leukemia among patients who have been receiving them for an extended period of time. Likewise, prolonged exposure to high doses of ionizing radiation is also associated with leukemia. In cases of prolonged toxin and radiation exposure, a latency of up to 20 years may pass before a leukemia diagnosis is established. Shorter latency periods are seen following exposure to chemotherapeutic agents that inhibit the

DNA-splicing enzyme topoisomerase II, such as etoposide, doxorubicin, or mitoxantrone.

Pathophysiology

Acute Nonlymphocytic Leukemia

By far, the largest number of adults with acute leukemia (as high as 80%) suffer from acute nonlymphocytic leukemia (ANLL). ANLL is a category that includes the leukemias formerly known as AML and AGL. ANLL presents after age 40 years and increases in incidence with each year thereafter. It originates in the malignant transformation of a single stem cell or a few select cells. At least 85% of all cases have been associated with defined clonal karyotypic abnormalities. Cells in the progenitor line are universally affected, thus providing a clue that the leukemia is intrinsic to the cell line following malignant transformation.

ANLL has been divided into eight distinct morphological classes (M0 to M7), according to the French-American-British (FAB) system, with classes M3 to M5 further subdivided into two subclasses each. Thus, the pathophysiology of ANLL is exceedingly complex. Each of these subtypes is characterized by one or more cytogenetic abnormalities that may be used to predict prognosis and guide treatment, as they can determine responsiveness to specific chemotherapies. For example, acute promyelocytic leukemia (AML class M3) is associated with a translocation between chromosomes 15 and 17 that juxtaposes the PML and retinoic acid receptor (RAR)–alpha genes, repressing the latter and preventing retinoic acid–induced differentiation of promyelocytes. Nonetheless, this mutation portends a favorable prognosis, as promyelocytic M3 cells are particularly sensitive to therapy with all-trans retinoic acid (ATRA).

In contrast, abnormalities that carry a particularly poor prognosis include mutations with monosomy (entire chromosomal deletion) of chromosomes 5 or 7 or trisomy of chromosome 8. The former monosomies are particularly associated with AML resulting from previous chemotherapy with alkalinizing agents or exposure to ionizing radiation. In contrast, AML associated with past exposure to topoisomerase II inhibiting agents is often associated with mutations in chromosome 11.

Acute myeloblastic leukemia (AML class M2) and acute myelomonocytic leukemia (AML class M4) have both been associated with a balanced translocation between chromosomes 8 and 21, which juxtaposes the transcription factor genes *AML1* and *ETO,* leading to dysregulated transcription of genes directly involved in myeloid cell division (e.g., granulocyte-monocyte colony stimulating factor, interleukin-3, and the antiapoptotic gene *BCL-2*). AML class M4 has also been associated with inversions or translocations in chromosome 16, creating a fusion of the genes *CBFB* and *MYH11,* which leads to repressed transcription of genes involved in myelocytic differentiation. Acute monoblastic leukemia (AML class M5) is associated with rearrangements of chromosome 11, whereas mutations in chromosome 3 appear to confer thrombocytosis in the setting of AML.

Acute Lymphoblastic Leukemia

ALL can appear among persons of all ages but is clearly a disease predominantly of early childhood, as noted earlier. B-cell lymphoblasts or, in far fewer cases, T-cell lymphoblasts increase in number after a single hematopoietic stem cell undergoes transformation (immortalization). Interestingly, the cytogenetics of ALL in children is far different from that in adults. For instance, the Philadelphia chromosome (a balanced translocation between chromosomes 9 and 22 that juxtaposes and activates the *BCR* and *ABL* oncogenes) is seen in only 5% of childhood cases, whereas this is the most common abnormality in adult ALL and may be found in up to 40% of cases. In contrast, hyperdiploidy (in which greater than 50 chromosomes are found in malignant clones) is seen in up to 30% of childhood cases but in no more than 5% of affected adults.

In contrast to CML (see next section), the presence of the Philadelphia chromosome is a poor prognostic indicator in ALL, contributing to dysregulated activation of the RAS intracellular signaling pathway that leads to uncontrolled cell division. These patients often have additional karyotypic abnormalities such as monosomy of chromosome 7. Studies have shown that ALL patients with the Philadelphia chromosome may be divided into two subsets that are distinguished by differing translocation breakpoints along the BCR gene—one in which this karyotypic abnormality appears restricted to a B lineage lymphoblastic cell clone and another in which the Philadelphia chromosome is further identified in myelogenous cell lines as well, indicating that these patients may actually have a indolent form of CML that underwent a B-lineage lymphoblastic crisis at the time of diagnosis.

As with AML, different forms of ALL have been distinguished on the basis of morphology, with certain cytogenetic profiles correlating with each. For instance, ALL of L3-type B-cell origin often shares a translocation of chromosomes 8 and 14 that is also seen in B-cell–derived Burkitt's lymphoma, suggesting that these cancers are varied manifestations of the same underlying malignant transformation event. Pre–B-cell ALL has been associated with translocations between chromosomes 1 and 19, which lead to a fusion protein between the highly active transcription factors *E2A* and *PBX1,* with subsequent immortalization of this early B-cell progenitor and a particularly poor prognosis. Infantile ALL has been associated in up to 80% of cases with translocations involving the mixed lineage leukemia (MLL) gene at chromosome 11q23, which is thought to regulate a number of downstream genes involved in lymphocyte differentiation, thereby resulting in extremely poor outcomes. A poor prognosis is also seen in ALL associated with translocations between chromosomes 4 and 11, a mutation that is commonly seen in AML class M5.

Translocation between chromosomes 12 and 21 that produces a fusion protein between the transcription factors *TEL* and *AML1* is the most common mutation seen in childhood ALL. Fortunately, this translocation confers a favorable prognosis in ALL, as does the presence of hyperdiploidy (a cellular complement of 50–60 chromosomes) with occasional structural abnormalities such as partial duplications and translocations. Multiple copies of chromosome 21 and the X chromosome are the most common findings in hyperdiploidy, but several other duplications have been noted as well (e.g., chromosomes 4, 6, 10, and 14). The high prevalence of these karyotypic abnormalities in childhood ALL underlies the generally favorable outcomes associated with this leukemia in children.

T-cell ALL is a less common entity that typically strikes young men. Related to T-cell lymphomas, these patients may present with particularly high WBC counts, invasion of malignant cells into the central nervous system (CNS) via the cerebrospinal fluid, and the presence of a mediastinal tumor. Well over half of these cancers are characterized by mutations in genes coding for the various protein components of the T-cell receptor—alpha, beta, gamma, or delta subunits. The T-cell receptor is a heterodimeric protein composed of either alpha–beta or gamma–delta subunits, expressed on the surface of the T cell, allowing for the recognition of specific antigens. Mutations commonly occur in chromosome 14, which encodes the alpha and delta receptor subunits, or chromosome 7, which encodes the genes for the beta and gamma chains. Translocations at these sites typically juxtapose these genes with various transcription factors that lead to dysregulated expression of the receptor subunit and proliferation of the T-cell clone. Mutations in the same chromosomes that do not involve these receptor subunits as well as others such as chromosomes 6 and 11 have also been identified in T-cell ALL. Interestingly, prognosis does not appear tied to these particular cytogenetics, and outcomes are generally favorable in both adults and children with T-cell ALL.

Chronic Myelogenous Leukemia

CML (chronic myelocytic leukemia, chronic myeloid leukemia) is most commonly associated with the development of the Philadelphia chromosome in a hematopoietic stem cell that commits to the myeloid lineage. Although differentiation is typically unaffected, the leukemic stem cell is self-renewing and produces a tremendous number of daughter cells, with the same leukemic clone dominating up to 90% of the bone marrow at the time of diagnosis. In this mutation, breaks occur in the DNA resulting in an equivalent exchange of genetic material between chromosomes 9 and 22. Oncogene activation occurs, as the reciprocal translocation [t(9;22)(q34;q11)] juxtaposes the *BCR* and c-*ABL* genes, creating a BCR–ABL fusion protein that confers a proliferative advantage to the leukemic clone, even in the absence of cellular growth factors.

The functions of the native BCR and ABL proteins are not fully elucidated, and neither gene alone is capable of malignant transformation; however, the fusion protein is oncogenic, giving rise to malignant clones through upregulated tyrosine kinase (phosphorylation) activity within a number of intracellular signaling pathways contributing to cell division (e.g., RAS, c-myc, and JAK/STAT molecular pathways). This explains the effectiveness of treatment with the tyrosine kinase inhibitor imatinib (Gleevec). Depending on the site of the chromosomal breaks, various types of the BCR-ABL fusion protein may be formed. In turn, cells transformed by these different species appear to respond differentially to specific therapies.

Although IL-3 and G-CSF mRNA transcripts are both upregulated in leukemic cell clones, the precise role of cytokines in the dysregulated growth of these cells remains unclear. As with other forms of leukemia, leukemic cell clones appear to arise from a self-renewing pool of mutated leukemic stem cells, which are typically less mature than the differentiated granulocytic leukemic clones themselves. In fact, the Philadelphia chromosome has been further identified in a number of cell lineages in CML, including granulocyte, macrophage, erythrocyte, megakaryocyte (platelet), and B-lymphocyte precursor cells, indicating that the mutation first occurs in an early, noncommitted, multilineage hematopoietic stem cell.

The creation of the Philadelphia chromosome may predate the onset of disease symptoms by many years, a pattern suggesting that the disease progresses through a latent or asymptomatic phase before becoming active. For example, the karyotypic abnormality may first arise in the third decade of life, with symptom onset as much as 10 to 20 years later. In fact, normal bone marrow function is characteristic of the disease trajectory in the early years after development of the Philadelphia chromosome. The pool of leukemic stem cells may not be expanded in number; however, leukemic daughter cells undergo clonal expansion and eventually crowd out normal bone marrow components. In addition, cell surface adhesion factors (e.g., beta-1 integrin) are downregulated, eliminating adhesion-dependent growth inhibition in which normal cells are triggered to stop proliferating after coming into contact with one another.

As with any chronic leukemia, a dreaded complication of CML is degeneration into a leukemic blast crisis, in which leukemic progenitor cells develop self-renewing properties as they undergo further mutations resulting in clonal proliferation of either myeloid or lymphoid (almost exclusively B lineage) blasts, given the widespread presence of the Philadelphia chromosome in multiple lineages. Most commonly, the additional mutations described include trisomies of chromosomes 8 or 19, duplication of the Philadelphia chromosome itself, or mutations in the *p53* tumor suppressor gene on chromosome 17. These blast cells may express many of the same proteins as hematopoietic stem cells, such as the transcription factor beta-catenin. Both leukemic stem

cells and their progeny appear more resistant to apoptosis than wild-type (nonmutated) cells, but the significance of this to the pathogenesis of CML is not fully known. However, resistance to apoptosis appears to be important, because the life span of leukemic cell clones is not significantly greater than that of wild-type granulocytes and does not appear to account for their increase in number.

Finally, CML may also occur in the absence of the Philadelphia chromosome mutation, which is known as atypical CML. Up to 15% of CML patients may suffer from this condition, although some hematologist-oncologists have chosen to classify these patients as having a distinct myeloproliferative disease, rather than true CML. For reasons that are poorly understood, these patients have a worse prognosis with a poorer response to therapy and shorter survival times.

Chronic Lymphocytic Leukemia

CLL is a chronic lymphoproliferative disorder typically associated with increased numbers of small B lymphocytes. In fact, it is clinically indistinguishable from small lymphocytic B-cell lymphoma. After a malignant alteration occurs in a B-cell precursor, thus forming a malignant line, the clonal abnormality is passed on to slowly replicating progeny that are functionally incompetent.

The genetics of the malignant alteration in CLL are not as well established as they are for CML. Malignant B cell clones are known to be frozen in a state of differentiation somewhere between the pre-B and mature B-cell phase, with rates of proliferation and cell death varying widely among different individuals. These cells express very low levels of surface immunoglobulin, various B-cell–specific cell surface proteins (e.g., CD19, CD20, CD21), as well as CD5, which is primarily considered a T-cell marker. Variant forms exist that do not adhere to these criteria, although some hematologist-oncologists feel that a proliferation of non–CD5-expressing B cells represents a leukemic phase of non-Hodgkin's lymphoma, rather than true CLL.

The relative percentages of both T cells and natural killer (NK) cells are reduced in CLL, although absolute numbers of T lymphocytes may be increased, given the tremendous expansion of lymphocytes. Moreover, some CLL patients demonstrate unusual forms of T cells with low levels of surface CD4 and CD8 proteins. Such nonclassical T cells are also found in other autoimmune diseases. In addition, although hypogammaglobulinemia is common in patients with CLL, immunoglobulin receptors on leukemic cells may demonstrate autoimmune specificity, which may explain the increased frequency of AIHA, idiopathic thrombocytopenic purpura (ITP), and pure red cell aplasia in persons with CLL. Owing to their lack of protective antibodies, infection by gram-negative or encapsulated organisms is the most frequent cause of morbidity and mortality in persons with CLL.

Cytogenetic analysis of CLL cell clones has revealed chromosomal abnormalities in up to 70% of cases. The most frequent karyotypic abnormalities include trisomy of chromosome 12, partial deletions in chromosome 13 that affect the tumor suppressor retinoblastoma gene, and partial deletions in chromosomes 11 and 17 that are associated with a particularly poor prognosis and shorter survival. The *p53* tumor suppressor gene located on chromosome 17 is often affected, either by deletion or expression of a mutated, nonfunctional protein, with both conditions leading to unregulated cellular proliferation. In contrast, the overexpression of survival factors has also been identified in B lineage CLL, including the antiapoptotic molecules BCL-2 and inducible nitric oxide synthetase.

Clinical Presentation

Subjective

Patients with acute leukemia complain of bone and joint pain. Fevers, chills, palpitations, shortness of breath, and signs of infection typically constitute the initial subjective presentation. Patients may also have gingival bleeding associated with gingival hyperplasia. Skin eruptions, easy bruising, or prolonged bleeding time from simple wounds form a significant part of the subjective history.

Patients with chronic leukemia complain of fatigue, night sweats, and low-grade fevers. Although there is no clear differentiation in subjective findings between CML and CLL, CML may present with the symptoms of leukostasis associated with very high WBC counts (greater than 500,000 cells/mcL). The syndrome of leukostasis is characterized by blurred vision, respiratory distress, and occasionally priapism (prolonged and painful erection that lasts for several hours). Nausea and vomiting may be associated with organomegaly in both types of chronic leukemia. Bone and joint pain are typically limited to the myeloproliferative stages of CML.

Objective

The clinician will often note a high fever in patients with acute leukemia. Tachycardia and tachypnea are related findings. Patients appear pale and manifest eruptions such as petechiae and purpura. The patient's confusion—related to hypoxemia and fever—may be evident using standardized evaluation tools such as the Folstein Mini–Mental State Exam (MMSE).

In chronic leukemia patients, heart and lung sounds are typically within normal limits except during infection, in which case the lungs may reveal adventitious sounds. Splenomegaly may be evident and variably associated with hepatomegaly and/or lymph node enlargement. Temperature may not be elevated in chronic leukemia, as it often is in acute leukemia, unless the disease has progressed or there is a concurrent infection. In addition, the patient's skin color varies between pale and normal, and few, if any, skin eruptions are evident.

Diagnostic Reasoning

Diagnostic Tests

Initial testing for suspected acute leukemia includes a CBC with peripheral blood smear and platelet count. The WBC count may be significantly elevated (more than 300,000 cells/mcL). Granulocytes (polysegmented and banded forms) are typically diminished in number as will be platelets (often less than 50,000/mcL). A hematocrit of less than 30% is a common finding, especially if the WBC count is markedly elevated. The peripheral smear reveals a blastocystosis of greater than 25% in almost all cases.

Initial tests for suspected chronic leukemia are the same as for acute leukemia: CBC, peripheral blood smear, and platelet count. The WBC count should be elevated in CML and CLL, but typically more so in CML (elevations greater than 100,000 cells/mcL are common). Lymphocytosis, however, differentiates CLL from CML. Lymphocytes occupy as much as 90% of the peripheral smear in CLL. The peripheral smear of CML is characterized by a left-shifted myeloid series, with mature forms of myeloid cells predominant in the smear. Platelets may be elevated and are rarely diminished.

Subsequent testing for both acute and chronic leukemia includes a bone marrow aspirate. Results should parallel the peripheral blood smear, thus confirming the initial diagnosis with greater accuracy in quantitative and qualitative indices. In acute leukemia, the bone marrow aspirate reveals hypercellular components, which are dominated by blasts. At least 30% of the cells must be blasts to diagnose acute leukemia. Auer bodies are rod-shaped structures, present in the cytoplasm of myeloblasts, myelocytes, and monoblasts in leukemic patients. They predominate among myeloblasts in the bone marrow aspirates of patients with AML. Serum chemistry profiles are critical for secondary testing in acute leukemia patients because of rapid cell turnover in the WBC population, which liberates intracellular uric acid and leads to significant increases in serum concentration.

In CML, bone marrow evaluation typically reveals the Philadelphia chromosome along with a left-shifted myelopoiesis. Blasts occupy less than 5% of the aspirate sample. Subsequent testing of CML also includes measuring leukocyte alkaline phosphatase, which is usually low, thus reflecting the abnormal function of neutrophils. Additional testing includes measuring the vitamin B_{12} level and serum chemistries. The vitamin B_{12} level should be elevated, as should the uric acid level.

Subsequent CLL bone marrow results confirm the initial peripheral blood smear. Small, mature lymphocytes dominate the field. Surface immunoglobulin on the monoclonal malignant lymphocytes aids in distinguishing these small cells from their normal counterparts. Another secondary test, immuno-electrophoresis, further supports the diagnosis of CLL in about half of patients. The profile from the electrophoresis shows that the patient is hypogammaglobulinemic.

Molecular methods of cytogenetic analysis (fluorescent in situ hybridization [FISH], Southern blot, reverse transcriptase–polymerase chain reaction [RT-PCR]) to identify the Philadelphia chromosome and other karyotypic abnormalities are critical for predicting prognosis and determining the most effective treatment plan for each type of leukemia. These analyses have revolutionized leukemia treatment by facilitating the use of individualized, directed therapy.

Differential Diagnosis

Acute Leukemia The left-shifted (immature) bone marrow aspirate of acute leukemia must be distinguished from the left-shifted aspirates that are associated with recent exposure to toxic chemicals and radiation. The clinician should expect that the full recovery period after toxic exposure will be at least 6 weeks and may extend to 12 weeks. It is possible to rule out so-called false-positive left-shifted aspirates by repeating the procedure several days later. If the exposure to toxins and not monoclonal malignant mutations was the cause, then the subsequent test should reveal maturing cell lines.

Acute leukemias must be distinguished from their chronic counterparts and from similar myeloproliferative disorders, such as polycythemia. ALL resembles lymphoproliferative diseases, such as lymphomas and mononucleosis; therefore, a skilled pathologist is required to distinguish the lymphoproliferative disorders from particular acute leukemias.

Chronic Leukemia The Philadelphia chromosome of CML distinguishes this disease from myeloproliferative responses to infection, systemic inflammation, and other malignancies. Clinical wisdom will also help the practitioner distinguish the leukocytosis of CML from other reactive states. CML will likely present with more than 50,000 cells/mcL, but reactive states will not mount as great a response. In addition, CML is clearly different from other myeloproliferative diseases; the erythrocyte count, RBC indices, and hematocrit are generally normal in CML.

Microscopic evaluation of a bone marrow aspirate differentiates CLL from other lymphocytic disorders, such as viral infections. Unlike CLL, viral infections will present with flu-like symptoms, which include fever, chills, myalgias, and arthralgias. Thus, CLL is perhaps the easiest among the leukemias to distinguish.

Management

The probability of successful treatment and subsequent cure for acute leukemia decreases with increasing age. In addition, a cure for acute leukemia is less probable if the patient is diagnosed late in the disease trajectory, after several physiological systems have become involved. In general, treatment begins with combination chemotherapy to induce remission (i.e., induction phase), followed by a stage of chemotherapy called the consolidation

phase, and finally a prolonged maintenance phase. Unlike the acute leukemias, the chronic leukemias usually follow an indolent course, which means that myelosuppressive chemotherapy may not be initiated until symptoms necessitate action. Symptoms, therefore, are managed as they appear.

Acute Leukemia

ANLL patients receive combination chemotherapy. (Medications are listed in Table 17.2.) The oncologist will set the dose ranges for at least two drugs—daunorubicin (Cerubidine) or idarubicin (Idamycin) plus cytarabine (Ara-C). The clinician is responsible for monitoring hepatic function throughout the course of combination therapy, which may run in 3- to 6-day cycles every 3 to 4 weeks for a total of 3 to 6 months, depending on successful remission and patient tolerance. Combination therapy produces bone marrow aplasia, which abates after 2 weeks following the conclusion of therapy. Aplastic patients, therefore, require supportive antibiotic prophylaxis, vigorous stoma care given severe denuding of mucosal surfaces, and possible RBC transfusions. The clinician's role is to comanage the adverse effects of the chemotherapy and to monitor serum chemistries, including liver function tests.

Adult patients with ALL may enter remission in initial management (albeit not as quickly or easily as children with ALL) without the aplastic disorders associated with the initial treatment of AML. Combination chemotherapy is the mainstay for initial management, including vincristine (Oncovin), daunorubicin (Cerubidine), and prednisone (Deltasone). Other combinations are under investigation. Comanagement with the oncologist is the same as for patients with ANLL, except that vigorous stoma care and associated weight reduction may not figure as prominently in ALL. Glucose intolerance may develop due to prednisone therapy, particularly in patients suffering from diabetes mellitus at baseline. Thus, the clinician is responsible for making adjustments to antidiabetic agents during chemotherapy.

After remission has been achieved for the patient with acute leukemia, a consolidation course of management is begun. Consolidation cycles differ for the acute leukemias. ANLL patients receive one complete chemotherapy consolidation cycle. Alternatively, they may receive a bone marrow transplantation (BMT) to consolidate the gains of earlier therapy. Transplantation may be autologous (an individual's own marrow saved before treatment), allogeneic (marrow donated by someone else), or syngeneic (marrow donated by an identical twin). Advanced Practice Nursing Interventions 17.1 presents information that should be provided to the patient who will be undergoing bone marrow transplantation.

Patients with ALL, on the other hand, face different challenges. They must receive CNS prophylaxis against malignant lymphocytes that may have crossed the blood–brain barrier to hide in meningeal crypts. CNS prophylaxis typically consists of intrathecal methotrexate and cranial irradiation.

Chronic Leukemia

Patients with CML are initially managed with watchful vigilance. Should treatment be required for extreme hyperleukocytosis–related symptoms, such as blurred vision and respiratory distress, leukophoresis may be initiated. In addition, depending on severity of symptoms, hydroxyurea (Hydrea) may be initiated at 2 to 4 g/day PO, followed by maintenance therapy of 0.5 to 2 g/day. The leukopenic goal of 5,000 to 10,000 WBCs/mcL requires frequent monitoring.

Symptom management and clinical vigilance are the initial therapies for patients with CLL. Symptoms that require intervention include thrombocytopenia (less than 50,000 platelets/mcL), anemia (less than 27% Hct), lymphadenopathy that impedes activities of daily living, and fatigue that reduces nutritional intake and immobilizes the patient. Whereas some sources cite a threshold of 50,000 platelets/mcL for thrombocytopenia requiring intervention, most oncologists tolerate much lower values before giving transfusions of platelets (even as low as 10,000/mcL, provided there is no active bleeding). If combination chemotherapy is utilized, the monitoring of platelet and erythrocyte counts is required because of myelosuppression secondary to chemotherapy.

Exogenous erythropoietin (Epogen, Procrit, or Aranesp) may assist in countering chemotherapy-induced anemia. In addition, the use of pegfilgrastim (Neulasta) and other granulocyte colony-stimulating factors may counter neutropenia.

Follow-up and Referral

When suspicion is elevated concerning a diagnosis of leukemia, the clinician should refer the patient to an oncologist. Pertinent laboratory results along with a clinical history should accompany the patient for the oncologist's appointment, although the oncologist typically requests and interprets bone marrow analyses.

For the patient with acute leukemia, comanagement of adverse effects from combination chemotherapy will require primary care follow-up monthly during the course of chemotherapy. The oncologist will direct treatment recommendations and adjustments and supervise laboratory analyses. The primary care clinician will provide oversight of the same laboratory results, along with recommendations for symptom management.

For the patient with chronic leukemia, if clinical vigilance is all that is required, the clinician should order laboratory evaluations including a CBC, platelet count, and peripheral blood smear every 6 weeks. Depending on symptom onset and severity, physical examinations may be done as infrequently as every 2 to 3 months, if the patient is otherwise stable. Once chemotherapy intervention begins, however, the oncologist will make treatment recommendations and alterations.

Advanced Practice Nursing Interventions 17.1 Bone Marrow Transplantation

The following information should be provided to patients undergoing bone marrow transplantation.

What It Is

A bone marrow transplantation (BMT) is the intravenous administration of 500–700 mL of bone marrow. The patient is "conditioned" to receive the bone marrow through a regimen of immunosuppressive therapy (chemotherapy or radiation). This conditioning eradicates malignant cells, provides immunosuppression, and creates a space for the bone marrow to engraft the transplanted marrow stem cells. The marrow is usually infused 48–72 hours after the patient's last dose of chemotherapy or radiation.

The bone marrow is "harvested" from a donor. It may be an autologous transplant (aspirated from the pelvic bones of the patient during a remission), an allogeneic transplant (from a compatible donor such as a parent or sibling with a similar tissue type), or a syngeneic transplant (from an identical twin). Peripheral stem cell transplants are currently the state of the art in bone marrow reconstitution, in which rare peripherally circulating stem cells are collected from the donor through an apheresis procedure, rather than harvesting whole marrow directly from the pelvic bones. This has greatly reduced the pain, discomfort, and complications associated with bone marrow (i.e., hematopoietic stem cell) donation.

What Will Happen Before the Procedure

- The health-care provider should provide complete information about the specific procedure (e.g., pretreatment, medication and activity restrictions), answer any questions, and provide emotional support.
- The patient should prepare for an extended hospital stay.
- The patient should prepare for side effects that are anticipated with immunosuppressant and cytoablative therapies (e.g., nausea, vomiting, cataracts, sterility, hair loss).

What Will Happen During the Procedure

- The nursing staff will do the following:
  1. Monitor vital signs and for complications (e.g., allergic reactions, fluid overload, pulmonary embolism)
  2. Provide support and reassurance

What Will Happen After the Procedure

- The nursing staff will monitor the following:
  1. Routine vital signs
  2. Signs and symptoms of infection (e.g., fever and chills)
  3. Potential complications from chemotherapy given to prevent graft-versus-host disease
  4. Signs and symptoms of graft-versus-host disease (e.g., rash, jaundice, joint pain, diarrhea, failure to engraft [pancytopenia])
- Mouth and skin care will be provided every 2 hours to help prevent infection
- IM injections will be avoided because they may lead to increased bleeding into the muscles

What To Do After Discharge

- Avoid infection by staying away from crowds and people with known infections
- Avoid sharp objects; for example, shave with an electric razor rather than an exposed razor blade

Patient Education

The patient may not be prepared for diseased-based education soon after receiving a clinical diagnosis of leukemia; therefore, it is important to involve not only the patient but also significant others in any education provided. Particular attention should be focused on treatment recommendations and their proposed impact on daily life and the patient's state of well-being. Treatment recommendations that include myelosuppressive therapies will require self-care activities that may not be in the patient's repertoire of capabilities. Thus, education should begin with an assessment of the patient's ability to monitor for infection, adverse effects of treatments, integrity of skin and mucous membranes, and fluid/nutritional status. Any deficits in the patient's ability to follow through with self-assessment should increase suspicion of complications from treatment yet to come; thus, resources that can aid the patient in self-assessment should be lined up before treatment is started.

In addition to self-assessment, the patient's education must address the anticipated burden on caregivers. Older patients and family members may not be able to adapt to the demands of treatment schedules, aplastic crises, and the like. A number of strategies can assist in this regard. The clinician should plan teaching sessions with the patient and caregivers present. The information should be repeated in subsequent sessions, and the patient should be asked to recall and repeat instructions provided in earlier sessions to confirm proper understanding. In addition, the clinician should monitor not only the patient but also caregivers for signs of strain and possible depression.

Patients need to be reassured that for all forms of leukemia, clinical vigilance is a form of treatment just as surely as is chemotherapy. Thus, if clinical vigilance is indicated, the patient and caregivers should learn the reasons to withhold pharmacological interventions while maintaining a watchful eye. Finally, patient education may require referral to support groups with other patients who have learned to live with cancer. Thus, referrals can include connections to other patients with leukemia within a primary care practice as well as support groups

convened by local chapters of the American Cancer Society. The goal of support group referral is to advance the patient's connection with others who can share treatment-related information and advance coping strategies. Caregivers may require a separate support group where they can discuss issues that are unique to their role.

COMMON IMMUNE PROBLEMS

ALLERGIC REACTIONS

Allergy is defined as an immune-mediated reaction to a foreign environmental allergen. It is characterized by an inflammatory response to allergen exposure to the body. Typical sites for allergen exposure are the skin and respiratory tree, where local reactions may occur. Allergen exposure may also lead to a systemic response, however, whereby multiple organs and the circulatory system may become involved. Allergenic shock or anaphylaxis is an extreme example of this systemic response.

Atopy is a term used to characterize an IgE-mediated immune response that is exaggerated or out of character for exposure to what appear to be innocuous environmental allergens. Whereas allergic skin reactions are classically characterized by raised, erythematous wheal and flare reactions termed urticarial plaques, another common allergic skin condition, atopic dermatitis, has several different manifestations whose pathophysiology extends beyond IgE-mediated allergic processes (see Chapter 7).

Epidemiology and Causes

In contrast to autoimmune reactions, which tend to have a female predominance, allergic reactions are equally distributed between the sexes, affecting women as often as men, without regard to race. The incidence of allergies is greater in children than adults, perhaps because of the immaturity of immune responses in children and the tendency toward humorally mediated T helper cell–2 (Th2) type responses.

Seasonal allergies vary according to hemispheric geography, which means that pollen, mold, and fungal spores affect individuals according to seasonal patterns of exposure in the Northern and Southern hemispheres. In North America, pollens rise and fall in a May to September pattern, whereas molds follow a March through December pattern in outdoor environments; therefore, there are only 2 to 3 months of the year, in the late winter, when pollens and molds tend not affect the population. During cold weather, however, individuals remain indoors for longer periods of time, which can increase the risk of more frequent exposure to dust mites and other indoor allergens, including indoor mold species that tend to propagate in cool, dark interior environments, such as damp basements or bathrooms.

Causes of allergies include a wide array of environmental allergens and the corresponding intrinsic immune complexes formed by the body as it mounts a vigorous response to allergenic exposure. Environmental allergens include natural *inhalants* such as pollen, mold, and fungal spores, *ingestants* such as food and drug allergens, *injectants* such as animal or insect venoms, and *contactants* including dust mites and their feces, animal hair and dander, as well as chemical components in hair- and skin-care products. Regardless of the source, the allergen invades the body, either locally or systemically, eliciting a complex immune-regulated response that results in either local or systemic effects.

Pathophysiology

All allergens are foreign substances to the body. Cellular and humoral immune responses occur after initial exposure to a foreign substance. Immune responses result from a complex, coordinated set of events requiring several different cell types, cell surface signaling proteins, and secreted regulatory cytokines. Key cell types include histamine-containing mast cells and basophils, as well as highly granular eosinophils. Also important are antibody-secreting plasma cells that are specialized, differentiated B-lineage cells designed to produce monoclonal antibody of a single antigenic specificity. Also important are CD4+ T helper cells that are also antigen specific and produce an array of regulatory cytokines after their T-cell receptors come into contact with specific antigens. Helper T cells of the Th2 class produce cytokines (e.g., IL-4, IL-5, IL-13) that upregulate humoral antibody-mediated immune responses, whereas Th1 helper T cells produce a separate set of cytokines (e.g., IFN-γ, IL-12) that upregulate cell-mediated antibody-independent cytotoxic responses.

According to the Gell-Coombs classification system, there are four basic types of immune responses to allergens (termed *hypersensitivity responses* as a group), categorized by whether or not they are dependent on circulating antibodies (types 1 through 3) or only cellular immune components (type 4). Type 1 immune responses are considered classic allergic hypersensitivity reactions. However, type 3 immune responses often underlie what are termed *drug and food allergies,* whereas type 4 immune reactions mediate contact dermatitis, a pathological response to certain skin irritants, such as the allergens in poison ivy and poison oak.

Type 1: IgE-Mediated Immediate Hypersensitivity Response

In the first step of initial exposure to an allergen, the immune system must recognize that the allergen is foreign. Immunoglobulin E (IgE) is an immunoglobulin class present in relatively low concentration in the circulation. As with all immunoglobulins, IgE molecules are antigen specific in their variable arms, allowing for binding of more than one IgE molecule to a single circulating

antigenic molecule. However, the constant portion of the IgE molecule (Fcε) allows for its binding to the surface of cells specifically expressing high-affinity receptors for the IgE molecule (FcεRIII). IgE molecules are bound to tissue-derived mast cells located primarily in the skin, respiratory system, and gastrointestinal (GI) tract, where allergens are most likely to contact or invade the body. In addition, circulating basophils are bound to allergen-specific IgE molecules.

Antibody cross-linking is the process by which two or more IgE molecules bound to the cell surface bind a common antigen, thereby triggering intracellular signaling and degranulation, with the release of cytokine mediators. Such responses do not typically occur on initial exposure to an allergen. On first exposure, specific IgE molecules are formed via class-switching of preformed antigen-specific B cells of the IgG or IgM classes to IgE, based on the constant portion of cell surface antibody molecules. These molecules then bind to mast cells and basophils, and upon reexposure to the same antigen when an allergen again binds to cell-bound antigen-specific IgE, a cascade of cellular events occurs, resulting in intracellular calcium shifts, which facilitate cyclic nucleotide signaling molecules to trigger leukocytic degranulation.

This leads to the excretion of preformed inflammatory mediators including histamine, heparin, tryptase, and other proteolytic enzymes, thromboxane, arachidonic acid, prostaglandins, superoxides, and several eosinophilic and neutrophilic chemotactic factors, as well as triggering the synthesis of newly formed inflammatory mediators including leukotrienes and key cytokines.

Inflammatory mediators cause venules, capillaries, and arterioles to dilate and become hyperpermeable. The mucous membranes are triggered to increase mucus excretion and the walls of hollow visceral structures to spasm as a result of smooth muscle contraction. Dehydration may result from a relative shift of fluid that follows intravascular proteins out of the vasculature and into the extravascular space, thus potentially lowering the blood pressure. Hypotension may also be aggravated by other environmental factors such as relative heat and humidity.

IgE activation and cellular excretion of inflammatory mediators may take place within seconds to minutes after antigenic exposure. Whereas the effects of initial inflammatory mediators may last for 30 minutes or less, repeated allergenic exposure can prolong the inflammatory cycle for hours. A prolonged and intractable inflammatory cycle produces the clinical picture of atopic (hypersensitivity) diseases characterized by type 1 allergic responses, such as allergic rhinitis and allergic asthma, which are heavily dependent on inflammatory cells including mast cells, eosinophils, and Th2 cells.

A second category of type 1 allergic reaction is *anaphylaxis*. Unlike atopic diseases, which are characterized by localized effects in the skin or respiratory tract, anaphylaxis is systemic in scope. All of the inflammatory processes of hypersensitivity become exaggerated, leading to life-threatening hypotension, bronchospasm, laryngospasm, angioedema, smooth muscle and visceral organ contractions, and raised inflammatory skin eruptions (generalized urticaria). Anaphylaxis may follow exposure in susceptible individuals to well known allergens, such as insect venom (bee or wasp stings) or certain drugs such as penicillin. However, these responses are not limited to individuals with a history of atopic disease and may occur unexpectedly in any individual. Therefore, a history of atopy does not predict anaphylaxis. If left untreated, anaphylaxis is typically fatal. Advanced Practice Nursing Interventions 17.2 describes a seven-step treatment algorithm for anaphylaxis.

Type 2: Antibody-Mediated Cellular Cytotoxicity Response

Type 2 antibody-mediated cellular cytotoxicity responses introduce an immune mechanism different from type 1

Advanced Practice Nursing Interventions 17.2
The Seven-Step Treatment For Anaphylaxis

- Step 1: Administer aqueous epinephrine 1:1,000 dilution 0.3–0.5 mg (0.3–0.5 mL) IM into the upper lateral thigh, in a supine position with head below heart level, if possible.
- Step 2: Repeat epinephrine every 5–15 minutes as required by clinical picture. If hypotensive, position the patient supine with feet elevated.
- Step 3: Support bronchodilation if patient is without laryngospasm by administering albuterol 3 mL (2.5 mg) inhalation via nebulizer.
- Step 4: If patient is in laryngospasm or pulmonary arrest, perform emergency endotracheal intubation and provide respiratory support.
- Step 5: Start IV fluids using normal saline or Ringer's lactate solution to maintain systolic blood pressure greater than 90 mm Hg. The rate of flow should be determined by the blood pressure reading but typically may be bolused.
- Step 6: If the patient is conscious and without laryngospasm, administer diphenhydramine (Benadryl) 25–50 mg to relieve cutaneous symptoms. H_2-blockers may also be added (particularly if GI symptoms are present) but have not been shown to be as effective as H_1-blockers.
- Step 7: Transfer the patient to an acute-care emergency center for continued support and observation. Add corticosteroids (IV or PO) to prevent late-phase anaphylactic reactions, which may be as severe as early-phase reactions.

See text regarding teaching about injectable epinephrine (EpiPen, Twinject).

immediate hypersensitivity responses. Type 2 responses involve the activation of antigen-specific IgM and IgG molecules. These humoral immune molecules bind to foreign antigens and activate serum immune complement. This leads to destruction of any cell to which an allergen-antibody complex is bound; thus, a type 2 immune response is cytotoxic. Examples of such type 2 responses include neonatal Rh-incompatibility hemolytic disease and immune-mediated hemolytic anemia. In addition, once antibodies bind to foreign antigens such as microbial cell surface proteins, these invading microbes become prone to phagocytosis and destruction by other immune cells, a process known as opsonization.

Type 3: Antibody–Allergen Immune Complex Response

The third category of immune responses also requires immunoglobulin M (IgM) and IgG activation, as is characteristic of a type 2 immune response. However, type 3 responses denote an immune complex that is formed between these immunoglobulins and the allergen. These complexes become deposited into the various tissues of the body, activating serum complement that in turn triggers various inflammatory mediators. These illnesses tend to be systemic, as immune complexes affect multiple organs and tissue types throughout the body. The reaction is not immediate, and in fact, may occur up to 2 to 3 weeks after antigenic exposure. Hypersensitivity-type pneumonitis secondary to inhaled allergen and serum sickness are two examples of type 3 immune responses. Delayed drug reactions are also classic examples of type 3 responses, with the most common offenders being the antiepileptic drugs phenytoin, phenobarbital, and carbamazepine, as well as various antibiotics.

Type 4: Delayed-Type Cellular Hypersensitivity Response

The fourth category of immune responses is defined as a cell-mediated delayed-type immune response that is unlike the three previous categories, which are all mediated by humoral factors (antibody-dependent). The other three categories directly involve few, if any, T lymphocytes. However, type 4 reactions are T-cell dependent and usually begin in the skin, where large numbers of T cells are found. Antigen contacting the skin is endocytosed (taken up) by antigen-presenting cells, which process and relocate small antigenic peptides on the cell surface, coupled to antigen-presenting proteins known as major histocompatibility complex (MHC) molecules.

Antigen-specific T-cell receptors recognize and bind to these antigenic peptide–MHC complexes, which leads to a series of inflammatory reactions including cellular lysis of the antigen-presenting cell and cytokine production. Because of this delay in cellular lysis, which may take up to 2 to 3 days after antigenic exposure, skin eruptions do not appear immediately. Contact dermatitis (e.g., poison ivy, chemical irritations, nickel metallic allergies) is the classic example of a type 4 immune response. In addition, the wheal and flare response to *Mycobacterium tuberculosis* purified protein derivative (PPD) used in TB screening is also a type 4 immune response, when resulting positive in persons previously exposed to TB. This explains why the tuberculin skin test (TST) is read at 48 to 72 hours after placement.

Clinical Presentation

Subjective

Patients with classic atopic disease report fatigue and/or malaise, irritability, itchy and watery eyes, sneezing, rhinorrhea, nasal congestion, coughing without sputum production (unless a secondary bacterial infection accompanies the allergy), pruritus, and, in more severe cases, wheezing. Two elements are common to subjective complaints associated with allergies. First, an exposure to an allergen precedes the onset of symptoms. Thus, allergic rhinitis can be distinguished from perennial rhinitis because environmental seasonal allergen exposure precedes the former. Second, patients typically attempt to control their symptoms with self-care. For example, their subjective picture usually includes self-medication and may be somewhat controlled with over-the-counter (OTC) agents. A history of subjective allergic symptoms, therefore, requires accompanying inquiry concerning the use of OTC antihistamines and decongestants.

Objective

The sinuses may be tender to percussion if nasal congestion has predisposed a patient to sinusitis (due to impeded mucous drainage); otherwise, the sinuses are typically nontender in uncomplicated allergic rhinitis. The conjunctivae and mucous membranes in general will be injected. Nasal turbinates should be erythematous. Cervical nodes will feel shotty, with few greater than 1 cm in size. Postauricular nodes and thoracic nodes may not be involved. Tympanic membranes may appear dull to light but will be otherwise unremarkable.

Tachycardia typically accompanies OTC decongestant use, but fever does not contribute to the tachycardia because fever is almost always absent. Drowsiness is also typical with OTC antihistamine use (especially with first generation H_1-blocking agents). Lungs will be clear after several deep breaths and coughs unless allergic asthma causes wheezing to appear. Except in patients with anaphylaxis or allergenic invasion of the GI tract, the abdominal exam will prove unremarkable. In these exceptional cases, profound abdominal tenderness may inhibit deep palpation.

Skin eruptions will depend on the type of allergic reaction and may include urticarial (type 1 response), fissures, circumscribed papules, bullae, and petechiae. The clinician should expect no singular picture of skin eruptions that corresponds with the allergenic source; however, there are associations in skin presentation and

history that lend themselves to diagnostic conclusions. For example, a history of exposure to poison ivy and multiple circumscribed papules in the anatomic place of exposure provides an association that is diagnostic of a specific exposure. Poison ivy, poison oak, and poison sumac all produce contact dermatitis by virtue of the oily irritant substance urushiol, which is contained in the leaves of these plants and acts as a contact allergen, leading to a delayed, cell-mediated (type 4) immune response.

If the patient's sensorium is affected, an objective mental status examination may reveal diminished problem-solving ability, impairment in recent recall, and unfocused attention. These signs are particularly evident in older adults and others who practice polypharmacy with combination OTC agents. Thus, it may be difficult to distinguish between the sedative effects of antiallergy medications (in particular, antihistaminic agents) versus the impact of a chronic atopic condition that is affecting the patient's sleep–wake cycle, such as severe allergic rhinitis or nighttime asthma.

Diagnostic Reasoning

Diagnostic Tests

Initial evaluation begins with the clinical history. The clinician should ask the patient to describe any changes in diet, skin-care products, or activities involving environmental exposures that preceded the onset of allergic symptoms. Suspicions raised by the history will often be confirmed or at least supported by subsequent diagnostic testing. Thus, particularly with regard to the evaluation of environmental exposures, a detailed history informed by the clinical presentation should largely drive diagnostic allergy testing.

Type 1 Response Initial testing continues with skin tests to diagnose the response to specific allergens. Skin tests involve first pricking the epidermis with a small amount of a liquid extract of the allergens of interest and later injecting the intradermal layers of the skin with these extracts, which is believed to be a more sensitive form of testing. (Patch testing, in which small amounts of emulsions of potential allergens are applied directly to the skin and left in place for 24–48 hours, is generally performed to diagnose contact dermatitis reactions and other manifestations of type IV hypersensitivity reactions.) Skin pricking testing is the first stage of allergen testing because of the very slight but potentially fatal risk that the applied allergen could cause a systemic allergic response (anaphylaxis). For every negative prick test, an intradermal injection may be placed as a more sensitive, albeit potentially higher risk, method of allergen testing.

The selection of antigens to be tested follows a pattern of reasoning based on the question: What are the most likely culprits? The exact composition of skin-test panels is determined by regional and patient-specific determinants. The allergist will expose the patient to small amounts of regional and suspected environmental allergens in skin-test panels by prick or injection. If the test is positive, a wheal should appear in 15 to 20 minutes. The reliability and sensitivity of skin testing make it the preferred test for initial diagnosis. Skin tests are done with both positive (histamine) and negative (inert substances, such as saline) controls, and results must be judged against these controls as some individuals are sensitive to any kind of scratching or pricking of the skin, just by the nature of the insult to the skin, and not due to hypersensitivity to the antigen. However, given the sensitivity of allergen skin testing, a high false positive rate means that this testing should not be done indiscriminately or overinterpreted. In fact, many environmental and food allergens may test positive in up to half of the general population who otherwise demonstrate no other manifestations of hypersensitivity to these antigens. In turn, skin tests are far more useful in ruling out (i.e., excluding, rather than confirming) specific antigenic hypersensitivities, when reactions are negative.

Alternatives to allergen skin testing include in vitro serum-based testing methods, such as the radioallergosorbent test (RAST), the enzyme-linked immunosorbent assay (ELISA), and the fluorescent antibody staining technique (FAST). These serum tests reduce the risk of hypersensitivity-type reactions from allergens as seen in skin testing because they only measure antigen-specific IgE levels in the blood, rather than assess for functional hypersensitivity responses. Thus, skin tests are typically more sensitive than serum RAST tests in detecting true hypersensitivity responses because more atopic individuals will be positive on skin tests than will have elevated antigen-specific IgE serum levels. RAST tests are usually considered more specific than allergen skin testing as nonatopic individuals are unlikely to have high allergen-specific IgE levels, which must be balanced with their relatively decreased level of diagnostic sensitivity.

Consideration of sensitivity and specificity of allergy testing is particularly important for food challenge testing, which often utilizes skin prick testing as an initial screen, given its high sensitivity. Some clinicians also complement skin testing with RAST testing because although some food allergies may be type 3 immune complex responses, there certainly are anaphylactic food allergy reactions, which are IgE mediated and may be clinically severe. Definitive testing for such reactions may take place in an office setting by an allergy specialist (with ready access to endotracheal intubation supplies and injectable epinephrine) in the presence of physicians or other persons qualified to treat anaphylactic reactions. Set amounts of food are given to persons suspected of food allergy (typically children) in progressively increasing amounts, and individuals are subsequently monitored for several hours for any reaction. This is a highly specific test and is thus very effective in ruling out food allergies. Obviously, however, this testing method carries a great risk of anaphylaxis. Thus, RAST testing may be done instead of an observed food challenge to avoid needlessly subjecting individuals with

high food-specific IgE levels to intentional exposure with that food trigger.

The most common form of asthma is an allergen-driven atopic disease characterized by type 1 immune responses to environmental allergens although it is distinct from systemic anaphylaxis. Atopic airway hyperreactivity may also be triggered by environmental irritants, such as tobacco smoke, which is not a true allergen. Thus, these individuals do not express true tobacco-specific IgE levels although smoke and other environmental pollutants may certainly trigger an asthma attack. Reactive airway disease (bronchial hyperresponsiveness), therefore, may be either allergic or nonallergic in origin. As asthma is largely an atopic, allergen-driven disease, sputum from an asthmatic patient may reveal eosinophils after staining with methylene blue dye, because sputum from atopic individuals typically demonstrates higher levels of eosinophils than in the nonatopic population.

Type 2 Response Rh testing of blood during pregnancy is the initial test to determine prospective Rh incompatibility. With reference to immune-mediated hemolytic anemia, an elevated indirect bilirubin level indicates hemolysis. Red blood cell (RBC) hemolysis is further associated with decreased serum haptoglobin levels. AIHA is also associated with a positive Coombs' test, which detects RBC-specific antibodies in the blood.

Type 3 Response Initial tests are employed to detect complement activation. A complement ELISA will give specific evidence of complement activation and consumption of complement proteins. For example, the ELISA might show lower levels of C_3 and/or C_4, which are two elements of complement that may be diminished if an allergic inflammatory reaction has activated complement. Similarly, the CH50 test, which is a measure of overall complement protein levels, will also be low in this setting. Skin manifestations in type 3 immune responses may be biopsied and stained for immune complex deposition, which is a hallmark of such reactions.

Type 4 Response Skin testing is the initial test of preference for cell-mediated hypersensitivity, e.g., tuberculin skin testing. Allergens are either injected intradermally or applied topically onto patches of skin. Results are then read 48 hours after application. Positive responses consist of induration (for injected allergens) and erythema and papules (for topically applied skin patch testing).

Antigen-specific serum IgE levels may aid in distinguishing allergic from nonallergic immune responses. For example, classic type 1 hypersensitivity reactions are IgE mediated, whereas cell-mediated type 4 responses are not. Although both type 2 and type 3 responses are antibody mediated, the IgE immunoglobulin class is not typically involved. An elevated peripheral eosinophil count may also provide secondary confirmation of recent IgE-mediated atopic disease.

Differential Diagnosis

Clinical history is the mainstay of differentiating allergic disease. Allergies are triggered by exposure to environmental antigens. The history, therefore, must support allergenic exposure proximal to the onset of symptoms and may often reveal partial or temporary relief of symptoms from OTC allergy remedies, as well as possible familial allergic patterns. Additional differentiation of classical allergic disease from other types of immune responses comes from skin test results, antigen-specific IgE levels, and other diagnostic tests aimed at identifying antibody-mediated immune responses.

Alternatively, irritants that enter the body but do not initiate classical immune-mediated hypersensitivity responses include nonallergic sources, such as air pollutants and tobacco smoke. In addition, some research has suggested that susceptible asthmatic patients may experience worsening of symptoms associated with barometric changes in the atmosphere, although it is unclear whether this weather-related phenomenon may actually be due to increases in airborne pollen levels associated with atmospheric pressure changes.

Management

Allergy management requires both symptomatic relief and prevention of exposure to specific allergens. Following the initial diagnosis and treatment of acute symptoms, priority should be given to identifying and avoiding triggering allergens, whether with respect to respiratory symptoms (asthma, allergic rhinitis), cutaneous manifestations (urticaria), ocular allergies, or systemic allergic reactions (anaphylaxis). (Atopic dermatitis, another core atopic disorder, is covered in detail in Chapter 7.) For both allergic rhinitis and asthma patients, long-term immunomodulatory therapy with allergy vaccines (i.e., allergen immunotherapy) offers both effective prophylaxis and attenuation of future atopic symptoms.

Initial Management

The patient must become vigilant in avoiding further allergenic exposure. After clinical history, skin testing, and antigen-specific IgE levels have identified likely triggering allergens, avoidance behaviors should be initiated. For example, individuals diagnosed with hypersensitivity to penicillin must avoid not only penicillin but also cephalosporins, given the likelihood of cross reactivity. However, although penicillin remains one of the most common triggers of antibiotic hypersensitivity, penicillin allergy is typically overdiagnosed on the basis of limited self-reported history. Thus, a detailed patient history should focus on whether an anaphylactic reaction to penicillin truly occurred, as research involving confirmatory skin testing and antibiotic challenge has consistently demonstrated that the majority of patients who report penicillin allergies do not have true penicillin hypersensitivity reactions or contraindicating anaphylaxis. Moreover, when use of a specific antibiotic class is deemed essential in an allergic patient, desensitization to penicillin or other antibiotics can be performed in a controlled clinical environment with the capacity to treatment anaphylaxis and other forms hypersensivity (e.g., intensive care unit).

Along the same lines, bee venom reactions can be avoided in venom-allergic patients by not disturbing beehives or wasp nests. Dust mite–allergic patients may use specially designed mattress and pillow covers that seal in dust mites and their allergenic fecal matter, avoid dust-collecting ceiling fans, remove carpets from bedrooms to limit dust mite exposure during sleeping hours, and regularly wash plush toys and any other potential dust reservoirs in hot water. Patients with pollen allergies should keep windows closed in favor of using air conditioning in both the home and car, as well as bathe soon after outdoor exposure to pollen, which can adhere to clothes and hair. Air conditioning filters should be changed regularly, although high-efficiency particulate air (HEPA) filters and chemical agents purported to reduce the concentration of aeroallergens have not been shown to be consistently effective.

Subsequent Management

Subsequent management consists of ongoing symptom control and immunotherapy. Symptom control can be achieved either through prescribed or OTC agents for common respiratory, ocular, and cutaneous manifestations. There are many classes of drugs that have demonstrated efficacy for symptom management in allergic disease, for example, sympathomimetics (used as decongestants), antihistamines (both oral and topical), corticosteroids (topical, inhaled, or systemic), cromolyn, and theophylline. Newer generation antihistamines have been designed to have less anticholinergic effects and central nervous system penetration and, therefore, cause less tachycardia and sedation than first generation agents.

Of special note, in addition to future allergen avoidance, the most severe form of allergic disease, anaphylaxis, requires emergent treatment (e.g., epinephrine, IV fluids) for immediate life-threatening manifestations caused by preformed inflammatory mediators, as well as prophylactic treatment (e.g., corticosteroids) for delayed, late phase manifestations caused by de novo, newly formed immune mediators, as described in Advanced Practice Nursing Interventions 17.2. Because late phase anaphylactic reactions may occur up to 24 hours following allergen exposure and can prove fatal, prophylactic corticosteroids should be given although they are ineffective in treating acute symptoms, given their slow onset of action.

Symptom Control Many OTC agents are sympathomimetic (alpha-receptor agonist) in activity. Common examples of oral drugs in this class include pseudoephedrine (Sudafed), chlorpheniramine (Chlor-Trimeton), and oxymetazoline (Afrin). In addition, epinephrine (Primatene Mist) was previously available OTC as an inhalational therapy in the same class of sympathomimetic drugs. However, sale of the chlorofluorocarbon (CFC)–containing formulation of inhaled epinephrine was prohibited by the U.S. Food and Drug Administration (FDA) in 2012.

Sympathomimetic agents may display both alpha-adrenergic and beta-adrenergic properties. They vasoconstrict engorged mucosa (alpha-adrenergic property) and dilate the bronchioles by relaxing smooth muscle (beta-adrenergic property). Therefore, they support antihistamines in drying secretions while opening up the airways of the nasopharynx and bronchial tree. In addition, however, they also typically increase heart rate and may lead to palpitations (beta-adrenergic effect). Because of their low molecular weight and solubility, sympathomimetics may cross the blood–brain barrier, resulting in irritability, anxiety, and addiction potential, particularly when combined with other psychoactive substances such as ethanol. In addition, topical intranasal agents such as oxymetazoline are well known to induce tachyphylaxis (decreased response to the drug following frequent use over a relatively short period of time), resulting in rebound nasal congestion upon withdrawal after chronic use (rhinitis medicamentosum).

The abuse potential of OTC sympathomimetics remains high for many reasons. They are available for purchase and consumption without professional supervision, are relatively inexpensive, provide rapid symptomatic relief, and are heavily marketed. In addition, sympathomimetic formulations may be readily manipulated to form highly addictive illicit drug substances, such as methamphetamine (which in recent years has resulted in increasing restrictions on the OTC availability of some of these drugs, such as pseudoephedrine). In addition, some studies suggest that regular use of short- and long-acting beta-adrenergic inhalants, such as albuterol (Proventil) and salmeterol (Serevent, Advair) may increase disease morbidity in asthmatic patients, including both exacerbations and asthma-related deaths.

Another class of agents widely used for allergic reactions and chronic atopic disease are the antihistamines. With both first and second generation agents now available OTC, antihistamines are widely used in allergic disease for their ability to block H_1-histamine receptors and thereby reduce the effects of histamine released early on in the inflammatory cascade. The blockade of H_1-receptor sites also contributes to the therapeutic effect of drying secretions. Adverse effects include overdryness and sedation. The risk of sedation, particularly in older adults and children, may require dose reduction or a limited drug trial. Newer generation antihistamines such as desloratadine (Clarinex), fexofenadine (Allegra), and cetirizine (Zyrtec) are typically less sedating than first generation agents (diphenhydramine [Benadryl], hydroxyzine [Atarax]). Thus, at prescribed doses, these second generation agents dry secretions without causing excessive drowsiness in most patients and can be dosed once daily. They are also not associated with untoward cardiac events (QTc prolongation, fatal arrhythmias), which had been observed with other long-acting second generation antihistamines now withdrawn from the market (astemizole [Hismanal], terfenadine [Seldane]), particularly when used in combination with macrolide antibiotics or azole antifungals.

Anticholinergic agents such as intranasal ipratropium (Atrovent) are also very effective at drying secretions.

H_2-receptor antagonists such as cimetidine (Tagamet) and Ranitidine (Zantac) may also be useful in managing mild allergic reactions, although they are primarily used to decrease the production of stomach acid for GI symptoms. In some cases when allergy patients have failed to improve after receiving epinephrine and diphenhydramine, they have responded to cimetidine. However, H_2 blockers are known to cross the blood–brain barrier and may have mood-altering effects, particularly in elderly patients.

Corticosteroids form a third group of drugs used in symptom control. Given their long onset of action (several hours), they have little role in the acute treatment of symptoms. However, they may prevent the recurrence of symptoms in patients with mild allergic reactions, such as urticaria, and they also constitute part of the long-term treatment regimen of life-threatening allergic reactions, such as the manifestations of systemic anaphylaxis, including severe laryngeal edema, bronchospasm, or hypotension. For most hypersensitivity reactions, a dosage of 1 to 2 mg/kg per day of prednisone for 4 or 5 days is usually sufficient to prevent recurrent or late-onset symptoms. Short-term pulse dosing such as this does not require tapering. However, the clinician should consider tapering the regimen if the patient has received corticosteroid therapy in the recent past or if there are plans to continue therapy for more than several weeks. When given as short-term therapy, prednisone and other corticosteroids have fairly benign adverse effect profiles. However, prolonged use of systemic corticosteroids has a number of implications, including the development of Cushingoid syndrome, adrenal insufficiency, and hyperglycemia. Inhaled corticosteroids such as fluticasone propionate (Flovent) are used as standard prophylactic controller medications in allergic asthma (see Chapter 9). Intranasal corticosteroids such as mometasone furoate (Nasonex) are extremely effective for long-term control of both nasopharyngeal and ocular allergic rhinitis symptoms (see Chapter 8). Because corticosteroids are immunosuppressive, anti-inflammatory agents, they effectively downregulate the allergic immune responses characteristic of atopic disease.

Immunotherapy Allergen immunotherapy (allergy vaccine) offers the patient long-term control of atopic disease. Given the small, albeit well documented, risk of anaphylaxis or other hypersensitivity reactions associated with allergen immunotherapy, its use is usually limited in scope to patients with intractable allergic rhinitis or asthma whose disease fails to be controlled with symptom management or for whom consistent allergen avoidance is not possible. Immunotherapy regimens should be prescribed and administered by a qualified specialist with expert knowledge in allergic diseases as the first step is the proper identification of key allergens, which serve as the patient's most troublesome environmental triggers. Depending on the number of allergens identified, these extracts are combined into one or more allergy vaccine mixtures, taking into account both cross-reactivity of individual allergens and the reduced stability of certain allergen extracts (e.g., plant pollens, animal dander) in combination with others, given the presence of proteolytic enzymes in many fungal and insect (e.g., dust mite, wasp or bee venom) extracts.

Injections of commercially prepared extracts of these allergens are given subcutaneously in 0.5 mL allotments of diluent that progress from minimal dilutional strength to higher concentrations. The weekly injections continue, increasing in concentration until symptoms are controlled and/or the maximum concentration of allergen extract is achieved, at which time the frequency of injections may be decreased to a goal of once monthly. Of note, immunotherapy may require more than 12 months of treatments before maximal effects are observed. There are also "rush immunotherapy" protocols that are being evaluated, which are shorter course regimens that escalate a patient to maximal allergen extract concentrations more quickly than traditional regimens. Current guidelines recommend continuing allergen immunotherapy for 3 to 5 years, after which many individuals experience lasting suppression of allergic hypersensitivity, allowing for the tapering and eventual cessation of extract injections. However, many patients experience recurrence of allergic symptoms when they attempt to stop or even taper the frequency of maintenance immunotherapy. Thus, although not generally recommended, some patients may continue immunotherapy for life.

Injection allergen immunotherapy has been used for over a century. However, a newer development is sublingual formulations, in which liquid extract is administered in drops under the tongue. The concept behind these regimens is the same as traditional subcutaneous and intradermal injection immunotherapy although the convenience of this dosing route is self-evident, particularly given the potential for self-administration in nonclinical settings. Although sublingual immunotherapy (SLIT) has gained acceptance in Europe, its use is not widespread in the United States because evaluations of its safety and efficacy are ongoing.

Other forms of biological immunotherapy exist for allergic diseases. For extremely refractory cases of atopy, such as severe allergic asthma with atopic dermatitis, Xolair (omalizumab; anti-IgE–specific monoclonal antibody immunotherapy) may be effective. Xolair is FDA approved for moderate to severe persistent asthma in persons 12 years and older. This therapy acts by binding up circulating IgE and preventing its interaction with cell-surface molecules on blood cells that mediate allergic hypersensitivity responses, including mast cells, basophils, and eosinophils, thereby preventing initiation of the allergic cascade.

One clinical scenario, which offers insight into a patient who might benefit from immunotherapy, would

be that of a 55-year-old woman diagnosed with severe and persistent allergic rhinitis refractory to both OTC and prescription controller medications. Her primary triggering allergens are dust mites, ragweed pollen, egg, and *Aspergillus.* Food-based allergen immunotherapy is not considered an acceptable therapeutic strategy, given the relatively higher risk of anaphylaxis to food antigens. Thus, she completely avoids egg in her diet. To avoid dust mite exposure, she has removed all carpeting from her bedroom and replaced her curtains with window blinds. However, she cannot relocate from her home in the midwestern United States, where ragweed pollen levels are elevated between July and October. Her husband cleans the bathroom tiles and kitchen cabinets where *Aspergillus* might grow. For the past 3 months, she has consulted the clinician on six occasions. Her medication regimen includes a prescribed inhaled intranasal corticosteroid and both long- and short-acting antihistamines. Nonetheless, her symptoms keep her awake at night, and recently she has started to wheeze, requiring use of an albuterol metered-dose inhaler. Her primary care clinician referred her to an allergist, who made the specific allergen diagnoses and recommended allergen immunotherapy on the basis of the severity and recurrence of her symptoms, as well as her refractoriness to other medications. Of note, given the risk of anaphylaxis associated with allergen immunotherapy, the risk–benefit ratio of this approach will have to be discussed extensively with the patient before she initiates the allergy vaccine regimen.

Follow-up and Referral

Follow-up consists of both regular visits and increased consultations during seasonal allergy periods, depending on symptoms. Follow-up tests include a CBC to evaluate for leukocytosis and eosinophilia, as well as fasting blood sugar tests to assess for hyperglycemia, should systemic corticosteroids be required.

An allergist should be consulted if the symptoms cannot be controlled. The allergist is responsible for ordering and evaluating skin tests and for prescribing, administering, and evaluating the effectiveness of immunotherapy.

Patient Education

Depending on the patient's clinical manifestations, she or he must know what foods or other environmental allergens to avoid. The patient and clinician should decide together how to identify and control exposure to triggering allergens that may have been unknown by the patient before the diagnosis. For example, few patients know the places that dust mites hide or understand how to kill *Aspergillus* with simple household chemicals.

Patients with significant respiratory symptoms may need to learn how to use nasal inhalants for significant rhinitis symptoms or metered-dose inhalers (MDIs) for bronchial/pulmonary symptoms. Initial use under the clinician's supervision can provide both the patient and clinician with reassurance that the drug will be delivered correctly. The use of spacers for MDIs should be discussed and encouraged as a means of maximizing medication delivery (see Chapter 9). The patient should learn which drugs may be taken together without significant risk of interaction and which should be administered alone or with food to facilitate absorption. The narrow therapeutic index of some drugs, such as theophylline, will require vigilance on the part of the patient to report the early symptoms of drug toxicity.

Patients with a history of anaphylaxis must have epinephrine available at all times for emergencies should they come in contact with the offending allergen. The immediate use of epinephrine after any exposure to a known anaphylactic triggering agent is crucial.

The clinician should prescribe a self-administered epinephrine kit and have the patient demonstrate understanding of its use before leaving the office. There are several brands of epinephrine available in kit form (Ana-Kit, AnaGuard, EpiPens, TwinJect). The expiration date for most kits is 1 year, and some kits contain more than one dose of epinephrine, which the patient injects IM for rapid delivery in a postexposure setting. The patient should be instructed that whenever a dose is self-administered, emergency department care should be sought in case the reaction worsens or recurs, requiring more advanced therapy such as IV epinephrine or crystalloids. Given the life-threatening nature of anaphylaxis, susceptible individuals with a history of systemic hypersensitivity reactions to environmental triggers must always have access to a readily available source of epinephrine.

Many patients will take OTC agents to help with allergy symptoms and should be taught to read and interpret drug labels correctly to check for ingredients that might cause tachycardia, drowsiness, or other adverse effects. Patients should be cautioned to be alert for any OTC formulations containing ephedrine, phenylephrine, phenylpropanolamine, or pseudoephedrine.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis (RA) is a chronic, progressive, systemic inflammatory disease that primarily affects the synovial joints although it may affect many organ systems. Joints are destroyed over a long course of disease remissions and exacerbations. Structural deformities, which create emotional as well as physical trauma for the patient, are common as the disease progresses. *Healthy People 2020* has three objectives related to this chronic debilitating condition: (1) increasing the proportion of adults with chronic joint symptoms who have seen a health-care provider for their symptoms, (2) increasing the proportion of adults with physician-diagnosed arthritis who have had effective evidence-based arthritis education as an integral part of the management of their condition, and (3) reducing the proportion of adults

with physician-diagnosed arthritis who find it "very difficult" to perform specific joint-related activities.

Epidemiology and Causes

In the general U.S. population, RA is the second most common connective tissue disease and the most destructive to the joints. Women with the disease outnumber men at a ratio of 2.5 to 3.1:1, with a worldwide incidence of approximately 3 in 10,000 persons. Prevalence increases with age, with a peak of cases occurring between ages 40 and 60 years after an onset of disease between ages 20 and 40 years. RA has been observed across all racial and ethnic groups, but familial patterns have been observed, with first-degree relatives of affected patients having approximately a twofold to threefold higher risk of developing disease. Characterizing the genetic predispositions for disease remains an area of active research, and an association between rheumatoid arthritis and the human leukocyte antigen (HLA) system, a series of linked genes on the sixth chromosome, has been observed. Although genetic risk factors have been identified, the cause of the disease is as yet unknown. In turn, most therapies target the inflammatory pathways that mediate disease manifestations. Other potential etiological factors that have been implicated include infection, autoimmunity, environmental triggers, and hormonal influences.

Pathophysiology

Rheumatoid arthritis causes joint destruction through a number of immunopathogenic mechanisms. Proteolytic enzymes, known as proteases, digest the tissue components of affected joints. This is speculated to occur due to local antigens that evoke the inflammatory cascade in the joint space; however, the source of these antigens is not fully characterized. These antigens may be autoimmune targets (e.g., type II collagen found only in articular cartilage and the vitreous of the eye, glycoprotein-39 found in cartilage, citrulline-containing peptides [CCPs] including citrullinated fibrin, and glucose-6-phosphate isomerase), which activate self-reactive T cells that initiate the inflammatory cascade.

T cells comprise nearly half the immune cells in an inflamed rheumatoid joint and are characterized by an activated T-helper phenotype based on the cell surface expression of HLA-DR (MHC class II) antigens, CD27, CD4, as well as the costimulatory molecules CD28 and CD40. However, it has been difficult to characterize the antigenic specificity of the initial set of T cells that trigger this immune response, because the inflammatory cascade is characterized by widespread recruitment of so-called "bystander T cells" that do not express autoantigen specificity but nonetheless proliferate and contribute to the destruction of the affected joint through cytokine expression. Interestingly, some evidence indicates that it may not be the antigens themselves that trigger self-reactive T cells, but rather genetic mutations that alter specific amino acids within MHC class II antigen-presenting molecules (such as HLA-DRβ1) found on antigen-presenting cells. Other work has implicated superantigen interactions, in which several different T cell clones are activated independent of their association with MHC class II molecules.

Cells of the synovial (joint) lining including joint endothelium, T cells, and fibroblast-like cells proliferate, producing cytokines (e.g., interleukin-1 [IL-1], IL-6, IL-8, IL-15, IL-18, IFN-γ), neuropeptides such as substance P, and chemotactic factors that induce expression of cell adhesion molecules (e.g., intercellular adhesion molecule [ICAM]–1, vascular cell adhesion molecule [VCAM]–1, P-selectin, E-selectin). This leads to increased recruitment of an array of immune cells into the affected joint, including mast cells that produce histamine, tryptase, leukotrienes, cytokines, and chymase; multinucleated cells and macrophages which are the main source of potentially toxic nitric oxide and destructive matrix metalloproteinases (MMP) (e.g., collagenase [MMP-1], stromelysin [MMP-3], macrophage elastase [MMP-12]); and self-reactive plasma cells capable of producing autoantibodies (e.g., rheumatoid factor). Synovial fibroblasts further produce MMP-13, which has great specificity for type II collagen and is primarily responsible for soft tissue invasion in the affected joint.

Particularly noteworthy in the pathogenesis of RA is the production of rheumatoid factor—polyclonal antibody species typically of the IgM class that have specificity for the constant Fc region of IgG. Rheumatoid factor thus forms large immunocomplexes capable of activating complement proteins that themselves are cytolytic and chemotactic. The production of these antibodies is enhanced by cytokines secreted by regulatory CD4+ T helper cells. The plasma cell genes that encode rheumatoid factor undergo somatic mutations that increase their affinity for IgG, a process known as affinity maturation. Although rheumatoid factor is not pathognomonic of RA (as it may also be present in scleroderma, systemic lupus erythematosus [SLE], and even some viral infections) and may be absent in up to 25% of cases, the presence of these antibodies in the peripheral circulation correlates with invasive disease of greater severity.

Another type of autoantibody found in the blood of RA patients, anti-CCP antibodies (primarily specific for the protein filaggrin), are considered more specific for RA than rheumatoid factor and are now widely used in the diagnosis of early RA. However, they do not appear to play as significant a role in joint destruction and immunopathogenesis of RA as rheumatoid factor, because citrullinated peptides (which are the target of anti-CCP antibodies) are not typically found in the synovium of affected joints.

Tumor necrosis factor–alpha (TNF-α) is one of the main cytokines that trigger the proliferative rheumatoid synovium, which explains the efficacy of anti–TNF-α immunotherapies in treating RA. However, in addition

to TNF-α, a wide array of cytokines have been implicated in the pathophysiology of the rheumatoid joint, including granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-2, IL-13, IL-17, and transforming growth factor–beta (TGF-β). Moreover, cells of the synovial lining undergo transformation into a rapidly proliferating state (although incapable of true metastasis) in which several types of transcription factors (NF-κB, Fos, Jun, Raf, Myc) and intracellular kinases (e.g., mitogen-activated protein kinase [MAPK]) are upregulated.

As these various inflammatory pathways elaborate over time, joints are progressively destroyed by an invasive rheumatoid pannus. Similar to a destructive malignancy, the rheumatoid pannus is a creation of the inflamed synovium. It consists of granulated vascular tissue extending from the vascular bed into the joint space and is characterized by increased angiogenesis (new blood vessel formation), which is mediated by the upregulation of several angiogenic cytokines and growth factors, including hypoxia-inducible factor (HIF)–1, vascular endothelial growth factor (VEGF), heparin-binding growth factors, macrophage angiogenic factor (MAF), epithelial neutrophil activating peptide-78 (ENA-78), TNF-α, PGE_1, PGE_2, and IL-8. Nevertheless, this increased vascularity is often inadequate for the exaggerated level of cellular proliferation in the rheumatoid synovium. In addition, the increased intra-articular pressure within the affected joint resulting from this cellular proliferation, fibrin and clotting factor deposition, and fluid accumulation may tamponade articular vessels, resulting in progressive joint ischemia.

Mutations and overexpression of certain cell cycle regulatory proteins such as the *p53* tumor suppressor gene have been identified in cells of the rheumatoid synovium, which may render them less susceptible to apoptosis (programmed cell death). As discussed, cells in the pannus release proteolytic enzymes (e.g., MMP, glycosidases) that destroy the connective tissue matrix, including glycosaminoglycans, fibronectin, proteoglycans such as chondroitin sulfate, collagen, and eventually subchondral bony structures. Moreover, certain components of the rheumatoid pannus, such as regulatory T cells and bone marrow stromal cells, induce differentiation and proliferation of bone osteoclasts, which leads to further joint destruction. Fortunately, however, the pannus remains responsive to antiproliferative immunosuppressant treatments.

Within the synovial fluid, an inflammatory response also ensues but with a notably different distribution of immune cells. Polymorphonuclear neutrophils are the most prominent cellular infiltrate, numbering upwards of one billion in severely inflamed joints. These cells secrete a host of proteolytic enzymes into the joint fluid (e.g., myeloperoxidase, collagenase and other MMPs, elastase, and lysozyme), as well as inflammatory cytokines (e.g., prostaglandins, IL-1β), and chemotactic factors (e.g., leukotriene B4, platelet activating factor). Because accumulation of joint fluid distends the joint capsule and contributes greatly to articular pains, aspiration of this exudative fluid may provide instant relief.

The immunopathology of RA is widespread and extends well beyond the joint synovium. Constitutional signs and symptoms including fever, anorexia, weight loss, and fatigue may be prominent during acute flares, reflecting the systemic nature of the disease, which may involve layers of the heart muscle, cardiac valves, pulmonary visceral pleura, spleen, larynx, dura mater, and sclera (extra-articular manifestations). In turn, other organ manifestations of RA may include pericardial effusions, cardiac dysfunction (including myocardial infarction), and rarely pericarditis. Lung manifestations may include pleural effusion, pleuritis, interstitial fibrosis, and bronchiolitis obliterans with organizing pneumonia (BOOP). Hematological findings are not uncommon and may include anemia of chronic disease or thrombocytosis, whereas RA associated with both splenomegaly and neutropenia is termed *Felty's syndrome.* Ocular manifestations include keratoconjunctivitis associated with dry eye syndrome (sicca), as well as episcleritis, uveitis, and nodular scleritis, which can be sight-threatening.

Another common extra-articular manifestation of RA is rheumatoid nodules, which typically appear on the elbows but may be found on any extensor surface of the body that is subject to repeated mechanical stress, pressure, or irritation. Found in up to 25% of RA patients, these initially microscopic nodules are subcutaneous and may form into larger granulomas, characterized by a central section of fibrinoid necrosis, which is surrounded by a palisade of radially arranged and elongated connective tissue cells that are enveloped by chronic granulation tissue.

Clinical Presentation

Subjective

In the early stages of the disease, the RA patient may complain of malaise, diffuse arthritis, weight loss, anorexia, and low-grade fever. In addition, the patient may complain of neuropathic pain in the extremities, painful eyes, and chest pain upon deep inspiration.

The patient typically awakens with joint pain and stiffness but reports that it improves as the day progresses. Not only does pain subside, but the swelling associated with joints in the early morning also abates with moderate activity, thereby leading to decreased joint stiffness. If left untreated, however, as the disease progresses over time, recurrent pain and swelling in both small and large peripheral joints form the subjective picture that is ultimately associated with diminished activity and a downward spiral of worsening pain and immobility.

Objective

The key physical findings are peripheral symmetric polyarthritis and morning stiffness, which typically lasts longer than 1 hour. The clinician will note that some joints demonstrate more involvement than others. These

include the proximal interphalangeal (PIP) and metacarpophalangeal (MCP) joints in the hands and wrists, as well as the knees. The toes and ankles also tend to be affected. The clinician should expect the affected joints to be tender (painful to pressure), edematous, and partially immobile. Radiographic x-ray changes in early disease may be nondescript or absent even though synovial changes have already begun, although advanced magnetic resonance imaging (MRI) has shown promise as an imaging modality capable of detecting early joint manifestations with increased sensitivity compared with x-ray studies.

As the disease progresses, affected joints will appear more deformed and rigid, with diminished range of motion. Characteristic findings of advanced disease include the boutonnière deformity of affected fingers, in which the PIP joint is in a nonreducible state of flexion, along with hyperextension of the distal interphalangeal (DIP) joint, as well as the complementary swan neck deformity, in which the PIP joint is hyperextended and the DIP joint is in a constant state of flexion. The most severe form of structural joint damage in the hands is known as arthritis mutilans, which is characterized by extensive bone resorption, complete loss of the joint space, shortening and malpositioning of the fingers, and almost complete loss of function. In contrast to small joint involvement, monoarticular arthritis of a large joint is a far less common presentation in RA and is more suspicious for reactive arthritis, which does not typically manifest with morning stiffness.

Physical examination may also reveal additional significant findings associated with extra-articular organ manifestations of the disease. A cardiac rub associated with pericarditis may be detected. A pulmonary friction rub or diminished respiratory excursion may suggest inflammation in the visceral pleura, as well as involvement of the bony structures of the ribs and sternum. Dry crackles may reflect an interstitial pulmonary process in advanced chronic disease. A finding of injected sclera suggests scleritis. Loss of sensation, especially in the lower extremities, indicates peripheral neuropathy, and ecchymotic lesions may appear on the arms and legs. Rheumatoid nodules are commonly observed over the olecranon process or other extensor surfaces of the limbs and may be tender.

Diagnostic Reasoning

Diagnostic Tests

The initial test of preference for diagnosis is peripherally circulating rheumatoid factor (RF), which is an IgM class autoantibody that binds to the FC portion of IgG. The test result provides both qualitative and quantitative information that is useful in correlating with physical markers of RA. For example, a positive titer of greater than 1:150 indicates a poorer prognosis and is often accompanied by findings of severe disease such as rheumatoid nodules. It is necessary to interpret both the presence of RF (qualitative) with the dilutional titer (quantitative) because rheumatoid factor may be present in other diseases and its incidence increases with age. It is estimated that only 75% of RA patients are positive for RF.

Because RF alone is not diagnostic of RA, a more specific test is for circulating anti-CCP antibodies in the peripheral blood. This autoantibody species is more specific for RA than rheumatoid factor is and may be detected earlier in the disease process. However, anti-CCP titers correlate less well with severity of disease or prognosis, compared with rheumatoid factor.

Initial testing should also include an erythrocyte sedimentation rate (ESR), which will be elevated if the disease is active. C-reactive protein (CRP) is an acute-phase reactant, which, like ESR, is reflective of a heightened inflammatory state. Thus, CRP may be evaluated in addition to or in place of ESR as a nonspecific indicator of inflammation. Other tests include a complete blood count (CBC) to rule out anemia as a potential cause of fatigue and to evaluate for an associated leukocytosis or, alternatively, neutropenia. A platelet count (showing normal or high values) will become more elevated as joints become more inflamed. In addition, joint fluid analysis may aid in distinguishing rheumatoid arthritis from other causes of joint inflammation, such as infection. Aspirates from rheumatoid joints will show between 2,000 and 50,000 WBCs/mcL and a pronounced neutrophil component. Advanced Assessment 17.1 compares the typical results of synovial fluid analysis in RA and other inflammatory and infectious disorders.

Subsequent laboratory tests may be used as markers of disease progression. For example, ESR and CRP act as markers of inflammation, which may be helpful in charting the course of disease and response to therapy. Quantitative antinuclear antibodies (ANAs) may also help in differentiating rheumatoid arthritis from SLE, because lower titers suggest rheumatoid disease. If the diagnosis is in doubt, a comprehensive autoantibody panel may be drawn to help distinguish RA from other autoimmune connective tissue disorders, such as Sjögren's syndrome, although interpretation of such panels typically requires expert rheumatologic knowledge.

Radiographic x-ray changes in the joints may not be evident in the initial phases of the disease. However, after the disease has run its course for 6 months or more, radiographs will reveal bone erosions in the joints of the hands and feet. Plain films may show bony erosions in up to 30% of patients within 1 year of diagnosis and up to 90% of cases after the first 2 years. MRI has gained wider acceptance in recent years as a more sensitive (albeit significantly more expensive) detection method for joint changes in early disease. Research is ongoing into the cost-benefit assessment of early disease detection with MRI as a trigger for earlier medical intervention that could potentially lead to decreased disease progression and subsequent complications over time, thereby off-setting the initial expense.

Advanced Assessment 17.1 Analyzing Synovial Fluid

	Normal	Noninflammatory	Inflammatory	Purulent	Hemorrhagic
Clarity/color	Clear, yellow	Transparent, xanthochromic	Opaque, white or translucent	Opaque, white	Opaque, hemorrhagic
Leukocytes/mL	<200	200–2000	2,000–50,000	50,000–300,000	Variable
Percent of PMN	<25%	<50%	>75%	50%–100%	Variable
RBCs	Low	Low	Low	Low	High
Possible causes	Normal	Osteoarthritis Trauma SLE Polyarteritis nodosa Scleroderma Corticosteroid therapy	Rheumatoid arthritis Rheumatic fever Reactive arthritis Crystal synovitis	Septic arthritis Bacterial infection Fungi Tuberculosis	Trauma Blood dyscrasias Tumor Anticoagulants Sickle cell disease Myeloproliferative diseases

Differential Diagnosis

In general, an array of connective tissue diseases must be considered in the differential diagnosis. These include osteoarthritis, gout, chronic Lyme disease, SLE, infection by human parvovirus B19, polymyalgia rheumatica, Sjögren's syndrome, sarcoidosis, and various neoplasms. Osteoarthritis almost never affects the wrists and the metacarpophalangeal joints. Osteoarthritis is classically known for affecting the DIP joints with Heberden's nodes (hard, bony swellings) in the fingers. In contrast, these distal joints are less commonly affected in RA, and there are typically no Heberden's nodes in the hands. Within the thumb, the carpophalangeal joint is typically affected in osteoarthritis, whereas the interphalangeal joint is more often affected in RA.

Gout is distinguished by its gold standard test, which is a synovial aspirate revealing urate crystals. For crystalline arthritides, gout crystals are negatively birefringent, whereas pseudogout has positively birefringent calcium pyrophosphate crystals. Chronic Lyme disease usually involves only a single joint and is not polyarthralgia. A characteristic expanding bull's-eye rash known as erythema migrans is typical, and positive serological markers against the causative agent *(Borrelia burgdorferi)* distinguish Lyme disease from RA.

In reference to infection by human parvovirus B19, which may also manifest with joint pain, serological evidence of antiparvovirus B19 IgM antibody and a characteristic rash with an erythematous "slapped cheek" appearance distinguish this infection from RA. When considering acute viral polyarthritis, other causative infections include hepatitis C and rubella (rubeola virus), which may be distinguished from RA via specific immunoassays and organism-specific antibody titers.

SLE arthritic changes are almost never deforming, nor would one typically expect erosive changes on radiographs. Patients with polymyalgia rheumatica are usually negative for rheumatoid factor or have low titers. In addition, this disease usually strikes persons older than 50 years. Whereas qualitative RF positivity increases with age and may be nonspecifically present in older adults, patients with polymyalgia rheumatica suffer from myalgias but not distinctive arthralgias or arthritis.

A more challenging disease to distinguish from RA is psoriatic arthritis, because joint manifestations may not occur concurrently with cutaneous psoriatic findings in these patients. However, if psoriatic lesions are not present at the time of evaluation, a family history of psoriasis and joint manifestations in one or more relatives usually supports this diagnosis. Finally, some neoplasms can mimic rheumatoid disease, but again, RF is typically negative or quantitatively low in this setting.

Management

Management of RA progresses from conservative interventions to aggressive symptom management. Although the disease is debilitating over time, clinicians have recognized the potential adverse effects of immunosuppressive and anti-inflammatory therapies, including increased infection risk and hepatotoxicity. Thus, systemic therapy is typically initiated in response to symptom manifestations, thereby sparing the liver and GI tract from early use of potentially toxic agents.

The overall goals of management are to reduce pain and inflammation and to spare joint function. It is possible to achieve these goals in early management without pharmacological agents. This section on management,

therefore, includes nonpharmacological interventions as therapy for RA, particularly early in the disease process.

Initial Management

Joint swelling and immobility on rising, which abate or diminish throughout the day, characterize early rheumatoid disease. Early disease symptoms can be managed by one or a combination of the following: physical and occupational therapies, heat and cold applications, exercise, rest, assistive devices, splints, meditation, chiropractic adjustments, and weight loss.

Physical and occupational therapists are educated to identify strategies that promote function and prevent immobility. Their special skills in motivating patients to remain active should not be underestimated in early disease management. Often patients attend therapy sessions and derive accompanying educational and emotional benefits from associating with other patients diagnosed with RA.

Heat and cold applications provide analgesia and relaxation to muscles and connective tissue. It is usually necessary to try both heat and cold therapy with individual patients because some respond better to one than the other. Application in anticipation of exercise may enhance joint mobility during exercise. Particularly helpful to some patients is to remain seated in warm water for 10 to 30 minutes.

Exercise reduces pain and inflammation only if the affected joints are not stressed during an inflammatory period. Outside an inflammatory event, the joints may undergo judicious stress through an increase in resistance exercises to promote strength and endurance. Thus, isometric exercises should be prescribed for inflamed joints, and isotonic exercises should be done at other times. Patients may also benefit from low resistance aerobic exercise at the shallow end of a swimming pool.

Rest reduces pain and inflammation by controlling joint movement. However, one must distinguish between systemic rest and resting the joints. Systemic rest signifies a prescribed period of relaxation that may involve sleep. Patients with mild inflammation may benefit from systemic rest in the prone position for 1 to 2 hours per day; the rest period may extend upwards to 2-hour periods three or four times daily during waking hours, as necessitated by severe inflammation. Like systemic rest, resting the joints should be done in a prone position to avoid hip contractures; however, the duration of rest is much shorter than systemic rest, usually lasting only 20 to 40 minutes. In either case, the patient should prepare a method for awakening to prevent excessive systemic rest, because excessive rest may signal depression or other underlying disease.

Assistive devices include those that the patient requires to complete activities of daily living. Canes or crutches can relieve stress to affected weight-bearing joints during periods of acute inflammation. Once the inflammation subsides, the patient may walk free of the device. When the clinician or physical therapist recommends using a cane or crutches, it is important to the patient's self-esteem and inner hope to explain that these may be required only temporarily. Other assistive devices for the home include bars for gripping the inside of a shower or bathtub or beside the toilet, a raised toilet seat, retrieval–extension devices for picking up items from the floor or at a distance, and an electronic chair lift to help the patient manage stairs.

Splints reduce pain, promote function, and stabilize involved joints. The hands and wrists are the preferred regions for splints, which are usually applied at night. Splints of the hips and knees are usually not preferred over lying prone. The position of optimal function should be considered when applying the splint. Moreover, the material of the splint should be lightweight, unabrasive, and durable enough to withstand frequent applications. Because self-application is preferred, the splint should be structured so that the patient can apply it without assistance.

Meditation relieves depression and anxiety associated with chronic disease and disability. In addition, it promotes self-care practices and self-efficacy. Meditation may follow traditional spiritual paths, whereby patients learn from teachers in traditional religious communities. Alternatively, meditation may involve guiding the attention through the use of restful music, images, spiritual charms, and breath-work. Patients with RA should meditate in a prone position to prevent postmeditation joint stiffness and pain.

The role of chiropractic adjustment remains controversial among traditional Western medicine practitioners; however, its benefits to the patient with RA must be considered. Chiropractors can relieve pressure to unaffected joints that compensate for decreased weight-bearing or activity in the affected joints. Although adjustments may require repeated manipulations and therapeutic benefits may be short lived, other benefits include an increased sense of well-being and improved quality of life.

Weight loss reduces pressure on weight-bearing joints in the lower extremities and enhances activity. Alternatively, overeating may be a sign of depression. Thus, weight gain must be addressed in an overall plan of encouraging weight reduction (if applicable) to achieve ideal body weight.

Subsequent Management

Drug therapies include analgesics, NSAIDs, corticosteroids, nonbiological and biological disease modifying antirheumatic drugs (DMARDs), and older therapies as described in the sections that follow.

Analgesics Analgesics such as acetaminophen (Tylenol) or capsaicin cream, gel, lotion, or roll-on may be effective even though they have no anti-inflammatory effects. Though aspirin has been the mainstay of therapy for RA, acetaminophen as a nonopioid pain reliever may help for mild pain. Of note, opioid analgesics have also been used

for more significant pain although these agents are addictive and are not disease modifying in RA. Given the public health risks associated with the overuse of prescription opioids, reliance on narcotic analgesics as primary RA therapy is strongly discouraged and presents a significant danger for the patient.

NSAIDs Subsequent management begins with a consideration of cyclooxygenase inhibitors, which include aspirin and other NSAIDs. Drugs of this class need not be used daily during the early stages of disease. Rather, the patient can employ them only when there is pain that is unrelieved by nonpharmacologic means. Patients may be individually more responsive to one type of NSAID than another, and trial courses are sometimes required to determine the most effective agent although simultaneous use of multiple NSAIDs is discouraged. Different NSAIDs may also differ in their side effect profiles (e.g., sulindac 150 mg PO 2 times daily conferring fewer GI side effects than other NSAIDs). However, the adverse effects of NSAIDs as a class are well documented, including renal toxicity, GI side effects, platelet inhibition, and idiosyncratic hypersensitivity reactions. Thus, they should not be used indiscriminately.

Extra-strength (1,000 mg) aspirin can be used up to three to four times per day if baseline liver function studies, platelet count, renal function studies, and Hct are within normal limits. Caution must be exercised when prescribing 4 g of aspirin per day to persons older than age 65, however, as their liver and renal functions may be impaired by age. Dosage reductions are warranted should adverse effects ensue or laboratory markers dictate.

Aspirin should always be taken with 8 ounces of water or milk to avoid pill erosion or ulceration of the gastric mucosa. Enteric-coated aspirin is preferred to prevent gastric erosion. Concurrent anticoagulant therapy is a relative contraindication to aspirin and other NSAID use, which means that they should either be avoided altogether or prescribed in lower doses, relative to coagulation studies and clinical history.

Other NSAIDs may be substituted for aspirin should adverse effects or diminishing therapeutic efficacy warrant the switch. Notably, over time and with chronic use, individual drugs of the same class of NSAIDs can lose their effectiveness in an individual patient; therefore, NSAIDs provide a wide range of therapeutic options, and clinicians can recommend another drug in the class if treatment effects diminish with a given agent.

The primary adverse effect of the NSAIDs is GI upset. Their inhibition of gastric prostaglandin E (a natural protectant) predisposes the gastric mucosa to erosion. Most of the NSAIDs can be taken with an H_2-blocker such as ranitidine (Zantac) to reduce dyspepsia; however, H_2-blockers do not reduce hemorrhage or mucosal erosion. Proton pump inhibitors such as omeprazole (Prilosec) OTC or esomeprazole magnesium (Nexium) suppress gastric acid secretion and may be preferred to H_2-blockers for GI prophylaxis.

With reference to liver function, minimal elevations in serum transaminases are to be expected at daily doses of 2,400 mg ibuprofen (Motrin, Advil) for adults younger than age 65 years; the maximum dose may go as high as 3,200 mg/day if no adverse effects are apparent, but prolonged use of such doses may confer significant renal, hepatic, or GI toxicity, as well as iatrogenic hypertension. Should transaminase levels exceed two times normal, a dose reduction is indicated along with laboratory evaluation for infectious causes, such as hepatitis B and C.

Toxicity from prolonged NSAID use may result in renal impairment and present with acute renal failure requiring emergent care, as patients are prone to overuse NSAIDs, given their OTC availability and highly marketed nature. Thus renal toxicity is as important a consideration as are gastritis and ulcer formation. A rise in serum creatinine or blood urea nitrogen after starting NSAID therapy is an indication for further testing and a possible dose reduction or cessation. Fortunately, should renal failure develop, it is usually reversible after withdrawing the agent, given the proper supportive care.

Corticosteroids Corticosteroids (up to 7.5 mg of PO prednisone daily or injected intra-articularly, such as triamcinolone) may be helpful. However, side effects of prolonged corticosteroid use include adrenal insufficiency, hyperglycemia, osteoporosis, increased infection risk, and skin discoloration, which explains why maximal daily therapy is not recommended for more than 6 months. In addition, calcium, vitamin D, and bisphosphonates are indicated with prolonged corticosteroid use to mitigate bone demineralization. (The adverse effect profile of corticosteroids is thoroughly covered in the atopic dermatitis section of Chapter 7.)

Disease-Modifying Antirheumatic Drugs Disease-modifying antirheumatic drugs (DMARDs) include immunosuppressants and immunomodulators of various types, many of which have been used for decades. However, the newest class of DMARDs are biological immunotherapeutic agents, including anticytokine immunotherapies (TNF-α inhibitors, IL-1 inhibitors, IL-6 inhibitors) and anti–B-cell and anti–T-cell agents (see Drugs Commonly Prescribed 17.1: Disease-Modifying Anti-Rheumatic Drugs). Active disease should be treated early with DMARDs within 3 months of disease onset and even more aggressively in severe disease. Potential side effects of these therapies include the risk of reactivating latent or dormant TB infection with anti–TNF-α therapy, given the inhibition of cell-mediated immunity; therefore, TB screening should be instituted in all patients before starting biological immunosuppressive agents (Level I; Singh et al, 2012).

Combination therapy with DMARDs is more effective than monotherapy, and several different combinations have been tested. There is strong evidence for the efficacy of the combination of three DMARDs—methotrexate, sulfasalazine, and hydroxychloroquine—versus methotrexate monotherapy or dual therapy with only sulfasalazine and hydroxychloroquine (Level I;

Drugs Commonly Prescribed 17.1 Disease-Modifying Antirheumatic Drugs (DMARDs)

Drug	Adverse Reactions and Prescribing Considerations
Aminoquinoline	
hydroxychloroquine (Plaquenil)	May cause irreversible retinopathy, alopecia, blood dyscrasias.
Immunosuppressant	
cyclosporine (Neoral)	Indicated only in patients who have not responded to methotrexate. Pregnancy Category C. Monitor renal and hepatic function. Reduce dose if hypertension occurs.
Pyrimidine Synthesis Inhibitors	
leflunomide (Arava)	Monitor LFTs. May cause GI upset, leukopenia, thrombocytopenia.
Salicylate Sulfonamides	
sulfasalazine (Azulfidine)	Monitor LFTs. May cause GI upset, leukopenia, thrombocytopenia, urine or skin discoloration.
Folic Acid Antagonist	
methotrexate (Rheumatrex)	Monitor LFTs. May cause blood dyscrasias, GI upset, hepatotoxicity, opportunistic infections, fatal skin reactions.
Tumor Necrosis Factor (TNF)-α Blockers	
	Caution with all TNF-α blockers against reactivation TB and hepatitis B, predisposition to serious infection, development of lupus-like syndrome, development of selective cytopenias and pancytopenias, worsening of demyelinating syndromes, worsening of heart failure, increased malignancy rates, and cautious use in patients at risk for hepatic injury or with elevated liver function tests.
adalimumab (Humira)	May be used with or without methotrexate in moderate to severe RA.
etanercept (Enbrel)	May be used with or without methotrexate in moderate to severe RA.
infliximab (Remicade)	Should be used in combination with methotrexate for moderate to severe RA.
certolizumab (Cimzia)	May be used with or without methotrexate in moderate to severe RA.
golimumab (Simponi)	Should be used in combination with methotrexate for moderate to severe RA.
Interleukin-1 Receptor Antagonists	
anakinra (Kineret)	May cause predisposition to infections, headache, GI upset, neutropenia.
Interleukin-6 Antagonists	
tocilizumab (Actemra)	May be used with or without methotrexate in patients with an inadequate response to one or more DMARDs, including TNF-α blockers. May predispose to infections, hyperlipidemia, GI perforation in at-risk patients.
Anti–B-cell Agents	
rituximab (Rituxan)	Indicated for use with methotrexate in patients who do not respond to TNF-α blockers. Stop hypertension medications during treatment. May cause angioedema, GI upset, blood dyscrasias.
Anti–T-cell Agents	
abatacept (Orencia)	May be used as monotherapy or with other DMARDs, other than TNF-α blockers. May predispose to infections, headache, or respiratory adverse events in COPD patients.
Tyrosine Kinase Inhibitors	
tofacitinib (Xeljanz)	May be used as monotherapy or with other DMARDs, other than TNF-α blockers or potent immunosuppressants such as azathioprine or cyclosporine. May predispose to infections, hepatic enzyme elevations, neutropenia, anemia, GI perforation in at-risk patients.

O'Dell et al, 2002). There is also a high level of evidence for adding a TNF-α blocking agent to methotrexate therapy in patients with moderately or highly active disease after 3 months of methotrexate monotherapy (Level I; Singh et al, 2012; Maini et al, 1999). In turn, although the anti–TNF-α agents are considered first-line biological DMARDs, other biological agents have been approved for use in patients with an inadequate therapeutic response or intolerance to anti–TNF-α agents (e.g., abatacept, rituximab, tocilizumab), as well as the small molecule tyrosine kinase inhibitor tofacitinib. It is not recommended, however, that immunosuppressive biological agents with different mechanisms of action be used in combination, given the heightened risk of serious infection. Thus, therapies should be crafted based on the tolerance of side effects and the presence of comorbid conditions.

Older Therapies Many other DMARDs are possible options in the event of treatment failure with aspirin and other NSAIDs, but these are used less often now, given their low therapeutic index (higher toxicity risk) and the development of the newer agents discussed previously. These include azathioprine (Imuran), gold sodium thiomalate (Myochrysine), antimalarials, penicillamine (Depen), sulfasalazine (Azulfidine), and minocycline hydrochloride (Minocin). Hydroxychloroquine is an antimalarial usually used in milder disease, compared with sulfasalazine, which is used more often in moderate disease. Most of the COX-2 inhibitors, which were a mainstay of therapy in the past, are no longer marketed because of their cardiovascular risks. Celecoxib (Celebrex) is one of the last remaining.

Methotrexate is an older agent that is also used in many common chemotherapeutic regimens for the treatment of cancer. In contrast to many other older DMARDs, methotrexate remains highly effective in RA, including early on in the disease process (Level I; Singh et al, 2012) at low-dose regimens. It may be administered in adults younger than age 65 years at an initial weekly dose of 7.5 mg PO. The dosage may be doubled the second week if tolerance and therapeutic aims necessitate, although its full therapeutic effect may take 4 to 6 weeks to manifest. Maximum dosage is typically 25 mg per week.

Toxic effects of methotrexate include interstitial pneumonitis, hepatic cirrhosis, and teratogenicity. It is therefore not used in women at risk of pregnancy or in patients with chronic liver disease or elevated hepatic function tests. Combined use of methotrexate with NSAIDs, sulfonamides (e.g., sulfamethoxazole/trimethoprim [SMX/TMP]), or sulfonylureas such as glipizide (Glucotrol) increases the chance of hepatotoxicity, so concurrent use of these drugs is discouraged. Increased risk of hepatotoxicity is also seen with diabetes, obesity, and renal disease, in association with methotrexate use. Initiation of therapy, therefore, must be weighed against its potential risks and the availability and appropriateness of alternative therapeutic options.

Follow-up and Referral

Follow-up of patients with RA requires routine clinical laboratory evaluation and episodic adjustments in interventions. Routine clinical laboratory evaluation is performed every 90 days and includes CBC, platelet count, serum liver and renal function studies, and fasting blood sugar. Most of the adverse effects of drugs used in the management of RA can be monitored with this routine panel. If methotrexate is used, a serum albumin level should be added to the routine panel of tests to monitor for hepatic synthetic function.

The CRP blood test is a nonspecific method for evaluating the severity and course of the inflammatory process. CRP is normally less than 0.8 mg/dL and is, therefore, typically elevated in RA before treatment. Failure to decrease the CRP level after initiating treatment may thus indicate a lack of efficacy of the therapeutic agent or the presence of underlying infection or tissue necrosis; therefore, CRP should be monitored to determine the effectiveness of therapy. ESR may follow this same pattern during the course of treatment and may serve as a less technically involved, and therefore more widely available, alternative test compared with CRP.

Following scheduled laboratory evaluations, each visit to the clinician should address the clinical history since the last visit. Attention focuses on the efficacy of relief measures and the onset, duration, and frequency of pain and swelling of the joints. Standardized and validated disease assessment tools may be completed by the clinician at each visit to assess how well treatment interventions have achieved the targeted goals of low disease activity and complete disease remission, commonly known as "treating to target."

The clinician should refer the patient to a rheumatologist if initial management (including aspirin or NSAID therapy) fails. The rheumatologist is responsible for initiating therapies such as methotrexate and other DMARDs, including newer biological agents. Comanagement may mean that the rheumatologist will evaluate the patient twice each year once stable or more frequently, as signs and symptoms necessitate. In particular, specialist input is typically required to effectively "treat to target."

Patient Education

Patient education focuses on the goals of therapy, which are reduction of pain, control of inflammation, and preservation of function. Many of the key patient education topics were covered under Initial Management. In addition, education should address the therapeutic and adverse effects of any drugs employed. Finally, because RA is a chronic disease, education should also envelop the emotional, social, and spiritual sequelae of living with recurrent bouts of pain and disability.

The goals of therapy are best realized by promoting self-care. Education concerning self-care should include caregivers who must share common therapeutic goals for

the patient before they can support self-care practices. To help keep the patient from sinking into a cycle of seeking secondary gains from the "sick" role, the caregiver should support normal social role behaviors by encouraging self-care. The caregiver, therefore, becomes integral to achieving the goals of therapy. In turn, these therapeutic goals should be reviewed at each visit. This is an ideal context to employ the *Circle of Caring* model involving all medical modalities, nursing modalities, complementary therapies, and the patient's family.

INFECTIOUS MONONUCLEOSIS

Infectious mononucleosis is a viral syndrome characterized by prolonged malaise and fatigue, fever, sore throat, tender cervical lymphadenopathy, and a predominant monocytosis with a reactive lymphocytosis on peripheral blood smear. Also present may be GI manifestations including nausea, vomiting, and anorexia; abdominal organomegaly; headache; and, occasionally, a morbilliform viral exanthem (rash). Infectious mononucleosis results from acute infection with Epstein-Barr virus (EBV) or, less commonly, cytomegalovirus (CMV). Saliva is the most common source of infectious virions, which explains the traditional adage that refers to this condition as the "kissing disease."

Epidemiology and Causes

Infectious mononucleosis occurs predominantly among sexually active individuals aged 10 to 35 years. Sexual activity, in this sense, implies the exchange of bodily fluids between sex partners, particularly the exchange of saliva. Although the disease can occur outside of this age range, case reports are rare. Its distribution is equal among genders, economic classes, and educational levels, although the incidence of clinical infection is up to 30 times higher in whites than blacks.

The cause of the disease is recent infection by EBV (90% of all cases, with an incubation period of 30–50 days) or, to a much lesser extent, CMV, toxoplasmosis, human herpesvirus–6 (HHV-6), or acute HIV infection. Even certain medications such as isoniazid, phenytoin, or carbamazepine may induce a mononucleosis-like illness. However, it is EBV infection that has been best characterized, associated with a prolonged recovery period with persistent symptoms lasting up to a year, and is connected most consistently to the significant sequelae of infectious mononucleosis.

Pathophysiology

Both EBV and CMV are members of the Herpesviridae family of viruses. Infection by these viruses is particularly widespread, with up to 95% of adults being seropositive for EBV-exposure. Humans are the major reservoir for latent EBV infection, which typically spreads through intimate contact with asymptomatic viral shedders. EBV infection may result in a number of conditions, given its tropism for (ability to infect) B and T lymphocytes.

EBV typically enters the body via oropharyngeal epithelial and lymphoid cells, which explains the ability of the virus to be shed in saliva. Migration of B cells throughout the lymphoreticular system allows for widespread dissemination of this virus. Circulating antibodies are soon formed against viral antigens, as well as against unrelated RBC-specific antigens, the latter being termed heterophile antibodies. These IgM antibodies serve as a primary means of early detection of EBV infection, although they are not highly specific, given that they may also be present in HIV infection, lupus, or with underlying lymphoma. In addition, up to 20% of EBV-infected adults and teens may not produce heterophile antibodies.

An atypical peripheral lymphocytosis occurs 1 to 3 weeks after the onset of clinical symptoms, which is characterized largely by an activated set of HLA-DR+, CD8+ T cells, as well as nonspecific CD16+ natural killer (NK) cells. These cells are key to preventing the acute lysis of virally infected cells (lytic phase of infection) and establishing nonlytic, subclinical lifelong infection (latent phase of infection). Acute symptomatic manifestations of EBV infection such as infectious mononucleosis are believed to result from suboptimal lymphocytic immune responses, rather than from ongoing viral replication. In turn, antiviral therapies are ineffective in the treatment of infectious mononucleosis.

Although the majority of EBV infections are subclinical, significant manifestations include not only infectious mononucleosis but also relatively benign cases of upper respiratory infection, otitis media, and even potentially fatal cases of Hodgkin's and non-Hodgkin's lymphoma. Sequelae of EBV infection are largely determined by the age of the infected host, with adolescents and young adults being most susceptible to infectious mononucleosis. The precise reasons for these differential manifestations are not fully understood. However, they are thought to relate to the size of viral inoculum and the extent of the host B cell immunoresponse, both of which vary with age. In turn, patients with infectious mononucleosis due to EBV may develop serious sequelae affecting virtually any organ system. In contrast, infectious mononucleosis caused by CMV is typically a self-limited condition without significant complications, except in significantly immunosuppressed individuals.

Clinical Presentation

Subjective

Patients present with an acute history of fever, neuropathies, headache, photophobia, dysphagia, sore throat, diffuse chest pain, dyspnea, cough, nausea, anorexia, myalgias, and arthralgias. They usually cannot identify a known contact with EBV before the onset of symptoms.

Objective

Patients may report fevers as high as 39°C (greater than 102.5°F) among children and teenagers. Cervical and postauricular lymphadenopathy may be painful

on examination. Nuchal stiffness associated with painful lymph nodes may be present although not as rigid as in meningitis. The pharynx is typically injected, and there may be exudate across the tonsils or in the tonsillar crypt. Tachycardia may be accompanied by other arrhythmias, in particular premature atrial contractions. The lungs may reveal fine, scattered inspiratory crackles (rales). Splenomegaly is present in up to 60% of patients. Although splenic rupture is rare (2 in 1,000), it is a potentially fatal sequela. The liver may also be enlarged and tender to deep palpation.

A maculopapular rash may be evident across the trunk and upper extremities although this finding is infrequent. More commonly, antibiotics may be inadvertently started because of a suspicion of bacterial infection. This often results in a characteristic maculopapular or morbilliform rash, seen most commonly with concurrent use of beta-lactam antibiotics such as amoxicillin or ampicillin, or occasionally with antibiotics of other classes, such as azithromycin and fluoroquinolones. Such rashes can be particularly concerning for parents because they may be mistaken for an antibiotic allergy. Although the pathophysiology of these antibiotic-induced rashes is unclear, they are likely related to circulating non-IgE antibodies specific for the antibiotic but are not typically associated with immediate hypersensitivity reactions such as anaphylaxis.

Diagnostic Reasoning

The diagnostic reasoning for infectious mononucleosis should progress in stepwise fashion, according to the complexity of its presentation. The symptoms of mononucleosis mimic those of many diseases; therefore, laboratory findings play an important role in the differential diagnosis.

Diagnostic Tests

The first set of laboratory tests to be ordered includes a complete blood count (CBC), heterophile antibody test (Monospot), rapid plasma reagin (RPR) test (which may be positive in infectious mononucleosis, as well as syphilis infection), throat cultures, serum liver transaminases, and serum bilirubin. The goal of initial testing is to establish a pattern of results that would indicate infectious mononucleosis. Lymphocytosis predominates—atypical lymphocytes account for at least 10% of total lymphocytes. Mild thrombocytopenia and neutropenia are frequent transient findings. Liver enzyme levels, particularly serum transaminase levels, are mild to moderately elevated in about 90% of patients with infectious mononucleosis.

The Monospot test detects heterophile antibodies, and although not highly sensitive, is the most commonly run laboratory test in the work-up of EBV infection. These antibodies are found in 80% to 90% of patients with acute infectious mononucleosis although the test may take up to 3 weeks to become positive. Thus, retesting may be necessary if the first test was done early on in the disease process. Heterophile antibodies usually disappear by 3 months but are sometimes present for up to a year. The test is less sensitive in younger patients (75% sensitivity in children aged 24–28 months and 25% in children aged 10–24 months). EBV-specific serologies should therefore be checked in children. In fact, further testing of serum IgM antibodies to EBV may prove useful in adult patients as well, if a diagnosis based on initial testing is questionable. Anti-EBNA and anti-VCA are two specific anti-EBV serology tests that are widely available, although they are also less sensitive in younger patients (60% sensitivity in infants, but up to 100% sensitivity in young adults). False-positive results for EBV have been noted in HIV-infected individuals but are considered rare.

During the first 20 to 30 days after EBV infection, the CBC could show a granulocytopenia but no rise in lymphocytes. By the fourth week after infection, however, the CBC could reveal a lymphocytic leukocytosis, with more than 10,000 WBCs/mcL and more than 30% of those being lymphocytes. Under microscopic examination, lymphocytes are larger than normal and typically stain more darkly using standard cell microscopy preparations.

In isolated infectious mononucleosis, throat cultures will be negative for *Streptococcus* and other bacteria. Although RPR will be negative in most cases, a transient false-positive RPR result may occur in up to 10% of cases. Serum levels of liver transaminases and bilirubin will likely be elevated.

Differential Diagnosis

Many diseases present similarly to infectious mononucleosis; however, careful assessment of the patient's signs and symptoms as well as diagnostic tests will assist in making the diagnosis. Table 17.3 presents a comparison of the signs and symptoms of EBV-related syndromes. Glandular variant infectious mononucleosis, in which lymphadenopathy is out of proportion to the pharyngitis, differs from systemic variant mononucleosis, which presents with fever and fatigue and typically has mild or absent lymphadenopathy and pharyngitis.

A positive result on the heterophile antibody (Monospot) test will distinguish infectious mononucleosis from other diseases of similar presentation. In the differential of exudative pharyngitis, streptococcal, adenoviral, diphtherial, gonococcal, and herpes simplex infections should all be considered. HIV-infected or otherwise myelosuppressed teenagers and young adults may present with findings similar to those of EBV mononucleosis if they are infected with CMV or toxoplasmosis, but the heterophile (Monospot) test is more likely to be negative in these cases. In addition, peritonsillar abscess should be ruled out by an adequately collected throat culture.

Management

Symptom control is the mainstay of management for someone with infectious mononucleosis. The overall plan of care, therefore, involves supportive measures, including providing a quiet atmosphere for prolonged rest and recovery.

Table 17.3 Epstein-Barr Virus–Related Syndromes

	Infectious Mononucleosis	Oral Hairy Leukoplakia	Duncan's Disease (X-linked Lymphoproliferative Disorder)
Malaise	+	+/–	+
Lymphadenopathy	+	+	+
Fever	+	+/–	+/–
Splenomegaly	+ (50% of cases)	+/–	+
Pharyngeal exudate	+	–	–

+ present; – absent.

Antivirals are not available for either initial or subsequent therapy as symptom manifestations are largely unrelated to active viral replication. Rather, initial management focuses on symptom relief with rehydration, NSAIDs, gargling with warm salt water for throat pain, and OTC throat lozenges. Acetaminophen may be used for supportive, analgesic, and antipyretic treatment, although it will not confer anti-inflammatory benefits. In cases in which the airway is in danger of obstruction due to significant lymphadenopathy or mucosal swelling, corticosteroid therapy (prednisone) should be introduced over the course of 5 days (40 mg/day PO, potentially followed by a longer tapering period for persistent symptoms). Steroids may reduce viral shedding but do not affect symptom duration or the duration of convalescence.

Complications may arise in some patients over the course of the disease. Although peritonsillar abscess is rare, the soft palate and tonsils may become so edematous that the airway may be threatened. Therefore, the risk of airway obstruction should be assessed. In addition, a mild hepatitis may be seen in 90% of cases and requires cessation of any hepatotoxic medications if possible, and in extreme cases, interferon-alpha injections. Impending splenic rupture due to significant splenomegaly necessitates surgical resection of the spleen, and the wearing of an abdominal guard is often recommended as a presurgical preventive measure.

Acyclovir may reduce the severity of the lytic phase of active viral replication, but it does not affect the latent phase and therefore has no clear therapeutic role in infectious mononucleosis. Results of human vaccine trials against specific viral proteins (gp350/220) that target the B cell surface receptor for the virus (CD21) have been mixed; however, research is ongoing on novel vaccines, including vaccinia-based recombinant vaccine constructs.

Follow-up and Referral

Patients should be followed-up to monitor for the development of serious sequelae. Neurological complications may include Guillain-Barré syndrome, facial nerve palsy, meningoencephalitis, aseptic meningitis, transverse myelitis, or optic neuritis. Hematological complications may include hemolytic/aplastic anemia, thrombocytopenia, thrombotic thrombocytopenic purpura (TTP), hemolytic uremic syndrome, disseminated intravascular coagulation, or potentially fatal splenic rupture (spontaneous or traumatic). Cardiovascular complications may include myocarditis. Renal and genitourinary complications may include glomerulonephritis or genital ulceration, and GI complications may include pancreatitis.

It is important to provide the patient with a full clinical picture of the disease, including its prolonged course of recovery, so that the patient may play an active role in self-assessment during the follow-up period. Referrals are rare unless significant complications ensue. Patients with hemolytic anemia and TTP should be referred to a hematologist. Any patient with encephalitis will require an immediate neurology consultation. Patients with pericarditis must be referred to a cardiologist.

Patient Education

Young, school-age patients must be warned of the dangers of contact sports and rough-housing for at least 4 weeks after the onset of symptoms, because splenic rupture occurs predominantly within 3 weeks of symptom onset and may occur in the absence of frank splenomegaly (50% of splenic rupture cases). In addition, up to half of all splenic rupture cases may occur without any preceding trauma, and rupture does not correlate with symptom severity or abnormal laboratory results. A good rule of thumb is that the patient's energy level must be at baseline before the resumption of strenuous or risky physical activity, and this must not occur before 4 weeks. However, strict bedrest is required during this entire period and will be driven largely by the patient's energy level.

Patients must learn that their recurrent fevers will typically disappear long before they feel recovered; fevers will typically subside after 10 to 14 days although energy level will not rebound to baseline until 1 to 3 months postinfection. Therefore, teenagers and young adults who typically manage busy schedules and active lives will need to accept that they require rest for a prolonged recovery period that will last weeks, rather than days.

Other elements to consider in patient education include giving information about prescribed drugs, including appropriate dosage and adverse effects. The clinician

should also caution patients to avoid alcohol and cigarette use because they will aggravate coughing and nausea. Alcohol should be avoided for a minimum of 3 months after liver function tests return to normal. Appropriate follow-up and patient education should also include age-appropriate counseling regarding sexual practices, given that, unlike infectious mononucleosis, some sexually transmitted infections may be fatal or significantly affect future fertility.

CHRONIC FATIGUE SYNDROME AND FIBROMYALGIA SYNDROME

Chronic fatigue syndrome (CFS) remains poorly understood, despite abundant attention in the scientific and lay press. The lack of agreement as to its cause, laboratory markers, and clinical course may explain why the syndrome is not discussed in some medical texts. There appears to be significant overlap between CFS and fibromyalgia syndrome (FMS), another controversial chronic pain syndrome. The majority of patients with CFS meet criteria for FMS, and at least 70% of patients with FMS meet criteria for CFS. Moreover, both these disorders have been widely recognized in persons with comorbid psychiatric illness, because nearly two-thirds of CFS patients and one-third of FMS patients meet criteria for depression, dysthymia, or anxiety disorders. Many authors have criticized the historical and physical diagnostic criteria for both conditions as having a strong potential for overlap with somatization disorders. See the Iceberg figure for additional fibromyalgia syndrome information.

Epidemiology and Causes

Without a generally accepted working definition of CFS, it is difficult to systematically ascertain its epidemiology. Chronic fatigue is a presenting complaint in up to 25% of patients presenting to ambulatory care settings, and it is estimated that approximately 10% of these individuals meet diagnostic criteria for CFS. Numerous books in the popular press have advanced the belief that women are affected two times more often than men. The same references tend to agree that younger women are more often affected. Causes of CFS have been hypothesized to be autoimmune and infectious in etiology; however, the causes for the syndrome have yet to be determined. Importantly, it is a diagnosis of exclusion. The incidence of CFS ranges from 4 to 8.6 cases per 100,000 adults.

More epidemiological data for FMS exist in the medical literature. An estimated 11 million people in the United States have FMS, and 80% to 90% are women. The prevalence of FMS has been estimated at 0.5% for men and 3.4% for women, with some studies claiming an increased prevalence in women compared with men of up to 10:1. Prevalence is higher in older patients, at more than 7% for women aged 60 to 79 years.

These numbers are reflected in the clinical impact of FMS as up to 20% of all patient visits to rheumatology practices are for FMS. It is now considered the most common cause of generalized musculoskeletal pain in women aged 20 to 55 years. FMS may occur with greater frequency in patients with disorders characterized by systemic inflammation, including rheumatoid arthritis (RA), systemic lupus erythematosus, and hepatitis C infection. However, an underlying inflammatory etiology to FMS is unclear, because relatives of patients with fibromyalgia are seven times more likely than relatives of patients with RA to have FMS. In addition, several studies have shown that up to 50% of patients with FMS have a history of sexual and/or physically violent abuse, suggesting the importance of psychological factors in the development of FMS.

Pathophysiology

Despite extensive investigation, the pathophysiology of CFS and FMS are not clear. It has been hypothesized that both syndromes may be disorders of muscle energy metabolism, inflammatory or immunopathological diseases of muscle, generalized disorders of pain perception, neuronally mediated hypotension, neuroendocrine disturbances, dysregulated serotonin secretion, sleep disturbances, or a sequela of sexual abuse or domestic violence. However, it is important to note that none of these etiologies has been consistently confirmed through randomized and controlled prospective studies. Although depression and anxiety disorders demonstrate great overlap with both CFS and FMS, it is controversial as to whether these conditions occur concurrently, whether CFS and FMS lead to psychiatric sequelae, or whether these chronic conditions are somatic manifestations of underlying mood disorders. In turn, patients commonly experience accusations of malingering (intentionally fabricating symptoms for secondary gain), which, by definition, would be unfounded if any of the aforementioned etiologies are confirmed.

Extensive work has explored a potential infectious etiology for CFS, focusing on EBV, retroviruses, and human herpesvirus–6 (HHV-6) as causative agents. However, there has been difficulty in reproducing positive results across different laboratories. Moreover, no consistent serological profile has been identified that distinguishes patients with CFS from control groups across multiple studies.

Several studies, however, have demonstrated qualitative and quantitative differences in immune function between patients with CFS and controls, including reduced numbers of NK cells with depressed function, reduced levels of immunoglobulin and immune complexes, and increased numbers of cell surface adhesion molecules, among others. However, the differences are of questionable clinical significance and have been inconsistent and even conflicting between different studies.

Studies that have examined neuroendocrine differences between affected patients and controls have produced similarly inconclusive results. Although some evidence points to undersecretion of adrenocorticotropic

hormone (ACTH) and reduced serum cortisol levels, these findings are not specific for CFS and have also been observed in FMS, as well as in healthy subjects with altered sleep patterns related to overnight work shifts.

Studies attempting to clarify the etiology of FMS have also not been definitive. For many years, FMS was considered a disorder of muscle metabolism, possibly related to chronic hypoxia of muscular tissue. However, studies of lactate levels, muscle force studies, and postexertional pain have demonstrated a marked similarity between patients with FMS and sedentary controls. Thus, the most current theories suggest that patients with FMS suffer from disproportionate perceptions of pain, exacerbated by muscle inactivity and deconditioning. In fact, lower pain perception thresholds have been documented in first-degree relatives of patients with FMS.

Although no studies have been conclusive, altered pain perception is more likely to be a central rather than peripheral nociceptor (pain receptor) phenomenon. This is supported by observations in FMS patients of altered patterns of sleep and mood, decreased blood flow to pain centers in the brain, and alterations in serotonin secretions and the pituitary-hypothalamic-adrenal neuroendocrine axis. In addition, autonomic dysregulation of heart rate and systemic blood pressure has also been implicated on the basis of tilt-table testing for orthostatic hypotension; however, again, these findings have not been consistently reproduced. An anti-inflammatory component to the myalgias of FMS has never been shown, which likely explains the lack of efficacy of NSAID and corticosteroid therapies in this condition.

Clinical Presentation

Subjective

The symptomatic presentation of CFS and FMS may overlap considerably. Patients may report postexercise malaise, fatigue, multiple joint pains, headaches, impaired memory and concentration, depressed mood, cognitive disturbances, sore throat, restless and disordered sleep, and myalgias. Often the patient will also report having consulted one or more specialists concerning these vague symptoms.

Objective

The onset of CFS is sudden and may be preceded by a mononucleosis-like illness or by significant gastrointestinal findings. This same type of preceding event may also herald the onset of FMS.

The patient will appear tired. The skin may be pale. Cervical lymph nodes, if enlarged, will be shotty and nontender. Otherwise, the examination may be unremarkable. Despite complaints of impaired memory and concentration, the results of objective mental status assessments may vary with reference to recent recall and problem-solving abilities.

For a diagnosis of FMS to be made, the patient must have widespread muscular pain that has been present for at least 3 months; the pain should be present in 11 of 18 trigger points (also called tender points) on digital palpation with an applied pressure of 4 kg/cm (enough force to whiten the examiner's nailbed). The 18 trigger points are bilateral sites at nine key locations (see Table 17.4). Pain at these sites should be significantly greater than at

Table 17.4 Diagnostic Criteria for Fibromyalgia*

History Criteria	Pain is considered widespread when ALL of the following are present: Pain in the left side of the body Pain in the right side of the body Pain above the waist Pain below the waist Axial skeletal pain (cervical spine, anterior chest, thoracic spine, or lower back)
Pain Criteria	Pain exists in 11 of 18 tender points (trigger points) on digital palpation (at a force of at least 4 kg): Occiput: Bilateral, at the suboccipital muscle insertions Low cervical: Bilateral, at the anterior aspects of the intertransverse spaces at C5–C7 Trapezius: Bilateral, at the midpoint of the upper border Supraspinatus: Bilateral, at origins above the scapula spine near the medial border Second rib: Bilateral, at the second costochondral junctions, just lateral to the junctions on upper surfaces Lateral epicondyle: Bilateral, 2 cm distal to the epicondyles Gluteal: Bilateral, in upper quadrants of buttocks in anterior fold of muscle Greater trochanter: Bilateral, posterior to the trochanteric prominence Knee: Bilateral, at the medial fat pad proximal to the joint line For a tender point to be "positive," the client must state that the palpation was painful. A statement of "tender" is not considered "painful."

*Client must have a history of widespread pain (present for at least 3 months) in specific anatomic areas and must exhibit this pain during an examination of tender points.

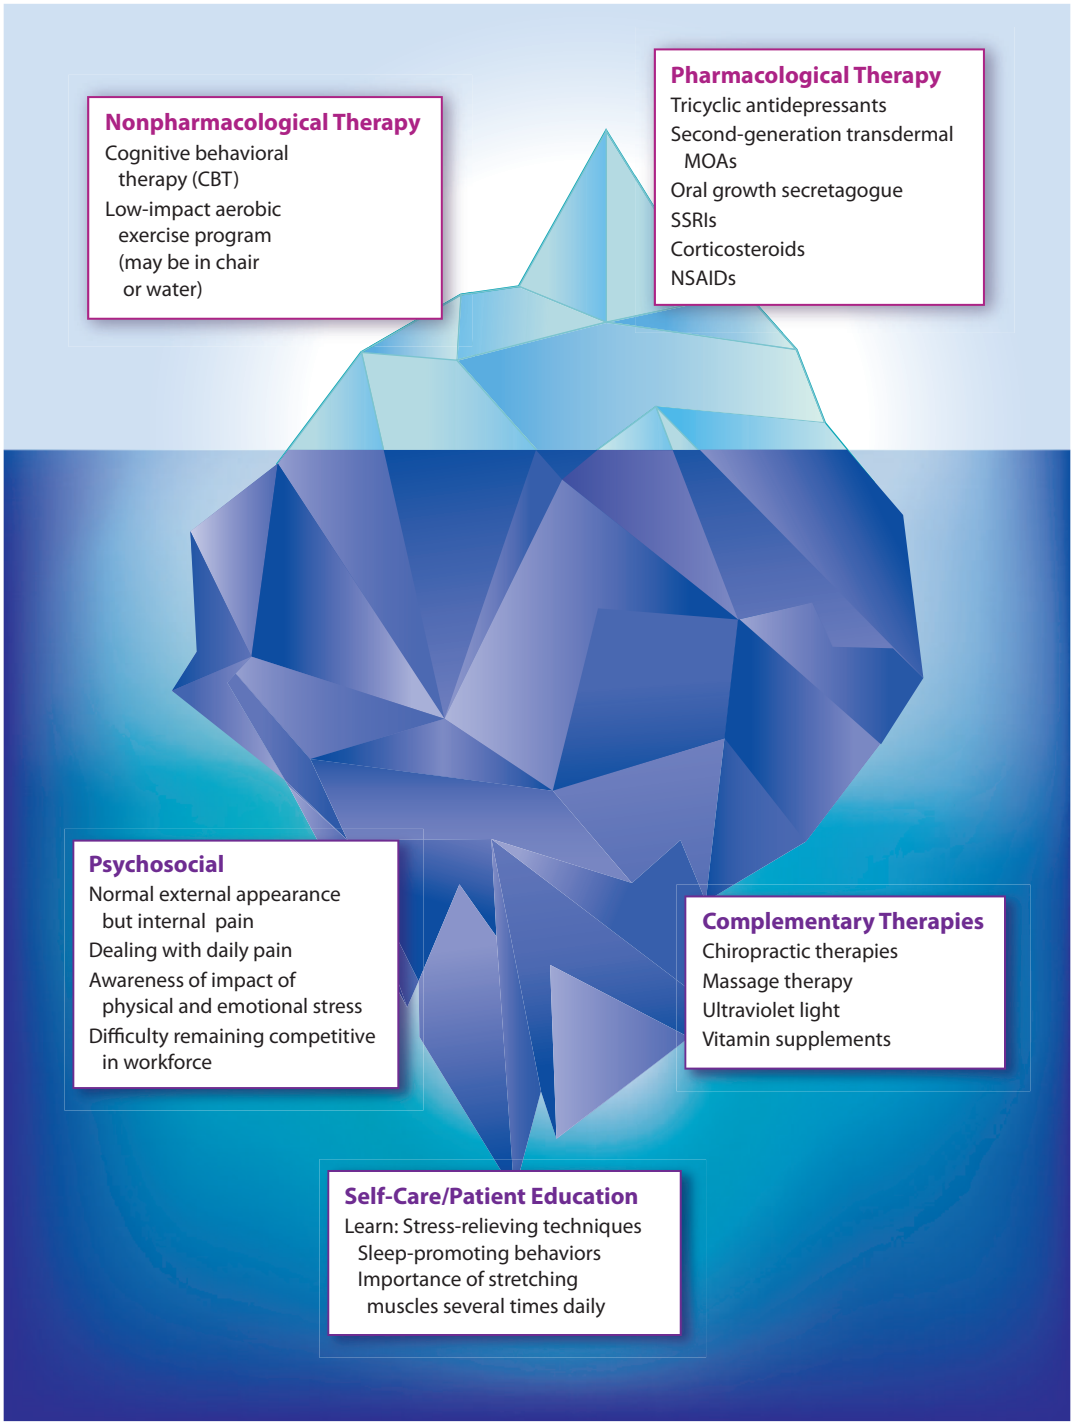
The Iceberg of Fibromyalgia



control sites, which are not expected to be tender, such as the patient's thumbnail or midforearm.

Diagnostic Reasoning

Diagnostic Tests

Chronic fatigue syndrome tends to strike once active, highly functional adults. The physical exam for CFS is typically normal. Advanced imaging tests such as CT and MRI are not indicated in the absence of significant physical findings. In addition, virus-specific serologies against EBV or Lyme disease are also not recommended without a strong suspicion by history or physical exam findings, because any positive result is likely to be a false positive in the setting of low suspicion.

Laboratory testing for FMS should include the same screening tests as for CFS, as well as muscle enzymes (creatine kinase, aldolase). ANA is often not helpful unless an autoimmune disorder such as systemic lupus erythematosus (SLE) is highly suspected because it may provide a false-positive result that incorrectly labels these patients as having lupus.

Differential Diagnosis

There is a wide differential diagnosis for both CFS and FMS. The majority of alternative diagnoses can be ruled out via the basic laboratory studies mentioned in the preceding text. The differential includes rheumatic disease, such as SLE, rheumatoid arthritis, and polymyalgia rheumatica; endocrinological diseases, such as thyroid disease and parathyroid disease, metabolic myopathies, and neuropathies; infectious diseases, such as Lyme disease; mood disorders and psychiatric diseases, including depression, dysthymia, personality disorders, and psychotic illness; malingering; and other conditions such as irritable bowel syndrome, cancer, and parkinsonism.

Myofascial pain syndrome involves a more limited number of tender muscular trigger points than FMS, as well as involuntary constrictions of muscular fascia (fibrous connective tissue that surrounds muscles), which has been considered as either a separate clinical entity or a regional variant of FMS.

The patient should be classified as having CFS or idiopathic chronic fatigue if severe fatigue persists or relapses for 6 months or longer. It should be classified as CFS if the fatigue criterion is met and four or more of the following symptoms are concurrently present for 6 months: impaired memory or concentration, sore throat, tender cervical or axillary lymph nodes, muscle pain (myalgia), multiple joint pains (arthralgias), new headaches, restless sleep, and postexertion malaise.

The Centers for Disease Control and Prevention (CDC) diagnostic criteria for CFS are based on clinically evaluated persistent or relapsing fatigue without explanation with at least four of the following self-reported symptoms (but no criteria for physical exam findings): impaired concentration/short-term memory, sore throat, tender cervical/axillary nodes, muscle pain, arthralgias without redness or swelling, poor sleep, new-onset headache or headache of a new and worsening pattern, and malaise after activity that lasts at least 24 hours. For patients with chronic fatigue who do not fit these criteria, the term *idiopathic chronic fatigue* is used, but these criteria are still being evaluated for validity. Sjögren's syndrome should also be considered as a differential diagnosis as many CFS patients also present with anhydrosis.

Management

Management of CFS and FMS remains controversial. The goal of therapy is to enable the patient to have the best quality of life possible within the limitations of chronic disability related to pain.

The two therapies that have been shown to be beneficial in terms of symptom relief and increased function (albeit not curative) are cognitive-behavioral therapy (CBT) that changes beliefs and behaviors that are barriers to recovery, and graded exercise. Increased bedrest should not be encouraged. A supportive approach to the patient–clinician relationship is critical. This reinforces that CFS or FMS is a genuine diagnosis and, thus, avoids the debate between psychological and "organic" etiologies.

The following pharmacotherapies have been tried with little consistent success: the Alzheimer's drug galantamine (Reminyl), intravenous immune globulin (IVIG), acyclovir (Zovirax), and selective serotonin reuptake inhibitors (SSRIs) such as citalopram (Celexa), fluoxetine (Prozac), and paroxetine (Paxil). Corticosteroids have shown some benefit in uncontrolled studies but come with the risk of adrenal suppression. Moreover, controlled, blinded studies have not confirmed these benefits.

Positive Lyme titers should not be taken as a definite sign of infection unless IgM is positive with a strong suspicion of this disorder, because false positive rates will be high otherwise. Thus, antibiotics should not be given indiscriminately, based solely on positive Lyme titer results.

The long-term prognosis of CFS is better than the short-term prognosis. However, certain factors have been cited as predicting a poor prognosis: (1) having more than eight medically unexplained physical symptoms other than the ones cited as CFS diagnostic criteria, (2) lifetime history of dysthymia, (3) chronic fatigue lasting more than 1.5 years, (4) less than 16 years of formal education, and (5) age greater than 38 years at the onset of disease.

For FMS, acetaminophen (650 mg 4 times daily) and tramadol (Ultram; 75 mg 4 times daily) as combination therapy may be helpful analgesics, but there is little to no evidence that NSAID or corticosteroid therapy is beneficial. As a narcotic, tramadol carries abuse potential, but this is generally considered less than for higher potency narcotic pain medications, such as oxycodone, hydrocodone, or morphine. Amitriptyline (Elavil), 75 mg daily in divided doses, remains one of the medications most frequently prescribed. Although it helps some patients, research has

shown that after 3 months it has no greater effect than placebo. Additionally, this and other tricyclics have anticholinergic side effects. A similar transient therapeutic effect has also been seen with cyclobenzaprine (Flexeril), which appears effective for the first 3 months, initially taken at 5 mg three times daily and then increasing to 10 mg three times daily. The adage of "start low and go slow" applies to this medication as well. Desipramine (Norpramin) is an alternative tricyclic agent with fewer side effects and may work in patients who respond to amitriptyline but cannot tolerate it. Of all the SSRIs, fluoxetine has been most promising when taken in doses from 20 to 80 mg daily. Dual norepinephrine and serotonin reuptake inhibitors such as duloxetine (Cymbalta) (40–60 mg daily) have shown some benefit as well. Although management guidelines are not well established, tramadol should probably be added only after psychotropic medications are tried first. In addition, low-dose clonazepam (Klonopin, 0.5 mg at bedtime) may be helpful, and research is also being done on the usefulness of antiseizure medications. One of the most recently approved agents for FMS is pregabalin (Lyrica), which may be started at 75 mg two times daily and increased to a maintenance dose of 150 to 225 mg 2 times daily. Pregabalin may cause dizziness or somnolence, however, and has the potential to cause severe allergic reactions.

An ongoing low-impact aerobic (cardiovascular) exercise program (walking, swimming, biking, water aerobics) with CBT, hypnotherapy, or electromyogram biofeedback therapy may be a useful adjunct in certain patients, because these therapies have been shown in limited trials to increase quality of life (although not affect symptom severity). Chiropractic and massage therapies are only weakly supported. Trials with ultraviolet light (especially blue light) exposure have shown mixed results. Vitamin supplementation also has received mixed results in small clinical trials.

Follow-up and Referral

Follow-up should occur according to the symptoms reported. Because many of these patients have been treated for affective psychiatric disorders in the past, they may already know what psychological manifestations should trigger professional assistance.

Typically, patients are referred to rheumatologists initially to assist in confirming the diagnosis by ruling out autoimmune syndromes. Referral to regional specialists who study and treat CFS and FMS may be required. Psychiatric referral could be necessary if mood disorders are apparent or mental status test results warrant.

Patient Education

For both CFS and FMS, management relies on helping the patient cope with a chronic condition by learning methods to deal with the chronicity of the symptoms. While validating its impact on the patient's life, clinicians should stress that the patient does not have a fatal disease. Although symptomatic, it may be relatively benign in terms of the risk of complications, and the patient can live a normal and productive life. Living with the uncertainty of the diagnosis and the chronicity of the problem are continuing challenges for both the patient and clinician. This is illustrated in The Patient's Voice 17.1. Patients may be encouraged to use whatever alternative means they believe might assist them with pain relief such as chiropractic, therapeutic touch, guided imagery, hypnosis, and so on. At present, there are no definitive answers or guaranteed treatments for these conditions. Pain is as the patient perceives it, and any treatment may relieve the pain if the patient believes it to be helpful. Patients should understand that physical and emotional stress can worsen their symptoms. Patient education has been shown in unblinded studies to improve FMS symptoms and quality of life and is a critical component of treatment. The *Circle of Caring* model is tested in cases in which a patient is frustrated and experiences daily pain. It is especially trying when a patient outwardly appears to be fine but is mentally suffering on the inside. Conditions such as these may require multiple resources and for all involved with the patient to focus on finding what works best for each individual patient. Nursing Research–Based Practice Box 17.1 describes the responses of parents and families to the presence of CFS as a chronic parental illness and the challenges that exist.

The Patient's Voice 17.1

Chronic Fatigue Syndrome

I have been chronically tired for years. It started out that I would drive the kids to school in my nightgown, then I'd go back to bed. I had given up my job the year before. Thank goodness we could afford it. My husband thought that I was depressed, so I went to doctor after doctor and tried all sorts of antidepressant medications with no relief. One doctor suggested that I needed to see a psychiatrist because the antidepressants were not working and he said I was obviously depressed. I knew "deep down" that I wasn't depressed, but I also knew that something wasn't right. I knew I had to do something when I overheard one of my kids on the phone telling his friend not to come over because his Mom was just "having another lazy day in her PJ's."

That same week, I heard an ad on the radio inviting participants for a study on chronic fatigue syndrome. I had heard about the syndrome vaguely and thought it was just a "catch-all term" for tiredness. I didn't really think it was a medical condition. I called the phone number given for the study and just answering a few questions over the phone, I felt 200% better! There actually is a medical name for the condition that I know I have. Now, I know I'm not crazy or just lazy. I can't wait to participate in the study. Even if it doesn't help me, I'll feel better knowing that what I have is "real."

Nursing Research-Based Practice 17.1

Donalek, JG. When a parent is chronically ill: Chronic fatigue syndrome. *Nurs Res* 58(5):332–339, 2009.

As chronic illness may reshape not only the life of the ill parent but also that of the entire family, this study was undertaken to describe the responses of parents and the ensuing family system responses to the presence of chronic fatigue syndrome as a chronic parental illness. This qualitative study involved eight ill parents and multiple members of their families. After interviews were conducted, thematic analyses at the individual, intrafamily, and across-family levels were used to explore the phenomena. The parents described the onset of illness, an ongoing struggle to receive diagnosis and care, and the significance of the illness in transforming present and future roles of family members. Multiple members of their family together with the ill parent described how they struggled with the reality of the illness, the shifting roles and responsibilities of the parents and their children, the reduced family income, and the frequent social isolation that could be exacerbated by the controversial nature of the illness. Families described and demonstrated their struggles to maintain a normal family life and make plans in the face of continuing uncertainty. Recommendations are made for future directions in family nursing research exploring the responses of families in which a parent is chronically ill.

LYME DISEASE

Lyme disease is a multisystem inflammatory disease of infectious etiology that does not take its name from the spirochete that causes it, *Borrelia burgdorferi.* Instead, it is named for a town in Connecticut (Old Lyme) where it was isolated among residents in the 1970s. It is a tick-borne illness that is prevalent among people who live in wooded areas of the eastern United States, with 96% of cases occurring in the following 13 states: Connecticut, Delaware, Maine, Maryland, Massachusetts, Minnesota, New Hampshire, New Jersey, New York, Pennsylvania, Vermont, Virginia, and Wisconsin. In addition, Lyme disease has been isolated in eastern provinces of Canada, some parts of Europe, and Australia.

Epidemiology and Causes

According to Centers for Disease Control and Prevention (CDC) data, the incidence of Lyme disease rose steadily over 10 years to a peak in 2009, but declined in 2010 and 2011. Some estimates suggest a tripling in the number of cases over the last several decades. However, epidemiological data gathering policies at the state level have been criticized as being imprecise and leading to exaggerated case numbers, with both overreporting and overdiagnosis being cited as potential confounders. For example, although incidence should be correlated with isolates of *B burgdorferi,* spirochete isolates have not been consistently identified in a number of states where cases have been reported.

Vector-borne diseases do not distinguish among races, gender, or other demographic traits. Lyme disease in the United States is limited only to individuals with exposure to *B burgdorferi* via tick bites. In Europe and Asia, other species of *Borrelia* such as *B afzelii* and *B garinii* are also causative agents, but these are not typically isolated in the United States. These differences in bacteriology may underlie the differing clinical manifestations of this disease by geography, for example, a higher frequency of arthritis and erythema migrans (bull's-eye) rash seen in the United States.

Pathophysiology

The likelihood of infection relates to the duration of tick exposure. The infected tick must feed for at least 24 to 48 hours before it passes along the spirochete to the host. Up to 90% of cases are transmitted via bites from ticks in the immature nymph stage, rather than due to bites from adults. Because of the small size of the tick (which is smaller in comparison to the typical wood ticks found on dogs), finding the tick before 24 hours have elapsed may prove difficult. However, vigilant inspection of skin and hair after exposure to wooded areas heightens the success of locating and removing the tick and, thereby, preventing spirochete transmission.

Lyme disease is transmitted primarily by the tick *Ixodes scapularis.* Once hatched from summer leaf clutter blanketing the forest floor, tick larvae acquire spirochetes on taking their first blood meal from infected mice, birds, or other small mammals. The larvae eventually detach from their hosts to molt and emerge the following spring as infected nymphs that are prone to spreading disease when feeding in the late spring, summer, and early fall. After this blood meal, these nymphs detach from their hosts and molt into adult forms later in the fall, in turn, seeking blood meals and transmitting the infection most often to white-tailed deer throughout the rest of the season and into the winter and early spring, before laying another egg mass the following summer to begin the cycle again. Thus, the 2-year tick life cycle and the ability to identify and avoid bites from larger adult ticks help to explain the seasonal preference for Lyme disease being spread by nymphs in the summer months, rather than in the winter.

Half of the ticks that occupy the eastern and midwestern United States in localized hotspots of high disease incidence may be infected with the spirochete; therefore, there is a high likelihood of infection by tick exposure in the wooded areas of these regions. Few ticks along the Pacific Coast of the United States are infected (*Ixodes pacificus*), so tick bites in this region are less likely to pass the spirochete to a human host. Although only 30% of affected persons can clearly recall an antecedent tick bite,

blood meals by infected ticks remain the only well-documented mechanism of spirochete transmission to human hosts. Some evidence exists for transplacental transmission from infected mothers to developing fetuses, but this generally results in good outcomes, and the clinical significance of intrauterine infection is questionable.

The causative organisms of Lyme disease are capable of producing systemic tissue injury with a relatively low microbial load. This occurs despite the absence of any excreted microbial toxins or widespread host inflammatory responses, such as a lymphocytic infiltrate. At the initiation of infection, spirochetes are believed to bind fibronectin and epithelial cell–derived proteoglycans in the extracellular matrix (e.g., heparin, dermatan sulfate) via glycosaminoglycan receptors. This initiates a mild local inflammatory response that causes cutaneous erythema at sites of spirochetal invasion and centrifugal spread from the original tick bite. Subsequent spirochetemia and tissue-specific binding allows for the development of neurological sequelae (via glycosphingolipid receptors), a vasculopathy similar to endarteritis obliterans seen in syphilis, and cardiac conduction defects in certain individuals. Arthritis is thought to be due to joint inflammation from localized exposure to spirochetal antigens, such as outer surface protein A (OspA) or the heat shock protein groEL.

B burgdorferi has been shown to exert immunomodulatory influences on host cells, including both decreased MHC class II antigen-presenting molecules on Langerhans cells isolated from late-phase cutaneous skin lesions and upregulation of the class II MHC molecules HLA-DRβ1, HLA-DR2, and HLA-DR4 on synovial endothelial cells in arthritic joints. The role of cytokines in this disease has not been fully elucidated, but several studies have demonstrated increased levels of macrophage-derived tumor necrosis factor–alpha, interleukin-1 (IL-1), and IL-6 in the blood, synovial fluid, and cerebrospinal fluid (CSF) of affected persons.

In addition, an autoimmune pathology has also been implicated in late disease manifestations. Most notably, the predominant T-cell receptor found on activated T lymphocytes after infection is specific for an epitope of OspA presented within certain class II MHC molecules that are upregulated in affected patients. Moreover, this OspA epitope has been shown to be cross-reactive with the leukocyte adhesion molecule human lymphocyte function associated antigen–1 (LFA-1), which is highly expressed on T lymphocytes. Studies of transgenic mice tolerant to OspA suggest that this protein does not fully explain these autoimmune phenomena.

Some evidence has suggested the importance of a *Borrelia*-specific superantigen. In addition, IgM antibodies against the spirochete protein flagellin are cross-reactive with human axonal proteins and myelin; these have been suggested to mediate the neurological sequelae of Lyme disease. Several other types of autoantibodies have been identified in the CSF of Lyme disease patients. However, it is not known whether these antibodies play a role in the actual pathogenesis of the disease or are simply a benign secondary consequence of infection.

Clinical Presentation

Subjective

Early in the course of the disease, the patient typically complains of a flu-like illness, including fever, chills, and myalgia. The patient may report having discovered a rash or red spot that grew in size. The report of a rash may be accompanied by objective findings on examination.

Later in the course of the disease, malaise, fatigue, headache, neck pain and stiffness, and generalized pains may constitute presenting symptoms. Left untreated, the disease will progress so that complaints will include multiple joint arthritis. Late in the disease trajectory, the patient may complain of memory loss, cognitive disturbances, mood changes, and peripheral neuropathy in addition to arthritis.

Objective

In early-localized disease, occurring days to 1 month after exposure, rash is seen in 90% of cases, accompanied by the nonspecific findings of fatigue, malaise, headache, myalgias and arthralgias, cervical stiffness, and lymphadenopathy. The patient may also present with a low-grade fever. The exanthem is called erythema migrans, which is a rash caused by the tick bite that is typically located on parts of the body where the tick selectively feeds, such as the axilla, groin, and waistband. The bull's-eye–appearing rash grows in size as it spreads ("migrates") from the site of the bite. The classic rash of erythema migrans is occasionally pruritic and/or burning, may develop central clearing, and is typically greater than 5 cm in size. The presence of this rash is essentially diagnostic of Lyme disease in the setting of appropriate clinical findings and may obviate the need for serological confirmation.

In early-disseminated disease, which occurs days to 10 months after infection and often in the absence of erythema migrans, the patient presents with systemic manifestations including carditis (less than 10% of cases) and neurological manifestations (10% of cases) such as lymphocytic meningitis, cranial nerve (CN) palsies (especially of CN VII) and radiculoneuritis. This neurological triad is known as Bannwarth's syndrome and is more common in European cases of Lyme disease than in the United States.

In late disease, which may be months to years after exposure, symptoms are characterized by intermittent arthritis (50%, which responds to oral antibiotic therapy) and arthralgias (20%), with 10% having monoarthritis of the knee. In addition, patients may have neurological manifestations known as tertiary neuroborreliosis, including encephalopathy, neurocognitive impairment, and peripheral neuropathy, as well as cutaneous manifestations such as solitary lymphocytoma and acrodermatitis chronica

atrophicans. These cutaneous manifestations are typically seen only in European cases due to *B afzelii.*

Objective findings later in the disease include regional or organ-specific physical abnormalities. Cardiac findings include dysrhythmias and a prolonged P-R interval. A rare finding is third-degree heart block. If the neurological system is involved, objective findings may include nuchal rigidity, sensorimotor disturbances, and paresthesias. Mental status examination may be positive for impaired problem resolution. Skin eruptions resembling the erythema migrans of early infection may recur later, as well. Very late in the disease trajectory, musculoskeletal findings predominate. In particular, joints become edematous and are associated with pain to touch. Gait disturbance may occur in association with encephalopathy. In contrast, upper respiratory or GI symptoms are more consistent with viral syndromes than with Lyme disease.

Diagnostic Reasoning

Diagnostic Tests

The term *chronic Lyme disease* is not preferred because it tends to foster fixation on this diagnosis as a cause of chronic, nonspecific complaints. Cultures of the skin lesion or rash can isolate *B burgdorferi* in half of the cases. Because the culture takes a long time to grow, serological studies are preferred. Histological and immunological staining is low yield in diagnostic testing owing to the low frequency of causative organisms. Positive serologies with ELISA tests against *Borrelia* sonicates containing mixtures of bacterial antigens (which often have suboptimal specificity, giving a number of false positives due to cross-reactivity with normal human proteins, other spirochete infections, EBV infection, or autoimmune disorders such as SLE or RA) must be confirmed by Western blot tests in which specific spirochetal proteins (e.g., heat shock proteins, flagellins) are directly detected by antibody staining. Western blot (or immunoblot) tests have lower sensitivity than the ELISA, but have greater specificity, so they are useful to confirm Lyme disease but may not be preferred for general screening. These tests should be measured against CDC testing standards, however, and not just those of an individual laboratory, as there will be a great deal of variation between laboratories. It may be best to send blood samples to a laboratory associated with an established academic medical center doing research on Lyme disease. A hepatic panel may also be helpful when characterizing the disease, because hepatitis may be apparent.

Patients are often seronegative with early localized disease manifesting only with the characteristic rash (erythema migrans); thus, blood testing may be ineffective as an initial diagnostic method. However, patients are usually positive for *Borrelia*-specific IgM and IgG by the early disseminated phase (6–8 weeks after exposure). Early antibiotic therapy may render serological tests negative for unknown reasons, as spirochetes may still be detected. In contrast, previous vaccination with LYMErix (a Lyme vaccine that is now off the market) can lead to false-positive ELISA tests for several years after vaccination. Also, antibody tests may stay positive even after Lyme disease has been treated and has fully resolved. IgM levels can remain elevated for more than a year, so they cannot be used to make a diagnosis of active disease, but rather only to confirm a diagnostic suspicion, if suspected for other reasons. These tests are nearly always positive in late stage disease, and a negative ELISA in these patients has strong negative predictive value and should not be followed by a Western blot test, because these will have lower sensitivity. *Borrelia*-specific antibody levels should be measured in the synovial fluid and CSF if there is clinical evidence of localized inflammation in the joints or CNS (closed-space inflammation) to determine whether this inflammation is due to *Borrelia* infection or is merely coincidental.

Lyme disease should never be diagnosed based on laboratory tests alone. Laboratory tests are only confirmatory, not diagnostic, and they should never be used as screening tools, because the false-positive rates are too high. A diagnosis of Lyme disease should also be made only with findings that clearly suggest this disease, rather than with only nonspecific chronic complaints. However, research-based diagnostic criteria for Lyme disease may be too narrow to be used for clinical diagnosis, because these will exclude many cases. For a number of reasons, the following tests for Lyme detection are not widely accepted because they may be considered experimental: variable surface antigen (VlsE) ELISA, PCR, urinary antigen testing, T-cell proliferative responses, and immune complex disruption. Thus, these laboratory tests should not be trusted to confirm a diagnosis of Lyme disease.

Differential Diagnosis

Differential diagnoses for Lyme disease include viral syndromes, Rocky Mountain spotted fever, and relapsing fever. It is important not to confuse FMS or CFS, which are not inflammatory disorders and have never been shown to be clearly infectious in etiology. Although FMS may develop after the onset of Lyme disease, it is important not to simply accept a diagnosis of chronic Lyme disease made previously by another clinician, because there is little evidence that this condition actually exists, as opposed to the late manifestations of the disease, which are considered genuine aspects of the disease process. Human granulocytic ehrlichiosis, caused by *Anaplasma phagocytophila,* is an important consideration as an alternate or a comorbid diagnosis, especially in the setting of high fever and severe constitutional complaints, elevated liver enzymes or leukopenia/thrombocytopenia.

Management

The goal of management is not only to stop the manifestations of the disease at the time of diagnosis, but also

to prevent progression of the disease. About 90% of early-localized disease responds to antibiotic therapy, although empiric antibiotic therapy after any tick bite is not recommended. However, if a patient presents with a tick still attached to the skin that is positively identified as one of the known *Ixodes* carriers of Lyme disease from a geographical area confirmed to have high rates of *Borrelia* infection, antibiotic therapy may be initiated immediately after initial laboratory testing and later stopped if the diagnosis is not confirmed. The duration of treatment depends on the extent of involvement. Regimens for early-localized disease should last for 10 to 14 days, whereas 30 days of therapy are required for cardiac, neurological, and arthritic manifestations.

Doxycycline (Vibramycin) 100 mg two times daily may be used in the initial management of erythema migrans. Doxycycline, or any tetracycline, is not recommended for children younger than 8 years of age or pregnant women. The dosage is 2 mg/kg for children older than 8 years. Doxycycline is also effective against ehrlichiosis, however, which is an important differential diagnosis and may present as a comorbid infection. Alternative agents include amoxicillin (Amoxil), cefuroxime (Ceftin), and erythromycin (E-mycin). Cefuroxime is typically more expensive than doxycycline or amoxicillin. The amoxicillin dose is 500 mg three times daily (50 mg/kg per day divided every 8 hours, with this same maximum dose in children). The cefuroxime dose is 500 mg two times daily in adults and up to 30 mg/kg per day divided two times daily with this same maximum dose for children. Up to 15% of patients may display worsening of symptoms with rigors, fever, or hypotension in the first 24 hours of antibiotic therapy due to an acute inflammatory cytokine surge involving TNF-α, IL-6, and IL-8. This is referred to as a Jarisch-Herxheimer reaction and is well documented in tick- and louse-borne relapsing fever conditions. Macrolides such as erythromycin are not as effective as doxycycline, amoxicillin, or cefuroxime and should be used only for patients intolerant to these other first-line choices. A first generation cephalosporin such as cephalexin (Keflex) should not be used because these are not active against *Borrelia.*

Early-disseminated disease with mostly musculoskeletal manifestations should be treated with the same oral agents for 2 to 3 weeks total as long as meningitis or third-degree heart block is not noted. If neurological sequelae (other than isolated facial nerve palsy) or third-degree heart block is noted, IV antibiotic therapy should be started with ceftriaxone (2 g daily) or cefotaxime (2 g three times daily) for 2 to 4 weeks. First- and second-degree heart block and isolated facial nerve palsy can be treated with 3 weeks of oral antibiotics. A lumbar puncture should be done to analyze the CSF for anti-*Borrelia* antibodies or inflammatory cells (WBCs), because neurological manifestations may be subclinical. If subclinical meningitis is suspected with elevated WBCs in the CSF, IV antibiotic therapy is required. Third-degree heart block should be treated with IV ceftriaxone or cefotaxime, and prednisone 40 to 60 mg/day in divided doses may be added if patients do not respond within 4 days, but this approach has not been validated in randomized trials. Late Lyme disease is treated with amoxicillin or doxycycline for at least 4 weeks if arthritis is the primary manifestation. If patients fail one or two courses of oral antibiotic therapy or if late disease presents with neurological sequelae (or if a lumbar puncture shows subclinical meningitis with WBC or autoantibodies), IV antibiotic therapy of ceftriaxone or cefotaxime for 4 weeks should be used.

All IV antibiotic therapy may be completed on an outpatient basis if the patient has reliable IV access (generally, a peripherally inserted central catheter or a central venous catheter, as opposed to a peripheral IV line) and a stable social situation. In addition, at least the first IV dose should be given in a monitored setting to evaluate for drug hypersensitivity. Weekly CBCs should be done to monitor for leukopenia, which may be seen with ceftriaxone and cefotaxime. Ceftriaxone may cause biliary sludging, which can be monitored with weekly hepatic panels to evaluate for hyperbilirubinemia. If this occurs, the patient should be switched to cefotaxime. GI effects, including *Clostridium difficile* colitis, may also occur. Doxycycline causes photosensitivity, and amoxicillin and cefuroxime can cause drug rashes.

Combination antibiotic therapy, an oral course of antibiotics following IV courses, pulse therapy with weekly IV treatments, and extended regimens lasting beyond 2 to 4 weeks have never been validated through randomized trials and should be avoided. These are only likely to increase drug toxicity. There is also no evidence that pharmacological treatment of asymptomatic seropositivity, found on routine "screening" for instance, is of any benefit. These patients should be thoroughly evaluated, however, to determine whether an asymptomatic phase is actually latent infection that will eventually manifest as late disease, because such individuals typically do not progress through early disease manifestations.

Failure of antibiotic therapy may relate to coinfection with other tick-borne diseases, such as ehrlichiosis. Headache, fatigue, and malaise may persist after treatment, but continued infection or the presence of a comorbid condition should probably be suspected only if symptoms worsen after treatment, if new signs of inflammation develop, or if there are documented changes on neuropsychiatric testing.

Follow-up and Referral

Follow-up for symptomatic presentations, before an actual diagnosis is made, may require weekly sessions. Thus, antibiotic therapy may be started after initial laboratory testing, if Lyme disease is highly suspected, and later stopped if the diagnosis is not confirmed on follow-up.

The rash of erythema migrans begins to resolve after the fifth dose of oral antibiotics, whereas fibromyalgic and CFS-like symptoms (e.g., headache, weakness,

fatigue, arthralgias) may persist for years after infection. Actual FMS is also recognized as a postinfectious complication of Lyme disease.

Referral to a specialist may not be required if the diagnosis is straightforward. However, if the diagnosis is unclear, rather than overtreating with antibiotic therapy, a referral to an infectious disease specialist is indicated for further evaluation and recommendations. Neurological, cardiac, and other serious manifestations may necessitate appropriate specialist referrals should these manifestations persist, despite primary care management.

Patient Education

People should be encouraged to avoid foliage, especially at the ankle level, along wooded paths and to walk in the center of the path to avoid low-lying brush. Hikers should wear clothing that can prevent ticks from attaching to skin. When planning an activity in the woods, the patient should wear long pants and boots, and pants should be tucked inside the boot lip. Shirt collars should be closed. Tick repellant should be applied to the exposed skin and scalp. After removing clothing, the patient should inspect the axillae, groin, and waistband areas, in particular, for evidence of attached ticks or bites.

If infection has already occurred, the patient needs to learn the course of the disease and that recurrence of symptoms after initial treatment might occur. Seropositivity does not equal immunity against reinfection. Reinfection is possible with *Borrelia* of a different strain if the patient remains exposed to high-risk environments, although symptoms do not tend to be worse than those of the initial infection.

SJÖGREN'S SYNDROME

Sjögren's syndrome (SS) is a chronic inflammatory autoimmune disorder caused by exocrine dysfunction. It presents as dryness in all areas of the body where there are exocrine glands associated with mucous membranes, most notably the salivary and lacrimal glands. However, SS has the potential for affecting a wide array of organ systems including the skin, lung, kidney, and heart. In addition, the hematopoietic system may be affected with a propensity for lymphoma.

Epidemiology and Causes

SS has a worldwide distribution with an annual incidence of 4 in 100,000; 70% of these cases may be primary, whereas the others are associated with comorbid conditions and are considered secondary. Accurate estimates of disease prevalence are complicated by a lack of agreement as to the defining diagnostic criteria of the disease. However, it is generally agreed that SS strikes women nine times more often than men. Rheumatic diseases often accompany it. The typical age range for disease onset is 40 to 60 years. The cause of the syndrome has not been fully characterized, although it is generally considered autoimmune in nature. Because SS typically accompanies underlying rheumatic diseases, investigations evaluating the etiological links among these conditions are ongoing.

Pathophysiology

As an autoimmune disorder, lymphocytic infiltration in all affected organs is the pathophysiologic hallmark of SS. Pooling of lymphocytes and plasma cells in the lacrimal glands causes the characteristic dry eye conjunctivitis of the syndrome called keratoconjunctivitis sicca, while parotid enlargement and diminished salivary excretions result from a similar infiltrate within the salivary glands along with hyperplasia of the ductal epithelium, which produces characteristic dry mouth (xerostomia).

At least three-quarters of these infiltrating cells are T lymphocytes, primarily of the CD4+ T helper subset, with classical TCR αβ receptors and expressing a memory cell phenotype including LFA-1 surface adhesion molecules. About 10% of the infiltrating cells are B-lymphocytes and plasma cells that produce significant amounts of oligoclonal immunoglobulin. The adjacent glandular epithelium expresses high levels of class II MHC (HLA-DR) and costimulatory molecules such as B7, suggesting antigenic T-cell stimulation is central to the pathogenesis of SS. It is unclear whether these stimulatory antigens are autoantigens and/or certain viral antigens.

Evidence for a genetic predisposition to SS is supported by studies that recognize a familial propensity for specific HLA-DR3, HLA-DR5, and HLA-DRβ3 alleles in affected patients and their relatives. Primary SS has also been linked to genetic polymorphisms in regulatory DNA sequences of the IL-10 gene, a cytokine that influences cell-mediated immunity. However, IFN-γ and IL-2 appear to be the primary immunomodulatory cytokines in SS. Produced by ductal epithelium, IFN-γ upregulates the expression of HLA-DR molecules on epithelial antigen presenting cells and potentiates T-lymphocyte cellular cytotoxicity. Cytolytic destruction of exocrine gland tissue does not appear to explain the full pathology of SS, however, because decreased saliva and tear production does not correlate well with the degree of histological damage on glandular biopsies.

The importance of autoantibodies in the pathophysiology of SS has long been emphasized. Autoantibodies specific for acetylcholine receptors in salivary glands have been suggested to impair the secretion of saliva in histologically normal glands. Far more common, however, are autoantibodies to specific nucleoproteins associated with RNA, including anti-Ro (SSA) antibodies seen in up to 90% of SS cases and anti-La (SSB) antibodies seen in up to half of cases. Although the pathogenetic role of these antibodies is unclear, the same antibodies can be found in a variety of other autoimmune disorders, including neonatal lupus, in which they may mediate complete heart block after crossing the placenta from mother to child. Anti-α-fodrin antibodies may be even more sensitive and specific for SS than anti-Ro or

anti-La, but their pathological significance is not fully established.

Infection by various viruses, including EBV, retroviruses such as human T-cell lymphotropic virus (HTLV-1), hepatitis C virus, and coxsackievirus, has been suggested to underlie primary SS. In vitro studies and preclinical animal models have demonstrated that infection with these viruses is capable of leading to lymphocytic infiltrates of the salivary and lacrimal glands, recreating many of the same symptoms as SS. Although viral particles are typically not present in high numbers, viral infection has been suggested to break tolerance to autoantigens and lead to SS via autoimmune activation. The relationship between SS and viral infection is not entirely clear, however, because much of the etiological evidence is indirect and does not predominate for any single virus.

Disorders of estrogen have also been indirectly implicated because primary SS is seen predominantly in women. Moreover, postmenopausal women taking estrogen-containing hormone replacement therapy (HRT) have a higher incidence of ocular dryness compared with non-HRT controls. This evidence remains circumstantial, however.

Clinical Presentation

Subjective

A patient may complain of dryness of the eyes and the feeling that a particulate is in them. Keratoconjunctivitis sicca is dryness of the cornea caused by a deficiency of tear secretion in which the corneal surface appears dull and rough and the eye feels gritty and irritated. The patient may also complain of dryness of the mouth (xerostomia) caused by cessation of normal salivary secretions. In addition, the patient may complain of loss of taste and smell, recurrent dental caries, dysphagia, vaginismus, and rectal bleeding. Associated complaints may be those of rheumatoid arthritis (RA), including joint swelling, pain, and malaise, as well as low-grade fever.

Objective

The patient may appear chronically ill, particularly if RA precedes SS. The patient's breath may smell fetid because of dental caries and mucosal dryness, and mucosal beds of the nose and throat will be pale and may reveal small fissures. The tongue could be beefy red because of dryness. Similar findings are associated with the vagina and anus.

Many other systemic, albeit rare, manifestations of SS may be present: a macular, papular, vesicular, or purpuric skin rash; arthralgias and myalgias; cardiopulmonary manifestations such as pericarditis or pulmonary hypertension from lymphocytic interstitial pneumonitis; pulmonary emboli due to circulating antiphospholipid/anticardiolipin antibodies; interstitial nephritis leading to renal tubular acidosis or glomerulonephritis (similar to that of systemic lupus erythematosus [SLE]); gastroesophageal reflux disease (GERD); hypothyroidism due to autoimmune thyroiditis; neurological sequelae including peripheral (mononeuritis multiplex or symmetric neuropathies) and autonomic neuropathies, CNS manifestations mimicking multiple sclerosis, transverse myelitis, optic neuritis, or ischemic strokes that may be due to vasculitis, thrombosis, or demyelination. Fatigue is another important aspect of the presentation, due to disrupted sleep patterns from mucosal dryness or accompanying systemic symptoms such as arthralgias and myalgias.

Diagnostic Reasoning

Diagnostic Tests

SS is diagnosed via clinical and laboratory findings, rather than identification of a single causative agent. Clinical diagnosis of SS includes six defining criteria: (1) inadequate tear production (evaluated using the Schirmer test with filter paper to blot tears on the lateral third of the lower eyelid [less than 5 mm of wetting in 5 minutes is abnormal] or using artificial replacement tears more than 3 times daily); (2) signs of corneal epithelial damage from dry eye using Rose-Bengal or fluorescein staining and slit-lamp examination; (3) decreased saliva production; (4) lymphocytic infiltration of labial salivary gland tissue on histopathology following labial gland biopsy—the closest test to a gold standard for diagnosis (greater than 50 immune cells surrounding an intact glandular lobule); (5) impaired salivary gland function by objective testing via radionuclide technetium scanning (quantitative salivary gland scintigraphy demonstrating poor uptake), parotid sialography with parotid gland cannulation and injection of oil-based contrast material, or spontaneous salivary production of less than or equal to 1.5 mL/15 min; and (6) autoantibodies including anti-Ro (SSA) and/or anti-La (SSB).

Initial lab tests include a CBC, rheumatoid factor, ANA, and gamma-globulin. The CBC might reveal an anemia of chronic disease, which is typically mild, leukopenia, and/or eosinophilia. The eosinophilia is caused by autoimmune factors and not by external antigens. Rheumatoid factor (RF) is positive in three-fourths of samples. ANA is typically elevated, as are gamma-globulin levels.

Electrophoresis studies are required to determine whether SS is present alone or in combination with other rheumatoid disease. SS alone typically manifests more specific autoantibodies—anti-Ro/SSA and anti-La/SSB—whereas SS and rheumatoid disease together may reveal antibodies against exocrine ducts and RA-associated nuclear antigens.

Differential Diagnosis

As patients with SS have a higher prevalence of hypothyroidism, this should be screened via a thorough history and TSH/free T_4 level. Further laboratory work-up includes a basic metabolic panel with hepatic function tests

(liver transaminases), RF (to assess for RA), and ANA (to assess for SLE). HIV and hepatitis C testing may also be indicated. Sarcoidosis could be evaluated with a chest x-ray exam to evaluate for hilar lymphadenopathy or interstitial lung disease. An MRI or ultrasound and biopsy should be done if there is unilateral salivary gland enlargement to rule out malignancy or specific glandular pathology, such as acute bacterial sialadenitis. Bilateral salivary gland swelling may be due to acute viral infection (e.g., mumps, coxsackievirus, echovirus, or EBV) or chronic infection with HIV or hepatitis C; granulomatous disease such as sarcoidosis, amyloidosis, or TB; malnutrition; alcoholism; and eating disorders such as bulimia or anorexia with purging features.

Further differentials for SS include other autoimmune disorders that may exist concurrently, such as SLE, scleroderma, or RA. In fact, RF may be positive in up to 75% of cases. It is also critical to distinguish SS from patients with FMS or depression who may have significant anticholinergic toxicities from psychiatric medications, which can lead to dry eyes and especially dry mouth. Dry eyes may also result from impaired blinking due to muscular or neurological disorders, vitamin A deficiency leading to mucin deficiency (xerophthalmia), conjunctivitis, infiltration of the lacrimal glands (from sarcoidosis, lymphoma, or amyloidosis), or blepharitis from Meibomian gland dysfunction. Dry mouth can also result from sialadenitis from obstructing salivary gland stones, chronic viral infections (hepatitis C, HIV), and iatrogenic anticholinergic drug effects. In fact, the following conditions are exclusion criteria in terms of meeting the defining criteria of SS: previous head/neck irradiation or preexisting lymphoma, comorbid infection with hepatitis C or HIV with AIDS, sarcoidosis, graft versus host disease, or recent use of anticholinergic medications. Symptoms of mucosal dryness are also common in liver disease and depression, so these must be considered.

Management

The management of this syndrome consists primarily of symptom-directed supportive care, although research into immunomodulatory therapies is ongoing. To address the primary manifestations of dry eyes and dry mouth, normal saline eyedrops can relieve lacrimal dryness, and hard candies and gum may be used to stimulate salivation but should be sugar-free to avoid worsening dental caries. Dried fruits that contain malic acid may also be helpful in stimulating salivation. In extreme cases of salivary dryness, the patient should be encouraged to apply an artificial salivary gel or use a mouth spray. Fluids can also keep the mouth well lubricated as long as they do not contain caffeine (a diuretic) or ethanol (as used in mouthwash), which can be drying. Special toothpastes and toothbrushes designed for a dry mouth are also available. Quarterly dental evaluations, along with vigorous flossing and regular brushing, may prevent dental caries. Dry lips may be treated with Vaseline and dry skin with moisturizing lotions, and vaginal dryness may be treated with intravaginal lubricant jelly.

Artificial tears and salivary gels often contain hypromellose (0.3%) or methylcellulose (0.3%) and may be used every 2 to 4 hours if needed. Several of these can be irritating to certain individuals. Pilocarpine (Salagen) 5 mg PO three to four times daily and cevimeline (Evoxac) 30 to 60 mg PO three times daily are specific cholinergic (muscarinic) agonists (parasympathomimetics) for stimulating aqueous secretions. These drugs are contraindicated in persons with narrow-angle glaucoma or iritis, owing to their mydriatic effects. Cevimeline should not be used if a patient has asthma, because it can worsen respiratory secretions. Acetylcysteine can be used as a mucolytic if thick mucous fibers coat the eyes, but this smells like rotten eggs because of its sulfur content. Spreading agents such as polyethylene glycol and dextran-70 0.1% drops are also available for dry eyes. Topical cyclosporine 0.05% 1 gtt every 12 hours is FDA approved to increase tear production, presumably by decreasing T-cell infiltration within the conjunctivae. If these treatments prove ineffective, the patient may undergo punctal occlusion, in which collagen plugs are placed by an ophthalmologist in the lacrimal puncta on the inferior eyelid so that tears (artificial or natural) cannot drain away to the nose.

The following are rarer systemic manifestations of SS, along with specific treatments:

- Macular, papular, vesicular, or purpuric skin rashes may require biopsy and treatment as a form of vasculitis.
- Arthralgias and myalgias may respond to NSAIDs or hydroxychloroquine.
- Inflammatory cardiopulmonary manifestations such as pericarditis or pulmonary hypertension from lymphocytic interstitial pneumonitis may require treatment with corticosteroids (prednisone) or other immunosuppressants (azathioprine, chlorambucil, cyclophosphamide).
- Interstitial nephritis leading to renal tubular acidosis or glomerulonephritis (similar to that of SLE) may require corticosteroid or immunosuppressant therapy (cyclophosphamide, mycophenolate).
- Rare neurological sequelae such as peripheral mononeuritis multiplex or symmetrical neuropathies and autonomic dysfunction (confirmed by tilt-table tests) may require mineralocorticoid therapy.
- Neuropathies and CNS manifestations mimicking multiple sclerosis, transverse myelitis, optic neuritis, or ischemic strokes may be due to vasculitis, thrombosis, or demyelination and require treatment with immunosuppressants.

Follow-up and Referral

Follow-up consists of ongoing evaluation to assess the effectiveness of symptom management and the need for

alterations in treatment. If SS presents as an isolated condition, follow-up evaluations may occur as infrequently as twice per year. However, more frequent evaluations are necessitated by concurrent disease. Referrals may not be necessary except when this syndrome accompanies other diseases. The clinician may consult with a rheumatologist initially to differentiate the disease from other rheumatic conditions and to confirm the diagnosis.

During follow-up examinations, it is important to monitor for dental caries or oral candidiasis, which can lead to severe mouth pain and requires antifungal therapy. It is also important to screen for infectious conjunctivitis and complications from nasal dryness and laryngotracheal reflux, which can stimulate vagal responses and mimic allergic or recurrent sinusitis symptoms, including repeated throat clearing and postnasal drip–like symptoms. This type of reflux may be treated with proton pump inhibitors (similar to GERD), with referral to an ear, nose, and throat specialist if needed.

Patient Education

The patient should learn that mucosal dryness can be controlled with conservative interventions. Regular application of artificial lubricants locally can prevent the soreness and untoward effects of dry mucosae. The patient should be encouraged to wear sunglasses to protect the eyes from strong light, wind, and dust, as well as to avoid low-humidity environments that exacerbate dryness. If the patient has sore lesions in the mouth, tobacco, alcohol, and both spicy and salty foods should be avoided. OTC medications that decrease pharyngeal secretions, such as antihistamines, antidepressants, anticholinergics, and atropine derivatives, should be avoided. Patients should be warned that they are at greater risk with surgeries requiring general anesthesia and intubation, given their increased risk for thick, inspissated mucus and atelectasis.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is an inflammatory autoimmune disease. It tends to affect many organ systems. Spontaneous remissions and exacerbations characterize the clinical picture. SLE can be mild or aggressive and even life-threatening in presentation.

Epidemiology and Causes

The prevalence of SLE is 40 to 50 cases per 100,000 and is associated with age, gender, race, and genetics. Nearly 85% of patients with SLE are women, most often in their 20s and 30s. However, 15% of cases present after age 55 years. Juvenile cases are not uncommon, though, with 20% of diagnosed patients being younger than 16 years. In children, the female to male ratio is 3:1; in adults, it is 10 to 15:1. Epidemiological studies have identified sex hormones as potential causative factors for SLE, because onset of the disease in women typically occurs between menses and menopause. Estrogen has been shown to stimulate T cells, B cells, and macrophages, as well as increase expression of cytokines, endothelial cell adhesion molecules, and antigen-presenting major histocompatibility complex (MHC) molecules. SLE flares have also been associated with hyperprolactinemia. In contrast, androgenic hormones such as testosterone tend to be immunosuppressive, which may also contribute to the gender specificity of SLE. Of note, although men typically experience less photosensitivity than women, they are often considered to have more severe disease manifestations, with a greater incidence of serositis and higher 1-year mortality rate, although tending to present at an older age at onset.

Persons of African descent are four times more likely to develop the disease, compared with Caucasians. SLE also disproportionately affects patients of Asian ancestry, with other studies showing higher rates in Hispanic patients. Several lines of evidence have demonstrated a genetic component to SLE, for example, a high concordance rate between monozygotic twins, a propensity for specific HLA-DR class II MHC genes in affected individuals, and positive gene linkage studies in affected siblings. Poor prognostic factors include concurrent hypertension, male gender, having active disease at a young age, low socioeconomic status, and being African American. In particular, trends related to ethnic background (i.e., higher disease rates in people of color) have been observed with many chronic diseases and are multifactorial in nature. They must not be attributed solely to "genetic differences between the races," because worse outcomes are also associated with the presence of prothrombotic antiphospholipid antibodies (e.g., lupus anticoagulant, anticardiolipin) and highly active inflammatory disease, both of which may be addressed through individualized treatment plans to decrease the risk of morbidity.

Although not causative of SLE, several triggering factors for acute exacerbations have been identified. These include exposure to ultraviolet (UVB and UVA) rays, which is believed to cause increased cytokine and cell adhesion molecule expression; microbial infection (e.g., EBV, *Mycobacteria,* trypanosomes) that may stimulate cross-reacting autoantibodies; emotional stress, which, although controversial, has been tied to mild disease flares; pregnancy and postpartum hormonal fluctuations; and surgery, which may increase the formation of autoantibody-containing immune complexes via the release of intracellular antigens into the circulation from tissue trauma. Exposure to cigarette smoke or silica dust also increases the risk of developing SLE, which implicates inflammatory lung pathology.

Pathophysiology

The pathophysiology of SLE is best understood by a review of the diagnostic criteria. The diagnosis of SLE is

made after 4 or more of the following 11 criteria are met in the absence of medications or other disorders known to induce these effects, as defined by the American College of Rheumatology (ACR):

- Arthritis—nonerosive and usually involving two or more joints
- Photosensitivity—often triggering skin rashes, exposure to the sun's UVB rays may be a triggering event for SLE exacerbations
- Oral (or nasal) ulcers—typically painless
- Malar rash—bilateral butterfly formation across the cheeks and nasal bridge
- Discoid rash—red raised patches, sometimes with denuded central areas
- Serositis (inflammation) of the pleura or pericardia
- Renal disease (any one of three indicators): more than 0.5 g/day proteinuria, 3+ or more proteinuria (as detected by dipstick), or cellular casts
- Hematological disorders (any one of four indicators): hemolytic anemia, leukopenia (less than 4,000 WBCs/mcL), lymphopenia (less than 1,500 lymphocytes/mcL), thrombocytopenia (less than 100,000 platelets/mcL)
- Neurological disease (e.g., seizures, psychoses) not otherwise explained by iatrogenic or metabolic causes
- Positive ANA
- Immunological abnormalities (any one of four indicators): positive antiphospholipid antibodies such as anticardiolipin or lupus anticoagulant, antibody to double-stranded native DNA (anti-dsDNA), anti-Sm (Smith) antibody, false-positive serological test for syphilis (VDRL, RPR)

SLE is, at its core, a condition of disordered immunity in which mechanisms that normally prevent immune cell activation by autoantigens are eliminated. A number of factors have been identified that contribute to this autoimmune activation, for example, an inhibition of suppressor T cells that normally downregulate immune responses, an increase in CD4+ T helper cells, increased cytokine production (e.g., IFN-α, IL-4, IL-6, IL-10), polyclonal B-cell activation, and dysregulated intracellular signaling (particularly pathways involving cytosolic calcium). These changes contribute to a significant production of autoantibodies that are considered to be a hallmark of the disease. Mouse models of SLE have demonstrated dysregulated apoptosis in which nuclear antigens (e.g., DNA, ribonucleoprotein, histones) are exposed on the cell surface, capable of recognition by autoreactive lymphocytes. In turn, autoantibodies often appear in the serum years before the actual onset of SLE symptoms.

Autoantibodies are also formed against cell surface antigens, including antibodies specific for red and white blood cells, platelets, and neuronal and renal cells. These antibodies mediate cellular destruction via complement activation, antibody-dependent cellular cytotoxicity, and opsonization. Although not seen universally, autoantibody-derived immune complexes are believed to underlie the pathology of a majority of clinical manifestations of SLE. Histochemical staining has identified immune complex deposition along the basement membrane in nephritic kidneys, at the dermal–epidermal junction in skin lesions, within the choroid plexus, as well as the pleural cavity and pericardium—all major sites of SLE pathology. The biochemical nature of both the autoantigen and autoantibody (e.g., size, charge, binding affinity, rate of phagocytic clearance, ability to be neutralized by complement proteins) determines where these complexes form and the extent of tissue damage after their deposition.

One of the organ systems most severely affected by immune complex deposition is the kidneys. In addition to the deposition of circulating immune complexes along the glomerular basement membrane, autoreactive IgG_1 and IgG_3 anti-DNA antibodies also bind directly to autoantigens in the basement membranes, serving as a nidus for complement activation. These chemotactic complement proteins then attract leukocytes and mononuclear cells that phagocytose the immune complexes, releasing cytokines and clotting factors that lead to fibrinoid necrosis, ongoing inflammation, renal scarring, and kidney dysfunction. Diffuse proliferative glomerulonephritis is the most common histological form of lupus nephritis, which results from this inflammation. In contrast, lupus membranous nephropathy is not associated with inflammation. Rather, in this setting, immune complex activation is separated physically from circulating immune cells by the glomerular basement membrane, resulting in epithelial injury and proteinuria without active inflammation.

A subset of individuals with SLE is also prone to developing antiphospholipid antibodies, including antibodies against the β-2-glycoprotein I complex and cardiolipin, as well as the lupus anticoagulant. These individuals have more severe disease, related primarily to an increased thrombogenic state, which predisposes to both venous and arterial thromboembolism, resulting in a greater incidence of deep venous thrombosis, pulmonary embolism, cerebrovascular accidents (strokes and transient ischemic attacks), and recurrent first-trimester miscarriages due to placental infarcts. Normally, β-2-glycoprotein has an anticoagulant effect, which is abrogated by these antiphospholipid antibodies.

One of the most characteristic physical findings of SLE is a bilateral malar rash. This and other SLE skin rashes are exacerbated by sun exposure, largely due to ultraviolet damage to DNA in skin keratinocytes and alterations in membrane phospholipid metabolism. Thus, anti-DNA, anti-RNA, anti-Ro, anti-La, and antiphospholipid autoantibodies form that mediate keratinocyte destruction and local skin inflammation. IL-1 production from cutaneous keratinocytes and antigen-presenting Langerhans cells potentiates this inflammatory response.

Clinical Presentation

Subjective

The patient may complain of malaise, fever, anorexia, and unplanned weight loss. The patient may also complain of blurred vision and conjunctival swelling. Sleeplessness and depression are also common complaints. Joints may be reported to be swollen and painful by history, but this may not be evident on examination. Shortness of breath and painful inspiration may be present if lung pathology exists. Vague abdominal pains and/or abdominal cramping could also enter into the history.

Objective

Integumentary findings may include the following:

- A characteristic "butterfly" rash, as well as other photosensitive rashes.
- Alopecia and scalp exanthema are typical findings.
- Splinter hemorrhages, periungual erythema, and fingertip lesions may be observed on the fingers and toes.
- Lymphadenopathy in several regions of the body indicates systemic disease.
- Discoid lupus presents with scarring and highly inflammatory (even ulcerating) skin lesions but often does not present with the familiar autoantibodies of SLE, including ANA, anti-dsDNA, and anti-Smith antibodies.
- Raynaud's phenomenon, a vascular condition, may be seen in up to 40% of patients as whitish-blue skin color changes in response to cold temperatures, which then change to red upon rewarming, often predating other symptoms.

Musculoskeletal findings may include the following:

- Musculoskeletal joint pains (asymmetrical, nondeforming, migratory arthritis—often in the hands and fingers) occur in 90% of cases and are often the presenting complaint.
- Swollen joints may not follow a particular pattern, as in other rheumatic diseases; joint inflammation is typically nonerosive on radiographs.

Neurological findings may include the following:

- Cognitive thought processes may be impaired. Therefore, the clinician should carefully listen to the patient's explanations in response to questioning, in order to establish lapses in logic; however, these deficits often are not evident in mental functioning assessments commonly used in primary care settings, such as the Folstein Mini-Mental State Exam.
- Evidence of peripheral paresthesias and diminished deep tendon reflexes may be present.

Cardiac findings may include the following:

- A systolic murmur may be present.
- Distended jugular veins suggest right-sided cardiac failure, which may be seen with pulmonary hypertension or interstitial lung disease.

Gastrointestinal findings may include the following:

- Painless oral and nasal ulcers may be seen.
- Right upper abdominal quadrant tenderness may accompany the finding of hepatomegaly; hepatitis is a common finding.
- Right lower quadrant tenderness suggests right colon enlargement, which may be caused by intestinal vasculitis.

Diagnostic Reasoning

Diagnostic Tests

Initial testing should include a CBC with platelet count, basic metabolic panel (serum electrolytes and kidney function tests), serum albumin (which will be reduced in nephropathy), ANA, urinalysis (UA), and antibody screens for anti-dsDNA (highly specific with 75–95% sensitivity), antiphospholipid antibodies, and anti-Sm antibodies (highly specific but with only 25% sensitivity). Other common autoantibodies include those against single-stranded DNA and nucleoprotein, including antiribonucleoprotein as seen in scleroderma and both anti-Ro (SSA) and anti-La (SSB) as seen in SS.

The CBC may show either anemia or leukopenia or both. If the patient is leukopenic, the differential may reveal lymphocytopenia. One-third of patients with SLE will be thrombocytopenic. ANA results are likely to be elevated in more than 90% of samples; however, this is not specific for SLE. Numerous other inflammatory diseases are also associated with an elevated ANA. Changes in serum levels of autoantibodies (rising anti-dsDNA levels) or complement (decreasing CH50, C3, and C4) correlate with active SLE disease. Elevated ESR and CRP levels are nonspecific markers of active inflammation. Proteinuria is a possible finding from the UA in nephrotic or nephritic patients, with hematuria in the latter. All these tests should be used in conjunction with clinical presentation (history and physical examination) to evaluate for worsening of the disease state and should not be overinterpreted or underinterpreted in isolation. These initial laboratory tests, along with characteristic clinical manifestations, should be sufficient to confirm a diagnosis of SLE. Of note, as reflected in the SLE diagnostic criteria, RPR tests for syphilis may be falsely positive (due to anticardiolipin antibodies or other SLE-related phenomena).

Pertinent imaging tests should be guided by clinical presentation, such as a chest radiography for pulmonary symptoms, renal ultrasound in the face of renal failure, and plain films for arthritic joints. If indicated in the setting of pulmonary findings, pulmonary function tests often have a restrictive pattern, given inflammation and scarring in the lungs. More invasive procedures such as renal biopsy are indicated when histology is needed to determine prognosis and guide therapy. Electrocardiography and echocardiography are indicated to evaluate for pericarditis and other cardiac pathology, and specific tests such as ventilation–perfusion (V-Q)

scans or high-resolution spiral CT scans of the lungs are used to evaluate for pulmonary emboli in prothrombotic patients. As with other thrombotic phenomena, a negative D-dimer test may effectively rule out thrombosis; however, the nonspecific nature of this test in inflammatory conditions typically decreases its diagnostic utility in SLE.

As with SS, keratoconjunctivitis sicca may result, as can pathognomonic, although rare, cotton wool retinal exudates from retinal vasculitis. Scleritis and anterior uveitis may occur but are both uncommon. Mild to moderate cytopenias may affect all three major cell lines (i.e., leukopenia, anemia, thrombocytopenia), with thrombocytopenia leading to easy bruising and purpura. Rarely, severe autoimmune hemolytic anemia can also result. In contrast, thrombophilia may also occur, increasing the risk of thrombosis, including deep vein thrombosis and arterial blood clots, especially if antiphospholipid antibodies or lupus anticoagulant are present (the latter being paradoxically named, as it increases the risk of thrombosis). This prothrombotic state is the cause of recurrent miscarriages (abortions) early in pregnancy, usually in the first trimester. Thus, such an obstetric history should always make the clinician think of antiphospholipid syndrome and SLE as a potential underlying diagnosis.

Differential Diagnosis

The differential diagnosis for SLE includes vasculitis, rheumatoid arthritis, scleroderma, SS, juvenile idiopathic arthritis (particularly the systemic form), chronic active hepatitis, drug reactions, drug-induced lupus, and polyarteritis. The diagnostic criteria set forth under pathophysiology in this section should aid in distinguishing SLE from these other diseases. Hypothyroidism also needs to be ruled out as a cause of fatigue; the TSH and free T_4 test should provide this information. Drug-induced lupus has a milder presentation and is associated predominantly with procainamide, hydralazine, and minocycline, as well as anti-TNF biological immunodulators.

Management

The principal goal of therapy is symptom control. Many patients require little or no intervention. Mild joint pain may be managed with nonpharmacological interventions, as provided in the section on RA. Emotional support and referral to SLE support groups are both helpful in establishing control over some symptoms. Dietary modifications should consider the specific clinical presentation. For example, active inflammatory states may require higher calorie diets if weight loss is a concern; in contrast, corticosteroid-induced surges in appetite may call for lower calorie diets, whereas corticosteroid- or NSAID-induced hypertension and hyperlipidemia (or that accompanying lupus nephritis) may call for low-salt and low-fat/low-cholesterol diets, respectively. Likewise, a lack of sun exposure because of photosensitivity may require vitamin D and calcium supplements to prevent bone loss, especially given chronic corticosteroid use. If conservative management fails, however, the patient may require antimalarials, corticosteroids, immunosuppressants, or immunomodulatory biological agents.

Constitutional symptoms are often the most troubling for patients. Fatigue is the most common symptom and tends to be the most debilitating. It can happen even in the absence of signs of active inflammation. Fatigue may be multifactorial, but if due predominantly to SLE, it tends to respond to treatment with hydroxychloroquine, corticosteroids, or even dehydroepiandrosterone (DHEA). In addition to weight loss associated with hyperinflammatory states, weight gain may also occur due to generalized edema resulting from hypoalbuminemia in nephrotic syndrome (anasarca) if there are kidney manifestations or water retention and increased appetite associated with glucocorticoid use. If fever is present, it is important to deduce whether it is due to the SLE itself, infection (more likely if fever occurs while the patient is on active corticosteroids or immunosuppressive therapies and is episodic), or a drug reaction that may also present with a morbilliform rash and be prolonged, without response to NSAIDs or acetaminophen.

NSAIDs are effective for mild musculoskeletal symptoms and mild serositis (inflammation of serosal layers, such as the pleura or pericardia). Cyclooxygenase-1 (COX-1) inhibitors are used most frequently, as several COX-2 inhibitor NSAIDs have been withdrawn from the market due to serious cardiovascular health risks. In turn, the remaining COX-2 inhibitors should be used with caution.

Cutaneous manifestations of lupus, including discoid lupus, respond well to antimalarials such as hydroxychloroquine (Plaquenil), which are also second-line agents for joint pains and myalgias. Antimalarials are also effective in treating serosal inflammation (pleuritis and pericarditis) and constitutional symptoms including fatigue and fever. Given their association with the long-term reduction of multiple SLE-related complications, their use is recommended in nearly all SLE patients. However, these agents are not without side effects and require appropriate monitoring, including for potential ocular toxicity.

When multiple organ systems are involved or manifestations within a given organ system are moderate to severe, glucocorticoids may be given alone or in combination with another immunosuppressant. Prednisone and other glucocorticoids are effective at treating and preventing relapses if started as soon as a marked rise in anti-dsDNA is observed in the setting of clinical disease manifestations. In turn, it is not uncommon for SLE patients to be maintained on low doses of corticosteroids. However, although they are often considered a mainstay of SLE treatment, the clinician must be aware of the important side effects of systemic (both IV and PO) corticosteroids, which include avascular necrosis (i.e., reduction in blood supply to a major joint such as the knee or hip, which results in joint necrosis), osteopenia and osteoporosis with fractures

or vertebral collapse, growth inhibition in children, glaucoma and cataracts, hyperglycemia and diabetes, hypertension, weight gain, early atherosclerosis that can lead to long-term coronary artery disease and heart damage, as well as cognitive dysfunction and behavioral changes, which may be associated with both short-term and chronic use. Thus, although corticosteroid therapy is associated with a delayed time to onset of organ damage after diagnosis, the side effects and health risks of corticosteroids are well documented and result in significant morbidity in SLE patients. In turn, many lupus specialists strive to decrease corticosteroid use whenever possible, particularly through the use of steroid-sparing agents.

One of the newest additions to the SLE treatment armamentarium is the FDA-approved biological immunomodulatory agent belimumab (Benlysta), a monoclonal antibody therapy that binds the soluble B-cell growth factor B-lymphocyte stimulator (BLyS), thereby preventing signaling through its cognate B-cell surface receptor. As BLyS is known to support autoreactive B cells in SLE, belimumab effectively inhibits the production of autoantibodies capable of mediating organ damage and inflammation. Although not a curative therapy for SLE and not indicated to treat acute flares, belimumab has been shown to decrease disease activity, reduce disease flare rates, and improve symptoms in autoantibody-positive lupus patients, as well as lead to reductions in controller corticosteroid therapy.

Persistent evidence of SLE-related organ damage or symptomatic flares in the face of NSAID or antimalarial controller therapy may signal the need for more aggressive immunosuppressive therapy, such as higher-dose glucocorticoid pulse therapy or the addition of other immunosuppressants such as mycophenolate mofetil (Cellcept), azathioprine (Imuran), methotrexate, or cyclophosphamide (Cytoxan). For example, pulmonary manifestations related to lung inflammation may include pleuritis with a pleural friction rub, lung effusions, pneumonitis, interstitial lung disease, alveolar hemorrhage, or eventually pulmonary hypertension.

Of note, GI manifestations often relate to SLE treatments, rather than to the disease itself, such as gastritis and peptic ulcers resulting from chronic NSAID and corticosteroid use. However, SLE-related vasculitis can lead to inflammation of the pancreas, large intestine, and serosal layers of the peritoneum, as well as to esophagitis and GERD. Both hepatomegaly and splenomegaly may also be detected, along with lymphadenopathy.

The cardiovascular system may manifest with pericarditis or a verrucous form of nonbacterial endocarditis known as Libman-Sacks endocarditis. This is associated with antiphospholipid antibodies and can produce emboli due to valvular insufficiency and turbulent blood flow. There is also a well-documented phenomenon of transplacentally delivered anti-Ro (SSA) and anti-La (SSB) anti-single-stranded DNA antibodies from a mother with SLE to her developing fetus, which can result in potentially fatal third degree heart block for the baby. This is known as neonatal lupus, which is not a manifestation of primary lupus in the fetus, however, and is not the same as pediatric SLE.

CNS and psychiatric manifestations of SLE are quite varied and may require aggressive immunosuppressive treatment. These may include cognitive defects, delirium, depression, mania, anxiety, psychosis (which may also result iatrogenically from corticosteroid use), headache, aseptic meningitis, and various neuropathies. Ischemic CNS damage from thromboembolic cerebrovascular accident may underlie these symptoms as well.

Kidney involvement may be clinically apparent in up to half of all SLE patients and is the primary reason for lupus-related hospitalization. Renal biopsy may reveal several histological subtypes of lupus nephritis. Type I is normal. Type II is pure mesangial and carries with it a good prognosis. Type III is segmental and focal proliferative lupus nephritis and usually responds to corticosteroids. Type IV is diffuse proliferative lupus nephritis, which is typically considered to carry the worst prognosis, presenting with hypertension and leading to end-stage renal disease (ESRD) or death in up to 50% of cases. Type IV patients typically require an induction of remission and maintenance treatment regimen with high-dose corticosteroids and immunosuppressants such as azathioprine (Imuran), mycophenolate mofetil (Cellcept), or cyclophosphamide (Cytoxan). Type V is membranous nephritis with a variable presentation that worsens as complement levels decrease due to more immune complex formation and organ deposition. One-third of Type V patients need no treatment other than that for other SLE symptoms, one-third require low to moderate dose corticosteroids, and one-third need high-dose corticosteroids. Type VI is advanced sclerosing lupus nephritis, which nearly always leads to ESRD, given the irreversibility of renal fibrosis.

Although SLE-related organ damage often signals the need for aggressive immunosuppressive therapy, the severity of organ damage does not always correlate with the severity of inflammation. For instance, kidney dysfunction may relate to irreversible scarring from past kidney inflammation that has since resolved and, in turn, may not be effectively treated with immunosuppressants. This is an important distinction for the clinician to make because worsening or ongoing inflammation may be treated with corticosteroids or immunosuppressants, whereas treating noninflammatory organ damage with this same regimen just increases the risks of side effects and iatrogenic complications due to immunosuppression, without improving the underlying organ damage.

Disease progression in the face of potent immunosuppressants, such as cyclophosphamide, portends a particularly poor prognosis. Several immunomodulatory treatments are being explored, including immune system ablation with high-dose chemotherapy, with or without stem cell transplantation. In addition, although not

FDA approved to treat lupus, the anti-B cell (anti-CD20) monoclonal antibody immunotherapy rituximab (Rituxan) is often used in refractory SLE patients, given its familiar side effect profile and relatively long record of clinical use in other indications.

Five-year survival in SLE has greatly improved in recent decades, given the therapeutic advances discussed in this section, and is currently greater than 90%. However, the course of SLE tends to be relapsing and remitting, characterized by recurrent flares with intermittent periods of quiescence, sometimes resulting in prolonged periods of remission lasting several years. In turn, CNS and renal involvement, especially diffuse proliferative nephritis or advanced sclerosing nephritis, portend the worst prognosis. Indeed, most SLE inpatients are admitted for renal issues, whereas patients with isolated cutaneous and joint/muscle manifestations have the best prognosis. Short-term death is also often due to infection related to immunosuppression by multiple classes of SLE medications, in addition to organ involvement associated with active inflammation in the heart, kidney, or CNS.

Follow-up and Referral

Follow-up of SLE patients is critical to track the course of the disease, which is highly variable across patients. SLE patients who require only nonpharmacological management should still be seen at least twice per year to assess for disease progression. Patients requiring medication are typically seen at least every 3 months after stabilization on an optimal controller regimen. Before consultation with a rheumatologist, patients should receive laboratory evaluation in the primary care setting including CBC, UA, CRP, and ANA to follow the course of the disease. In addition, SLE patients have a greater risk of lymphoma. A greater risk of breast cancer, abnormal Pap smears, and squamous cell skin cancer has also been suggested. Thus, appropriate cancer screening in the primary care setting is critical.

Referral to a rheumatologist is indicated if antimalarials, corticosteroids, immunosuppressants, or biological immunomodulators are to be prescribed.

Patient Education

Newly diagnosed patients should receive referrals to information hotlines for SLE and an array of patient advocacy groups, given the potential life-changing impact of this disease. Many organizations, which are listed in the Resources section at the end of this chapter, will provide patients with access to materials that support symptom control. In addition, patients should learn their individualized trajectory of disease and prognosis, depending on their particular clinical manifestations.

Patients should learn that rest is essential during disease exacerbations (lupus flares). The need for increased oral fluids and correct dosing of NSAIDs are also essential parts of the educational plan. Patients should understand the need for professional intervention when their temperature escalates beyond 101.5°F (38.5°C), because fevers can signal the onset of an opportunistic infection or a lupus flare, for which the clinician should be consulted immediately.

Immunizations have not been shown to "bring out SLE" and should not be avoided, except for live attenuated vaccines in immunocompromised hosts. If possible, sulfonamide antibiotics (e.g., trimethoprim/sulfamethoxazole [Bactrim]) and tetracyclines should be avoided, because they may lead to adverse effects in SLE patients, including exacerbation of photosensitivity. Women should be encouraged to avoid pregnancy until the disease is in remission for at least 6 months because there are high miscarriage rates due to thromboembolus. In addition, birth control pills may exacerbate disease manifestations, although low-dose estrogen pills appear to be better tolerated. Corticosteroids, NSAIDs, and hydroxychloroquine are usually used to treat pregnant women, whereas other immunosuppressants such as methotrexate and cyclophosphamide are contraindicated in pregnancy due to potential teratogenic effects.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION

Infection by HIV results in eventual destruction of the immune system. HIV binds to the CD4+ T-cell receptor in conjunction with the cellular coreceptors chemokine C-C motif receptor 5 (CCR5) or C-X-C chemokine receptor 4 (CXCR4) to enter and infect immune cells in the human body. In early HIV infection, the patient's CD4+ T-cell (T4 cell, T4 lymphocyte) count remains above 500 cells/mcL of peripheral blood. Over time, the immune system weakens as HIV infection leads to significant immune dysregulation, and the patient's CD4+ T-cell count begins to decline. When this occurs, the patient becomes susceptible to opportunistic infections.

Although there is no cure at this time for HIV infection, viral suppression of HIV to undetectable levels in the peripheral blood can be achieved by a combination of potent antiretroviral (ARV) agents. With early detection and initiation of treatment, HIV infection can be managed as a chronic but controllable infectious disease.

Table 17.5 presents the Centers for Disease Control and Prevention (CDC) HIV classification system for adults and adolescents.

Epidemiology and Causes

HIV was originally identified in homosexual men in the 1980s, but the virus affects men and women of all races, ethnicities, and sexual orientations, as well as infants, children, and adolescents. In 2011, an estimated 34 million people were believed to be infected with HIV worldwide. Although new infections have fallen by more than 20% since 2001, there were still 2.5 million new infections in 2011 or close to 7,000 new cases per day. HIV has affected all regions of the world. According to the Joint United Nations Programme on HIV/AIDS (UNAIDS),

Table 17.5 CDC HIV Classification System for Adults and Adolescents

This system emphasizes the importance of CD4+ T-lymphocyte testing in clinical management of HIV-infected persons. The system is based on three ranges of CD4+ T-cell counts and three clinical categories, giving a matrix of nine exclusive categories.

Criteria for HIV Infection

Persons age 13 years or older with repeatedly (two or more) reactive screening tests (ELISA and specific antibodies identified by a supplemental test such as the Western blot). Other specific methods of diagnosis of HIV-1 include virus isolation, antigen detection, and detection of HIV genetic material by PCR or bDNA assay.

AIDS-Defining Condition

The term *AIDS-defining illness* refers to any of a list of infections, diseases, or conditions that, when occurring in an HIV-infected person, leads to a diagnosis of AIDS, the most advanced stage of HIV infection. AIDS is also diagnosed if an HIV-infected person has a CD4+ T-cell count below 200 cells/mcL, regardless of whether that person has an AIDS-defining condition. Twenty-six conditions were identified and classified as AIDS-defining conditions in 1993 by the Centers for Disease Control and Prevention (CDC).

Clinical Category	CD4+ T-cell Count*	Clinical Manifestations
A1	≥500 cells/mcL	Category A consists of one or more of the conditions listed below in a person with documented HIV infection. Conditions listed in Categories B and C must not have occurred. • Asymptomatic HIV infection • Persistent generalized lymphadenopathy (noted in two or more extrainguinal sites, at least 1 cm in diameter for ≥3 months) • Acute (primary) HIV infection with accompanying illness or history of acute HIV infection
A2	200–499 cells/mcL	See A1.
A3	<200 cells/mcL	See A1.
B1	≥500 cells/mcL	Symptomatic HIV infection (but not A or C conditions) Examples include but not limited to: • Bacillary angiomatosis • Candidiasis, vulvovaginal: Persistent >1 month, poorly responsive to treatment • Candidiasis, oropharyngeal • Cervical dysplasia, severe, or carcinoma in situ • Constitutional symptoms such as fever or diarrhea >1 month (The above must be attributed to HIV infection or have a clinical course or management complicated by HIV.)
B2	200–499 cells/mcL	See B1.
B3	<200 cells/mcL	See B1.
C1	≥500 cells/mcL	Category C includes the clinical conditions listed below; for classification purposes, once a Category C condition has occurred, the person will remain classified as category C: • Bacterial pneumonia, recurrent (≥2 episodes in 1 year) • Candidiasis: Esophageal, tracheal, bronchi, lungs • Cervical cancer, invasive • Coccidioidomycosis, disseminated or extrapulmonary • Cryptococcosis, extrapulmonary • Cryptosporidiosis, chronic intestinal (>1 month) • Cytomegalovirus disease in other than liver, spleen, nodes (e.g., CMV retinitis) • Encephalopathy, HIV-related • Herpes simplex with mucocutaneous ulcer >1 month, bronchitis, pneumonia, esophagitis • Histoplasmosis, disseminated or extrapulmonary • Isosporiasis, chronic intestinal >1 month

Table 17.5 CDC HIV Classification System for Adults and Adolescents—cont'd

		• Kaposi's sarcoma • Lymphoma: Burkitt's, immunoblastic, primary central nervous system • *Mycobacterium avium* complex or *M kansasii,* disseminated or extrapulmonary • *M tuberculosis,* pulmonary or extrapulmonary • *Mycobacterium,* other species, disseminated or extrapulmonary • *Pneumocystis jiroveci* pneumonia (PCP) • Progressive multifocal leukoencephalopathy (PML) • *Salmonella* bacteremia, recurrent • *Toxoplasma gondii* (brain) • Wasting syndrome due to HIV (involuntary weight loss >10% of baseline body weight) with either chronic diarrhea (≥2 loose stools per day for ≥1 month) or chronic weakness and fever ≥1 month
C2	200–499 cells/mcL	See C1.
C3	<200 cells/mcL	See C1.

*There is diurnal variation in CD4+ counts, averaging slightly higher in the afternoon, in HIV-positive persons. Blood for sequential CD4+ counts should be drawn at about the same time each day.

Source: Public Health Service Revised Classification System for HIV Infection (Adolescents and Adults) 1993 Revised. In C. Kirton (Ed.), *ANAC's core curriculum for HIV/AIDS nursing,* ed 2. SAGE, Thousand Oaks, CA, pp. 351–353.

two-thirds of all people living with HIV are in sub-Saharan Africa (23 million), with 58% of these cases being women.

Significant epidemiological changes have occurred in the United States with respect to HIV infection. In 1992, the majority of cases in the United States were among white, non-Hispanic individuals. In more recent years, the face of the epidemic has changed, as minorities and women have been disproportionately affected. Reports from the CDC note that African Americans accounted for nearly half of all new HIV infections in the United States in 2010, despite comprising only 12% to 14% of the population. Reflective of this disproportionate impact, the rate of new infections among African American men was seven times as high as in white men, and the rate in African American women was nearly 20 times that of white women. Hispanics/Latinos have also been disproportionately affected, representing 20% of all new HIV infections in 2009, despite comprising only 16% of the population, with an overall infection rate nearly three times as high as whites. Latina women, in particular, are affected at even higher rates, estimated at four times the rate of white women. These trends may reflect differences in socioeconomic factors, such as income, education, and health-care access, rather than only racial or ethnic background.

The largest decline in reported cases has occurred among men who have sex with men (MSM). In contrast, the greatest increase in HIV infection is now seen in individuals with heterosexual contact. Also of concern is the increasing rate of HIV infection in persons older than 50 years. Concerns have similarly been raised about the incidence of HIV infection in adolescents and young adults. CDC data indicate that in 2009, 39% of all new HIV infections were in young people aged 13 to 29 years, with most having been acquired sexually. In contrast to the larger gay community, infection rates appear to be increasing among MSM in this younger age-group, with disproportionately higher rates among young people of color. In 2010, HIV disease was the sixth leading cause of death among people aged 25 to 34 years in the United States.

HIV-1 is the type of virus found predominantly in the United States. HIV-2 is relatively rare in the United States, except among immigrants from West Africa, where the predominance of cases originate. HIV-2 is biologically similar to HIV-1 but shows reduced virulence, with a slower rate of CD4+ T-cell decline. Blood banks now routinely test for both HIV-1 and HIV-2. Co-infection with both HIV-1 and HIV-2 may occur, and HIV-2 should be considered in patients who were born in Africa, have traveled in Africa, or have had sexual contact or shared needles with someone from Africa.

Transmission

HIV is transmitted through the exchange of blood and body fluids and cannot be transmitted by casual contact (e.g., handshakes, closed or open-mouth kisses, and hugs). HIV is considered a sexually transmitted disease (STD; sexually transmitted infection) because both the human immunodeficiency virus and CD4+ T cells may be present in semen and vaginal secretions. During vaginal or anal sex, friction can cause minute tears to these highly vascular mucous membranes. These minute tears can allow systemic exposure to HIV-infected bodily fluids during penetrative intercourse, particularly on

ejaculation. The use of latex condoms can help prevent the exchange of secretions. Anyone who has had unprotected sex (without a condom or other adequate form of barrier protection) is considered potentially at risk for HIV infection. The risk of HIV transmission from a single episode of unprotected receptive vaginal intercourse with a known HIV-positive sexual partner is estimated to be between 0.08% and 0.2%, and the infection risk associated with a similar episode of receptive anal intercourse is 0.1% to 0.3%. The risk of HIV transmission from oral sex (mouth to genital or mouth to anal contact) is difficult to determine, because most people who practice oral sex also practice other forms of sex during the same encounter. Oral to vaginal (cunnilingus), oral to anal (anilingus), and receptive oral to penile (fellatio) sex carry little risk of HIV transmission. However, the highest risk of HIV transmission from oral sex would be to a person performing fellatio on an HIV-infected man who ejaculates. Factors that increase the risk of HIV transmission from oral sex include oral or genital ulcers or cuts, bleeding gums, and concurrent sexually transmitted infections.

HIV can also be transmitted through the sharing of needles with an HIV-infected person; therefore, injection drug users (intravenous [IV] drug abusers) are a high-risk group for HIV infection. Of particular relevance to health-care workers, needle-stick injuries are the most common cause of occupational exposure to HIV. Treatment Standards/Guidelines 17.1 presents the postexposure prophylaxis guidelines for health-care workers, and The Patient's Voice 17.2 presents one health-care worker's perspective when faced with such a situation. The risk of HIV transmission from a single episode of needle-sharing during injection drug use with a known HIV-positive partner has been estimated at 0.67%, and the risk from an occupational needle stick from an HIV-positive patient is estimated at 0.3%.

Before blood banks began universal testing for HIV, people who had blood transfusions were at risk for HIV infection, as were hemophiliacs who might have been given contaminated blood products. Routine testing of all blood products for HIV-1 and HIV-2 has now virtually eliminated this route of transmission in the United States and other developed nations with universal blood testing standards. However, given the potential of an HIV-positive individual to donate blood during the asymptomatic and undetectable window period before HIV-specific seroconversion has occurred, transmission rates as low as 1 in 1,000,000 to 1 in 2,000,000 are typically cited during informed consent procedures for transfused blood products.

HIV can be maternally transmitted from mother to newborn. The AIDS Clinical Trials Group (ACTG) 076 study, which provided oral zidovudine (Retrovir; ZDV;

Treatment Standards/Guidelines 17.1 Postexposure Prophylaxis for Health-Care Workers

Postexposure Prophylaxis (PEP) Regimens

Three-drug combination regimens lasting 1 month are recommended in all cases of occupational exposure. In contrast to prior guidelines, two-drug regimens are no longer recommended, unless in consultation with an HIV specialist.

Preferred regimen: *Integrase inhibitor PLUS 2-NRTI backbone*

- Raltegravir (Isentress, RAL) 400 mg twice daily PLUS Truvada (tenofovir DF 300 mg + emtricitabine 200 mg) 1 tablet once daily

Alternative regimens: *Integrase inhibitor or NNRTI or PI (ritonavir-boosted) PLUS 2-NRTI backbone*

Alternative Integrase inhibitor

- Elvitegravir (EVG) 150 mg once daily; available as a fixed-dose combination (Stribild/Quad Pill) with cobicistat (cytochrome P450 3A enzyme inhibitor) 150 mg, tenofovir DF (TDF 300 mg), and emtricitabine (FTC) 200 mg taken once daily

Alternative NNRTI

- Etravirine (Intelence, ETR) 200 mg (comes as 100 and 200 mg tablets) twice daily
- Rilpivirine (Edurant, RPV) 25 mg once daily (comes as 25 mg tablet); also available as a fixed-dose combination (Complera) with tenofovir DF (TDF 300 mg) + emtricitabine (FTC) 200 mg taken once daily

Alternative PI (ritonavir-boosted)

- Darunavir (Prezista, DRV) 800 mg (comes as 400 mg tablets) once daily with ritonavir (Norvir; RTV) 100 mg (comes as 100 mg capsule) once daily
- Darunavir (Prezista, DRV) 600 mg (comes as 75, 150, and 600 mg tablets) once daily with ritonavir (Norvir; RTV) 100 mg (comes as 100 mg capsule) twice daily
- Atazanavir (Reyataz; ATV) with ritonavir (Norvir; RTV): ATV 300 mg (comes as 100, 150, and 300 mg capsules) with ritonavir (Norvir, RTV) 100 mg twice daily; may be taken as ATV 400 mg (comes as 200 mg capsules) without ritonavir once daily, but not if taken with tenofovir DF (TDF)
- Saquinavir (Invirase; SQV) with ritonavir (Norvir; RTV): SQV 1,000 mg (comes as 500 mg tablet) with RTV 100 mg (comes as 100 mg capsule) twice daily

Alternative 2-NRTI Backbone

- Zidovudine (Retrovir; AZT; ZDV) 600 mg daily with food (300 mg twice a day or 200 mg three times a day) PLUS lamivudine (Epivir; 3TC) 300 mg (300 mg once a day or 150 mg twice a day); can be dosed as Combivir (combination drug of Retrovir 300 mg and Epivir 300 mg) taken as one tablet twice a day

Treatment Standards/Guidelines 17.1 Postexposure Prophylaxis for Health-Care Workers—cont'd

Begin PEP:

After occupational exposure:

- Begin PEP promptly, as quickly as possible, preferably within hours, rather than days, after exposure, according to the regimens listed above.
- If possible, determine HIV status of exposure source to assist in guiding HIV PEP, but PEP should not be delayed while awaiting test results. It is also unnecessary to rule out whether an exposure source that tests negative is within a seronegative window period, unless acute antiretroviral syndrome is suspected clinically.
- Consultation with an HIV specialist should not delay initiation of HIV PEP but may be indicated in the following situations: delayed exposure reporting (>72 hours); unknown exposure source (e.g., used needle in sharps container); pregnancy or breastfeeding in exposed health-care provider; suspected HIV drug-resistance in exposure source; concurrent illness in exposure source (e.g., hepatitis B or C co-infection).
- Contraindicated in PEP: nevirapine (hepatotoxicity, rhabdomyolysis, hypersensitivity).
- Generally not recommended in PEP: didanosine (serious and life-threatening adverse events); nelfinavir; tipranavir (serious and life-threatening adverse events); stavudine + didanosine (peripheral neuropathy, pancreatitis, lactic acidosis).
- Recommended only with expert consultation: abacavir (requires negative HLA B57–01 testing before use); efavirenz (teratogenic, neuropsychiatric effects, serious or life-threatening drug interactions); enfuvirtide (subcutaneous dosing, significant side effects, antidrug antibodies may develop and lead to false positives on HIV testing); fosamprenavir; maraviroc (requires Trofile assay to confirm R5 HIV strain tropism before use); saquinavir; stavudine.
- All health-care workers (HCWs) with occupational exposure to HIV will need follow-up, even if they do not start PEP, including short-term follow-up 72 hours after initial exposure and HIV antibody testing at baseline.
- Perform drug-toxicity monitoring, including a complete blood count and renal and hepatic function tests, at baseline and 2 weeks after starting PEP. If toxicity is noted, dose reduction or drug substitution should be considered with expert consultation, with further diagnostic studies as indicated.
- Provide follow-up counseling and medical evaluation periodically for 6 months postexposure (at 6 weeks, 12 weeks, and 6 months). Follow-up may be shortened to 4 months postexposure (at 6 weeks and 4 months) if a fourth generation combination p24 antigen-HIV antibody detection assay is used. Observe precautions (barrier contraception, avoidance of blood/tissue donation, avoidance of pregnancy and breastfeeding) to prevent secondary transmission of HIV throughout the entire follow-up period.
- Provide appropriate medical care for HCWs who become infected with HIV. An occupational exposure is an emotionally charged event for most HCWs and can have a severe psychological impact. Psychological support is needed to help deal with the stress of awaiting HIV test results and to assist in coping with the side effects of PEP.

The Patient's Voice 17.2

HIV Infection

I am furious! I've been a nurse for 20 years and have always been proud of my skills and techniques. I have been stuck by needles, but only a few times during my career . . . usually when a patient suddenly moved and not through negligence on my part. I thought nothing of it, until last month when I went to my doctor because I was feeling so tired and run down. He asked if I had been tested for HIV, and I said no. Just to appease him, I had the test done, and it was positive.

The only thing I can relate it to is a needle stick that occurred when I was working in home health several years ago. I didn't even think anything of it at the time, and I didn't even fill out an incident report. I don't have any recourse now since I can't prove I was infected "on-the-job." Now, I hear about the needleless syringes and all the safe guards in place. If I had them back then, I probably wouldn't be in the situation I am now! I am angry! What do I do now?

AZT) to HIV-infected women during pregnancy, with IV AZT during labor and liquid AZT to the newborn postnatally, demonstrated a dramatic decrease in HIV maternal transmission from 25% to 30% to as low as 8%. Current guidelines that employ elective cesarean section to avoid birth canal exposure, thorough STD screening and treatment, as well as updated prenatal and perinatal ARV regimens for both mother and child, have decreased this rate even further to less than 1% in some centers. However, HIV is present in the breast milk of infected mothers, so breastfeeding by an HIV-infected woman is still considered a potential route of transmission and is not recommended in the United States and other countries where adequate formula feeding is a readily available alternative.

HIV-infected women have poorer survival rates than men, but no difference has been found in the rate of disease progression. Some studies indicate, however, that survival is not necessarily related to sex or race; rather, it is related to unequal socioeconomic status and thus

unequal access to care and appropriate drug therapy, among other factors.

In response to the changing HIV epidemic, in 2003 the CDC proposed new strategies for advancing HIV prevention: (1) Make voluntary HIV testing a routine part of medical care. (2) Implement new models for diagnosing HIV infection outside of medical settings. (3) Prevent new infections by working with persons diagnosed with HIV and their partners to minimize risk of transmission. (4) Further decrease perinatal HIV transmission. As discussed in more detail under Diagnostic Reasoning, opt-out HIV testing has become increasingly common as a strategy to increase overall HIV testing rates.

Pathophysiology

HIV is a member of the Lentivirinae subfamily of "slow" retroviruses, known for their prolonged latent infectious period, persistent viremia, species-specific infectivity, tropism for cells of the immune and nervous systems, and subsequent destruction of host immune defenses including the triggering of autoimmune responses. Evolutionarily conserved members of this family include simian immunodeficiency virus (SIV) and feline immunodeficiency virus (FIV).

HIV was identified as the causative agent of AIDS in 1984. As the predominant strain worldwide, HIV-1 has been genetically divided into groups or subtypes M, N, and O. Accounting for the majority of HIV-1 cases, group M has been further subdivided into subclasses known as clades, designated A through J. In the United States, nearly all HIV infections are due to HIV-1 clade B, with estimates of up to 98%. Clades A, C, D, and E are most common in developing nations, with some studies indicating that clade E has a greater propensity for heterosexual transmission. HIV-2, found predominantly in West African nations, Angola, Mozambique, France, and Portugal, results in slower disease progression and appears less readily transmissible.

Studies utilizing quantitative assays of plasma HIV RNA have provided new insights into the pathogenesis of HIV infection. Molecular genetic studies have resulted in a better understanding of the viral genome and its complex replication process, which has led to multidrug therapy that attempts to suppress viral replication at different stages of the HIV life cycle. The HIV genome consists of several regulatory genes (*nef, rev, tat, vif, vpu,* and *vpr*) and three structural genes called *gag* (encoding several core capsid proteins), *pol* (encoding reverse transcriptase and integrase), and *env* (encoding several outer viral envelope surface proteins involved in binding of the HIV virion to target host cells).

These gene products produce an HIV virion consisting of a nucleoprotein core with two copies of single-stranded genomic RNA and several key proteins, including p6 and p7 (nucleocapsid proteins bound directly to genomic RNA), p24 (a capsid protein forming a shell around the genomic core), and p17 (a matrix protein that lines the inner surface of the virion's outer lipid bilayer, providing structural integrity). Also included in the core are several enzymes involved in viral replication including reverse transcriptase, integrase, and protease. This nucleoprotein core is surrounded by an outer lipid bilayer studded along its surface by two major glycoproteins named for their molecular mass in kilodaltons, gp120 and gp41.

The sequence of events in HIV infection begins with the transfer of the virus from one host to another. Once the virus is transmitted across the mucocutaneous barrier and into the bloodstream, HIV attaches to cells at the CD4+ receptor site via gp120. CD4+ receptors are found on many cells of the body, including cells of the central nervous system, GI tract, and immune system (e.g., CD4+ T cells, monocyte-derived macrophages, and tissue dendritic cells). At the onset of HIV infection, the average number of CD4+ T cells is about 1,000/mcL (normal range: 500–1,500/mcL).

Although CD4+ T cells were first identified as the primary target of HIV infection, it is now known that tissue dendritic cells called Langerhans cells found within the genital mucosal epithelium are believed to be the earliest targets of HIV infection, given their proximity to the initial site of HIV exposure. After infection, dendritic cells bind to CD4+ T cells and subsequently migrate to draining lymph nodes via regional lymphatic channels. Within these lymph nodes, HIV further infects follicular dendritic cells capable of presenting virus to circulating hematopoietic cells. Thus, the lymph nodes are a major site of viral replication and a focus of HIV infectivity.

After attaching to the target host cell, HIV enters the cell by fusion at the plasma membrane. This is a sequential process, which first involves a conformational change in HIV after gp120 binding to CD4 that allows the virion to interact with chemokine receptors on the host cell surface. This initiates another conformational change, which exposes the gp41 viral envelope protein and brings the virion into even closer proximity to the plasma membrane.

Thus, in addition to interactions with gp41, viral adhesion requires the aid of secondary coreceptors, most notably the chemokine receptors CXCR4 (also known as fusin), which binds T-cell–tropic HIV strains called X4 viruses, and CCR5, which binds macrophage-tropic strains or R5 viruses. Tissue dendritic cells express CCR5 and less commonly CXCR4. In turn, R5 viruses are more common early on in HIV infection, whereas X4 viruses predominate in the later stages of symptomatic infection. Studies of people who have had multiple exposures to HIV yet remain uninfected have shown that these people have defects or polymorphisms in these coreceptors, which may explain why they have not become infected. In turn, investigational studies are addressing each step in the viral fusion process as a potential target for pharmacological intervention, for example, the CCR5 antagonist maraviroc (Selzentry) and the gp41 fusion inhibitor T-20 (enfuvirtide [Fuzeon]).

Once HIV enters the healthy CD4+ T cell, the cell becomes infected, and HIV begins its replication activities by converting its own genetic material (RNA) into complementary DNA strands, using the RNA-dependent DNA polymerase enzyme reverse transcriptase (RT)—the hallmark of retroviruses. Viral DNA then becomes double stranded and is incorporated into the host cell genome by viral integrase, and the RNA template is digested by viral RNAse. This new DNA acts as a blueprint for replication, directing the infected host cell to make new viral particles. In recent years, ARV medications have been developed to inhibit the genomic integration step in the viral replication process, for example, the integrase inhibitor raltegravir (Isentress).

Because mammalian cells do not express reverse transcriptase, this enzyme was the first retrovirus-specific therapeutic target for HIV medications in the form of nucleoside (and nucleotide) RT inhibitors (NRTIs), as well as the nonnucleoside RT inhibitors (NNRTIs). These agents either serve as competitive chain terminators of elongating viral DNA strands or interfere with the DNA template-primer activity of RT.

Importantly, RT lacks the histone repair enzymes characteristic of mammalian DNA polymerases. This results in a high rate of uncorrected mutations during each cycle of viral DNA replication. In turn, this leads to the rapid development of resistance by HIV to most ARV agents, particularly if used suboptimally as monotherapy or, alternatively, as combination therapy with a high degree of patient noncompliance.

In addition to genomic replication, a large portion of viral DNA is transcribed and subsequently translated into a large polyprotein, which must then be activated. The HIV protease enzyme, acting like "chemical scissors," catalyzes the cleavage of polyproteins into mature structural proteins and enzymes. This process results in formation of a large number of infectious viral particles, which bud from the host cell and seek out new cells to infect. Given its effect on such a large number of viral proteins, HIV-specific protease serves as a critical target for one of the most potent classes of ARV agents—the protease inhibitors.

Once HIV enters the body, a series of stages occur in the infectious process:

- The acute retroviral stage or syndrome (or primary infection period)
- The asymptomatic stage (including a "window" period before seroconversion)
- The symptomatic stage of HIV infection, which may result in opportunistic infections and acquired immunodeficiency syndrome (AIDS)

The initial period of infection, or acute retroviral syndrome, resembles infectious mononucleosis and is accompanied by high HIV viremia, often in excess of 1 million viral copies/mL. Primary HIV infection refers to the 4- to 7-week period of rapid viral replication immediately following exposure and infection by the virus. About 30% to 60% of individuals with primary infection develop an acute syndrome characterized by fever, malaise, lymphadenopathy, pharyngitis, headache, myalgia, and sometimes rash. Importantly, common cold symptoms including rhinorrhea and congestion are typically absent during acute retroviral syndrome.

There is spontaneous recovery from these flu-like symptoms in 1 to 3 weeks. Within days after the initial infection, however, there is extension of virus to the regional lymph tissue, presumably by dendritic cells. This is followed by massive viremia with extensive involvement of lymphatic tissue. Within a few weeks, there is an immune response resulting from the complex interplay of HIV-specific cytotoxic T-cell responses, plasma and B-cell–mediated humoral antibody formation, and cytokine production. Seroconversion (the development of antibodies to HIV in the blood) usually occurs 1 to 3 months after viral transmission. Once seroconversion has occurred, the ELISA test used to diagnose HIV will be positive in infected individuals. However, from the point of initial infection before detectable seroconversion, there is a variable "window period," which may last anywhere from 2 to 14 weeks. Although the infected person will have a negative antibody blood test during this asymptomatic period, the patient is already infectious to others and may transmit the virus.

HIV infection is a dynamic process characterized by a high rate of viral replication and significant immune dysregulation. Complete viral latency, a "quiet time" for the virus, does not exist. Initially, in individuals with acute HIV infection, the viral load is extremely elevated (10^5–10^7 copies/mL). Once the host immune response begins, plasma HIV RNA levels decline rapidly. Without treatment, this level fluctuates for the initial 6 months of infection until a set point is reached. The "set point" refers to a steady state of the plasma HIV RNA level that persists for years. During this time, the immune system is actually in a hyperactivated state known as immune activation, in which markers of cellular immune activity such as proliferation, changes in cell surface proteins, and cytokine production are all increased, as are overall levels of immunoglobulin. However, these processes are not coordinated or effectively directed toward clearing the virus, and eventually, plasma HIV viral load begins to increase progressively. At that time patients begin to deteriorate clinically as CD4+ T-cell counts decline even further. Studies have demonstrated that the rate of CD4+ T-cell decline is not fully accounted for by the direct viral infection and destruction of these cells. Rather, the dysregulated state of immune activation, which directly correlates to HIV viral load, is a major contributing factor. Thus, it is important to understand that HIV-associated immune activation does not result in an effective immune response against the virus, but actually contributes to progressive immune suppression in the setting of HIV viral replication and a detectable viral load.

In turn, the magnitude of the viral set point predicts the rapidity of disease progression, and chronic therapy is designed to drive this set point down as far as possible.

Through the use of HIV detection assays to determine the level of viral activity in the peripheral blood (called viral load tests), it has been shown that the level of plasma HIV RNA is proportional to the rates of viral replication and CD4+ T cell destruction. Viral load is one of the most useful tests for predicting the risk of progression to AIDS. Because the natural history of HIV infection varies from one patient to another, the plasma HIV viral load can help predict the rapidity with which clinical immunodeficiency will develop. Fortunately, with the initiation of appropriate ARV therapy, the immune system appears to retain the capacity for cellular recovery even at later stages of HIV infection. Thus, therapeutic strategies were developed that avoided the rapid initiation of ARV medications at the time of diagnosis in favor of more conservative treatment approaches based on low CD4+ T-cell count thresholds, which sought to minimize the long-term side effects and genetic resistance that developed as a consequence of ARV medication exposure. However, more recent evidence has indicated that the regeneration of the immune system that results after initiating ARV treatment is more complete if therapies are started earlier in the course of the disease, such as when CD4+ T-cell counts reach 500 cells/ml. Thus, the optimum stage for initiating ARV therapy has yet to be firmly established, because several factors must be weighed simultaneously.

The half-life of a free HIV virion is less than 1 hour, whereas the half-life of an acutely infected T cell is approximately 1 day. In HIV infection, an estimated 1 to 10 billion viral particles are produced and cleared each day. Studies suggest that billions of CD4+ T cells may be destroyed every day, eventually overwhelming the immune system's capacity to regenerate. This rapid turnover of virus and CD4+ T lymphocytes occurs throughout the course of HIV infection. An additional pool of longer-lived macrophages and follicular dendritic cells infected with HIV may persist for up to several weeks. However, it is a smaller, long-lived pool of memory lymphocytes that numbers approximately 1 million, which may persist for several years in a latent infected stage, creating a viral reservoir within the host. These cells may be localized to tissue, rather than present in the peripheral circulation, and may be located in immune privileged sites, protected from both host defense systems and therapeutically effective medication levels. Thus, by avoiding the antiretroviral activity of current pharmacotherapies, these cells may enter into an active lytic stage of viral replication up to several decades later, exposing the immune system to rapid viral proliferation. Research suggests that the inability to clear HIV from the body in full and cure the infection is a function of this pool of long-lived HIV-infected reservoir cells, which current pharmacotherapies are unable to destroy completely.

Over a period of time, the replication activities of the virus eventually supersede the capacity for CD4+ T-cell regeneration. As the CD4+ T-cell count declines, patients become increasingly susceptible to opportunistic infections and malignancies. Falling below a CD4+ T-cell count of 200 cells/mcL due to HIV infection is the laboratory definition of developing AIDS. In some patients, the rate of CD4+ T-cell loss is extreme, with counts dropping below 200 cells/mcL within 2 years, whereas in a small subset of patients—called long-term nonprogressors—CD4+ T-cell counts above 500 cells/mcL may be maintained up to 10 years after infection, in the absence of any ARV medication. In addition, many of these patients are also able to suppress HIV RNA viral load without the use of ARV medications to less than 50 copies/mL of peripheral blood (often called "elite controllers"), which is the current lower limit of detection of most diagnostic HIV viral load tests used clinically in the United States. Extensive research programs are currently focused on this subset of long-term nonprogressors, whose individual immune responses may be critical to developing effective therapies to control viral replication and attenuate immunosuppression.

Clinical Presentation

Subjective

A careful history should be done to determine the patient's risk of HIV infection, because certain behaviors place a patient at higher risk of exposure to HIV than others. Focus on History 17.1 lists questions the clinician should ask to assess these risks. Although this list is not exhaustive, these questions can generate discussion and open the door to a more detailed history or clarify the patient's misconceptions regarding HIV infection.

In acute HIV infection, more than 8% of patients have symptoms such as fever (90%), sore throat (70%), myalgia (60%), headaches (60%), cervical lymphadenopathy (50%), and night sweats (50%). However, the majority of patients with acute HIV infection are asymptomatic.

Across the disease spectrum, the HIV-positive patient may present with symptoms reflecting any of the following clinical presentations: flu-like symptoms (acute retroviral syndrome typically seen in the early stage of HIV infection, anywhere from 6 days to 6 weeks after viral transmission); darkish colored purple spots on the skin (indicative of Kaposi's sarcoma); nonproductive cough, shortness of breath, and fever that has been present for several days or weeks, suggesting *Pneumocystis jiroveci* pneumonia (PCP, a fungal infection formerly known as *Pneumocystis carinii*), *Mycobacterium tuberculosis,* or other bacterial pneumonia, typically seen in patients with CD4+ T-cell counts below 200 cells/mcL; and/or constitutional symptoms such as weight loss, night sweats, chronic fever, and/or chronic diarrhea (usually seen in patients with advanced HIV infection, or AIDS, with CD4+ T-cell counts below 200 cells/mcL).

Focus on History 17.1 Evaluating Risk of HIV Infection

Sexual History and Sexually Transmitted Diseases
- Describe your sexual relationships.
- Describe your sexual orientation.
- Describe your sexual practices. Have you ever had anal sex?
- Have you ever had a sexually transmitted disease (STD)?
- Have you ever had vaginal discharge or problem (for women)? Penile discharge or problem (for men)?
- Have any of your sexual partners been tested for STDs?
- Do you practice safer sex, such as using condoms or other forms of barrier protection?
- What form of birth control do you use, if any?
- Have any of your sexual partners been told that they were HIV positive or had AIDS?
- Would you expect any of your sexual partners to have been exposed to a STD or HIV? Why or why not?

Substance Abuse
- Have you ever injected drugs (legal or illegal [street])?
- Have you ever shared needles, such as for injections, piercings, or tattoos?
- Have you ever used (in any form) illegal or street drugs?
- Do you drink alcohol? If so, how much?

Transfusion History
- Did you receive any blood or blood products between 1977 and 1985?
- Are you or your partner a hemophiliac?
- Have you ever received any donor sperm during artificial insemination?

Infection History
- Have you or a sexual partner ever had any form of hepatitis?
- Have you or anyone close to you been diagnosed with tuberculosis (TB)? If so, what is (or was) the treatment?
- Have you ever had a positive test for TB?
- Have you ever taken medications for TB?

Occupational History
- Do you work in the health-care field? In a long-term residential facility? In a jail or prison?
- Are you exposed to blood or other body fluids while on the job?
- Have you ever had a needle-stick injury?

Objective

The most common clinical signs and physical exam findings of HIV infection include the following:

- Persistent generalized lymphadenopathy: This is a relatively common feature early in HIV infection when the patient is often asymptomatic. During the assessment, the clinician must be alert for enlarged lymph nodes involving two noncontiguous sites, other than inguinal nodes. The clinician should measure and record the size of nodes if palpable, although significant nonpalpable lymphadenopathy may also be evident on imaging exams.
- Pulmonary symptoms: These are seen with community acquired pneumonia, PCP, tuberculosis, and bacterial pneumonia. The clinician should be alert for decreased breath sounds and reports of shortness of breath, nonproductive cough, fever, or night sweats.
- Localized *Candida* infections: Thrush is a common finding in HIV infection. The presence of thrush indicates advanced immunosuppression, with a high probability of a serious or opportunistic infection within 3 years. The clinician should carefully assess the oral cavity, using a high-quality flashlight. Look for the presence of white plaques (thrush), darkish purple lesions (possibly Kaposi's sarcoma), or a whitish, hair-like growth on the tongue (oral hairy leukoplakia caused by Epstein-Barr virus, seen in advanced states of immunosuppression). If white plaque is found, attempt to lightly scrape a portion with a tongue blade. If thrush is present, the plaque will bleed as it is scraped off. *Candida* esophagitis is a late complication of HIV infection; the usual presentation is thrush with odynophagia. *Candida* vaginitis in women with HIV infection is more likely to be recurrent or refractory to therapy.
- Kaposi's sarcoma: These lesions may be flat macules or raised, nodular papules—purple in color in light-skinned patients and dark brown to black in darker-skinned patients. The lesions can be found on any part of the skin or mucous membranes. Thus, the clinician should perform a thorough dermatological examination of the back, buttocks, extremities, hands, and feet. Transmitted by human herpesvirus–8 (HHV-8), Kaposi's sarcoma has become less common in the United States, with the advent of more effective ARV medications and an increased understanding of the fecal-oral route of transmission of HHV-8.
- Sexually transmitted diseases: STDs increase the likelihood of HIV transmission or acquisition. The clinician should do a thorough examination of the rectal and genital area, inspecting for perianal and genital herpes simplex lesions, as well as penile or vaginal discharges reflective of gonorrhea or other sexually transmitted infection.
- Neurological and ophthalmic signs and symptoms: Headache is a common complaint in acute retroviral syndrome, whereas neck stiffness and pain along with malaise and impaired cognition may be signs of smoldering meningitis, such as that caused by *Cryptococcus,* which, in contrast to bacterial meningitis, typically has an insidious onset. The clinician should also conduct a careful funduscopic exam to check the retina for signs of cytomegalovirus (CMV) infection or fungal endophthalmitis in patients with late-stage HIV infection.

- Weight loss: The clinician should document height and weight at the time of the examination and record the patient's description of weight loss (amount lost over what period of time), because this is a common presenting sign in patients with undiagnosed HIV infection and may herald progressive immunosuppression.
- Cytopenias: Anemia, leukopenia, and/or thrombocytopenia often complicate HIV infection. The clinician should check the overall complete blood count (CBC) with leukocyte differential, in addition to specific T-lymphocyte subset (CD4+ and CD8+) counts to assess the level of HIV-associated immunosuppression.

Diagnostic Reasoning

Diagnostic Tests

A diagnosis of HIV infection is based on the presence of antibodies to HIV in the blood. Most commercially available HIV test kits in the United States were developed specifically for HIV-1 detection; HIV-2–specific antibodies may also be detected by these tests but with much less sensitivity. Thus, it is important for the clinician to order diagnostic tests developed specifically for HIV-2 detection, if suspected either alone or as a co-infection with HIV-1.

Historically, for many years HIV testing was performed only after mandatory pretest counseling with informed consent, in which the implications of both positive and negative test results were discussed in detail, as well as privacy restrictions regarding test results. In recent years, however, public health measures have moved toward opt-out HIV testing in the United States as a more effective means of screening larger numbers of people (Level I; Branson et al, 2006). In opt-out strategies, pretest counseling is no longer mandated, although patients are informed that confidential HIV testing may be done in the course of normal health-care delivery (such as at prenatal clinics or during emergency department visits), unless patients specifically refuse (i.e., "opt-out" of) such testing.

Some jurisdictions also require that a patient be informed of his or her right to anonymous versus confidential testing. In anonymous testing, the patient is issued an identification number, and test results are associated with this number only. No names are used, and the results cannot be traced back to any personal identifier, regardless of result. In turn, anonymous test results are not typically reportable to health departments. In confidential testing, the patient's name is used, but the results may not be released without a patient's permission, except under certain circumstances as a matter of law. If the test result is positive, the patient's name and positive HIV status may be reported to the health department, as is done with other sexually transmitted and communicable diseases. Some jurisdictions only mandate reporting of AIDS cases, rather than all HIV infections. In turn, primary care providers should be aware of federal, state, and local HIV reporting requirements (which often change over time), educate the patient about them, and ensure that the patient is aware of the extent and limits of HIV test result confidentiality.

The preferred method for diagnosis of acute HIV infection is an HIV RNA viral load or cellular DNA assay, because HIV DNA and RNA may be detected before seroconversion. In contrast, the ELISA test cannot detect HIV infection during the window period (the time between transmission and seroconversion), when HIV-specific antibodies have not yet formed. It is important to understand that a cellular HIV DNA assay detects HIV viral DNA that has been integrated into the host cellular genome and is more sensitive than antibody-based tests or plasma HIV RNA viral load assays. Thus, despite their higher cost, cellular HIV DNA assays are the preferred diagnostic test in the immediate postpartum period for children born to HIV-infected women. Plasma viral load is typically suppressed by prenatal or perinatal ARV therapy, which may lead to false-negative results on HIV RNA viral load assays in HIV-infected neonates. HIV-specific antibody tests are also problematic in infants born to HIV-infected women, because maternal antibodies typically cross the placenta, potentially leading to false-positive results.

Some state, federal, and managed care companies do not perform a viral load test until after a serological diagnosis is made, given its greater expense. A viral load test costs approximately 15 to 20 times more than an ELISA test. For this reason, clinicians typically use an ELISA test to screen for HIV-specific antibodies. If the ELISA test is positive, a second, more sophisticated test, the Western blot, is done on the same sample of blood. The Western blot test involves the separation of individual HIV viral proteins into defined bands within a polyacrylamide gel matrix to which a patient's serum is then applied; any HIV-specific antibodies in the serum will then adhere to the HIV viral proteins in the gel matrix. The presence of any two of the following antibody specificities in the patient's serum—p24, gp41, or gp 120/160 bands—constitutes a positive Western blot result and serves as a more specific confirmatory test for diagnosing HIV infection. In many states, positive Western blot test results must be reported to health departments. Studies have shown that the frequency of false-negative test results in a high-prevalence population is about 0.3%. The usual cause of false-negative test results is testing during the window period, although Western blot tests also tend to be more sensitive than ELISA tests.

In recent years, commercial self-testing kits designed to be used at home, as well as rapid testing kits designed to be used in high-throughput clinical settings (such as emergency departments, labor and delivery units, or obstetric/gynecological clinics), have become increasingly common. For example, OraQuick Advance HIV-1/HIV-2 Rapid Antibody Test is a point-of-care diagnostic test designed for use with oral fluids (swabbing between the teeth and gums) or plasma specimens. After 20 minutes, the test device indicates if HIV-specific antibodies

are present in the sample by displaying two reddish-purple lines in a small window on the device. Several other rapid HIV tests for use with serum or plasma are also available (e.g., Uni-Gold Recombigen HIV, Reveal G3 Rapid HIV-1 Antibody Test, and MultiSpot HIV-1/HIV-2). A reactive result on a rapid HIV diagnostic test is typically considered a preliminary positive and should be confirmed by a Western blot test. The recently FDA-approved Alere Determine HIV-1/2 Ag/Ab Combo is able to detect simultaneously both HIV-1 p24 antigen and antibodies to HIV-1 and HIV-2 from serum, plasma, or whole blood samples, allowing the clinician to distinguish between acute onset (p24 antigen alone) and established (p24 antigen and HIV-specific antibodies) infection.

At the time of initial diagnosis, a T-cell subset blood test should be done to determine the patient's CD4+ T-cell count. A viral load test, which is a quantitative assay of HIV RNA concentration in the peripheral blood, should also be drawn to determine the patient's viral replication activity. These two tests are evaluated together to determine the stage of illness and as a predictor of disease progression. As mentioned earlier, the viral load test is the preferred method of diagnosing acute HIV infection, given its greater sensitivity at this early stage.

A discussion of these test results may be the beginning of a dialogue between the clinician and the HIV-infected client on the need for HIV prevention behaviors, to decrease the probability of an HIV-infected patient transmitting HIV to other persons, as well as acquiring additional strains of HIV from infected partners. It is unrealistic to assume that all HIV-infected persons will subsequently practice lifelong abstinence. Thus, a discussion of behaviors to minimize viral transmission via sexual activity or otherwise is a critical component to every patient visit.

Although over time with effective treatment, a plasma HIV RNA viral load assay may become undetectable (i.e., below the lower limit of detection, which is typically 50 copies/mL), the clinician and patient should understand that this test only reflects the level of cell-free virus in the peripheral blood. Thus, it is still possible that latently infected cells might transmit infection in the absence of detectable viremia.

Additional baseline laboratory evaluations in a newly diagnosed individual should include a CBC with differential to check for other cytopenias; a complete serum chemistry profile including hepatic transaminases, blood urea nitrogen (BUN), and creatinine levels; and a complete urinalysis. Additional studies for concurrent infections include the Venereal Disease Research Laboratory (VDRL) or rapid plasma reagin (RPR) tests for syphilis; serum anti-toxoplasmosis IgG titer; hepatitis A, B, and C serologies; and a Pap smear for female clients. A tuberculin skin test (TST; purified protein derivative [PPD]; Mantoux test) should be done unless the patient has a documented history of tuberculosis or positive TB skin test in the past. Other tests for sexually transmitted diseases should be done as determined from the clinical presentation and typically include evaluations for gonorrhea and chlamydia.

If a patient presents with pulmonary symptoms, vital signs should be assessed for fever and tachycardia. The clinician should also check the oxygen saturation level and obtain a chest x-ray examination and arterial blood gas analysis. Hypoxemia and bilateral pulmonary infiltrates on an x-ray film indicate a pulmonary process but may not differentiate between PCP and TB in the HIV-infected patient. Differentiating between the two requires additional diagnostic testing, such as pathogen-specific culture or staining assays of respiratory samples, for example, sputa or bronchial alveolar lavage fluid obtained via bronchoscopy. A TST may also assist in the work-up of TB, with or without the placement of one or more anergy controls to commonly encountered antigens, such as *Candida* or tetanus toxoid (in a vaccinated individual). Anergy testing may allow the clinician to disregard a negative TST result as excluding TB infection, because it is common for individuals with advanced immunosuppression to have impaired cell-mediated immunity. However, it is also possible that defects in cell-mediated immune responses may be selective for particular antigens over others. Thus, some clinicians feel that anergy testing is unhelpful in the setting of advanced immunosuppression and discount negative diagnostic test results based on cell-mediated immunity altogether.

Differential Diagnosis

Immunosuppression can be noted in a variety of situations besides HIV infection, such as the patient on chemotherapy, radiation therapy, or long-term corticosteroids. Certain cancers can also cause a decrease in the CD4+ T-cell count. Differential diagnosis for acute retroviral syndrome includes Epstein-Barr virus (EBV) mononucleosis, CMV mononucleosis, toxoplasmosis, rubella, viral hepatitis, syphilis, or drug reactions. Cytopenias including lymphopenia may be due to a primary or infiltrative bone marrow disorder and may require bone marrow biopsy if an HIV test is negative.

Management

Principles of management for early HIV infection include (1) initial disclosure of HIV status, (2) initiation of drug therapy to suppress the virus, and (3) monitoring of viral activity to determine any need to modify or revise drug therapy.

Key components of HIV infection management include prevention of transmission, preserving immune function, prophylaxis against opportunistic infections in the face of low CD4+ T-cell counts, early diagnosis and treatment of opportunistic infections, and optimizing quality of life. Figure 17.1 presents an algorithm for the management of early HIV infection.

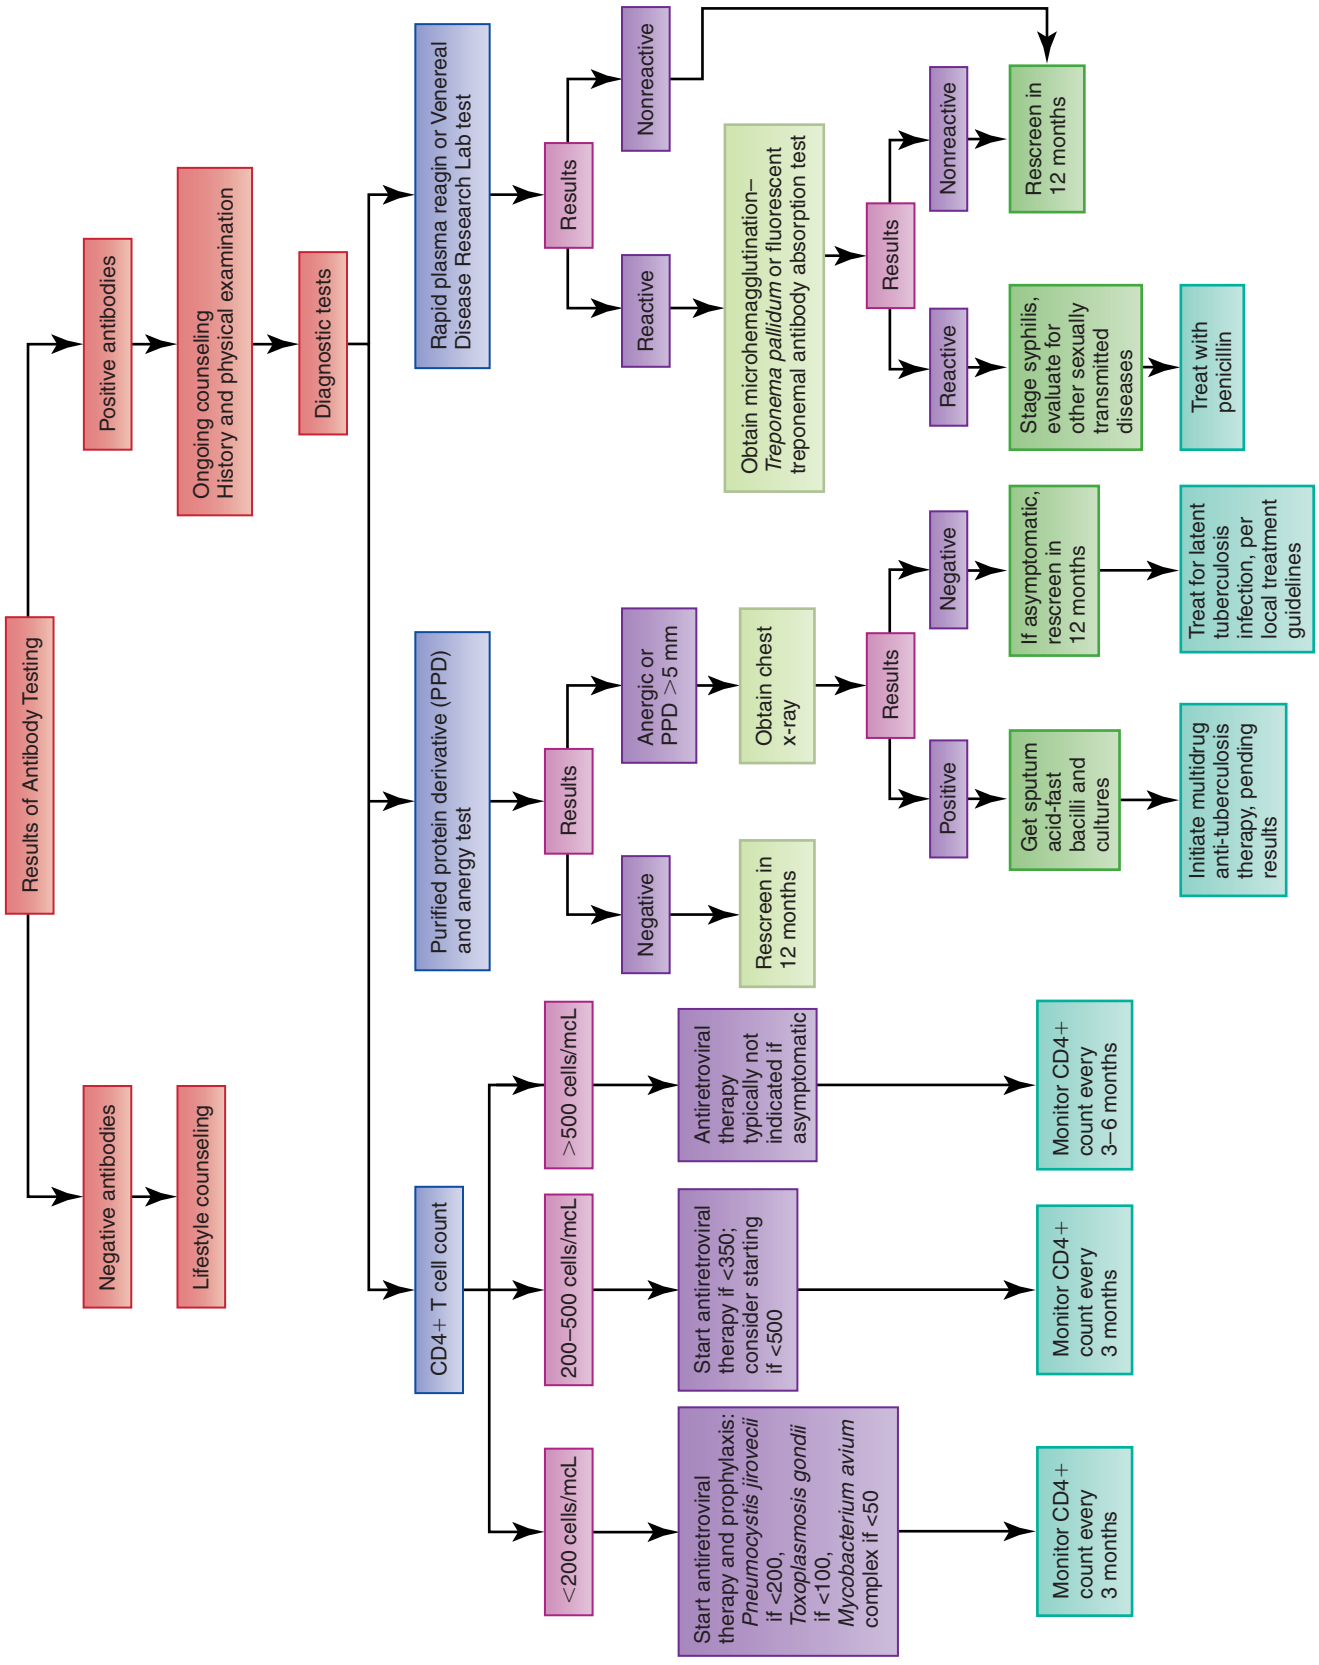


Figure 17.1 Treatment flowchart for management of early HIV infection.

Initial Disclosure

With the advent of rapid HIV testing and the CDC's emphasis on integrating HIV prevention into standard medical care, HIV test results may now be obtained during regular clinic visits. However, the disclosure of HIV test results is a critical event in the clinician–patient relationship. Disclosure counseling sets the tone and foundation for the patient's acceptance, knowledge base, and attitudes about his or her HIV infection. Disclosure of HIV test results is typically a stressful period for the patient, who may experience significant denial toward a positive test result. Even with a confirmatory Western blot test, some agencies offer to repeat the test to ensure that the diagnosis is correct and help the patient accept the reality of the diagnosis in a timely fashion. Some guidelines and concepts for disclosure counseling are summarized here:

- Disclosure counseling should be done face to face. In planning the disclosure of the patient's HIV status, the clinician should assess the degree to which the patient or parent/guardian is prepared to receive the results. The clinician should also assess the patient's social, demographic, cultural, and psychological characteristics, which may relate to coping with a positive HIV test. During the disclosure session, the provider should discuss the natural history of HIV infection, the potential effects of HIV infection on physical and mental health, the role of health maintenance practices, the availability of treatment, and the need to practice HIV prevention behaviors.
- The disclosure counseling process is an opportunity to provide immediate interventions and involve the patient in ongoing medical, mental health, social, and family support networks. Immediate interventions may include the following: assessing the patient for the risk of inflicting violence to themselves or others; ensuring that the patient will receive a thorough medical evaluation for staging and initial care; informing the patient of ongoing availability of services; scheduling the next appointment; addressing prevention of further HIV transmission; assessing the availability of an immediate support person and other care providers; providing available local and national resources of information on HIV infection; and making appropriate referrals for any ongoing services that cannot be provided on site.
- The patient should be informed of the potential for discriminatory practices against persons with HIV. Clinicians should assist patients in understanding the advantages and disadvantages of disclosing their HIV status to others by providing counseling, factual information regarding legal aspects of disclosure, opportunities for patient education and dialogue, and referrals as needed.
- The patient should be strongly advised and encouraged to disclose their HIV status to significant others, particularly sexual and needle-sharing partners. Some local and state health departments will do partner notification without disclosing the name of the HIV-positive person, providing partners with the knowledge that they have been exposed to a sexually transmitted disease and that HIV testing is advised.

The prevention of HIV transmission must be discussed at the time of the initial diagnosis of HIV infection. The patient's blood and semen become infectious to others shortly after the patient is initially infected, so risky sexual behaviors need to be addressed immediately. The patient should also be advised against donating blood, plasma, tissue, body organs, and sperm.

The patient must also understand that the virus mutates or changes within each person; therefore, the HIV-infected person is at risk of acquiring a slightly different HIV virus from another HIV-infected individual—a phenomenon known as superinfection. The existence in the patient of a second virus can complicate the selection of an appropriate ARV regimen, increase the likelihood of infectious complications, and hasten the progression of disease. Patients from West Africa are also at risk of co-infection with strains of both HIV-1 and HIV-2.

Initiation of Drug Therapy

Although HIV infection in the 1980s was almost universally associated with death within several years, it is crucial to emphasize to the patient that improved and simplified ARV regimens have prolonged survival and improved quality of life for many persons who are infected with the virus. In fact, some recent studies have suggested that with early and attentive medical care, optimized medication adherence, and healthy lifestyle habits, HIV-infected patients may enjoy nearly the same life expectancies as noninfected individuals in the United States. Thus, the importance of beginning appropriate drug therapy and the need for continual follow-up with a health-care provider must be stressed.

Concepts of Medication Therapy Fundamental concepts that underlie the foundation of ARV treatment for HIV infection include the following:

- Eradication of HIV infection cannot be achieved with current HIV drug therapy.
- Complete viral latency does not exist. Some level of viral activity is present throughout the course of the infection.
- The level of plasma HIV RNA is proportional to the rate of viral replication and the rate of CD4+ T-lymphocyte destruction. The plasma HIV RNA level can help predict the rapidity with which clinical immunodeficiency will develop.
- Treatment-induced changes in HIV RNA levels (and, to a lesser extent, changes in CD4+ T-lymphocyte counts) correlate with clinical outcome. Studies have demonstrated that greater reductions in viral load are associated with greater improvements in clinical

outcomes. These two markers have been shown to strongly predict the likelihood of disease progression, including death.

- Viral replication leads to the generation of viral mutants. Some of these mutants will be resistant to one or more ARV drugs. Therefore, the greater the immediate suppression of the virus, the fewer drug-resistant strains will be available to reproduce. Incomplete inhibition of viral replication leads to the emergence of drug-resistant populations and to resumption of disease progression. Therefore, emergence of drug resistance may be delayed by optimized suppression of viral replication.
- Complete immune reconstitution, particularly for those who have advanced HIV disease, may not be possible. Regeneration and increases in CD4+ T-cell counts are typically seen in patients receiving ARV therapy; however, the loss of CD4+ T-lymphocyte clones as the disease progresses may not be entirely reversible. Early intervention with ARV therapy is therefore a strategy to preserve immune function.
- An important sequela of ARV therapy is immune reconstitution inflammatory syndrome (IRIS; immune restoration disease), which is an exuberant immune response in a previously immunosuppressed individual, presumably due to the reduction in immune activation and dysregulated immune responses after the initiation of ARV treatment and HIV viral load suppression. Thus, IRIS may manifest as paradoxical worsening of infectious symptoms, due to a previously treated and clinically improved opportunistic infection. Alternatively, new opportunistic infections may spontaneously arise after starting ARVs in a form known as unmasking IRIS, believed to be due to subclinical opportunistic infection at the time of ARV initiation. Other manifestations of IRIS include autoimmune or malignant phenomena. Although the pathogenesis of this syndrome is not fully understood, IRIS may affect 10% to 40% of patients, ranging from mild to life-threatening presentations. Treatment usually involves anti-inflammatory medications (e.g., NSAIDs, corticosteroids) and supportive care, but in its most severe form, IRIS may require stopping ARV therapy.
- There are both benefits and risks to deferring HIV drug therapy. In the United States, the initiation of ARV therapy is recommended for all HIV-infected persons with CD4+ T-cell counts of 350 cells/mcL or lower (Level I; Emery et al, 2008; HIV Trialists' Collaborative Group, 1999; Zolopa et al, 2009). This treatment threshold is lower in some developing nations where health-care resources are more limited, but treatment delay is inversely correlated with a patient's ability to achieve maximal immune reconstitution after starting treatment. Some research suggests that initiating ARVs at even higher CD4+ T-cell counts (350–500 cells/mcL or greater than 500 cells/mcL) is more likely to restore the immune system to preinfection status. In turn, the question of when to initiate ARV treatment based on CD4+ T-cell count remains unsettled. However, regardless of CD4+ T-cell count, ARV treatment is recommended for HIV-infected individuals with AIDS-defining illnesses (see following section on AIDS), HIV-associated nephropathy, hepatitis B co-infection in whom antiviral treatment against hepatitis B is also indicated, or who are pregnant.
- Some benefits of deferring therapy include avoiding treatment-related side effects that may have a negative impact on quality of life, avoiding drug-related toxicities, preserving future treatment options, delaying the development of drug resistance related to incomplete viral suppression, and allowing time for the patient to understand the demands of drug treatment.
- Some risks of deferring therapy include potential irreversible damage to the immune system; potential progression to AIDS; and the potential for increased risk of transmission of untreated virus to others.
- Although HIV drug therapy has dramatically improved survival time, the long-term impact of drug therapy has not been established. Patients on drug therapy have experienced a wide variety of side effects, including increased cholesterol levels, hyperglycemia, metabolic acidosis, lipodystrophy, and wasting of the face and extremities (lipoatrophy). Drug-related lipodystrophy and lipoatrophy are also typically not improved by exercise or dietary modification. In turn, close and continual clinical monitoring of patients on HIV drug therapy is essential.

Drug Categories There are currently six FDA-approved drug categories of ARV therapy: nucleoside reverse transcriptase inhibitors (NRTIs), nonnucleoside reverse transcriptase inhibitors (NNRTIs), protease inhibitors (PIs), fusion inhibitors, integrase inhibitors, and chemokine (C-C motif) receptor 5 (CCR5) antagonist. Some clinicians further divide the drugs by using the category of nucleotide reverse transcriptase inhibitors (NtRTIs) to describe the unique characteristics of the NRTI drug tenofovir (Viread, TDF), which chemically is a nucleotide analog, rather than a nucleoside analog. In addition, fusion inhibitors are sometimes considered an overarching category that encompasses drugs with diverse mechanisms of action, including inhibition of gp41 fusion (e.g., enfuvirtide or T-20) and CCR5 antagonism (e.g., maraviroc). Combination drug therapy (also known as an HIV drug cocktail) is termed *highly active antiretroviral therapy* (HAART). These regimens consist of both base and backbone components, which together include at least three active ARV agents from at least two different drug categories, as described at the end of this section (see Treatment Standards/Guidelines 17.2: Antiretroviral Therapy).

Treatment Standards/Guidelines 17.2 Antiretroviral Therapy

Initiation of Therapy

- HIV drug therapy should be immediately started for all patients with a history of an AIDS-defining illness or severe symptoms of HIV infection regardless of CD4+ T-cell count.
- Therapy is now recommended for counts less than 350 cells/mcL; even stronger evidence for starting at T-cell counts <200 cells/mcL.
- The principles for initiation of ARV therapy and the goals of treatment are the same for HIV-infected women as for all adults and adolescents (Level I; Panel on Antiretroviral Guidelines for Adults and Adolescents, 2013). Therapy should be started in pregnant women with the goal of maximal viral suppression to prevent perinatal transmission to the fetus and newborn (Level I; Panel on Antiretroviral Guidelines for Adults and Adolescents, 2013) but may be stopped postpartum if not indicated in the mother herself.
- Therapy should also be started in patients with HIV-associated nephropathy or co-infection with hepatitis B virus (HBV) when anti-HBV treatment is indicated. In the HIV and HBV co-infected patient, the ARV regimen should include agents active against both HIV and HBV, such as emtricitabine, lamivudine, and tenofovir (Level I; Panel on Antiretroviral Guidelines for Adults and Adolescents, 2013). In patients co-infected with HIV and hepatitis C virus (HCV), ARV therapy should be considered regardless of CD4+ T-cell count (taking into account potential drug interactions of anti-HIV and anti-HCV therapy), because this may slow the progression of liver disease.
- Therapy is recommended for patients older than 50 years, regardless of CD4+ T-cell count, given the risk of non-AIDS related complications and the potential for a reduced immunological response in older HIV-infected patients.

Preferred Regimen (Level I; Panel on Antiretroviral Guidelines for Adults and Adolescents, 2013)

NNRTI base: Efavirenz OR PI base: ritonavir-boosted atazanavir, ritonavir-boosted darunavir (once daily), OR Integrase inhibitor base: raltegravir PLUS 2-NRTI backbone: tenofovir and emtricitabine

Alternative Regimen

- NNRTI base: efavirenz PLUS 2-NRTI backbone: abacavir and lamivudine
- NNRTI base: rilpivirine (only if pretreatment HIV RNA ≤ 100,000 copies/mL) PLUS 2-NRTI backbone: abacavir and lamivudine OR tenofovir and emtricitabine
- PI base: ritonavir-boosted atazanavir, ritonavir-boosted darunavir, ritonavir-boosted fosamprenavir (once or twice daily), ritonavir-boosted lopinavir (once or twice daily) PLUS 2-NRTI backbone: abacavir and lamivudine (OR tenofovir and emtricitabine for boosted-fosamprenavir or boosted-lopinavir)
- Integrase inhibitor base: raltegravir PLUS 2-NRTI backbone: abacavir and lamivudine OR cobicistat-boosted elvitegravir in fixed combination daily dosing with 2-NRTI backbone: tenofovir and emtricitabine

Therapy Not Recommended

- Efavirenz in the first trimester of pregnancy or in women at risk for pregnancy
- Efavirenz in people with unstable psychiatric disease
- Nevirapine in people with hepatic impairment, or women/men with pre-ARV CD4+ T-cell counts >250/400 cells/mcL, respectively
- Atazanavir in patients on proton pump inhibitors equivalent to 20 mg/day of omeprazole
- Once-daily boosted lopinavir in pregnant women
- Nevirapine with tenofovir/emtricitabine or fosamprenavir with delavirdine, given reports of early virological failure with these combinations
- Unboosted atazanavir with tenofovir or didanosine PLUS lamivudine/emtricitabine
- Tenofovir in patients with renal insufficiency
- Abacavir in patients with HIV VL >100,000 copies/mL or at high risk for cardiovascular disease
- Didanosine in patients with pancreatitis or peripheral neuropathy
- Zidovudine in patients with anemia or neutropenia

NRTIs were the first effective class of ARV drugs developed for HIV infection and are active against both HIV-1 and HIV-2. The nucleoside analogs work by incorporating themselves into elongating DNA strands of the virus during its replication cycle. Given their unique chemical structure, they cause a termination of the growing DNA strand immediately after incorporation. Because the resulting DNA is incomplete, it cannot contribute to a new viral particle. Drugs in this category include zidovudine (Retrovir; ZDV; AZT), lamivudine (Epivir; 3TC), didanosine (Videx; ddI), ddI-EC (Videx EC), zalcitabine (Hivid; ddC), stavudine (Zerit; d4T), Combivir (combination drug containing AZT and 3TC), abacavir (Ziagen; ABC), Epzicom (combination drug containing ABC and 3TC), Trizivir (combination drug containing ABC, 3TC, and AZT), emtricitabine (Emtriva; FTC), tenofovir (Viread; TDF), and Truvada (combination drug containing FTC and TDF).

Abacavir has been associated with a hypersensitivity syndrome characterized by influenza-like symptoms, including fever, malaise, rash, myalgias, headache, nausea, vomiting, and diarrhea. This syndrome is not mediated by drug-specific IgE antibodies and is not considered an immediate hypersensitivity reaction, although it typically

manifests within days of starting abacavir and the medication must be stopped immediately. In addition, abacavir hypersensitivity syndrome may manifest with severe and life-threatening symptoms such as hypotension, particularly on drug reexposure. Thus, abacavir should never be restarted in these patients. Genetic testing has revealed that the B*5701 allele of the human leukocyte antigen (HLA) gene complex has a strong association with this syndrome. Testing for this allele is indicated before starting abacavir, and presence of the allele is a contraindication for this drug (Level I; Mallal et al, 2008).

NNRTIs are called nonnucleoside inhibitors because, even though they work at the same stage as nucleoside analogs, they act in a completely different manner. NNRTIs stop HIV-1 production by binding directly to the reverse transcriptase enzyme and preventing the transcription of viral DNA from RNA (i.e., the unique action of the HIV reverse transcriptase enzyme). The NNRTIs are generally effective in crossing the blood–brain barrier and may be useful in managing HIV-associated dementia. The drugs included in this category include nevirapine (Viramune), delavirdine (Rescriptor), and efavirenz (Sustiva; contraindicated in pregnancy, due to teratogenicity). At present, agents in this category are considered specific for the reverse transcriptase enzyme of HIV-1 and are ineffective against HIV-2 infection.

PIs work at the end of the viral replication cycle by restricting the action of the HIV protease enzyme, which processes viral parent proteins into smaller functional component proteins. Thus, PIs prevent the successful assembly and release of new HIV virions from infected CD4+ T cells. The development of this class of drugs gave rise to HAART, as combination regimens containing agents from three distinct ARV classes were shown to be effective in reducing HIV viral load to below the limit of detection of currently available HIV viral load tests. The drugs in this category include saquinavir (Invirase; SQV), indinavir (Crixivan; IDV), ritonavir (Norvir; RTV), nelfinavir (Viracept; NFV), fosamprenavir (Lexiva; LXV; prodrug of amprenavir [Agenerase]), atazanavir (Reyataz; ATV), tipranavir (Aptivus; TPV), and Kaletra (lopinavir/ritonavir; LPV/r). PI drugs are typically given in conjunction with low-dose ritonavir, a practice known as "boosting" the PI. This is because ritonavir is a strong inhibitor of the cytochrome p450 enzymatic degradation pathway, which is the primary means of PI metabolism. In turn, PI drug levels are markedly increased in the presence of ritonavir, and lower doses of the primary (boosted) PI may be administered in order to minimize PI-related toxicities, such as GI upset. Kaletra is a fixed combination formulation of boosted lopinavir developed to minimize pill burden. PIs are active against both HIV-1 and HIV-2.

Fusion inhibitors work by stopping the virus from attaching to target cells. Enfuvirtide (Fuzeon; T-20) was the first FDA-approved drug in this category and, in contrast to other ARVs, is administered in adults via twice daily subcutaneous injection. An additional category of fusion inhibitors is the CCR5 antagonists, which prevent the binding of macrophage-tropic HIV R5 virions to the cellular coreceptor CCR5. Maraviroc (Selzentry) is the first drug to be FDA approved in this category. Clinical trials are ongoing of other CCR5 antagonists, as well as fusion inhibitors that block binding of T-cell–tropic HIV X4 virions to the other major cellular coreceptor, CXCR4. Of note, before initiating CCR5 antagonist therapy, a patient must undergo a test of viral tropism (Level I; Panel on Antiretroviral Guidelines for Adults and Adolescents, 2013) to determine whether M-tropic R5 viruses, T-tropic X4 viruses, or a mixture of the two predominate, known as dual tropism. This assessment is critical, as CCR5 antagonists will be effective only in the former setting and, in fact, may lead to treatment failure and contribute to disease progression in the presence of X4 viral strains. Given the cost of commercial tropism tests such as the Trofile Assay, this therapeutic option may be impractical in resource-limited settings.

One of the newer categories of ARV drugs to be developed is the integrase inhibitors, of which raltegravir (Isentress) is the first agent to be FDA approved. Another member of this class, elvitegravir, was recently approved for use with the cytochrome p450 inhibitor cobicistat (a drug with no anti-HIV activity of its own) in a fixed combination pill with the NRTIs tenofovir and emtricitabine. Integrase inhibitors directly inhibit the DNA strand transfer function of the HIV integrase enzyme, which allows incorporation of newly transcribed HIV DNA into the host cell genome. Inhibition of this critical step in the HIV replication cycle prevents the production of new HIV virions. As with other newly developed ARV drugs, integrase inhibitors were first evaluated for their potential role in multidrug salvage regimens given to patients who experience ARV treatment failure while on HAART, with reemergence of detectable viral loads. However, these drugs are gaining increased acceptance as first-line ARV agents.

HAART regimens have been successful in suppressing HIV viral load to below the limit of detection of commercial viral load tests (less than 50 copies/mL), although these drug cocktails are unable to clear the virus completely. The HAART base typically consists of either one NNRTI (preferably efavirenz) (Level I; Gulick et al, 2006), a PI boosted with low-dose ritonavir to allow for once daily dosing, or an integrase inhibitor (raltegravir); the HAART backbone usually consists of two NRTI agents (preferably tenofovir and emtricitabine) (Level I; Panel on Antiretroviral Guidelines for Adults and Adolescents, 2013). Drugs Commonly Prescribed 17.2: Highly Active Antiretroviral Therapy presents key prescribing information on these drugs.

Clinical Guidelines Clinical practice guidelines have been developed for the use of ARV therapy for

Drugs Commonly Prescribed 17.2 Highly Active Antiretroviral Therapy (HAART)

Drug	Adverse Reactions and Prescribing Considerations
Nucleoside Reverse Transcriptase Inhibitors (NRTIs)	Lactic acidosis and severe hepatomegaly with steatosis have been reported for individual and combination therapy. Immune reconstitution inflammatory syndrome is a potential sequela of any HAART regimen.
abacavir (Ziagen, ABC)	Take with or without food. Has caused severe allergic reactions resulting in death; occurs in about 8% of all patients, usually during the first 6 weeks of taking abacavir but can occur at any time. Patients should be screened before dosing for the presence of the HLA-B*5701 allele and not receive abacavir, if positive. Hypersensitivity syndrome to abacavir is a multiorgan syndrome usually characterized by at least two of the following manifestations; fever; rash; malaise, fatigue, or achiness; GI symptoms of nausea, vomiting, diarrhea, or abdominal pain; or respiratory symptoms including dyspnea, cough, or pharyngitis. Less common signs and symptoms of hypersensitivity include myolysis, edema, abnormal chest x-ray, and paresthesia. Anaphylaxis, liver failure, renal failure, hypotension, acute respiratory distress syndrome, respiratory failure, and death have occurred in association with hypersensitivity reactions. Inform patients to stop taking the drug and to seek medical care immediately if patients develop a skin rash or any two or more of the following symptoms; sudden fever; severe tiredness or achiness; diarrhea, nausea, vomiting, or stomach pain; sore throat, shortness of breath or cough; or generally ill feeling. These symptoms should be listed on a warning card included with the prescription, which patients should carry with them at all times. If these symptoms are caused by an allergic reaction, the patient should never take abacavir or an abacavir-containing medicine (e.g., Epzicom, Trizivir) again because death may occur within hours. If abacavir treatment is stopped for a period of time, it is important that the clinician be notified before the individual resumes dosing. Use with caution in patients with cardiovascular disease.
didanosine (Videx, ddI) ddI-EC (Videx EC)	May cause pancreatitis (alcohol exacerbates toxicity), peripheral neuropathy, retinal depigmentation, optic neuritis, hyperuricemia. Take on an empty stomach, at least 30 minutes before or 2 hours after eating. Monitor uric acid levels. If using buffered powder for oral solution, do not mix with fruit juice. Drugs such as ketoconazole or dapsone, whose absorption can be affected by the level of acidity in the stomach, should be administered at least 2 hours before didanosine. Use with caution in patients with impaired renal or hepatic function. Do not give with tetracycline.
emtricitabine (Emtriva, FTC)	Most common adverse effects: mild to moderate headache, nausea, diarrhea, and skin rash. Skin discoloration on palms and soles may occur. Rarely (1%), patients may develop elevated triglycerides >750 mg/dL or creatine kinase over five times the upper limit of normal. Take with or without food. In patients co-infected with HIV and hepatitis B virus (HBV), severe acute exacerbations of hepatitis B may occur after stopping drug; hepatic function should be monitored closely for at least several months after discontinuing emtricitabine in such patients.
lamivudine (Epivir, 3TC)	Generally well tolerated, but may cause GI distress or rarely peripheral neuropathy.
stavudine (Zerit, d4T)	May cause neuropathy, pancreatitis, nausea, vomiting, chills, fever, diarrhea. Take with or without food. Adjust dose if renal function is impaired.
tenofovir (Viread, TDF)	Nucleotide reverse transcriptase inhibitor (NtRTI); most common adverse effects: asthenia, diarrhea, nausea, and vomiting. Less common adverse effects: hepatotoxicity, lactic acidosis, abdominal pain, anorexia, flatulence, allergic reaction, dyspnea, Fanconi's syndrome, hypophosphatemia, pancreatitis, proximal tubulopathy, renal failure or insufficiency, and acute tubular necrosis. Follow renal function periodically. Studies have also shown decreases in bone mineral density and increases in serum levels of bone-specific alkaline phosphatase, osteocalcin, C-telopeptide, and urinary N-telopeptide, although it is not clear if long-term administration of tenofovir (greater than 1 year) causes bone abnormalities. Take with or without food. Closely monitor patients taking didanosine and tenofovir; suspend tenofovir if signs or symptoms of pancreatitis, symptomatic hyperlactemia or lactic acidosis develop;

(Continued)

Drugs Commonly Prescribed 17.2 Highly Active Antiretroviral Therapy (HAART)—cont'd

Drug	Adverse Reactions and Prescribing Considerations
	stop didanosine in patients who develop didanosine-associated adverse events. In patients co-infected with HIV and HBV who stop tenofovir, hepatic function should be monitored closely with both clinical and laboratory follow-up for at least several months, given the anti-HBV activity of tenofovir. If appropriate, initiation of anti–hepatitis B therapy may be warranted after stopping tenofovir.
zalcitabine (Hivid, ddC)	May cause peripheral neuropathy, pancreatitis (rare). Advise patient to watch for abdominal pain, nausea and vomiting, ulcers, mouth sores. Do not give with didanosine. Avoid simultaneous use with antacids.
zidovudine (Retrovir, ZDV, AZT)	May cause headache, GI distress, mild macrocytosis with or without anemia or neutropenia (bone marrow suppression). Take with food or antacids. Check CBC on ongoing basis. Hold if WBC falls to below 750 cells/mcL or with evidence of neutropenia. May take acetaminophen for headache, if not contraindicated. Stop if severe anemia develops; persistent anemia may respond to erythropoietin. Long-term use may result in myalgias, muscle wasting and weakness, increased creatine phosphokinase.
Combivir (combination of AZT and 3TC)	See information on zidovudine and lamivudine.
Epzicom (combination of ABC and 3TC)	See information on abacavir and lamivudine. Greater risk of early virological failure compared with Truvada (FTC and TDF) in patients with high HIV viral loads >100,000 copies/mL.
Trizivir (combination of ABC, AZT, and 3TC)	See information on abacavir, zidovudine, and lamivudine.
Truvada (combination of FTC and TDF)	See information on emtricitabine and tenofovir.
Nonnucleoside Reverse Transcriptase Inhibitors (NNRTIs)	Immune reconstitution inflammatory syndrome is a potential sequela of any HAART regimen.
delavirdine (Rescriptor, DLV)	May cause a skin rash on the upper body and arms. Take with water. Advise patient that skin rash usually lasts less than 2 weeks; use diphenhydramine or topical cortisone. Advise the patient with achlorhydria to take with an acidic beverage (orange or cranberry juice). Use with caution in patients with impaired renal function. Do not give at same time as antacids. If patient is also on didanosine, separate administration by 1 hour. Do not give if patient is on phenytoin, phenobarbital, carbamazepine, rifabutin, rifampin, cimetidine, famotidine, nizatidine, or ranitidine. Plasma concentrations of the following drugs are increased: indinavir, saquinavir, clarithromycin, dapsone, rifabutin, ergot derivatives, alprazolam, midazolam, triazolam, dihydropyridines (nifedipine, amlodipine, felodipine), quinidine, and warfarin. Do not use with fosamprenavir, given risk of early virological failure.
efavirenz (Sustiva, EFV)	May cause CNS symptoms (light-headedness, inability to concentrate, anxiety, dysphonia) or rash. Combination therapy may cause nausea, vomiting, diarrhea, headache. Do not give to women at risk of becoming pregnant; contraindicated in pregnancy.
etravirine (Intelence, ETR)	Approved in patients with resistance to other ARVs, including other NNRTIs. Contraindicated in lactose-intolerant patients. Reported cases of Stevens-Johnson syndrome, toxic epidermal necrolysis, erythema multiforme, hypersensitivity reactions, and hepatic failure.
nevirapine (Viramune, NVP)	May cause a rash (may decrease after initiation of therapy). Considered alternative NNRTI therapy compared with efavirenz, given risk of early virological failure in patients with high HIV viral loads. Do not use in men with pre-antiretroviral CD4 T cell counts greater than 400 cells/mcL or women with pre-antiretroviral CD4 T-cell counts greater than 250 cells/mcL, given risk of severe hepatotoxicity (including liver failure) in these individuals. Do not use in patients with moderate to severe hepatic impairment.

Drugs Commonly Prescribed 17.2 Highly Active Antiretroviral Therapy (HAART)—cont'd

Drug	Adverse Reactions and Prescribing Considerations
rilpivirine (Edurant, RPV)	Not recommended in patients with HIV RNA >100,000 copies/mL, given increased risk of virological failure. Not recommended for use with rifampin and its derivatives, proton pump inhibitors, St. John's wort, and antiepileptic drugs, including carbamazepine, phenobarbital, and phenytoin. Adverse events include rash, hepatotoxicity, depression, insomnia, and headache.
Protease Inhibitors (PIs)	May be boosted with low-dose ritonavir to increase drug levels. All PIs inhibit the CYP3A metabolic pathway to various extents. GI distress is significant class effect. May cause hypertension or diabetes mellitus. Not recommended for use with rifampin or its derivatives, given reduced PI levels. Caution against coadministration of PDE_5 inhibitors (sildenafil, tadalafil), because PIs may potentiate adverse effects of PDE_5 inhibitors (hypotension, visual changes, priapism). Caution when coadministering with HMG-CoA reductase inhibitors (statin drugs), because PIs may potentiate adverse effects of these drugs (myalgias, rhabdomyolysis). Immune reconstitution inflammatory syndrome is a potential sequela of any HAART regimen.
atazanavir (Reyataz; ATV)	Convenient once-daily dosing regimen. Do not coadminister boosted atazanavir and nevirapine. Atazanavir may cause headache, nausea, skin rash, allergic reaction, new onset or exacerbation of diabetes mellitus or hyperglycemia, asymptomatic hyperbilirubinemia, lactic acidosis, PR-interval prolongation, abdominal pain, back pain, increased cough, depression, diarrhea, lipodystrophy, nausea, vomiting, or microscopic hematuria. Take with food. Unlike other PIs, has minimal effect on lipid levels. Coadministration is contraindicated with drugs that are highly dependent on CYP3A for clearance, and specifically with rifampin, irinotecan, bepridil, lovastatin, simvastatin, indinavir, proton-pump inhibitors (e.g., pantoprazole, esomeprazole, omeprazole), and St. John's wort. Consider risk–benefit in patients with preexisting AV conduction abnormalities, given potential for PR interval prolongation. Concurrent administration with amiodarone, lidocaine, or quinidine may increase antiarrhythmic drug concentrations, resulting in serious or potentially life-threatening adverse events; caution and concentration monitoring is suggested. Risk–benefit should also be considered in patients with obesity, diabetes mellitus, or hyperglycemia, hepatic function impairment, elevated transaminase levels, hepatitis B or C, or type A or B hemophilia.
darunavir (Prezista, DRV)	Most common adverse effects: diarrhea, nausea, headache, and nasopharyngitis. May also cause abnormal liver and pancreatic function tests, abnormally high lipid levels, or decreases in WBC counts. Primarily metabolized by liver; use with caution in patients with hepatic impairment.
fosamprenavir (Lexiva; LXV)	Common adverse reactions include mild to moderate diarrhea, nausea, vomiting, headache, oral paresthesia, abdominal pain, depressive symptoms or mood disorders, or mild to moderate skin rash. Rarely (less than 1%), patients may develop severe or life-threatening skin reaction, including Stevens-Johnson syndrome; stop in patients with severe or life-threatening rash or with moderate rash accompanied by systemic reactions. Take with or without food. Use with caution in patients with known sulfonamide allergy. Concomitant use with lovastatin or simvastatin is not recommended. Coadministration with dihydroergotamine, ergonovine, ergotamine, methylergonovine, pimozide, rifampin, midazolam, triazolam, or products containing St. John's wort *(Hypericum perforatum)* is contraindicated. Serious or life-threatening drug interactions could occur between fosamprenavir and amiodarone, systemic lidocaine, bepridil, tricyclic antidepressants, or quinidine. Do not give with ritonavir, flecainide, or propafenone. Carbamazepine, phenobarbital, and phenytoin should be used cautiously in combination with fosamprenavir, because they may decrease fosamprenavir effectiveness. Do not use with delavirdine, given risk of early virological failure.

Drugs Commonly Prescribed 17.2 Highly Active Antiretroviral Therapy (HAART)—cont'd

Drug	Adverse Reactions and Prescribing Considerations
indinavir (Crixivan; IDV)	May cause nephrolithiasis, transient increases in bilirubin, abdominal pain, fatigue, weakness, flank pain, feeling unwell, nausea, diarrhea, vomiting, acid regurgitation, loss of appetite, dry mouth, back pain, headache, trouble sleeping, dizziness, taste changes, rash, upper respiratory tract infection, dry skin, or sore throat. Take on empty stomach and with plenty of fluids; do not take with grapefruit juice. Keep dry in container. May cause kidney stones due to crystallization of drug within the kidneys.
lopinavir (LPV)	May be at increased risk for pancreatitis or elevated triglyceride levels. Take with food. Risk–benefit should be considered if patients also have diabetes mellitus, hepatic function impairment, hepatitis B or C, or a history of pancreatitis. Do not use with rifampin, because it may lead to loss of virological response and possible drug resistance, including with other PIs or any other coadministered antiretroviral agent.
nelfinavir (Viracept; NFV)	May cause mild to moderate diarrhea, nausea, or flatulence. Take with meals or light snack. Contraindicated with drugs dependent on CYP3A for clearance, if serious or life-threatening reactions may result from elevated drug levels.
ritonavir (Norvir; RTV)	May cause nausea, vomiting, diarrhea, stomach pain, taste change, fatigue, mild to severe skin sensitivity, or numbness around the mouth. Take with meals (full stomach) to improve absorption of the drug. Keep in refrigerator. May mix oral solution with 8 oz. chocolate milk, Ensure, or Advera (nutritional supplement drink). Patients on birth control pills (ethinyl estradiol) may need to increase dosage. Also may need to increase dosage if on theophylline.
saquinavir (Invirase; SQV)	Take with meals. Do not give with rifampin, rifabutin, phenobarbital, phenytoin, dexamethasone, or carbamazepine.
tipranavir (Aptivus; TPV)	Most common adverse effects: diarrhea, nausea, vomiting, fatigue, and headache. Coadministration with ritonavir has been associated with clinical hepatitis and hepatic decompensation, including death. Vigilance warranted in individuals with advanced HIV disease or those with chronic hepatitis B or C co-infection. Individuals with hemophilia may have increased risk of bleeding. Women using estrogens may have an increased risk of rash. Other side effects include skin reactions, elevated lipid levels, and fat redistribution. Absorption increases when taken with a high-fat meal. Antacids reduce absorption. Contraindicated in individuals with moderate to severe hepatic insufficiency. Like other PIs, net inhibitor of CYP3A and may increase plasma concentration of agents primarily metabolized by this enzyme. Alternate methods of nonhormonal contraception should be used with women on estrogen-based birth control pills.
Kaletra (combination of lopinavir and ritonavir; LPV/r)	See information on lopinavir and ritonavir. Contraindicated in patients with known hypersensitivity to any component, including ritonavir. Contraindicated with drugs that are highly dependent on CYP3A for clearance and for which elevated plasma concentrations are associated with serious and/or life-threatening events, such as cardiac arrhythmias, prolonged or increased sedation, or respiratory depression. These drugs include some antihistamines, ergot derivatives, pimozide, and some sedatives. Do not use with rifampin, because it may lead to loss of virological response and possible drug resistance, including with other PIs or any other coadministered antiretroviral agent.
Fusion Inhibitors	Immune reconstitution inflammatory syndrome is a potential sequela of any HAART regimen.
enfuvirtide (Fuzeon; T-20)	Adverse side effects include local injection site reactions, hypersensitivity reactions, increased rate of bacterial pneumonia, peripheral neuropathy, sinusitis, conjunctivitis, pancreatitis, anxiety, decreased appetite, asthenia, cough, depression, herpes simplex, pruritus, insomnia, myalgias, and weight loss.
maraviroc (Selzentry, MVC)	CCR5 antagonist; before beginning therapy, patient must undergo test of viral tropism to determine if R5 (CCR5-binding M-tropic) viruses predominate, in the absence of X4 (CXCR4-binding T-cell–tropic) viruses.

Drugs Commonly Prescribed 17.2 Highly Active Antiretroviral Therapy (HAART)—cont'd

Drug	Adverse Reactions and Prescribing Considerations
Integrase Inhibitors	Immune reconstitution inflammatory syndrome is a potential sequela of any HAART regimen.
Elvitegravir (EVG)	See information on Stribild/Quad Pill. CYP3A4 inducers or inhibitors may alter blood levels. When combined with cobicistat, may lead to more drug interactions than raltegravir.
raltegravir (Isentress, RAL)	Common adverse reactions include headache, nausea, asthenia, and fatigue. Use with caution in patients at increased risk of myopathy or rhabdomyolysis, e.g., patients receiving concomitant medications known to cause these conditions such as HMG-CoA reductase inhibitors (statins).
Multiclass Combination Therapies	Immune reconstitution inflammatory syndrome is a potential sequela of any HAART regimen. Convenient once-daily HAART dosing regimen: 1 pill per day.
Atripla (combination of EFV, FTC, and TDF)	See information on efavirenz, emtricitabine, and tenofovir.
Complera (combination of RPV, FTC, and TDF)	See information on rilpivirine, emtricitabine, and tenofovir. Not recommended in patients with HIV RNA >100,000 copies/mL, given greater risk of virological failure. Take with meal.
Stribild/Quad Pill (combination of elvitegravir, cobicistat, FTC, and TDF)	See information on elvitegravir, emtricitabine, and tenofovir. Cobicistat has no antiviral activity but is a potent inhibitor of the CYP3A4 degradation pathway and, thus, boosts ARV levels. Not recommended to start in patients with creatinine clearance ≤70 mL/min; may increase risk of proximal renal tubulopathy. Adverse events include diarrhea, nausea, and headache. Not recommended for use with HMG CoA-reductase inhibitors, rifampin and its derivatives, anxiolytics (e.g., midazolam, triazolam), ergot derivatives, St. John's wort, and PDE_5 inhibitors.

HIV-1–infected adults and adolescents. These guidelines are revised on an ongoing basis by the Panel on Clinical Practices for Treatment of HIV Infection, convened by the U.S. Department of Health and Human Services, and are considered "living documents" that may be obtained online at www.AIDSinfo.nih.gov, a public access Web site maintained by the National Institutes of Health. Treatment Standards/Guidelines 17.2 presents the most current version of these HIV treatment guidelines for adults and adolescents. Clinical practice guidelines have also been developed by expert panels on HIV care for pediatric patients and pregnant women and may be accessed at this same website. It is critical for the clinician providing HIV care to be familiar with these guidelines, as specific recommendations exist regarding the timing of HAART initiation in different patient populations.

In contrast to HIV-1, far less is known about effective treatments against HIV-2. Given the slower progression and decreased virulence of HIV-2 compared with HIV-1, treatment guidelines regarding when to initiate therapy for HIV-2 infection are less established, and treatment decisions regarding HIV-2 infection should be referred to an infectious disease specialist.

Designing a Compatible Medication Regimen

The patient's ability to adhere to a potent combination drug cocktail must be discussed in detail before initiating therapy. Once a client is started on drug therapy, there is a risk of developing drug resistance if viral suppression is not maintained. Viral mutations causing drug resistance can rapidly occur within 2 weeks to as little as 2 days of a patient stopping medication or failing to take the full set of prescribed doses. ARV medications all have varying requirements regarding dosing, dietary restrictions, numbers of pills to be taken each day, and drug interactions. The clinician must prescribe a HAART regimen that is compatible with the patient's day-to-day activities, including lifestyle, eating habits, social habits, and work and home environments.

Nursing Research–Based Practice Box 17.2 discusses an alternative methodology for the prediction of adherence to anti-HIV treatment, because effective treatment is fundamental to controlling the progression to AIDS. Helping the patient to live with HIV requires a multidisciplinary approach. See the Iceberg figure for additional suggestions.

Monitoring HIV Viral Load

The HIV viral load test directly measures the concentration of viral particles in the patient's plasma. Thus, viral load test results are reported as either copies or units per milliliter of plasma. If the test result is below the detection threshold of the assay, the viral load is considered undetectable. This means that the amount of virus in the blood is so minimal that it cannot be measured by the test being used (i.e., below the level of detection), rather than indicating the virus has

NNRTIs = non-nucleoside reverse transcriptase inhibitors
OIs = opportunistic infections

Nursing Research–Based Practice 17.2

Thompson, IR, and the EuResist Network Study Group et al. An alternative methodology for the prediction of adherence to anti-HIV treatment. *AIDS Res Ther* 6:9, 2009. doi:10.1186/1742-6405-6-9

Successful treatment of HIV-positive patients is fundamental to preventing progression to AIDS. Treatment failure may be related to drug resistance and/or insufficient drug levels in the blood. Severe side effects, coupled with the intense nature of many drug regimens, can lead to treatment fatigue and consequently to periodic or permanent medication nonadherence. Although nonadherence is a recognized problem in HIV treatment, it is poorly detected in both clinical practice and health outcomes research and is often based on unreliable information such as self-reports, or in a research setting, Medication Events Monitoring System pill bottles or prescription refill rates. To meet the need for objective information on adherence, this study proposes a method using viral load and HIV genome sequence data to identify nonadherence among patients.

With nonadherence operationally defined as a sharp increase in viral load in the absence of drug resistance mutations, it was hypothesized that periods of nonadherence can be identified retrospectively based on the observed relationship between changes in viral load and HIV mutations. It was suggested that validation of the hypothesized approach would serve as a first step on the road to clinical practice. The information inferred from clinical data on adherence would be a crucial feature of treatment prediction tools to aid practitioners in daily clinical practice. In addition, distinguishing characteristics of biological markers routinely used to assess the progression of HIV disease may be identified in the adherent and nonadherent groups. This latter approach would directly help clinicians to differentiate between nonresponding (albeit adherent) versus nonadherent patients.

been completely eradicated from the body. Several different commercial assays measure HIV viral load, varying in cost and sensitivity (i.e., with lower detection limits). At present, the standard commonly adopted in the United States is a lower detection limit of 50 copies/mL, although less expensive assays with decreased sensitivity (detection limits of 400–500 copies/mL) are commonly used in developing countries, given resource limitations. Highly sensitive detection assays capable of measuring HIV viral load down to a single copy per milliliter have been developed for research purposes.

A baseline viral load is determined by taking two separate viral load tests, approximately 2 to 3 weeks apart. If the results of the two tests are similar, a stable baseline is established and used to monitor the effects of drug therapy. The viral load should be repeated 4 to 6 weeks after initiation of drug therapy or after any alteration in an ARV regimen is made. The initiation of ARV therapy should correspond with a decrease in viral load, typically by a factor of 10 after 2 to 4 weeks. Effective HAART will often suppress viral load fully after 8 to 12 weeks of therapy. Thus, if viral load is about the same or higher than the baseline level after initiating treatment, changes in the drug regimen are likely needed. It should be noted that reestablishment of complete suppression of the virus to below the detection limit of established viral load assays (e.g., HIV RNA less than 48 copies/mL) should remain the primary goal of ARV therapy (Level I; Panel on Antiretroviral Guidelines for Adults and Adolescents, 2013). Once an effective drug regimen has been established, the viral load should be repeated every 3 to 4 months to confirm chronic viral suppression. Of note, changes in viral load of less than threefold are not considered significant.

Because the tests measure viral activity, anything that affects the production of virus can influence the results. A sudden rise in viral load can occur after an active infection, such as from influenza or a herpes outbreak, as previously inactive HIV-infected CD4+ T cells may become activated by these infections and begin producing HIV. A viral load test can also be affected by the administration of a vaccine, so a test should not be done until 4 to 6 weeks after an acute illness or vaccination.

At present, there are at least three distinct assay methods commercially available to assess viral load: polymerase chain reaction (PCR), branched DNA (bDNA) test, and nucleic acid sequence–based amplification (NASBA). Because the methods of each test are slightly different, results may not be equivalent. Table 17.6 presents key information on several common HIV viral load tests.

CD4+ T-cell count is typically followed with similar frequency to assess for adequate immune reconstitution after initiating HAART, although cellular immune reconstitution typically lags behind decreases in viral load, with an expected increase in CD4+ T cells of 100 to 150 cells/mL annually in adequately treated patients. Immunological nonresponders who fail to undergo adequate cellular immune reconstitution on HAART, despite viral load suppression, remain at increased risk for opportunistic infection and may require alterations in their ARV regimen, as directed by an HIV specialist. Studies are currently underway to evaluate various immunostimulant therapies in this specific patient population.

Follow-up and Referral

Follow-up for a patient infected with HIV will be required for the rest of the patient's life. However, even if the results of an HIV antibody test are negative, the

Table 17.6 Viral Load Tests

- Viral load monitoring can establish the prognosis of a patient with HIV infection. Rising viral load indicates disease progression; falling viral load indicates a favorable prognostic trend.
- Plasma viral load may range from a few hundred virions (also called viral copies or viral equivalents) to more than a million per mL, a 10,000-fold range. Such large ranges are easiest to express in logarithms (logs).
- To express a number in logarithmic form, a base is raised to a power. The latter is the logarithm, or exponent. The base 10 is commonly used in medicine without being explicitly specified; often only the power (the exponent, or log) is shown. A viral load of 10,000 copies/mL, or 10^4 copies/mL, is 4 logs. A viral load 10 times as high, or 100,000 copies/mL, is 10^5 copies/mL, or 5 logs.
- Changes in viral load are commonly expressed in either numerical or logarithmic terms. For example, a twofold change is equal to approximately a 0.3-log change.
- In viral load measurements, the sum of the laboratory and biological variation is generally assumed to be 0.3–0.5 log (twofold to threefold). Therefore, only changes greater than this are considered meaningful. The following table gives further information on several of these exams.

Type	Manufacturer	Name	HIV Range
Polymerase chain reaction (PCR)	Roche Diagnostics	Amplicor HIV-1 Monitor Test 1.5	400–750,000 copies
PCR	Roche Diagnostics	Amplicor HIV-1 Monitor Test 1.5 Ultra Sensitive	50–75,000 copies
Branched DNA PCR	Chiron/Bayer	VERSANT HIV-1 RNA 3.0 Assay (bDNA)	<50–500,000 copies
Nucleic acid sequence–based amplification (NASBA)	Organon Teknika	NucliSens HIV-1 QT	80–10,000 copies

clinician should still discuss risk reduction behaviors with the patient to mitigate the chance of future infection. Moreover, the patient also needs to understand that the test may be negative if the patient is still in the window period before seroconversion. Thus, the HIV antibody test should be repeated in 3 to 6 months, without intervening risky behaviors, in order to confirm initial negative results. If any risky behaviors occur before the test is repeated, the time period for retesting will need to be recalculated, because the window period may last up to 3 months after initial infection.

For the patient who tests positive, the pros and cons of beginning ARV medications should be discussed thoroughly. The patient's present clinical condition, HIV viral load, and CD4+ T-cell count will need to be considered to determine the timing and composition of the most appropriate HAART regimen. Moreover, the patient should be educated regarding the major aspects of HAART so that he or she can actively participate in determining what ARV choices would be most compatible with his or her lifestyle and ability to adhere to different therapeutic regimens. Importantly, the patient may need time to accept the diagnosis in order to make the most informed decisions regarding future medical care. Thus, although these issues should be raised in a timely fashion, it may not be beneficial to the patient to discuss the choice of HAART regimens or other major medical decisions at the time of diagnosis. A follow-up visit should therefore be scheduled to discuss strategies for coping with the diagnosis, as well as specifics regarding the patient's choice of HAART regimen, if applicable. Follow-up will also be necessary to monitor the effects of drug therapy on HIV viral load and to discuss any factors affecting medication adherence.

In general, a primary care practitioner should refer the patient to an immunology or infectious disease specialist for follow-up HIV care, although in resource-limited settings where specialty physicians may not be available, many primary care practitioners are providing general HIV care as well. This becomes particularly important with regard to the appropriate management of prophylactic medications against common opportunistic diseases, including PCP and mycobacterial infections (see following section on AIDS). In addition, concurrent chronic viral infections, such as hepatitis B or hepatitis C, require specialty referral to an appropriate clinical specialist (such as a hepatologist), because these infections are typically more aggressive with a worse prognosis in the setting of concurrent HIV infection.

If the patient is having severe pulmonary symptoms, he or she may need to be admitted to the hospital to rule out PCP, TB, or community-acquired pneumonia. If Kaposi's sarcoma is suspected, the patient may need to be referred to an oncologist if the condition is severe or affecting any internal organs. If there is a suspicion of

CMV retinitis, the patient should be immediately referred to an ophthalmologist for a thorough eye exam because uncontrolled infection can lead to blindness.

In addition to appropriate therapeutic and prophylactic regimens, modifications in unhealthy lifestyle behaviors can have an enormous impact on the health and well-being of an HIV-infected client. Thus, the clinician should seize this opportunity to counsel the client on smoking cessation, limiting alcohol intake, and eliminating recreational drug use. Health maintenance of the HIV-infected patient also requires close attention to preventive immunizations, including pneumococcal vaccine (23-valent polysaccharide Pneumovax vaccine) that may be readministered after 5 years, annual influenza vaccination (but not the intranasal attenuated live virus vaccine, which is contraindicated in immunocompromised patients), tetanus toxoid boosters every 10 years, quadrivalent HPV vaccine, and vaccination for both hepatitis A (two vaccinations spaced 6 months apart) and hepatitis B (three vaccinations spaced 1 and 6 months apart). Importantly, attenuated live virus vaccines including measles, mumps, rubella (MMR), oral polio virus (OPV), bacillus Calmette-Guérin anti-TB vaccine (BCG), intranasal influenza vaccine, and those for varicella (chickenpox) and yellow fever are contraindicated in HIV-infected patients with advanced disease and significant immunosuppression. However, the MMR and varicella vaccines may be given early in the course of the disease to nonimmunosuppressed HIV-infected individuals.

Patient Education

HIV infection is a lifelong chronic disease. Education may facilitate self-care activities that can decrease the risk of superinfection with other HIV strains, hepatitis viruses, and opportunistic pathogens. The patient requires extensive personalized education for his or her specific medical conditions and therapeutic regimen, including specific drug contraindications and interaction warnings. It is also critical to provide adequate support to facilitate adherence to what may be a demanding HAART regimen. Likewise, the patient will need continual reinforcement and education on the need to attain and maintain effective HIV preventive behaviors, such as safer sex practices to decrease the potential of transmitting HIV to others or acquiring new HIV strains. A wide variety of patient education materials are available from pharmaceutical companies, AIDS support organizations, and government and health-care agencies (see Resources section at the end of this chapter). Educational programs for clinicians are also available through the Association of Nurses in AIDS Care (ANAC) at 1-800-260-6780.

ACQUIRED IMMUNODEFICIENCY SYNDROME

If left untreated, HIV infection will eventually undermine the immune system. Once the CD4+ T-cell count is below 200 cells/mcL, opportunistic infections become more frequent, and these can be life-threatening unless diagnosed and treated in a timely manner. Once the CD4+ T-cell count falls below 200 cells/mcL or the patient develops an opportunistic infection or other AIDS-defining illness, the HIV-positive patient is classified as having progressed from HIV infection to AIDS.

Epidemiology and Causes

AIDS, which is the advanced stage of HIV infection, is a leading cause of death in sub-Saharan Africa. In contrast, early detection of HIV infection and improved HIV drug therapy have dramatically decreased the death rate from AIDS in resource-rich nations.

There is tremendous variation in the natural history of HIV infection from one patient to another. Thus, it is impossible to predict precisely when AIDS will occur in a person infected with HIV, but studies from the 1980s to the mid-1990s indicated the usual survival time after the diagnosis of AIDS was just 3 years. In more recent years, however, the impact of early HIV diagnosis and treatment, including HAART initiation before the development of AIDS and prophylactic medications to prevent opportunistic infections, has increased the survival time and quality of life for many HIV-infected persons, including those with full-blown AIDS.

Unfortunately, some HIV-infected persons do not respond to drug therapy with adequate viral load suppression (referred to as treatment failures or virological failures) or CD4+ T-cell restoration (referred to as immunological nonresponders). These clients require close monitoring for opportunistic infections, malignancies, and other life-threatening conditions as their immune status deteriorates, despite standard treatment. Evidence suggests that these patients still benefit from HAART, although regimen changes should be considered as newer agents become available, particularly those from different categories of ARV agents.

Pathophysiology

HIV is well recognized for its lengthy latency period after acute infection, in which infected persons remain relatively asymptomatic in the absence of HAART, despite persistent low level viremia and progressive CD4+ T-cell destruction (approximately 40–80 CD4+ T cells/L per year in untreated patients). However, among individual patients, there is wide variability in length to progression to clinical AIDS. Although the average latency period in untreated individuals has been estimated at 9 years, a subset of HIV-infected persons known as rapid progressors will clinically deteriorate to AIDS within a period of months to less than 2 years after initial infection. This is in stark contrast to approximately 5% of infected persons known as long-term nonprogressors, who show little to no progression of disease for more than a decade, despite the absence of ARV therapy. A complex interplay of multiple environmental

and genetic factors of both the host and the infecting virus underlies this variation.

Anti-HIV immune responses include both humoral and cell-mediated mechanisms. HIV-specific antibodies form in the majority of individuals within several weeks to 3 months of initial infection; however, these antibodies are insufficient to prevent disseminated infection. These neutralizing antibodies appear to play a role in natural killer (NK) cell destruction of HIV-infected cells via antibody-mediated cellular cytotoxicity. In addition, CD8+ cytotoxic T cells also target HIV-infected cells for destruction. However, these mechanisms are unable to fully eradicate HIV infection from long-lived cellular compartments (e.g., follicular dendritic cells, memory T lymphocytes) or cells that are physically sequestered from the lymphatic system (e.g., central nervous system [CNS] cells).

Given HIV's tropism for cells of the hematopoietic and immune systems, CD8+ killer T-cell activity, which is key in clearing the high levels of viremia associated with initial HIV infection, also contributes significantly to CD4+ T-cell destruction and eventual progression to clinical AIDS. This can occur via single cell killing of infected host cells, resulting from an accumulation of unintegrated viral DNA and eventual cell lysis or via disruption of normal host cell protein synthesis. However, in vitro studies have also revealed that HIV-infected cells are capable of fusing with large numbers of uninfected CD4+ T cells to create large, multinucleated syncytia or multicellular aggregates. This process has been theorized to contribute to the rapid depletion of the helper T-cell compartment in advanced stages of HIV infection.

Shared structural homology between the HIV envelope glycoproteins gp120 and gp41 and MHC class II molecules is thought to underlie the cross-reactivity and autoimmune destruction of T lymphocytes and antigen-presenting cells in the HIV-infected individual. However, even before significant CD4+ T-cell depletion occurs, dysregulated B-cell activity and autoantibody production caused by regulatory T-cell dysfunction may lead to autoimmune damage of additional cell lineages and organ-specific tissues, including primary HIV-associated thrombocytopenia, HIV nephropathy, and HIV cardiomyopathy.

In addition to destruction at the cellular level, advanced HIV infection is also characterized by destruction of the gross lymphatic architecture over a period of months to years. This includes disruption of the lymph node follicular network, which is critical for immune cell trafficking and exposure to circulating antigens, both of which are necessary to mount effective immune responses.

Qualitative defects in immune cell function are also important to the pathogenesis of advanced HIV infection. Binding studies with gp120-specific immunoglobulins demonstrated that T-cell anergy (inactivation) could be induced by antibody binding of CD4+ T-cell surface receptors. In addition, increased rates of apoptosis (nonnecrotic programmed cell death) have been demonstrated in T cells repeatedly stimulated by a specific antigen; this mechanism may be particularly relevant to chronic HIV infection with persistent low level viremia.

Given this progressive immunosuppression, the patient with AIDS is at high risk for developing viral, bacterial, fungal, and/or protozoal opportunistic infections. Common viral infections include CMV, herpes simplex virus, varicella zoster virus, and progressive multifocal leukoencephalopathy (PML, due to the John Cunningham or JC virus). Common bacterial infections include *Mycobacterium avium* complex (MAC; due to *M avium* and *M intracellulare*) and TB. Common fungal infections include candidiasis, PCP, histoplasmosis *(Histoplasma capsulatum),* and cryptococcosis *(Cryptococcus neoformans).* Common protozoal infections include cryptosporidiosis, which causes chronic diarrhea, and cerebral toxoplasmosis (*Toxoplasma gondii* infection of the CNS), which can be life-threatening. Other potential problems include malignancies and AIDS wasting syndrome (involuntary loss of more than 10% of body weight with more than 30 days of either diarrhea or weakness and fever).

Clinical Presentation

Subjective

In assessing the patient with AIDS, it is important to realize that symptomatic manifestations of opportunistic infections are varied and may affect any organ system.

The patient may complain of visual problems, such as a loss of central or peripheral vision, blurring of vision, loss of visual acuity, eye pain, photophobia, or the development of "floaters." Such complaints should raise suspicion for CMV retinitis or fungal endophthalmitis (ocular histoplasmosis).

Neurological symptoms or alterations in mental status, including headaches, confusion, mood swings, personality changes, dizziness, neck stiffness, fever, lethargy, malaise, nausea, vomiting, photophobia (intolerance of light due to resulting eye pain), neurological deficits, hemiparesis, ataxia, cranial nerve palsies, or seizures, may be the result of herpes encephalopathy, PML, cryptococcal meningitis, or cerebral toxoplasmosis.

Gastrointestinal (GI) problems such as diarrhea and abdominal pain may present concurrently with unintentional weight loss, fever, chills, or night sweats, as a result of CMV enterocolitis, viral gastroenteritis, pancreatitis, AIDS wasting syndrome, MAC, *Salmonella* or other enteric bacterial infection, cryptosporidiosis, giardiasis, isosporiasis, or histoplasmosis. The clinician should note whether GI symptoms are of sudden onset or insidious, because chronic diarrhea may result not only from the more rapid onset of opportunistic infections, but also from progressive malabsorption syndromes or as a direct effect of HIV infection in the gut known as AIDS enteropathy.

Dermatological problems may develop, such as stinging or burning papules or bumpy rashes in a linear or clustered pattern, which may be indicative of herpes simplex or HPV infection, particularly if located in the anogenital region. Other painless lesions, such as the purplish plaques of Kaposi's sarcoma, may go unnoticed in areas poorly visible to the patient (e.g., the back).

The patient may also complain of pulmonary symptoms, such as shortness of breath or a persistent cough. These symptoms may be accompanied by fever, chills, night sweats, weight loss, purulent or blood-tinged sputa, or chest pain, which may be indicative of PCP, bacterial pneumonia, or active TB. The clinician should determine the onset of pulmonary symptoms, because PCP and TB are usually insidious in presentation, with worsening of symptoms over days to weeks, whereas pulmonary toxoplasmosis progresses more rapidly.

In addition, nonspecific complaints of fatigue, weakness, and fever with anemia and leukopenia could signify disseminated MAC with bone marrow involvement.

Objective

A complete physical exam is indicated for the patient with AIDS because an array of opportunistic infections and malignancies may affect literally any organ system (Level I; Panel on Opportunistic Infections in HIV-Infected Adults and Adolescents, 2013). Some of the most common physical presentations are presented in this section by organ system.

With CMV retinitis, retinal changes are seen on ophthalmoscopic exam. With toxoplasmosis encephalitis (the most common presentation of *Toxoplasma* infection), the clinician should check for altered level of consciousness, impaired cognition, and any stroke-like symptoms. Of note, the physical examination findings of cryptococcal meningitis are typically not as striking as the fulminant meningitic symptoms of bacterial meningitis.

Oropharyngeal examination may reveal erythematous mucosal ulcers, which should raise suspicion for herpes simplex or CMV, or if patchy white lesions are present, candidiasis or EBV-associated oral hairy leukoplakia, which is typically limited to the tongue, gingivae, and/or buccal mucosa.

A wide variety of skin lesions may present with AIDS. Herpes simplex lesions are initially papulo-vesicular (fluid-filled), painful, and pruritic; these clustered lesions become progressively erythematous and ulcerated, eventually crusting over before healing. The lesions of shingles are exquisitely painful papules and vesicles, which present with a burning sensation and are distributed over a well-demarcated region of the skin known as a dermatome, corresponding to the cutaneous area innervated by a single spinal nerve. Venereal warts associated with HPV infection (condyloma acuminata) appear as raised, flesh-colored papules, with or without stalks, in isolation or in clusters. Cutaneous Kaposi's sarcoma presents with one or more raised, darkish colored lesions that may occur anywhere on the body, whereas cutaneous cryptococcosis usually presents as a single ulcerated nodule at the site of infection. Papular pruritic eruption of HIV (PPE) is a highly pruritic rash that presents as widespread papular to nodular skin lesions; as a diagnosis of exclusion, the etiology of PPE is unclear but has been suggested to be due to a dysregulated immune response to arthropod bites, because it often improves after initiating HAART. Eosinophilic folliculitis is an overlapping diagnosis with PPE in which biopsy confirms perifollicular eosinophilic infiltration that has been suggested to be of autoimmune etiology.

Findings on pulmonary examination may be nonspecific in the setting of a wide variety of infectious processes, such as PCP, TB, or community-acquired pneumonia. Therefore, physical exam findings should be considered within the context of a careful medical history detailing clinical presentation and timing of symptom onset, along with appropriate diagnostic imaging and laboratory studies. Advanced Assessment 17.2 presents additional history and physical exam information to be gathered from the HIV-positive patient.

Diagnostic Reasoning

Diagnostic Tests

Ideally, the patient with AIDS should have had all initial diagnostic testing done when he or she was first diagnosed with HIV infection. However, a significant number of patients are initially diagnosed only after they progress to AIDS (particularly in resource-limited areas), as extreme physical manifestations typically lead patients to seek medical care. Once the peripheral CD4+ T-cell count falls below 200 cells/mcL, the patient is formally diagnosed with AIDS. Outside of the United States, in resource-limited settings without access to reliable HIV diagnostic testing or T-cell counts, clinical criteria are typically used empirically to determine a diagnosis of AIDS and initiate therapy.

HIV drug resistance testing is typically done for all patients before initiating HAART to help guide the choice of ARV regimen. Resistance testing is also typically repeated for clients who have been on HIV medications but do not respond to drug therapy or experience treatment failure with reemergence of a detectable viral load greater than 1,000 copies/mL (virological failure) (Level I; Panel on Antiretroviral Guidelines for Adults and Adolescents, 2013). The most common form of resistance testing is known as HIV genotyping, in which specific viral mutations are detected via DNA sequence analysis compared with a "wild type" (nonmutated) HIV reference sequence. Based on large epidemiological data sets of viral sequences from HIV-infected patients, mutations are classified as to their potential for leading to ARV drug resistance. Of note, the full array of HIV mutations detected in an individual typically does not represent a

Advanced Assessment 17.2 HIV-Positive Patient

History	
Present Illness	When did you take the HIV antibody test? Why did you take the HIV antibody test? What brought you to the clinic today?
Past Medical History	Have you been to a health-care provider for HIV care? Do you know what your viral load is? What your CD4+ count (T-cell count) is? When were these tests last done? Have you had any opportunistic infections such as PCP or thrush? Were you ever hospitalized for these infections? What is your past medical history? Surgical history? Are you using any nontraditional (alternative or complementary) therapies? If so, please explain. Have you ever had heart problems or a history of high cholesterol?
Social Support History	What is your living situation (e.g., home life, support system [friends, relatives], financial situation, emotional situation, occupational situation, sexual relationships)? What do you know about HIV infection? If you are sexually active, do you practice safer sex? If so, please explain.
Medication History	What HIV drugs have you taken in the past? How long were you on them? How long have you been off them? Have you been taking any medications for prophylaxis? Do you take them all or just some of the time? What other medications are you taking (prescription, over-the-counter, herbal)?
Nutritional History	Tell me about your usual diet. Do you eat raw eggs or raw fish? How do you cook your meat? Do you take any appetite enhancers? Do you take any nutritional supplements?
Travel History	Do you travel often? If so, where? Have you traveled or lived in other states or out of the country? If so, when, where, and for how long?
Physical Examination	
General Overview and Mental Status	Level of consciousness Confusion Difficulty in remembering Change in mental status or mood Fatigue Change in activities of daily living
Neurological System	Headaches and associated signs and symptoms Neurological exam; cranial nerve exam
Respiratory System	Shortness of breath or dyspnea and associated signs and symptoms Cough and associated signs and symptoms Hiccups Lung sounds Respiratory rate, rhythm, characteristics; use of accessory muscles
Cardiovascular System	Heart sounds Pulse rate, rhythm, characteristics
Hematological and Lymphatic System	Swollen, enlarged, or tender glands Night sweats, fever

Advanced Assessment 17.2 HIV-Positive Patient—cont'd

Gastrointestinal System and Nutrition	Sores or white spots in mouth or lips; dental assessment Problems eating or swallowing Nausea/vomiting Change in weight or appetite Change in bowel habits (diarrhea, constipation) Nutritional intake Anorectal symptoms

single HIV viral strain, but rather characterize a population of viral strains present in a given patient. Thus, ARV medications do not actually cause HIV genetic mutations to occur, but rather, these medications exert pressure on the viral population to enrich or select for strains that developed drug resistance mutations due to the background mutational error rate of the viral reverse transcriptase enzyme.

HIV phenotyping assays also exist in which drug resistance is measured by growing viral isolates from a patient in the presence of individual ARV agents and comparing these growth rates to those of a wild type HIV strain. Given the higher cost of HIV phenotyping tests, however, these are done much less frequently than HIV genotyping tests.

Table 17.7 includes additional laboratory tests to perform and how to interpret them, as guided by the patient's presenting signs and symptoms. For clients with suspected TB or PCP, the clinician should order a PPD, arterial blood gas (ABG), chest x-ray, and sputum examination for smear and culture. Tests for acid-fast bacilli (AFB) are done for TB, and a silver stain will detect fungal forms in PCP. In addition to sputa, bronchoalveolar lavage fluid (from bronchoscopy) may be examined, as well as specific blood cultures. For patients with neurological symptoms, a referring physician should order a computed tomography scan or magnetic resonance imaging of the brain to check for the presence of ring-enhancing lesions, which could be associated with *Toxoplasma gondii* or CNS lymphoma, or nonenhancing areas of white matter (demyelination), which could indicate PML.

If diarrhea is present, with or without other GI symptoms, the clinician should send stool cultures for infectious organisms, including examination for protozoal forms, ova, and parasites. Viral infections such as CMV colitis may require colonoscopic biopsy of the GI mucosa for definitive diagnosis.

Differential Diagnosis

The differential diagnoses for AIDS-associated illnesses are quite extensive, particularly with regard to pulmonary, neurological, and GI manifestations. In the pulmonary differential, consider TB, PCP, MAC, histoplasmosis, or other bacterial, viral, fungal, or protozoal infections of the pulmonary system, as well as internal Kaposi's sarcoma affecting the lungs. Regarding the neurological system, the clinician should consider CNS lymphoma or other malignancy, in addition to the cerebral infections discussed earlier of toxoplasmosis and PML. In the GI system, CMV and disseminated MAC infection must be considered, as well as protozoal infections (cryptosporidiosis, isosporiasis, giardiasis) and malabsorption syndromes. Pan-cytopenias should raise suspicion of disseminated MAC infection in the bone marrow.

Management

In addition to prophylactic treatment and ARV medication, therapy for the person with AIDS is both supportive and educational, geared toward maximizing both the quantity and quality of life. In contrast to the early years of the HIV epidemic, given the effectiveness and availability of current ARV treatments, most HIV-infected patients are now able to live in a state of chronic, relatively stable infection for many years, rather than progressing to full-blown AIDS, provided treatment guidelines are adhered to and healthy lifestyle behaviors are followed. In turn, long-term medical management of HIV-infected patients in the United States and other developed nations is largely focused on the prevention and treatment of many of the same chronic diseases seen in the general population, such as cardiovascular disease (see Chapter 10).

However, opportunistic infections still affect a substantial number of HIV patients, even in resource-abundant settings, given factors such as therapeutic nonadherence, barriers to health-care accessibility, and comorbid medical conditions that interfere with effective HIV treatment. Thus, correctly identifying the causative organism of a presenting opportunistic infection is crucial to initiating appropriate treatment in a timely fashion. Because CD4+ T-cell count serves as the major clinical indicator of immunocompetence in HIV-infected individuals, when CD4+ T-cell count falls below 200 cells/mcL, the HIV-positive client becomes increasingly prone to opportunistic infections. PCP prophylaxis is required for CD4+ T-cell counts less than 200 cells/mcL, *Toxoplasmosis gondii* prophylaxis for counts less than 100 cells/mcL, and MAC prophylaxis for counts less than 50 cells/mcL.

Candidiasis

Oral candidiasis can be treated with fluconazole (Diflucan) 3 to 6 mg/kg (maximum of 100 mg/day) PO daily

Table 17.7 Diagnostic and Screening Tests to Evaluate the HIV-Positive Patient

Test	Interpreting the Results
Complete blood count (CBC)	Anemia is common, may be related to HIV, infection, or medication (particularly AZT). Explore to find cause: Bone marrow biopsy may be done; check for fungi, *M avium* or tuberculosis, CMV, parvovirus, and malignancy. If anemia is related to medication, may need to prescribe erythropoietin (ProCrit).
Platelets	Thrombocytopenia is often seen: In early infection idiopathic thrombocytopenia purpura may be seen; in later infection the thrombocytopenia may be because of marrow suppression. Thrombocytopenia may also be seen with Kaposi's sarcoma.
Differential white blood cell (WBC) count	Leukopenia is common; WBC counts less than 2,000 cells/mcL are common and by themselves are not a cause for alarm. If using medications that cause neutropenia, may need to prescribe colony-stimulating factors such as filgrastim (Neupogen).
Clinical chemistry	Renal function may be impaired because of HIV nephropathy, volume depletion from diarrhea, or wasting. Elevated LDH may be nonspecific or related to PCP, lymphoma, hemolysis, or muscle wasting, or may be caused by HIV or AZT. Elevated triglycerides may be a response to cytokine activation. Low albumin levels may indicate malnutrition. Elevated pancreatic enzymes may indicate pancreatitis due to certain NRTIs (didanosine, stavudine)
Interferon-gamma release assay or purified protein derivative (PPD), tuberculin skin test (TST)	Positive interferon-gamma assay result or PPD induration of 5 mm or more is considered a positive reaction (no reaction may be caused by anergy); evaluate for signs/symptoms of active TB with physical examination and chest x-ray.
CD4+ T-cell count	>500 cells/mcL: at low risk for opportunistic infections. 500–200 cells/mcL: low to moderate risk for opportunistic infections <200 cells/mcL: high risk for opportunistic infections; prophylaxis for PCP, MAC may be needed while awaiting increase in T-cell count in response to effective antiretroviral therapy To calculate absolute CD4+ count: number of WBC × % lymphs × % CD4+ = absolute CD4+ T cell count
HIV viral load	A decrease in the HIV viral load indicates effective response to antiretroviral therapy; an increase in the viral load indicates disease progression.

or itraconazole 200 mg PO daily for 14 days. Antifungal prophylaxis is not typically initiated until after an AIDS patient is treated for his or her first fungal infection and recurrent episodes become apparent.

Chronic Diarrhea

Infectious diarrhea may require specific antibiotic therapy. Often, however, chronic diarrhea will improve after starting suppressive HAART, as CD4+ T-cell count increases. For symptomatic relief of diarrhea, the patient may try loperamide (Imodium) 4 mg PO to start, then 2 mg every 6 hours or after each bowel movement, up to 16 mg/day. Other options are diphenoxylate-atropine (Lomotil) 2.5 to 5 mg three times daily; paregoric 5 to 10 mL four times daily; or tincture of opium 0.3 to 1.0 mL four times daily and as needed, up to 6 mL/day. Alternative/complementary therapies, including acupuncture and moxibustion, have been reported to decrease diarrhea and associated abdominal discomfort.

Cryptococcosis

For acute treatment of *Cryptococcus neoformans* infection, use amphotericin B deoxycholate (Fungizone) 0.7 to 1.0 mg/kg IV daily for 14 days, with or without 5-flucytosine 100 mg/kg PO divided four times daily, then fluconazole (Diflucan) 400 mg daily or itraconazole 200 mg PO two times daily for 8 weeks. In milder cases, fluconazole 400 to 800 mg daily for 8 to 12 weeks may be used, although inadequate treatment may lead to antifungal resistance. CNS infection (cryptococcal meningitis) should be treated with an initial period of IV induction therapy. Serum cryptococcal antigen (CRAG) titers should be followed, as well as cerebrospinal fluid (CSF) titers if applicable, to evaluate response to therapy. Secondary antifungal prophylaxis with fluconazole 200 mg PO daily is typically continued for life or until the CD4+ T-cell count is greater than or equal to 200 cells/mcL for at least 6 months.

Cryptosporidiosis

There is no definitive cure for *Cryptosporidium* infection. Patients typically improve with supportive care (rehydration) and resolve the infection after starting HAART. In severe cases, nitazoxanide 500 to 1,000 mg PO two times daily given with food for 14 days may help to clear the infection.

Cytomegalovirus

Several options are available for the acute treatment of CMV infection, which may affect diverse organ systems, causing enterocolitis, pneumonitis, or sight-threatening retinitis. Ganciclovir (Cytovene) may be given at 5 mg/kg IV every 12 hours for 14 days (discontinue zidovudine during this induction phase) or foscarnet (Foscavir) 90 mg/kg IV every 12 hours for 14 days. The dose of either drug should be reduced in patients with renal failure. In addition, cidofovir (Vistide) 5 mg/kg IV may be given with probenecid (Benemid) for 1 week, then reduced to every 2 weeks. Cidofovir should not be used in patients with renal insufficiency. Also, a combination of foscarnet/ganciclovir, or intravitreal injections or implants of ganciclovir (which treat only the affected area), may be tried. For maintenance, ganciclovir 5 mg/kg IV daily or foscarnet 90 to 120 mg/kg IV daily may be given. Oral ganciclovir 1 g PO three times daily is not as effective but should be considered for systemic CMV coverage for patients with ocular implants.

Herpes Simplex

For treatment of acute herpes simplex virus manifestations, the clinician should prescribe acyclovir 200 to 400 mg PO three times daily for 7 to 10 days, famciclovir 250 mg PO three times daily, or valacyclovir (Valtrex) 1 g PO two times daily for 7 to 10 days. For suppressive treatment, acyclovir 400 mg PO two times daily for 3 to 7 days per week should be given. Foscarnet 40 mg/kg IV every 8 hours for 10 days can be used for acyclovir-resistant herpes.

Herpes Zoster

Herpes zoster (varicella zoster virus, shingles) should be treated with acyclovir (Zovirax) 800 mg PO five times daily for 7 to 10 days or famciclovir (Famvir) 500 mg PO three times daily for 7 days plus topical silver sulfadiazine for skin lesions. In severe cases, the patient may require IV acyclovir (10 mg/kg per dose) every 8 hours. Valacyclovir (Valtrex), a prodrug of acyclovir, may also be used at 1 g PO every 8 hours for 7 days; although more expensive than acyclovir, its simplified dosing regimen may result in greater adherence.

Histoplasmosis

Primary prophylaxis with itraconazole 200 mg PO daily is indicated for patients with CD4+ T-cell counts less than 150 cells/mcL who live in endemic areas. Disseminated *Histoplasma capsulatum* infection is treated with a 2-week induction period of liposomal amphotericin B 3 mg/kg IV daily (5 mg/kg for meningitis), followed by itraconazole 200 mg PO three times daily for 3 days and then two times daily for at least 1 year. Secondary prophylaxis with itraconazole 200 mg PO daily, initiated after resolution of initial histoplasmosis infection, is often continued for life.

Kaposi's Sarcoma (Human Herpesvirus–8)

Although Kaposi's sarcoma has been associated with underlying HHV-8 infection, herpes-specific antiviral therapies are not utilized in current treatment regimens. Rather, cutaneous Kaposi's sarcoma typically improves on HAART, as HIV viral load is suppressed and immune status improves. However, disseminated disease may require more aggressive treatment, particularly if any internal organs are affected. Local treatment consists of cryotherapy, excision, intralesional vinblastine, or radiation. Systemic chemotherapy for more severe disease may include vinblastine, vincristine, doxorubicin, liposomal doxorubicin, liposomal daunorubicin, bleomycin, or paclitaxel. For more severe cases requiring chemotherapy, treatment is typically guided by a qualified oncology specialist.

Mycobacterium avium Complex

At CD4+ T-cell counts less than 50 cells/mcL, three drugs may be used for MAC prophylaxis: azithromycin (Zithromax) two 600-mg tablets together (1,200 mg) once a week; rifabutin (Mycobutin) 300 mg/day; or clarithromycin (Biaxin) 500 mg two times daily. However, prophylactic regimens readily induce multidrug resistance in MAC strains. Thus, MAC prophylaxis should never be initiated until active MAC infection has been thoroughly ruled out in any patient who presents with suggestive constitutional symptoms, such as fever, malaise, fatigue, or chills. MAC prophylaxis may be stopped if CD4+ T-cell counts increase above 100 cells/mcL for more than 3 months.

For acute treatment, use clarithromycin 500 mg PO two times daily or azithromycin 500 to 600 mg PO daily plus ethambutol 15 mg/kg PO per day, with or without rifabutin 300 mg PO daily. If the patient fails to respond, the provider should consider adding amikacin (Amikin) 10 mg/kg per day IV/IM for 1 to 2 months, or try ciprofloxacin or ofloxacin.

Mycobacterium tuberculosis

Several ARV drugs are contraindicated or require dosage adjustments when coadministered with TB medications capable of affecting the cytochrome p450 enzymatic pathway, such as rifampin and rifapentine. Thus, it is critical to review current guidelines for each HIV drug the patient is prescribed using a frequently updated resource such as AIDSinfo (www.aidsinfo.nih.gov), the official Web site sponsored by the National Institutes of Health, which posts national treatment and prevention guidelines for HIV infection. To reduce the risk of secondary reactivation TB, patients with latent TB infection (LTBI) diagnosed

as a positive tuberculin skin test (PPD) greater than or equal to 5 mm or a positive interferon-gamma release assay in the absence of active pulmonary disease (i.e., negative radiological imaging, absence of clinical signs and symptoms) should take isonicotinoylhydrazine (INH) (Isoniazid, Laniazid) 300 mg daily with pyridoxine 500 mg PO daily for 9 months. LTBI treatment with rifapentine is contraindicated for patients on PIs and most NNRTIs.

For active TB infection, patients should be started on INH 300 mg daily plus rifampin 600 mg plus pyrazinamide 15 to 30 mg/kg daily plus either ethambutol (Myambutol) 15 mg/kg daily or streptomycin 15 mg/kg IM daily (maximum 1 g), although ARV regimens should be modified to avoid potentially dangerous drug interactions between certain agents, such as rifampin and PIs/NNRTIs. In turn, rifabutin may be used as an alternate to rifampin, given its improved drug interaction profile. Patients on pyrazinamide should undergo regular serum uric acid monitoring, whereas ethambutol use requires periodic visual acuity and red-green color perception testing, given risks of ocular toxicity. Pyrazinamide and ethambutol may be discontinued after 2 months in order to minimize toxicity, depending on TB susceptibility testing. Thus it is critical to send sputum acid-fast bacilli (AFB) cultures as soon as possible. Combination treatment for active TB infection should be continued for at least 6 months after conversion to negative sputum cultures.

Oral Hairy Leukoplakia (Epstein-Barr Virus Infection)

These common oral lesions found mainly on the tongue typically improve after the initiation of effective HAART.

Pneumocystis jiroveci Pneumonia

There are several options for prophylaxis of PCP at CD4+ T-cell counts less than 200 cells/mcL. The first is trimethoprim-sulfamethoxazole (TMP/SMX, Bactrim, Septra) one double-strength (DS) tablet daily or three times per week. Prophylaxis may be better tolerated when begun with small doses leading to incremental increases, such as TMP/SMX suspension 1 mL PO daily for 3 days, then 2 mL PO daily for 3 days, then 5 mL PO daily for 3 days, then 10 mL PO daily for 3 days, then 20 mL PO daily for 3 days, and then 1 DS TMP/SMX tablet daily. Between 10% and 40% of all patients on this oral course will develop an allergic reaction with fever and a pruritic morbilliform rash and will have to stop treatment. However, this reaction is typically not IgE mediated nor is it considered an immediate hypersensitivity reaction. It may be mediated by an allergic reaction to the sulfa moiety, particularly in individuals of the slow acetylation phenotype who metabolize sulfonamides at slower rates. Given the effectiveness of TMP/SMX for PCP prophylaxis, rechallenge with TMP/SMX may be attempted at a later date. Dapsone (Avlosulfont) 100 mg PO daily, inhaled nebulized pentamidine (NebuPent) 300 mg every month, or atovaquone 1,500 mg PO daily can also be used for prophylaxis, although these regimens are not as effective as TMP/SMX prophylaxis. PCP prophylaxis may be stopped if CD4+ T-cell counts increase above 200 cells/mcL for more than 3 months.

For the treatment of mild to moderate PCP, the clinician may prescribe TMP/SMX 15 mg TMP/kg total daily dose, divided three times daily PO or IV. A typical adult dose is 2 tablets of DS TMP/SMX PO every 8 hours. Other treatments include pentamidine 4 mg/kg daily IV; dapsone 100 mg daily (check G-6-PD level before dosing, given the risk of anemia) plus TMP 15 mg/kg daily divided three times daily; clindamycin 600 mg PO or IV three times daily plus primaquine 30 mg daily; atovaquone (Mepron) 750 mg PO two times daily with meals plus pyrimethamine (Fansidar) 50 to 75 mg PO daily; or trimetrexate (Neutrexin) plus dapsone plus leucovorin (folinic acid; Wellcovorin), with continuation of therapy for 3 weeks before switching to maintenance therapy. Patients with acute PCP who develop respiratory distress will require hospitalization. If patients develop hypoxia as documented on a room air arterial blood gas with a PaO_2 of less than 70 mm Hg or an arterial-alveolar O_2 gradient greater than 35 mm Hg, patients should also be started on corticosteroids (prednisone 40 mg PO 2 times daily for 5 days, then 40 mg PO daily for 5 days, then 20 mg PO daily for 11 days; all doses given 30 minutes before TMP/SMX dosing) to reduce pulmonary inflammation associated with PCP.

Progressive Multifocal Leukoencephalopathy

There is no treatment for this progressively deteriorating disease caused by JC virus infection of the CNS. Some patients improve on ARV therapy for the underlying HIV infection, which adequately suppresses HIV viral load. In advanced or progressively deteriorating cases, however, the clinician and referring physician should consider discussing hospice care with the patient, family, or significant others, because the prognosis is nearly uniformly fatal.

Toxoplasmosis

For prophylaxis against *Toxoplasma gondii* at CD4+ T-cell counts less than 100 cells/mcL, use DS TMP/SMX 1 tablet PO daily or three times per week or dapsone 50 mg PO daily plus pyrimethamine 50 mg PO every week with folinic acid (Wellcovorin) 25 mg PO per week. Prophylaxis may be stopped if CD4+ T-cell counts increase above 200 cells/mcL for more than 3 months.

For acute treatment, use pyrimethamine 75 to 100 mg PO daily plus folinic acid 10 to 20 mg PO daily plus either sulfadiazine 1 to 1.5 g PO four times daily or clindamycin 600 to 900 mg PO four times daily for 6 to 8 weeks. For maintenance suppressive therapy, use pyrimethamine 25 to 50 mg PO daily plus either sulfadiazine 1 g PO two times daily or clindamycin 300 to 450 mg PO four times daily.

Follow-up and Referral

Clinical status, medication adherence, and the availability of social supports all determine how often the patient will need follow-up appointments. Follow-up visits tend to be more frequent on initiation of HAART or any new medications in order to assess for response to therapy, as well as drug tolerance. A CD4+ T-cell count should be obtained every 3 to 6 months. HIV viral load should be determined when initiating or switching ARV regimens, and a follow-up viral load must be done in 2 to 8 weeks to determine effectiveness of the medication regimen; viral load should fall by at least a factor of 10 after 2 weeks of HAART. Resistance testing should be considered if a therapeutic response is not noted with HAART or HIV viral rebound occurs despite adequate medication adherence. In stable patients, HIV viral load may be checked every 3 to 4 months. The goal of HAART should be complete viral suppression to below the limit of detection on standardized commercial HIV viral load assays.

Specialty referrals are unique to each patient and are guided by HIV-related complications, such as opportunistic infections and malignancies, which develop in the immunosuppressed individual. For example, in addition to periodic visits to an infectious disease or HIV specialist, a referral should be made to an ophthalmologist whenever the patient complains of visual problems, whereas unresolved diarrhea or GI problems may require referral to a gastroenterologist. Similarly, an oncology referral may be necessary for patients with Kaposi's sarcoma or if there is a suspicion of malignancy.

Patient Education

Patient education is an ongoing process and does not end with counseling after the initial diagnosis. Patient-centered education should include an ongoing review of health maintenance and HIV prevention behaviors, because sexual abstinence should not be assumed for any patient, regardless of HIV status. Patient education is particularly important regarding the early detection of visual problems. Other healthful behaviors, such as smoking cessation and limiting alcohol intake, should be discussed within the larger context of HIV infection, given the increased morbidity and mortality risk imparted by these behaviors. The clinician should also work with the client to convey the risks of drug interactions, given the complicated nature of HAART metabolism and both prophylactic and treatment regimens for opportunistic infections. Because blood levels of ARV medications may be increased or decreased by several other common medications, the client must understand the need to discuss any other medications being taken simultaneously. In addition, a thorough understanding of self-care practices to avoid opportunistic infections is critical. Table 17.8 presents household infection precaution guidelines.

Because AIDS has taken on a "female face," as an increasing number of women have become affected, the

Table 17.8 Household Infection Precaution Guidelines

Food and Cooking	• Sharing dishes and silverware is fine; wash them with hot soapy water between uses. • Do not eat or drink raw or unpasteurized milk products (because of risk of *Salmonella* infection [food poisoning]). • Do not eat raw or undercooked meat (because of risk of toxoplasmosis or other infections); cook all meat to a temperature of at least 140°F. • Use a separate cutting board for raw meat and fish; all cutting boards should be plastic and have no nicks or scratches. • Cook or peel organic fruits and vegetables; many organic foods are composted with substances such as manure that can contain infectious organisms. Avoid organic lettuce. • When cooking for other people, do not lick your fingers or taste food from the cooking spoon. Use a separate spoon to taste and use it only once.
Kitchen Cleaning	• Common mold and fungi found in the kitchen can be very dangerous to people with an impaired immune system. Use a cleansing agent to clean the kitchen counter; rinse area thoroughly. • Keep separate sponges for kitchen and bathroom. Always use clean sponges for washing counters and dishes; disinfect sponges by soaking them in a bleach solution (9 parts water to 1 part bleach) for 5 minutes. • To prevent mold from growing, frequently clean the inside of your refrigerator; use baking soda and water. • Mop the kitchen floor at least once a week and immediately clean up after spills. Pour mop water down the toilet, not the kitchen sink. • Keep the house well ventilated to prevent the spread of airborne infections. • Keep garbage in covered trash cans lined with plastic bags.

(Continued)

Table 17.8 Household Infection Precaution Guidelines—cont'd

Bathroom Cleaning	• Use a bleach solution (9 parts water to 1 part bleach) to clean the shower, bathtub, and sink; mop the bathroom floor at least once a week and immediately clean up after any spills. • If any body fluids are spilled (blood, urine, feces, vomit, semen) clean them up first; then use a bleach solution (9 parts water to 1 part bleach). Do not use the bleach solution directly on body fluids (it may cause a terrible-smelling gas). • Use full-strength bleach to disinfect the toilet. • Do not share washcloths or towels without washing them in between uses. • Never share toothbrushes, razors, or other personal equipment.
Pets	• If someone who does not have HIV cannot clean up after the pet, then wear gloves and wash hands thoroughly in hot soapy water afterward. • Change a cat's litter box every day. • Avoid handling turtles or cleaning their cages because of the risk of *Salmonella*.
Gardening	• Always wear gloves and wash hands thoroughly afterward.

need for women to use effective contraception and infection prevention methods has taken on a new urgency in recent years. In addition, affected women should be encouraged to get a Pap smear every 6 months because there is a higher prevalence of vaginal and cervical abnormalities among HIV-infected women. If abnormalities are present, they tend to be more severe and progress more rapidly in HIV-infected women.

All patients should be encouraged to complete advance directives early in the course of the HIV infection. If the clinician broaches this topic at a later stage of the disease (i.e., after a patient has developed AIDS), the patient may mistakenly assume that the clinician has additional information regarding his or her prognosis of which the patient is unaware. Thus, lines of communication need to be kept open between the clinician, the patient, significant others, and family members, depending of the extent of diagnosis disclosure by the client.

Complementary Therapies 17.1 lists complementary therapies that may be useful for some conditions discussed in this chapter.

Complementary Therapies 17.1*

Condition	Agent	Adverse Reactions and Considerations
Allergy	Methyl-sulfonyl-methane (MSM)	May cause bloating, diarrhea, difficulty concentrating, fatigue, GI discomfort, insomnia.
	Vitamin E	May cause abdominal pain, diarrhea, blurred vision, fatigue, headache. When given with anticoagulants/antiplatelets, may increase risk of bleeding. May interfere with chemotherapy effectiveness. When given in high doses, monitor coagulation panel.
Anemia	Vitamin A	May cause nausea, vomiting, anorexia, weight loss, weakness, alopecia, amenorrhea, arthralgia, blurred vision, bone pain, epistaxis, headache, rash. May increase risk of bleeding when given in high doses in conjunction with anticoagulants. Monitor vitamin A levels.
	Folic acid	May cause paresthesia, somnolence, diarrhea, polycythemia vera. May mask pernicious anemia. Antagonizes levodopa, phenytoin.
Pernicious anemia, sickle cell disease	Vitamin B_{12}	Do not give with aminosalicylic acid, chloramphenicol, or colchicine. Monitor vitamin B_{12} levels.
Fatigue		
Rheumatoid arthritis	Pantothenic acid	May cause diarrhea, dyspepsia, nausea. May increase risk of bleeding when given with antiplatelet agents/anticoagulants. Additive effect when given with cholinesterase inhibitors.

Complementary Therapies 17.1*—cont'd

Condition	Agent	Adverse Reactions and Considerations
	Selenium	May cause nausea, vomiting, hepatorenal dysfunction, irritability, garlic/metallic odor/taste, tremor, weakness. Prolongs sedation when given with barbiturates. Increases effectiveness of erythropoietin. Decreases efficacy of niacin and HMG-CoA reductase inhibitors.
	Feverfew	May cause nausea, bloating, constipation, diarrhea, dyspepsia, flatulence, headache, arthralgia, insomnia, muscle stiffness, photosensitivity. May increase risk of bleeding when given with antiplatelet agents/anticoagulants. Stop 2 weeks before surgery.
	Vitamin D	May cause nausea, vomiting, anorexia, constipation, dehydration, weakness, headache. Vitamin D may increase calcium levels, use with caution in patients with hypercalcemia, hyperparathyroidism, lymphoma, renal disease, sarcoidosis, or tuberculosis.
Fibromyalgia	Vitamin E	See above.
	Sam-e (*S*-adenosylmethionine)	May cause nausea, vomiting, diarrhea, anxiety, decreased blood glucose, dizziness, flushing, headache, insomnia, palpitations, skin rash. When given with SSRIs, may increase serotonergic effects; may increase risk of hypoglycemia when given with antidiabetic agents. Monitor blood glucose, LFTs.
	Magnesium (Mg)	May cause areflexia, asthenia, cardiac arrhythmias, drowsiness, hypotension, loss of tendon reflexes. Increases absorption of antidiabetic agents; additive effects when given with antihypertensive agents. Monitor blood pressure, blood glucose, LFTs.
Chronic fatigue syndrome	Coenzyme Q_{10}	May cause nausea, vomiting, diarrhea, dizziness, flu-like symptoms, hypotension, irritability, rash, thyroid hormone alterations. Additive effects when given with antihypertensives and antihyperlipidemic agents. Decreases effects of corticosteroids. Monitor LFTs, lipid profile, blood glucose, blood pressure.
HIV/AIDS	Vitamin A	See above.
	Vitamin B_{12}	See above.
	Vitamin C	May cause abdominal cramps, diarrhea, nausea, rash.
	Coenzyme Q_{10}	See above.
	Beta-glucan	May cause nausea, vomiting, flushing, dizziness, headache, keratoderma, urticaria. When given with antidiabetic agents, may increase risk of hypoglycemia. Additive effects when given with antihypertensive agents and antihyperlipidemic agents. Monitor blood glucose, BP, lipid profile, WBC count.
General Immune System Boosters	Vitamin A	See above.
	Vitamin B_6	Prolonged excessive use may cause neuropathy. May decrease levels of phenobarbital and phenytoin.
	Vitamin C	See above.
	Vitamin D	See above.
	Vitamin E	See above.

*Many patients use these agents and are convinced of their effectiveness. However, there is no Level I Evidence (high-quality randomized controlled trials) to support the use of these supplements.

This table may not be all-inclusive.

Chapter 18

Psychosocial Problems

Dianne M. Loomis, DNP, FNP-BC •
Kim S. Griswold, MD, MPH, AS, RN •
Patricia A. Pastore, MS, FNP-BC

OVERVIEW OF PSYCHOSOCIAL PROBLEMS

Psychosocial and mental health problems constitute 22% of primary-care visits. In the last decade there has been a substantial increase in the number of people living with serious mental illness and substance abuse disorders who receive care from primary-care providers and emergency department services. This increase is often related to the long wait times for initial evaluation by mental health providers and the nationwide shortage of such providers, particularly in rural communities. The chronic debilitating nature of serious mental health disorders places a heavy emotional and financial burden on the individual, his or her family, and society. A mental health disorder affects the patient's functional capacity, family relationships, and economic stability and can often lead to the development of comorbid chronic diseases and premature mortality.

The lifetime risk for a mental health disorder for individuals living in the United States is 50%. An estimated 26.2% of Americans aged 18 and older—about one in four adults—suffer from a diagnosable mental disorder in a given year. The main burden of illness is concentrated in a much smaller proportion—about 6%, or 1 in 17—who suffer from a serious mental illness. Serious mental illnesses include schizophrenia, bipolar disorder, severe depression, and other psychoses that lead to persistent functional impairment.

The economic impact of treating these disorders has increased over the last decade during which U.S. spending on mental health services has increased from $25 billion to $60 billion. These disorders comprise one of the five most costly medical conditions, extracting a severe cost burden on the nation and on the families and systems that provide support and care for people with a serious mental illness. Moreover, results from the National Comorbidity Survey funded by the National Institute of Mental Health revealed that major mental disorders cost the nation an additional $193 billion annually in lost earnings alone.

Psychological and physical health influence each other greatly and can be approached effectively in an integrated manner. The signs and symptoms of mental disorders exist on a continuum and affect patients, families, and society, each in a unique way. What determines the burden of illness is the severity of symptoms, their duration, and the level of functional impairment they cause. The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) emphasizes the relevance and significance of cultural factors and their influence on the expression and management of psychosocial illness. The Cultural Formulation Interview in the DSM-5 provides a mechanism for assessing the impact of culture on an individual's clinical presentation and course.

In this chapter, common complaints and the most prevalent mental health diagnoses are presented, with an emphasis on integrated management and collaboration. For individuals and families who do not have English as their first language, it is crucial that a bicultural, appropriately trained interpreter be provided for all interviews. Furthermore, it is optimal if the interpreter has specialized expertise and additional training in interpreting mental health issues. Management of mental health disorders during and after pregnancy is discussed in a separate section, accompanied by evidence-based recommendations for treatment, follow-up, and appropriate consultation during the prenatal and postnatal periods.

All primary-care clinicians should be familiar with the DSM-5. (See Advanced Assessment 18.1 for an overview of the DSM-5 diagnostic classification system.) For purposes of this textbook, the primary behavioral health diagnoses will be discussed; various clinical subtypes can be referenced directly from the DSM-5.

Advanced practice registered nurses (APRNs) are in an ideal situation to diagnose and manage patients whose psychosocial issues cause great suffering, yet are amenable to treatment. Patients may present to primary care with a constellation of signs and symptoms that have medical and psychological underpinnings. It is important both to consider previously identified psychosocial issues and to evaluate for undiagnosed mental health disorders. Patients benefit from continuity of care and from the nursing emphasis on patient-centered care.

Persons with serious mental illness are now dying 25 years earlier than the general population, which may be partially related to their mental illness or to side

Advanced Assessment 18.1 The Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition *(DSM-5)*

The DSM-5 is a descriptive manual of mental disorders authored by the American Psychiatric Association. The DSM-5 was recently released, and it addresses the scientific and practice advances witnessed since it was last published nearly 15 years ago. It provides the diagnostic criteria for each mental disorder. These descriptions enable clinicians to diagnose, communicate about, and treat people with various mental disorders. It has been demonstrated that the use of such criteria enhances agreement among clinicians.

Precise DSM-5 criteria have been defined for each diagnosis with the addition of and reorganization of some previously identified conditions. This manual is divided into three sections: Section I contains user information, Section II contains the diagnostic criteria, and Section III addresses cultural aspects and conditions that need further research, including emerging measurement tools.

Previously, the diagnostic codes provided in the DSM-IV-TR paralleled the official World Health Organization's International Classification of Diseases ICD-9-CM codes. This consistency in coding does not persist with the changes to the DSM-5 and ICD-10-CM but should be incorporated by the 2015 roll-out of the ICD-11-CM. Providers of mental health will need to become knowledgeable of both sets of codes.

Nonaxial System

The five-part clinical axis of the DSM-IV-TR has been changed to include a three-category, nonaxial system. The first category combines the clinical disorder(s) and/or the personality and/or the developmental disorder with the known medical conditions; category two identifies the applicable environmental and psychosocial stressors; and category three provides a global assessment of functioning. In previous editions, a companion resource for primary care was developed. There are no plans to provide such a companion, because one of the goals of the DSM-5 revision was to reorganize the text to incorporate clinical decision making for the disciplines of psychiatry and primary care, where many individuals seek and receive mental health care. Accurate identification and treatment has the potential to improve morbidity and mortality from mental health disorders.

Using DSM-5 Symptom Criteria

Specific symptom criteria are listed and defined for all DSM-5 disorders and problems. In most cases, these criteria include symptom type, number, intensity, and duration. To meet the symptom criteria for a particular disorder, the patient must have experienced the minimal number of specified symptoms for a defined period of time, and the symptoms experienced should be sufficient to cause distress or impair psychosocial functioning. Persons who have fewer symptoms of less duration or less intensity may have an atypical form of the disorder, or their condition may be described as subclinical. The term *subclinical* does *not* imply that treatment is unnecessary. Atypical symptoms and subclinical symptoms can cause significant distress.

Using DSM-5 Distress Criteria

Symptomatic patients typically report subjective distress. However, a patient's distress may also be observed by others or assessed by the practitioner. There are no absolute measures of symptom-induced distress: Symptoms that are highly distressing to one person may be only mildly distressing to another. The experience of distress should not be confused with the manner in which a person expresses his or her distress. It is possible for a highly distressed person who is suffering a great deal to have trouble expressing his or her distress, whereas others may be able to describe their distress in painful detail. Whether or not a distressed person is expressive should not overly influence the assessment. Often, simple verbal statements of symptom-related discomfort and suffering are sufficient.

effects of treatment. However, their increased morbidity and mortality is largely due to treatable medical conditions that are caused by modifiable risk factors such as smoking, obesity, substance abuse, and inadequate access to medical care.

Models of integrated and collaborative care are effective and lead to better outcomes for patients with mental health problems. Primary Care Medical Homes have assumed prominence in our health-care delivery system, and the Medical Home lends itself to the precepts of combined care. The collaborative method is based on Wagner's Chronic Care Model and emphasizes behavioral change, use of information systems such as the electronic health record, and a team approach, utilizing high-level expertise for illness management and strong community linkage.

When comparing chronic care collaborative models (CCCM) versus other care conditions, it has been found that in practices using the CCCM, patients scored higher on scales for quality of life and social role function, as

well as for management of specific illnesses. The collaborative model is one with which APRNs are familiar and in which they can use to best advantage a combination of their clinical and relationship skills.

ANXIETY DISORDERS

Anxiety affects approximately 40 million adults; thus, it is the most common psychiatric disorder in the United States. It most commonly presents in the 20- to 45-year-old age-group and affects women more frequently than it does men. For most people, anxiety is an unpleasant state of physical and psychological arousal that interferes with effective psychosocial functioning. Mild anxiety is a normal fact of life and can be positive; however, severe or chronic anxiety can become debilitating.

Anxiety symptoms are typically manifested in several dimensions: affective, cognitive, behavioral, and somatic. Affectively, anxiety is an experience of dread, foreboding, or panic, often accompanied by autonomic hyperactivity—primarily sympathetic—manifested as bodily symptoms. The affective component is typically countered by cognitions that seek to make sense of or minimize the discomfort. Some other affective symptoms of anxiety are apprehension, fear, irritability, intolerance, frustration, and overreaction or hypersensitivity to personal feelings of shame. Behaviors such as avoidance, distractibility, and restlessness reflect the anxiety or may evolve in response to it. Behavioral symptoms of anxiety may include apathy, compulsions, rigidity, overreactions, preoccupation, and repetitive actions such as hair pulling or nail biting. Somatic symptoms of anxiety range in intensity from a loss of appetite, dry mouth, and fatigue, to diarrhea, sweating, chest pain, hyperventilation, vomiting, and paresthesias. Highly anxious persons may experience the full range of anxiety symptoms or may have only one or two symptoms. The classification of *anxiety disorders* is largely based on clinical presentation (Table 18.1).

Differential Diagnosis

The primary-care provider must differentiate between patients with a relatively mild and transient anxiety state, often externally situated, and patients with a pervasive and more debilitating anxiety disorder. A variety of psychiatric disorders, such as mood disorders, certain psychoses, dementias, and substance-abuse disorders present with anxiety as a prominent part of their constellation of symptomatology. This can pose considerable diagnostic and treatment challenges for the primary-care clinician. For example, anywhere from 42% to 100% of depressed patients (average 67%) have anxiety symptoms, and 33% of depressed patients have panic attacks. In addition, 17% to 65% (average 40%) of anxious patients and 33% of patients with panic disorder have depressive symptoms.

Table 18.1 Classification of Anxiety Disorders

Generalized Anxiety Disorder (GAD)	• Occurs more days than not, for at least 6 months. • Excessive anxiety and worry about a number of things. • Inability to control worry. • Associated with three or more symptoms: Easily fatigued, difficulty concentrating, muscle tension, sleep disturbance, feeling "hyper," feelings of restlessness.
Anxiety Disorder due to a general medical problem	• General anxiety, panic, other manifestations as a direct physiological consequence of a general medical problem.
Substance-Induced Anxiety Disorder	• General anxiety, panic, other manifestations directly related to medication usage, intoxication, or withdrawal.
Anxiety Disorder Not Otherwise Specified	• Prominent and persistent anxiety and/or phobic avoidance that does not meet full criteria of any other anxiety disorder.
Post-Traumatic Stress Disorder (PTSD)	• Exposure to traumatic events that involved actual or threat of severe injury to self and/or others. • Response involves terror, helplessness, intense fear. • Event is consistently reexperienced by upsetting dreams, acting/feeling as if event is reoccurring, physiological reactivity, intrusive image re: event, intrusive thoughts re: event, intense distress on exposure to certain triggers. • Numbing. • Increased arousal from sleep, sleep disturbances, angry outbursts/instability, hypervigilance, exaggerated startle response. • Lasts longer than 1 month.

Source: Adapted from American Psychiatric Association. *Diagnostic and statistical manual of mental disorders, fifth edition* (DSM-5). American Psychiatric Association, Arlington, VA, 2013.

Many medical conditions in which there is stimulation of the sympathetic nervous system mimic anxiety, complicating the diagnosis. For example, undiagnosed arrhythmias and metabolic conditions, as well as drug reactions, may all manifest as anxiety (Table 18.2). In all cases, potential physical explanations for anxiety symptoms should be evaluated first. The extreme variability of anxiety presentations in primary care makes it one of the most commonly seen complaints.

Anxiety disorders are the most prevalent psychiatric conditions in the United States. Data from the National Comorbidity Survey indicate a 24.9% lifetime and an 18.2% 1-year prevalence rate for any anxiety disorder. Although anxiety disorders were once thought to be of minor clinical significance, it is now clear that they are serious illnesses, responsible for substantial morbidity and, possibly, mortality.

The anxiety disorders, like the mood disorders, can also be viewed on a continuum. Anxiety disorders encompass diagnoses of Panic Disorder, Panic Attack Specifier, Agoraphobia, Specific Phobia, and Generalized Anxiety Disorder. Several of these more common anxiety disorders are discussed next.

GENERALIZED ANXIETY DISORDER

Generalized anxiety disorder (GAD) is characterized by excessive worry (over 6 months) about multiple concerns that are difficult to control. Persons with GAD experience a range of upsetting physical symptoms, along with hyperarousal and insomnia. A diagnosis of GAD requires evidence of disrupted or impaired occupational or social functioning. GAD is more disruptive than normal anxiety, which is characterized by apprehension and mild physical symptoms of upset such as headache. From 50% to 90% of patients with GAD have another comorbid mental disorder, most commonly depression.

Epidemiology and Causes

Epidemiological studies indicate that in general, the yearly prevalence of anxiety disorders in adults is approximately 15%. Women tend to be diagnosed with anxiety disorders more often than men are. Individuals with a history of trauma—recent, childhood, or adolescent—can be more vulnerable to anxiety disorders, including panic disorder and specific phobias, as well as depression. Exposure to childhood trauma and its effects in health and behavioral outcomes have been well documented in the Adverse Childhood Experience (ACE) Study available at www.acestudy.org. Onset of GAD often occurs during childhood or adolescence. Prevalence in the general population is 5% to 6%, but this proportion rises to approximately 25% in primary-care populations.

People suffering from GAD have about a 60% chance of a comorbid psychiatric diagnosis, most often depression; this is associated with a poorer prognosis. A mixed anxiety and depressive disorder has become common enough that a new disorder—mixed anxiety and depression—has been identified. From 30% to 50% of individuals diagnosed with GAD also have a current depressive disorder.

There is solid evidence that at least some genetic component contributes to the development of anxiety disorders. For example, children of parents with an anxiety disorder have higher rates of anxiety disorders themselves. Data from twin registries support the hypothesis

Table 18.2 Physiological Causes of Anxiety

- *Cancers:* Carcinoid syndrome, pancreatic cancer, lung cancer, pheochromocytoma
- *Cardiac:* Mitral valve prolapse, arrhythmia, congestive heart failure, ischemic heart disease
- *Pulmonary:* Asthma, chronic obstructive pulmonary disease, sleep apnea, pulmonary embolism, hypercapnia, hypoxia
- *Neurological:* Ménière's disease, cerebrovascular accident (stroke), transient ischemic attack, multiple sclerosis, encephalopathy, subdural hematoma
- *Hematological:* Anemia
- *Metabolic:* Thyroid disease, hyperparathyroidism, Cushing's syndrome, Addison's disease, hypoglycemia, hyperglycemia, hyponatremia, hypokalemia
- *Nutritional:* Folate deficiency, vitamin B_{12} deficiency, iron deficiency

Medications and Medication Side Effects

Significant anxiety can develop as an adverse effect of prescribed or over-the-counter (OTC) medications. Medications commonly associated with drug-induced anxiety include:

- *Prescription drugs:* Aminophylline, digitalis, dopamine, epinephrine, levodopa, lidocaine, neuroleptics, NSAIDs, steroids, SSRIs, theophylline, sympathomimetics, thyroid preparations
- *OTC drugs:* Certain decongestants containing ephedrine and pseudoephedrine, caffeine, certain cough syrups, salicylates (in large doses), nicotine, monosodium glutamate, phenylpropanolamine
- *Herbal preparations:* Ephedrine, ginseng, yohimbine
- *Illicit drugs:* Amphetamines, marijuana, cocaine, ecstasy, methamphetamine, hallucinogenics
- *Others:* Alcohol, caffeine, organic solvents

that anxiety disorders are at least partially genetically determined. No anxiety disorders, however, are likely to result from a simple Mendelian abnormality. Anxiety disorders commonly coexist with depression and substance-abuse disorders.

Pathophysiology and Psychodynamics

It is well established that the autonomic nervous system of some patients with anxiety disorder, especially those with panic disorder, demonstrate increased sympathetic tone, adapt slowly to repeated stimuli, and respond excessively to moderate stimuli. The three major neurotransmitters associated with anxiety are norepinephrine, serotonin, and gamma-aminobutyric acid (GABA).

Functional brain-imaging studies, including positron emission tomography, single-photon emission computed tomography, and electroencephalography, of patients with anxiety disorders have variously reported abnormalities in the frontal cortex, the occipital and temporal areas, and, in one study of panic disorder, the parahippocampal gyrus.

Clinical Presentation

The primary symptoms of GAD are anxiety, motor tension, autonomic hyperactivity, and cognitive vigilance (see Table 18.1). The anxiety is excessive and interferes with other aspects of the patient's life. Shakiness, restlessness, and headaches are common manifestations of motor tension. Autonomic hyperactivity is commonly manifested by excessive sweating, various gastrointestinal symptoms (increased acidity, nausea, and epigastric pain), palpitations, tachycardia, headaches, and shortness of breath. Irritability and a quick-to-startle response are typical of cognitive vigilance. Often these patients seek help for their somatic symptoms.

The distinction between GAD and normal anxiety is emphasized by the specification that the symptoms of GAD must cause significant impairment or distress.

It is important to screen for anxiety, and a variety of questionnaires are available (see Table 18.4 later in the chapter). These include the Beck Anxiety Inventory, the Hamilton Anxiety Rating Scale, the Anxiety Disorder Interview Schedule, and the Primary Care Evaluation of Mental Disorders (PRIME-MD) (see Advanced Assessment 18.2), which asks about somatic symptoms such as stomach, back, and chest pain; dizziness; and sweating; as well as mood-related symptoms such as depressed feelings and loss of interest in activities.

Numerous epidemiological and survey studies have demonstrated high rates of comorbid psychiatric conditions in children and adults with anxiety disorders. Therefore, aggressive measures to diagnose anxiety disorders and comorbid depression or other mental disorders are essential because, left untreated, they can significantly disrupt an individual's life. Moreover, because of familial correlations, consider screening children of parents with anxiety disorder, as well as parents with children who have been diagnosed with panic or other anxiety disorders (Level II; Beidel and Turner, 1997).

Diagnostic Reasoning

The differential diagnosis of GAD includes all medical disorders that may cause anxiety and typically a medical work-up is necessary, including standard blood chemistry, electrocardiogram, and thyroid function tests specifically. Caffeine intoxication, stimulant abuse, and alcohol, sedative, anxiolytic, and hypnotic withdrawal must all be ruled out. A complete list of all medications, both prescribed and over the counter, must be reviewed, including all herbal agents. An environmental/occupational assessment

Advanced Assessment 18.2 Screening and Diagnostic Tool

PRIME-MD

The PRIME-MD is a two-stage instrument that assesses common mood, anxiety, eating, alcohol, and somatoform disorders. It has a self-report *screening/case finding* component, the Patient Questionnaire (PQ) to be administered *before* the clinical encounter. It consists of 25 Yes/No questions about signs and symptoms present during the previous month and one question about the patient's overall health. The questions are divided into five groups corresponding to the five categories of mental disorders assessed by the PRIME-MD.

A current version of the PRIME-MD, the Patient Health Questionnaire (PHQ), increases the efficiency of PRIME-MD by making the entire screening and diagnostic process largely self-report and taking only 3 minutes of the clinician's time. The PHQ is four pages long and contains questions similar to those in PRIME-MD-CEG (Clinical Evaluation Guide). However, the PHQ contains questions specific to women, with questions dealing with menstruation, pregnancy, and childbirth. The completed PHQ provides the clinician with most of the symptom-based information required to make the diagnoses at the beginning of the interview. This then allows more time for an assessment of the patient's life-situation and personal history. This tool was designed for a low-health-literacy population, but the tool may still prove difficult for some patients to fill in by themselves. This is especially so for elderly patients, immigrants, refugees, and persons with low educational attainment. These populations are all at risk for mental disorders. Information from the PHQ can provide baseline data for some disorders and may prove useful in tracking the patient's response and progress over time with repeated administrations.

might also be called for as inhalation of volatile gases—such as gasoline, paint, insecticides, carbon monoxide, and carbon dioxide—may all cause symptoms of anxiety.

The history and mental status exam should explore the diagnostic possibility of panic disorder, phobias, and obsessive-compulsive disorder. Distinguishing GAD from major depressive disorder and dysthymic disorder is difficult because of the frequency of co-occurrence. In patients with comorbid depression and anxiety, the symptomatic profile may be balanced or either symptom can predominate. Patients may meet all the criteria for one disorder and only partially those for the other; they may meet the criteria for both disorders; or they may demonstrate symptoms of both disorders but may not meet the full diagnostic criteria for either.

Any patient who has symptoms of anxiety or depression should be evaluated for current symptoms of both disorders. Both GAD and social anxiety disorder are commonly comorbid with major depressive disorder. Identification and treatment of depression in this group of anxious patients can lead to improved outcomes and quicker recovery. The practitioner needs to perform a thorough suicide and/or homicide risk assessment in all patients who present with significant or alarming psychosocial issues.

Management

Education and Self-Care Management

Planning care for the patient with GAD begins with education. All too often, the person with GAD lacks sufficient general information about GAD and has little understanding about his or her personal GAD symptoms. Patient education includes symptom recognition, effective interpretation of physical symptoms, a decrease in the intake of stimulants such as caffeine and nicotine, and relaxation training. Changes in coping should focus on developing more effective self-awareness and relaxation skills. Patients who develop routine methods of preventing acute anxiety and promoting relaxation are more successful than patients who attempt to cope with their GAD on an as-needed basis.

Areas of patient functioning that have been affected by anxiety should be well defined, and clear goals of improvement should be developed for each area. Some areas of functioning may be less affected by anxiety than others; however, improvement in major areas of functioning, such as being able to function at work or to maintain personal relationships, should be included.

Pharmacological Management

Some benzodiazepines (alprazolam and diazepam) can be helpful in the acute management of GAD, but it is important to remember that if the patient has comorbid depression, use of a benzodiazepine may exacerbate depressive symptoms. Dependence may also occur in those patients with predisposing factors and with long-term use. Nonetheless, unrelieved GAD symptoms can lead to additional new problems, such as substance abuse and severe social withdrawal.

Antidepressants, typically a selective serotonin reuptake inhibitor (SSRI), can be efficacious for the longer-term treatment of GAD and are particularly helpful if the patient has a coexisting depression. Escitalopram (Lexapro), paroxetine (Paxil), sertraline (Zoloft), and the serotonin-norepinephrine reuptake inhibitor (SNRI) venlafaxine (Effexor) are effective in the acute treatment of GAD as is the partial agonist buspirone (Buspar) (Level I; Baldwin et al, 2005). Treatment up to 24 weeks is associated with greater response rates (Level I; Baldwin et al, 2005). When a sedating medication is needed, moderately sedating tricyclic antidepressants (TCAs; [imipramine]) can be considered. One helpful regimen is to start the patient on both a benzodiazepine and an SSRI and then to taper the benzodiazepine as the SSRI reaches full effect. The goal of medication treatment for GAD should be to reduce or relieve symptoms sufficiently to enable effective self-care and to promote satisfactory levels of functioning. (See Drugs Commonly Prescribed 18.1: Antianxiety Agents.) Additional medications that have proven efficacy are the antipsychotic trifluoperazine (Stelazine), the antihistamine hydroxyzine (Vistaril), and the antiseizure medication pregabalin (Lyrica) (Level I; Baldwin et al, 2005).

Nonpharmacological Management

In acute management of GAD, nonpharmacological management has similar efficacy to pharmacological therapy (Level I; Baldwin et al, 2005). Cognitive-behavioral therapy (CBT; Table 18.3) has proven effective in dealing with GAD, as well as other disorders. Cognitive-behavioral treatment has a lower relapse rate in contrast to other forms of psychological modalities (Level I; Baldwin et al, 2005). It is unknown if combining drug and nonpharmacological treatments results in greater long-term improvements (Level I; Baldwin et al, 2005).

Follow-up and Referral

Monthly follow-up appointments may be needed until the patient with GAD has established alternative resources for support and assistance. A clear follow-up plan decreases the problem of excessive or ineffective appointments. Ongoing assessment includes evaluation of the primary symptoms, as well as assessment of the current risk of suicide/homicide. Complete documentation of the evaluation and plan is essential. Practitioners may wish to make themselves available to anxious patients, and referrals to patient education and support groups may be helpful for some patients with GAD. The plan should include strict criteria for seeking emergency services. The goal is to protect the patient from unknowingly becoming overreactive to his or her GAD symptoms. Improvement can become more obtainable when a realistic understanding of the illness is

Drugs Commonly Prescribed 18.1 Antianxiety Agents

Drug	Indication	Adverse Reactions and Prescribing Considerations
Classification Benzodiazepines: Short Half-life (<12 hours)		
alprazolam	Anxiety, GAD, panic disorder	C-IV controlled substance. All benzodiazepines are associated with potential anterograde amnesia, CNS depression, and paradoxical reactions. Sedation, memory deficits, ataxia, narrow-angle glaucoma. Association with falls and injury in the elderly. Caution with depressed patients and substance abuse, impaired hepatic or renal function. Most contraindicated in obstructive sleep apnea (OSA). Many drug–drug interactions (CYP pathways, CYP3A4-mediated). Withdrawal symptoms with abrupt discontinuation. The onset of withdrawal symptoms is usually seen on the first day without drug and lasts 5–7 days—slow taper. Treatment longer than 4 months should be reevaluated to determine the patient's need for the drug. Avoid valerian, St. John's wort, kava kava, gotu kola. Potential severe allergic reactions (anaphylaxis, angioedema) and complex sleep-related behaviors, which may include sleep-driving, cooking and eating food while asleep, and making phone calls while asleep.
oxazepam	Anxiety and ETOH withdrawal	See above.
temazepam	Insomnia, short-term	See above. Administer 30 minutes before bedtime. Lack of active metabolites; excellent option for the elderly.
triazolam	Insomnia, short-term	In elderly, higher incidence of CNS adverse reactions not a drug of first choice.
Classification Benzodiazepines: Intermediate Half-life (12–24 hours)		
alprazolam XR	GAD, panic disorder, anxiety with depression	Extended-release tablet: Should be taken once daily in the morning; do not crush, break, or chew. Onset 1 hour and duration 12 hours
estazolam	Insomnia short-term	No active metabolites
lorazepam	Amnesia induction Anxiety sedation induction Status epilepticus	
Classification Benzodiazepines: Long Elimination Half-life (>24 hours)		
chlordiazepoxide	Anxiety, ETOH withdrawal	The onset of withdrawal symptoms is usually seen after 5 days, with a duration of 10–14 days.
clonazepam	Absence seizures Lennox-Gastaut syndrome Myoclonic seizures Panic disorder	Less sedating than other anxiolytics; onset of full anxiolytic effect can take 3–6 weeks; less dependence. Risk of suicide ideation when used for seizures. Monitor complete blood count (CBC), liver function tests (LFTs).
clorazepate	Anxiety, ETOH withdrawal, partial seizures (adjunctive)	Increased risk of suicidal ideation when used for seizures. Long-acting metabolites; do not use in elderly. Monitor CBC, LFTs.
diazepam	Amnesia induction, anxiety, drug-induced seizures, ETOH withdrawal, muscle spasms, partial seizures, sedation induction Status epilepticus, tetanus, tonic-clonic seizures	Monitor CBC, LFTs.

Drugs Commonly Prescribed 18.1 Antianxiety Agents—cont'd

Drug	Indication	Adverse Reactions and Prescribing Considerations
flurazepam	Insomnia short-term	Avoid in elderly and debilitated. Active metabolites with extended half-lives may lead to delayed accumulation and adverse effects.
quazepam	Hypnotic	Long-acting; daytime sedation and fatigue, but this may prevent withdrawal symptoms when stopped.
Classification Nonbenzodiazepines		
Azapirones buspirone	Anxiety, GAD	Low risk of cognitive or motor impairment, may cause dopamine-related movement disorders (restlessness). Avoid St. John's wort, valerian, gotu kola, kava kava. May take 2–3 weeks to see full effect, little potential for abuse, needs continuous use, does not potentiate the effects of alcohol.
SSRIs escitalopram		See Drugs Commonly Prescribed 18.2.
SNRIs duloxetine venlafaxine		See Drugs Commonly Prescribed 18.2.

Table 18.3 Cognitive-Behavioral Strategies

Assumptions

- Alterations in content of underlying cognitive processes alter affective states and behavioral problems, i.e., thinking alters feeling and doing.
- Correction of these faulty constructs ("stinking thinking") can lead to clinical improvement.
- A person's appraisal/perception of situations is reflected in his or her cognitions (both thoughts and visuals).
- Through therapy, patients become aware of these faulty constructs and learn to alter them.

Processes

- Identify and alter cognitive distortions that maintain symptoms
- Time-limited, usually 15–25 weeks, once weekly
- Collaborative empiricism
- Structured and directive
- Assigned readings
- Homework and behavioral techniques
- Desensitization in some patients
- Identification of irrational beliefs and automatic thoughts
- Identification of attitudes and assumptions underlying negative thoughts

Source: Adapted from Kaplan & Sadock's *Synopsis of psychiatry*, ed 9. Lippincott Williams & Wilkins, Philadelphia, 2009.

maintained. Referral to a specialist is most useful when the patient needs this level of assistance in order to develop effective self-care skills.

Patient Education

Education about antianxiety medications should be reviewed with the patient and family members, including issues of overuse and dependency on medications, as well as potential adverse effects. The need to avoid combining antianxiety medications with alcohol should be addressed. The clinician should provide written instructions if the patient appears to have limited ability to concentrate. The practitioner should also discuss with the patient and family the causes and treatment of anxiety.

The provider may want to suggest to the patient and family complementary methods of anxiety management, such as relaxation techniques (see Complementary Therapies 18.1), guided imagery, music therapy, physical activity, yoga, and acupuncture. If appropriate, nutritional practices may need to be changed to include a healthier diet.

GAD cannot be managed with medication alone. Consistent and active patient self-care is required. At the same time, the highly symptomatic patient, no matter how motivated, is unlikely to be able to engage in self-care when his or her GAD symptoms are poorly controlled. GAD symptoms can increase the difficulty of learning new information, including learning new

Complementary Therapies 18.1 Relaxation Therapy Techniques

This breathing technique will help you relax, as well as provide increased energy, health, and concentration. Try using this technique for at least 15 minutes each day, on an empty stomach. Do not stand up suddenly after performing these exercises, because they can lower blood pressure, making you dizzy.

Step 1: Sit in a comfortable chair and in a quiet location to minimize distractions.

Step 2: Close your eyes.

Step 3: Begin by taking a slow, deep breath in through your nose and breathe out through your mouth slowly and deeply, like blowing out a candle.

Step 4: Breathe in slowly for a count of 4, hold for a count of 7, and breathe out for a count of 8. Repeat this several times.

Step 5: The following techniques may also help you to relax while doing the breathing exercise:

a. Visualize a favorite, peaceful setting, such as a beach, forest, desert, or meadow.

b. Play peaceful music in the background.

c. Begin at your feet and repeat to yourself that your feet are warm and heavy. Once you have achieved that, move up to your legs, your torso, and then your arms and hands. The sensation of heaviness and warmth should spread throughout your entire body.

d. Repeat a favorite phase, or mantra, with each breath.

e. Tighten different muscles while inhaling and relax them while exhaling (start with you feet and move systematically up your body.

self-care skills. Many primary-care settings now have access to comprehensive patient education programs in which the nurse practitioner can play a pivotal role. Giving patients enough time to practice newly adopted self-care skills, such as mindfulness-based stress reduction programs and meditation, may assist patients to cope with ongoing symptoms.

PANIC DISORDER

Panic disorder, which typically presents in young adulthood, is a disabling condition. It can impair the social, family, and working lives of the patient suffering from it. Panic disorder symptoms are recurrent, intense, short episodes of panic-level psychological and physical symptoms of anxiety. The initial panic episode must be spontaneous and unexpected, and it cannot occur when the person is the focus of others' attention, such as when speaking in front of an audience. A combination of sudden panic-symptom onset and panic-symptom severity creates secondary symptoms of fear. These secondary fear symptoms essentially define this disorder. Fear compels the patient with panic disorder to seek emergency health-care services repeatedly. To the patient, panic symptoms are life-threatening and signal a serious health problem or an impending nervous breakdown. Patients endure an unshakable sense of doom and danger that they cannot define.

Patients who have lived with panic disorder for a while come to associate the onset of their symptoms with specific circumstances. They may or may not be accurate in their assessment, but they may nevertheless believe that a given situation or set of circumstances triggers their panic symptoms. When this is the case, the patient may develop methods of avoiding the trigger situations and circumstances. Panic symptoms can be triggered by a wide variety of stimuli such as substance use, a change in daily routine, or exposure to feared situations, such as being in crowds or closed-in spaces. Panic triggers may or may not be easy to avoid. An episode of panic typically lasts about 10 minutes or less; however, the secondary distress that follows a panic episode can last for hours.

The frequency and severity of panic episodes and the triggered emotional and behavioral responses to panic symptoms can vary from patient to patient. Individual patterns also may vary. Panic disorder differs from occasional panic attack, now defined in DSM-5 as Panic Attack Specifier. The main distinction is that a diagnosis of panic disorder is based on a pattern of recurrent, unexpected panic attacks. At least one of these attacks must have been followed by 1 month or more of persistent worry and/or maladaptive changes in behavior. Persons with severe panic disorder become highly fearful of future panic episodes and may become preoccupied with searching for the "true meaning" of their panic symptoms. They are likely to make significant changes in their behavior and routines in the hope of avoiding future panic episodes. Without evidence of panic avoidance, it is difficult to confirm a diagnosis of panic disorder. Persons with panic disorder may become vigilant in their efforts to anticipate and thus avoid future panic episodes. Evidence of this anticipatory anxiety clarifies the diagnosis of panic disorder.

Epidemiology and Causes

The prevalence of panic disorder is generally believed to be 1.5% to 3%, although perhaps 10% of the population has had at least one isolated panic attack. Panic disorder is more common also in persons with medical conditions. For example, in pulmonary clinics (where patients with asthma and other conditions that cause shortness of breath seek treatment) 10% to 20% of patients may be affected by panic disorder. Ten percent to 20% of patients who present to the emergency department with chest pain are in actuality suffering from a panic disorder.

Panic disorders typically appear in late adolescence or young adulthood, with a peak at 25 years of age. There is a second peak between 35 and 44 years. Panic disorder affects women approximately twice as often as men. Empiric research indicates that approximately 70% of patients with panic disorder have at least one major depressive episode during their lifetime. These patients also suffer from social anxiety or social phobia; they may also be generally anxious, chronic worriers, with high rates of post-traumatic stress disorder (PTSD) and obsessive-compulsive disorder (OCD).

Panic disorders appear to have a genetic component. Several studies have suggested that patients with panic disorder are at high risk for suicidal ideation and attempts. Comorbidity with major depression can increase the rate of attempted suicides. Further, panic disorder patients have a propensity to self-medicate with alcohol and drugs. These facts should alert the clinician to the serious nature of this disorder.

Pathophysiology and Psychopathology

Structural brain-imaging studies, such as magnetic resonance imaging, have demonstrated pathological involvement in the temporal lobes, particularly the hippocampus, in patients with panic disorder. Some studies use specific panic-inducing substances (such as caffeine, lactate, or yohimbine) to assess effects of panic on cerebral blood flow. Anxiety disorders and panic attacks are specifically associated with cerebral vasoconstriction. This in turn may cause central nervous system symptoms such as dizziness and peripheral nervous system symptoms such as hyperventilation and hypercapnia.

Genetic predisposition to panic disorders, especially in those with agoraphobia, has been established in a number of studies. First-degree relatives of those with panic disorder have a fourfold to eightfold higher risk for the development of the disorder than first-degree relatives of other psychiatric patients. Twin studies have demonstrated a higher concordance for panic disorder in monozygotic twins than in dizygotic twins. No data indicating association between a specific chromosomal location or mode of transmission and panic disorder exist at this time.

Studies have shown that patients with panic disorder typically experience greater distress about life events than control subjects, and that in the months before the onset of panic, they demonstrate a higher incidence of stressful life events. What was primarily a mild feeling of anxiety suddenly becomes an overwhelming feeling of apprehension and dread, replete with somatic symptoms.

The pathogenesis of the panic attacks may be related to neurophysiological factors triggered by psychological reactions that are likely precipitated by the unconscious meaning assigned to stressful events. When assessing a patient with panic disorder, the practitioner should conduct a complete assessment of possible triggers, including inquiry about current or past abuse, loss of significant others, and other stressful life events.

Clinical Presentation

As with anxiety disorders, consider screening certain at-risk patients for panic disorder (Level II; Beidel and Turner, 1997; Biederman et al, 2001). Patients more at risk include those patients with a family history of panic and/or anxiety disorders and patients who have a comorbid psychiatric disorder, such as major depression, bipolar disorder, or substance-use disorders.

Ask the patient to describe the panic/anxiety episodes in detail, noting frequency, duration, and precipitating events. Panic disorder is marked by recurrent and unpredictable panic attacks. The panic attacks come on unexpectedly, developing suddenly within 10 minutes and usually resolving within the hour. These attacks are distinct episodes of intense fear and discomfort associated with four or more specific physical symptoms. Frequency and severity of attacks vary from once a week to clusters of attacks separated by months of well-being. The first attack often occurs outside of the home.

Spontaneous panic attacks have no obvious stimuli, whereas situational panic attacks are in response to a phobic stimulus. Limited symptom attacks are spells manifesting one or two symptoms such as dizziness, tachycardia, or respiratory distress. Often limited symptom attacks occur early in the course of panic disorder or between panic attacks. Although panic disorder may occur without any obvious causative events, it can occur in early adult life after a loss, threat of a loss, physical illness, or an episode of drug abuse.

After having several panic attacks, as many as 80% of patients begin to fear the next attack. They also experience phobic avoidance of circumstances associated with attacks. This is called anticipatory anxiety, which may become more disabling than the panic attacks themselves. Patients may become agoraphobic, culminating in increasingly circumscribed lives; some patients eventually become completely homebound.

The risk factor with the best predictive power for panic disorder is a positive family history. Other types of mood and anxiety disorders often are comorbid in patients who experience panic disorder. It is important to look not only for panic disorders in the family history but also for other mental disorders.

Perform a comprehensive physical examination to rule out organic causes for the patient's symptoms. If the history suggests that significant organic disease is unlikely, the physical examination should be focused primarily on the organ system of most concern (e.g., the heart in a patient with chest pain). Consider laboratory tests to rule out physical causality.

DSM-5 symptom criteria for panic attack include the following: fear of losing control, dying, or going crazy; chills or hot flushes; paresthesias; palpitations; choking sensations; shortness of breath; and gastrointestinal distress.

Diagnostic Reasoning

Diagnosis is generally clinical in nature. Tools that may provide a fairly accurate assessment in a relatively short time include the Mini-International Neuropsychiatric Interview (M.I.N.I.) and the PRIME-MD. Diagnosis will then structure appropriate treatment and follow-up. Consider the array of medical, cultural, or other psychiatric conditions that may mimic symptoms/signs of panic disorder, especially with the onset of any anxiety disorder (Level II; Simon and Fischmann, 2005). Panic symptoms are common, for example, in patients with schizophrenia, bipolar disorder, and depression. Cultural expression of panic may include headache, tinnitus, and sobbing.

Assess for medical conditions that may accompany, contribute to, or cause panic symptomatology; these conditions include pheochromocytoma, hyperthyroidism, seizure disorder, and cardiac arrhythmias that may originate from an acute myocardial infarction. Consider that the use of or withdrawal from therapeutic or recreational drugs may cause panic attacks. Therapeutic drugs include theophylline and steroids. Recreational drugs include cocaine, amphetamines, and caffeine. Drug withdrawal symptoms are typically associated with drugs such as alcohol, barbiturates, and benzodiazepines. As described previously, the differential diagnosis of panic disorder is complicated by a high rate of comorbidity with other psychiatric conditions, especially abuse of alcohol and benzodiazepines, which patients may initially use in an attempt to self-medicate.

Distinguish panic disorder from other anxiety disorders based on the patient's history as well as patient behavior and symptoms and the contexts in which they occur. To be diagnosed with panic disorder, the patient needs to satisfy the following four criteria:

1. A history of recurrent, unexpected panic attacks.
2. At least one of the attacks has been followed by at least 1 month by (a) a persistent concern about having additional attacks, (b) worry about the implications of an attack, or (c) a significant change in behavior related to the attacks.
3. The panic attacks are not due to effects of a substance (e.g., drug abuse, medication) or a general medical condition (e.g., hyperthyroidism).
4. The panic attacks are not better accounted for by another mental disorder, such as social phobia, OCD, PTSD, or separation anxiety disorder.

Management

Pharmacological Management

The pharmacological treatment of panic disorder is relatively straightforward and effective. The major recent advances in the treatment of panic disorder have been the advent of SSRIs and SNRIs and their recognition as powerful antipanic drugs. Generally, they are recommended as first-line pharmacological therapy in panic disorder (Level I; American Psychiatric Association, n.d.). Patients with panic disorder are often very sensitive to the pharmacological effects of various medications. When initiating pharmacological therapy, the practitioner may consider starting the drug at half of the recommended dose and gradually increasing the dose over several days. This strategy assists patients to slowly become acclimated to the effect of the medication. It is important to monitor and increase the dose until full therapeutic dosage is achieved. If the response to the initial SSRI is inadequate, the clinician may consider changing the drug, switching to another antidepressant, or adding a second medication (Level I; American Psychiatric Association, n.d.). Additional medications shown to be effective include the tricyclic antidepressants (TCAs), benzodiazepines, valproic acid (Depakote), or gabapentin (Neurontin). One should avoid extensive use of the benzodiazepines, except in specific circumstances where the patient is unable to tolerate an SSRI/SNRI or TCA, and they should not be utilized in a depressed patient as monotherapy (Level II American Psychiatric Association, n.d.). When they are used, a long-acting preparation is preferred, on an around-the-clock basis. When shorter-acting benzodiazepines are used "as needed," the risk is increased for greater tolerance and possible abuse or addiction. These particular anxiolytics can also exacerbate the depression that may coexist with panic disorder. After panic attacks have ceased, patients are maintained on medication for a minimum of 6 months. Pharmacological blockade of panic generally leads to a decrease in both anticipatory anxiety and phobic avoidance. A common approach is to use benzodiazepines for immediate relief. Other medications may be added, either concurrently or after symptoms are attenuated. Once these medications become effective, the benzodiazepine treatment may be tapered and discontinued.

Nonpharmacological Management

Cognitive-behavioral therapy (Table 18.3) is the first-line treatment for panic disorder, and useful adjuncts are self-help CBT-based books and self-help programs (Level I; American Psychiatric Association, n.d.). Patients who receive CBT have longer periods of remission and longer-term benefits. CBT is also useful to facilitate the gradual withdrawal from benzodiazepines (Level I; American Psychiatric Association, n.d.), which are often used for immediate symptom relief in panic disorder. CBT is aimed at altering the unproductive and dysfunctional thinking that helps to generate and maintain anxiety. Patients with panic disorder learn to face their fear, so that attacks are avoided. CBT is effective in treating maladaptive behaviors associated with anxiety, mainly by gradual exposure to more adaptive situations. CBT encompasses a range of treatments, each consisting of several elements, including breathing techniques (Level I; American Psychiatric Association, n.d.), education, continuous panic monitoring, development of anxiety management skills, cognitive

restructuring, and in vivo exposure. Some sources recommend brief, highly focused behavioral and cognitive psychotherapeutic techniques for panic. Hypnosis and alternative therapies (yoga, meditation) are sometimes useful as part of combined therapies but are not as effective as CBT. Some patients find relief in chiropractic treatment and acupuncture.

Follow-up and Referral

Patients with panic disorder can be managed in primary-care settings once a plan of care has been agreed to. Generally, pharmacological follow-up is scheduled every 1 to 2 weeks when initiating therapy, and then every 2 to 4 weeks until therapeutic dosage is achieved. Appointments can be spaced further apart as the dosage is stabilized and the symptoms reduced (Level I; American Psychiatric Association, n.d.). (See Advanced Practice Nursing Interventions 18.1.) As with any serious psychological condition, referral to specialist consultation or to hospital care should be made as appropriate. This includes *mandatory* inquiry about suicidal history, ideation, or intent. Also the practitioner should consider referring the patient to a psychiatrist if he or she fails to respond after 6 to 8 weeks of standard treatment. Similarly, patients should be referred to an appropriate medical specialist if an occult underlying organic disorder is suspected. The practitioner should assess the patient's response to treatment and symptom intensity and reinforce patient education at every visit, as well as review strategies to manage panic attacks. The ongoing therapeutic alliance with the primary-care clinician is crucial for long-term successful treatment.

Patient Education

For treatment to be effective, the patient and family must understand panic disorder and work together aggressively as active participants in the treatment plan. Moreover, the patient and family must be aware of the potential adverse effects of any drugs prescribed and work toward using relaxation techniques, deep breathing, and cognitive-behavioral strategies to control panic.

AGORAPHOBIA

A person can be agoraphobic without having a diagnosis of panic disorder. However, 30% to 50% of individuals with agoraphobia report panic attacks or are diagnosed with panic disorder.

The DSM-5 defines *agoraphobia* as marked fear about two or more of the following:

- Using public transportation
- Being in open spaces
- Being in enclosed spaces
- Standing in line or in a crowd
- Being outside of the home alone

Research of treatment options for agoraphobia without panic disorder has not been done. Currently it is recommended to follow the treatment guidelines for panic disorder with agoraphobia.

POST-TRAUMATIC STRESS DISORDER

Post-traumatic stress disorder (PTSD) is a syndrome that develops after a person witnesses, participates in, or hears of an extreme traumatic stressor. The reaction to this experience is typically fear and helplessness, reliving the event over and over, and trying to avoid being reminded of it. The symptoms must be severe enough to last for more than a month after the event and must significantly affect critical areas in the person's life such as interpersonal relationships and occupational roles.

PTSD symptoms are responses to experiences that are overwhelming, for example, war, torture, natural disasters, terrorism, assault, rape, serious accidents, fires, and the like. Typically, persons reexperience the trauma in their dreams and daily thoughts, and they try to evade anything that reminds them of the event. Patients can also undergo a "numbing" of responsiveness along with a physiological state of hyperarousal. This is usually accompanied by depression, anxiety, cognitive difficulties, and often substance abuse. Comorbid disorders make persons more vulnerable to developing PTSD (see Case Study 18.1).

Advanced Practice Nursing Interventions 18.1 Panic Disorder

Management

Goal: Full remission, elimination of panic attacks, anxiety, phobias, and disability; restoration of well-being.
Institute treatment with low-dose selective serotonin reuptake inhibitors (SSRIs); increase dose as tolerated to target dose.
Monitor closely for adverse effects.
Continue treatment for 12–24 months; phase out treatment slowly (over 4–6 months).
Refer to an anxiety disorder specialist if response is not satisfactory or if comorbid conditions are present.

Patient and Family Education

Teach the patient and family about panic disorder.
Advise patient not to abruptly stop medication.

Source: American Psychiatric Association. Practice guideline for the treatment of patients with panic disorder. Updated January 2009. Retrieved from www.guideline.gov/summary/summary.aspx?ss=15&doc_id=14230&nbr=007124&string=panic

CASE STUDY 18.1 Post-Traumatic Stress Disorder

Jennifer, a 45-year-old nurse and married woman with two children, presented to the Veteran's Administration Medical Center (VAMC). . . . She lived in a rural community and served a total of 24 years in the military (13 years active duty in the U.S. Army and 11 years in the U.S. Army Reserves). She was deployed for 7 months during the Gulf War and for 19 months to Kuwait and Iraq. The deployment to Kuwait and Iraq was extended several times and her support system was also affected when various individuals of the medical team were reassigned to different locations. Jennifer denied any previous psychiatric history but reported a random sexual assault at age 20 for which she never received treatment.

During her Operation Iraqi Freedom (OIF) deployment, she was at Abu Ghraib prison for 4 months and experienced mortar attacks, multiple casualties, prolonged working hours, and exposure to horrific injuries and death. She became adept at dissociating herself from these conditions until her fourteenth month of deployment. At that time, she lost interest in activities she normally enjoyed and became isolated from colleagues; her communication with family members also decreased. After redeployment, she began to have panic attacks, and she had intrusive symptoms and nightmare. Sensory experiences such as hearing helicopters, seeing blood, or smelling seared meat would provoke intrusive symptoms. She became increasingly isolated and alienated.

Jennifer's recovery encompassed the three stages of PTSD recovery. Providing a safe environment is a prerequisite to begin the process. During empowerment, the survivor can choose to speak about the experience, to remember, and to mourn. Narrative reconstruction and reconnection allows the survivor to reprocess the traumatic events into a tolerable form. And third, reconnection allows the individual to confront the traumatic past, accept the personal changes, and to reengage with the world and actively recreate a future.

Jennifer sought treatment at a VAMC outpatient psychiatric clinic 3 months after redeployment with the initial diagnoses of major depression and panic attacks. Her initial treatment included an SSRI and trazodone for sleep. On her third appointment, after utilizing a validated tool for PTSD, she was diagnosed with mild-moderate PTSD. As her medications began to improve her symptoms, she began to verbalize the traumatic experiences she had witnessed and could then reframe those experiences. Unfortunately, after four sessions her psychiatrist retired, and Jennifer was referred to group therapy, which she was unable to do. She sought care at a community health provider for the next year and continued the medications. Jennifer continued to heal through family support, retiring from the military, and receiving new career training.

Many veterans receive treatment outside of the VA system, and it is important for APRNs to be aware of the evidence-based pharmacological and nonpharmacological treatments for PTSD.

Source: Adapted from Feczer, D, and Bjorklund, P. Forever changed: Posttraumatic stress disorder in female military veterans, a case report. *Perspect Pscyhiatr C* 45(4):278–291, 2009.

Epidemiology and Causes

The lifetime prevalence of PTSD in the general population is approximately 8% to 9%, and it is twice as common in women. Women are most likely to suffer from PTSD as a result of rape or sexual molestation. Men are more commonly affected by military combat or witnessing other forms of extreme violence. The prevalence of the disorder can therefore be higher among specific groups, such as war veterans, victims of terrorist attacks, or survivors of disasters. Thus the development of PTSD varies with the degree of exposure, the type of traumatic event, and the severity of the precipitating cause. For example, most studies of adult survivors of disaster have found a PTSD prevalence of 30% to 60% after a disaster.

Recent immigrants from areas of social and/or political instability can be highly susceptible to PTSD. However, for many reasons, immigrant patients may choose not to share their traumatic experiences with a practitioner. This reluctance may have to do with significant feelings of vulnerability that a recent immigrant may feel.

Other risk factors include female gender, age (the very young and the very old are especially susceptible), race, education, socioeconomic status, education, family history, reported abuse in childhood, reports of other adverse childhood factors or trauma, poor social and/or family support, and comorbidities. Comorbidities with PTSD include an increased association with anxiety, substance abuse, and mood disorders. There is at least one psychiatric disorder present in more than 70% of men and women diagnosed with PTSD and an increased incidence of depression and mania in patients with PTSD, compared with the general population. (See Risk Factors 18.1.)

Risk Factors 18.1 PTSD

- Physical or sexual childhood abuse
- Sexual or other life-threatening assault/accident
- Combat exposure
- Being involved in fire, flood, hurricane, or other natural disaster
- Witnessing someone being badly injured or killed

The prognosis for patients suffering from PTSD is influenced by multiple factors, including whether the disorder is acute, chronic, or delayed; the presence or absence of previous mental disorders; the patient's premorbid personality; available support resources; compliance with treatment; and the patient's ability and desire to learn new coping mechanisms.

The adaptive person who suffers from acute PTSD after exposure to a traumatic event has a better chance for full recovery, especially if his or her family is supportive. Untreated, about 30% of patients recover completely, 40% continue to have mild symptoms, 20% continue to have moderate symptoms, and 10% remain unchanged or become worse.

Pathophysiology and Psychopathology

A number of biological variables have been implicated in PTSD. There is strong evidence, for example, for altered function in the noradrenergic system. Specifically, soldiers with PTSD-like symptoms may experience nervousness, high blood pressure, increased heart rate, palpitations, sweating, flushing, and tremors—all symptoms associated with adrenergic drugs. Veterans with PTSD demonstrate increased epinephrine concentrations in 24-hour urine samples, and increased urine catecholamines have been found in 24-hour urine samples of sexually abused girls. Some studies have revealed cortisol hypersuppression in trauma-exposed patients who develop PTSD, compared with patients exposed to trauma who do not develop PTSD.

A personal predisposition may be necessary for symptoms to develop after a traumatic event, and individuals apt to develop PTSD may have a preexisting mood or anxiety disorder or a family history of anxiety or other psychiatric disorder. Patients with existing serious mental disorders are at risk for victimization and, at times, assault, and they may be more likely to develop PTSD.

Clinical Presentation

The principal clinical features of PTSD are painful reexperiencing of the event, a pattern of avoidance, and emotional numbing. Typically, a combination of a trauma, the personal characteristics of the person experiencing the trauma, and a variety of post-traumatic factors all must coalesce for the person to develop PTSD. A diagnosis of PTSD will rarely be made unless the patient exhibits at least one symptom from each symptom category.

- Intrusive symptoms: The first category includes reexperiencing the traumatic event or having intrusive symptoms. This experience can manifest itself as a nightmare, a flashback, or simply sudden, vivid memories that are accompanied by painful emotions or images related to the trauma.
- Avoidance symptoms: The patient avoids any situation or activity that might revive memories of the trauma. This symptom can severely impair the patient's relationships with others because close emotional ties with family, friends, and colleagues may be included among the situations that the patient intentionally avoids. Patients suffering from PTSD commonly complain that they cannot feel emotions, especially emotions toward those who are closest to them.
- Hyperarousal symptoms: The third category includes hyperarousal symptoms. As a result of being hypersensitive or on edge, patients may experience episodes of unprovoked anger, jumpiness, and seem to be "on guard" most of the time. Patients may behave as though they are facing constant threats of danger or further trauma. They can become hyperreactive to unexpected sounds or encounters. Problems with concentrating or remembering current information are common, and terrifying nightmares can lead to severe insomnia.

In addition to hearing the patient's complaints, the practitioner needs to assess other pertinent factors to help establish goals for the patient as part of the planning process and to determine level of insight and functional status. A short diagnostic tool can help quickly assess if the patient is experiencing PTSD (see Table 18.4).

To meet the official DSM-5 criteria for a diagnosis of PTSD, symptoms must have persisted for more than 1 month and must have caused clinically significant distress in social, occupational, or other areas of functioning. PTSD is considered *acute* if symptoms have been present for less than 3 months; *chronic* if the symptoms have been present for more than 3 months; and *delayed* if symptom onset occurs 6 months or longer after the trauma.

Diagnostic Reasoning

DSM-5 Symptom Criteria

The DSM-5 symptom criteria for PTSD are as follows:

- Exposure to actual or threatened death, serious injury, or sexual violence by direct experience, witnessing an event, or being closely related to a person who has suffered a traumatic event.
- Presence of one or several of the clinical symptoms mentioned previously.

Management

In general, there is a lack of well-designed, randomized clinical trials to inform the pharmacological or nonpharmacological management of PTSD. There are gaps in the study of PTSD in subgroups, such as those individuals with traumatic brain injury, combat-related symptoms, or comorbid psychiatric disorders. There needs to be more rigorous research undertaken with veterans and an agreed-on "recovery" definition of the disorder.

Nonpharmacological Management

Crisis intervention immediately after the traumatic event may lead to avoidance of this disorder. However, critical incident debriefing, previously thought to be a helpful approach, was found to increase symptomatology when used with survivors of the September 11, 2001, terrorist attacks and is no longer recommended. Cognitive-behavioral therapy (CBT) has proven helpful for symptom relief when used individually and with groups.

Several specific CBTs for PTSD include prolonged exposure (PE), stress inoculation therapy (SIT), and image rehearsal therapy (IRT). PE was developed for women with rape trauma and is an effective first-line treatment with sustained benefit over time. One technique called "imaginal exposure" has the patient imagine and describe trauma and associated emotions and can be effective in reducing PTSD symptom severity. In vivo exposure uses systematic desensitization to triggers of trauma. With desensitization, the patient is exposed to his or her trauma "trigger" in a controlled environment. Improvement is achieved by gradually increasing the time of exposure to the trigger until the patient no longer reacts with panic.

SIT may be considered a "toolbox" for managing anxiety and focuses on correcting the patient's intrusive symptoms by teaching relaxation techniques, such as breathing exercises, that can be used to help self-manage intrusive symptoms when they occur. IRT is a brief approach—three sessions—that was found to decrease chronic nightmares and improve sleep quality. All of these approaches are specialized forms of care, but practitioners in primary-care settings can refer patients to providers who can offer these services.

Another intervention for PTSD is psychodynamic psychotherapy. This method focuses on helping the patient to examine personal values and how the experience of the traumatic event violated them. The goal is to resolve the conscious and unconscious mental conflicts that were created by the trauma. The patient works on strengthening his or her self-esteem as a way of increasing the ability to cope with the trauma.

Family therapy can be helpful when family relationships have been affected by the patient's symptoms. When family members complain that the patient does not communicate and is difficult or unpredictable, a family therapist can help the family accomplish positive changes in their relationships and functioning and help them learn to cope with their own feelings about the patient's experiences.

Group therapy or peer-counseling groups are also effective interventions for PTSD. Health groups can

encourage members to share similar traumas and symptoms safely. Through participation in these groups, individuals with PTSD can learn that they are worthy and that they are not somehow guilty for their trauma. Patients may find it easier to learn new coping techniques from other group members. Relaxation therapy and other forms of complementary therapies are also helpful for persons with PTSD. Massage, positive imagery, meditation, and yoga have all been shown to be beneficial.

Pharmacological Management

Various medications can improve symptoms. The SSRIs paroxetine (Paxil) and sertraline (Zoloft) are approved for use in PTSD, and they are at times effective in its acute treatment (Level II; Stein et al, 2006). They have been shown to improve all core PTSD clusters (numbing, intrusions, hyperarousal), and are effective in both genders, all trauma types, and in patients with comorbid disorders.

A review of pharmacological treatment for PTSD by the Institute of Medicine (IOM) in 2007 found insufficient evidence for the efficacy of most medications, including SSRIs, prazosin (Minipress), anticonvulsants, benzodiazepines, and second generation antipsychotics. Since 2012, an ongoing review process for the treatment of PTSD in war veterans has been undertaken by the IOM. One study demonstrated that prazosin improved global functioning, decreased PTSD symptoms, decreased nightmares, and improved the quality of sleep in in combat-related PTSD. For some patients, TCAs may be effective. Anxiolytic medications can be used for acute or short-term symptom management only. Buspirone (Buspar) may reduce intrusive symptoms for some patients and is a relatively safe anxiolytic.

Follow-up and Referral

If a patient is not fully recovering from a traumatic experience, he or she should be referred to a behavioral health specialist. The symptoms of PTSD can be very disturbing, and most patients will require more time and support than is available in primary-care settings. Pharmacological management may also require specialized management, especially if an SSRI has been tried and the patient proves refractory to treatment. Patients will most likely wish to continue with their primary-care practitioner for some aspects of their care. Recovery from trauma is a slow process; patients may stop and start treatment for years. When this is the case, their relationship with their primary-care practitioner becomes a stabilizing force.

Patient Education

It is important that the patient with PTSD and his or her family have a good understanding of the disorder, the chronic nature of PTSD, and the potential adverse effects of any medications prescribed. For some patients, interventions of a holistic nature may prove beneficial. Regular physical activity, good nutritional practices, and other self-care interventions can help to control symptomatology. Disease progression could lead to suicidal ideation and/or violence. The patient and family should be counseled regarding danger signs and the need for close follow-up and possible intervention.

OBSESSIVE-COMPULSIVE DISORDER

Epidemiology and Causes

Obsessive-compulsive disorder (OCD) is diagnosed when a person has obsessions (recurrent or intrusive thoughts) or compulsions (conscious, standardized, recurrent behaviors) severe enough to cause the person marked distress. OCD is a chronic disorder, with lifetime prevalence estimated at 2% to 3%. The disorder has its onset in childhood, late adolescence, or early adulthood. There is a male preponderance in earlier onset of the disorder, whereas females predominate when diagnosed at a later age. In many cases, there is an acute onset of the disorder, possibly after a significant stressful life event.

In childhood, a unique presentation is the Pediatric Autoimmune Neuropsychiatric Disorders Associated with Group A Beta-hemolytic Streptococcal Infection (PANDAS). Still to be fully explained, this subtype occurs before adolescence and is characterized by the acute onset of at least two episodes of OCD behaviors or tics and a documented group A beta-hemolytic streptococcal infection. OCD is a familiar disorder, and first-degree relatives of persons diagnosed with OCD or with Tourette's syndrome are at increased risk for development of OCD.

Pathophysiology and Psychopathology

There is a commonality between OCD and depressive disorder, evidenced by similarities in sleep electroencephalograph studies and in neuroendocrine dexamethasone testing. Recent studies of adults with OCD have elucidated particular symptom complexes that have some correlations with both genetic and neuroimaging modalities and may have treatment implications. These complexes are contamination/washing, symmetry/ordering, checking, and hoarding.

Behaviorally, obsessions may represent a conditioned response to anxiety, and the compulsions relieve or reduce the anxious symptoms and become an ingrained behavior. Psychiatric comorbidities in patients with OCD include eating, anxiety, and mood disorders. Children may also exhibit tics and attention-deficit disorder. Children presenting with coexisting OCD and bipolar disorder may have a poorer response to treatment.

Clinical Presentation

Patients may present in primary care with either depression or anxiety because of the distress and inability to

function caused by their symptom complex. However, it is quite likely that patients can keep their symptoms secret for many years and may not be diagnosed until quite late. Some patients may have already sought psychiatric care. Inquiry can be made about family psychiatric history, as well as the specific symptom complex exhibited by the patient. Common obsessions include concern with bodily wastes or germs, fear of death, a need for symmetry, forbidden or intense sexual thoughts, or intrusive sounds. Reported compulsions include excessive hand washing or bathing, repeated rituals, touching, checking, counting, and hoarding.

Diagnostic Reasoning

For a diagnosis to be made in the adult, the DSM-5 requires that symptoms must caused marked distress and cause interference with social and occupational functioning. The neurological differential includes Tourette's syndrome and temporal lobe epilepsy. Psychiatric considerations are schizophrenia, depression, phobic disorder, GAD, and PTSD. Remember that the patient with OCD has good insight into his or her symptomatology, which is not often the case in the psychotic disorders.

Rating scales for the severity of the disorder include the 10-item Yale-Brown Obsessive-Compulsive Scale (Y-BOCS) and in children the Children's Yale-Brown Obsessive-Compulsive Scale (CY-BOCS). A seven-item self-report OCD screen (SOCS) has a high sensitivity (0.97) and specificity (0.88) for differentiating patients with OCD from healthy controls. This questionnaire is available online (http://ocdyouth.iop.kcl.ac.uk/downloads/socs.pdf).

Children brought to the attention of the family nurse practitioner should be diagnosed and treated in concert with specialized psychiatric care. If PANDAS is suspected, appropriate clinical and laboratory testing should be performed (throat culture, ASO titers, judicious blood work).

(DSM-5 Symptom Criteria for OCD are presented in Table 18.1.)

Management

In general, due to the shame that the obsessions and compulsions can induce in patients, a strong therapeutic alliance and the building of trust are crucial for ongoing care. Families should be involved and given appropriate education and resources, such as information from the OCD Foundation Web site.

Pharmacological Management

SSRIs are recommended as first-line pharmacological management of OCD in children and adults (Level I; Soomro et al, 2008). Generally, higher doses of the SSRIs are required to treat OCD than are needed for depression or anxiety. Although use of SSRIs in children and adolescents carries a warning to be aware of a possible increase in suicidal ideation, studies have shown that in OCD, the benefits of treatment outweigh the risks. Clomipramine (Anafranil), a tricyclic, can be used as a second-line therapy; however, the risks of seizures, weight gain, and cardiovascular events must be carefully considered.

Nonpharmacological Management

CBT is also regarded as first-line management, either alone or in combination with an SSRI. CBT can be delivered individually, in group sessions, or with families. Exposure with response prevention (ERP) is another widely used counseling method, effective in both the adult and pediatric populations. This technique involves exposing patients to their obsessions, triggering their anxiety/discomfort, and working with them to overcome their compulsions.

Follow-up and Referral

The primary-care practitioner should address medical concerns coexisting in the patient with OCD and be mindful of medication side effects or interactions. When a medication is begun, the patient should be seen weekly for the first month, and a response should be seen within the first 6 weeks. Symptom severity can be assessed through the use of the aforementioned rating scales. OCD can be difficult to treat, because patients respond to treatment modalities quite differently with improvement responses of 40% to 60%. It is recommended that care be given in coordination with mental health specialists. Patients should be followed regularly, with attention paid to health maintenance issues. Referrals may be necessary for consequences of compulsive behaviors, such as to a dermatologist for trichotillomania, to a neurologist for coexistent Tourette's syndrome, or for dental care for excessive gum cleaning.

Patient Education

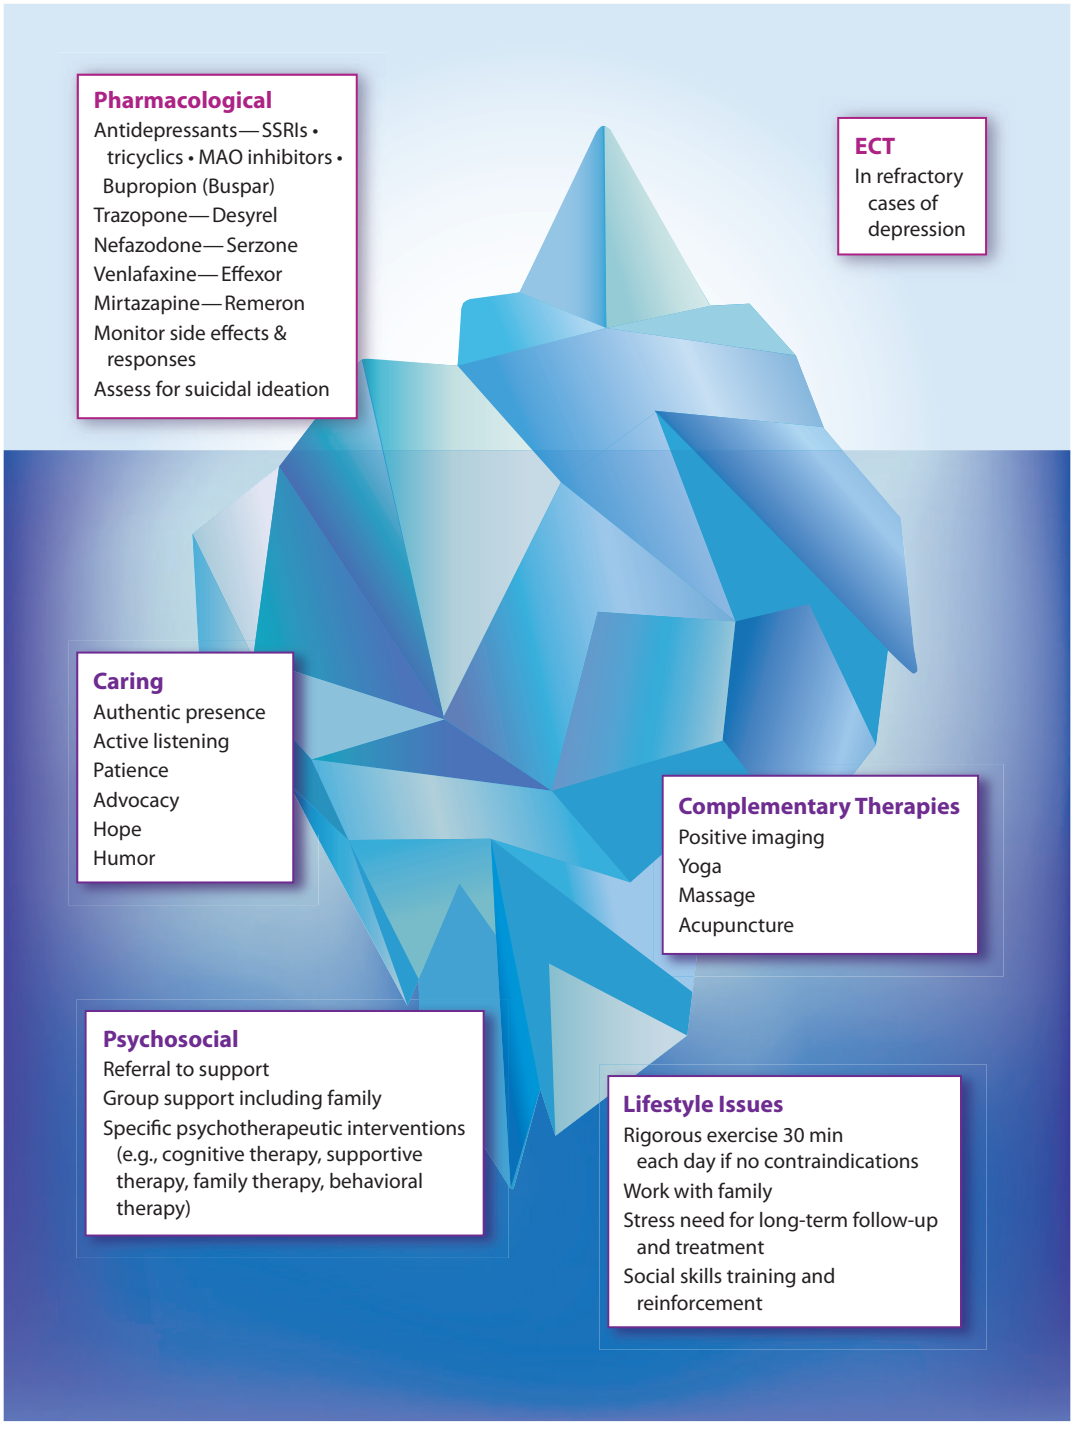
Education of the patient, family, and parents of the child with OCD is extremely important. Web sites provide information and links to support groups (e.g., http://familydoctor.org/online/famdocen/home/common/mentalhealth/anxiety/133.html; www.ocfoundation.org). Being educated and informed about the condition helps treatment compliance as well.

DISORDERS THAT MAY INCLUDE DEPRESSIVE SYMPTOMATOLOGY

OVERVIEW

The following sections include major depression, dysthymia, bipolar disorders, and schizophrenia. Major depressive disorder is the hallmark diagnosis in this

The Iceberg of Depression



category, and in DSM-5 a more chronic form, Persistent Depressive Disorder or Dysthymia, is included.

MAJOR DEPRESSIVE DISORDER

A common psychosocial symptom seen in primary-care settings is depression. Depression is common for many reasons. People use the term *depression* to describe a wide variety of negative emotional experiences, ranging from sadness to disinterest in pleasurable activities to self-hate. The hallmarks of major depression are sadness and apathy. In most cases, the sadness and apathy associated with major depression can be distinguished from ordinary changes in mood.

No description of depression, whether as a symptom or disorder, is complete without addressing the psychological pain and suffering of depression. The pain of depression can become so severe that some depressed persons are willing to go to any length to obtain even a moment of relief. Depression-related thoughts of death or suicide are not uncommon. Yet the pain of depression can be difficult to articulate: The depressed person may only be able to make vague references to "hurting" or "feeling bad." (See Nursing Research–Based Practice 18.1.)

Individual variations in the clinical presentation of depression can be great, sometimes making the condition difficult to recognize. The more common patient presentation of depression in primary-care settings is the person who has moderate to severe feelings of sadness or apathy that he or she attributes to depression. Common presentations also include complaints of unexplained fatigue, irritability, anger, anxiety, and hyperactivity. Many deeply depressed persons are unaware of their depression. Slowed thinking and emotional numbness—two severe symptoms of depression—can contribute to minimal self-awareness of depression. Gender can affect presentation, but gender should not influence assessment.

Cultural variations in the presentation of depression are also individualized, based on how traditional or nontraditional the individual's attitudes and behaviors are. Patients may focus less on personal experiences and more on physical aches and pains. Ethnic and cultural norms concerning privacy, embarrassment, and disclosure will have an impact on the patient's presentation.

Major depressive disorder is characterized by severe negative changes in mood, thinking, and behavior. A person who is severely depressed will have intense feelings of sadness, irritability, or apathy. These feelings may persist at all times and are unrelieved by circumstantial changes. At home, at school, at work, or in recreational situations, the mood of the depressed person basically varies little. In some cases, the mood of the depressed person may vary slightly but without improving significantly.

Negative changes in thinking associated with depression are common. Depressed thinking can be described as global, distorted, and circular. Rather than dealing with today, the depressed person may instead focus on distant events or think about the future as if it is a singular, knowable event. With depression, the balance between positive and negative thoughts about self, about life, and about the future becomes distorted. Negative views can seem more valid than positive views. Global negative thinking can take on a ruminative or circular pattern, so that the depressed person's negative thinking seems to always depart from and arrive at the same painful conclusions.

Major depression interferes with decision making and concentration. The smallest decision, such as whether or not to make a phone call, becomes difficult. Depression-related negative changes in thinking can be very upsetting. The depressed person may become alarmed by his or her inability to make choices or to concentrate. Although others may recognize negative changes in the depressed person's thinking, the onset of negative thinking can also develop without warning to the patient. The negative thinking associated with major depression may include thoughts of death and suicide. Some people make a clear distinction between passive thoughts of death and active thoughts of suicide, but both patterns are disturbing.

Changes in behavior associated with major depression may occur. The person's behavior may become uncharacteristic. For this reason, significant others may become aware of the depression before the depressed person does. Depression-related changes in behavior range from changes in grooming and in interpersonal interactions

Nursing Research–Based Practice 18.1 Postpartum Depression

Beck, CT. Teetering on the edge: A substantive theory of postpartum depression. *Nurs Res* 42(1):42–48, 1993.

This classic, grounded theory study utilized a qualitative approach to develop theory regarding women's perceptions of postpartum depression. Drawing a sample of 12 from a postpartum support group, the researcher conducted in-depth interviews with the women about their experiences of postpartum depression. What emerged was a rich description of the nature of postpartum depression and how these women managed their depression. "Teetering on the edge" was the hallmark metaphor that the researcher extracted to describe the process that the participants confronted during their depression. They felt "between" sane and insane, and the researcher identified several stages: "Encountering the terror" described the unpredictable nature of feelings that overwhelmed them, anxiety and panic attacks, obsessions, and loss of concentration. In the next stage, called "the dying of self," the women experienced isolation, withdrawal, and feelings of dissociation and depersonalization. Most had suicidal ideation. In the next stage, "struggling to survive," they began to grapple with their feelings. They searched out support groups, used prayer and faith to manage the depression, and began, hesitantly, and with some steps forward and some steps backward, to recover.

Women are at highest risk of developing postpartum depression from a few days to 6 months following childbirth. APRNs need to be aware of this type of depression and be alert to it. They need to educate others about the phenomenon and truly understand the meaning of the experience to these women.

to substance abuse, irritability, aggression, and social withdrawal.

Epidemiology and Causes

It is estimated that between 5% and 20% of the population will experience a significant depression at some time during their lives. The lifetime prevalence of a major depressive disorder (MDD) is 16.5% with a 6.7% 12-month prevalence rate. The prevalence of depression in older adults (over age 65) can be as high as 40% in hospitalized and nursing home patients and as high as 30% in community-dwelling elders or in adults living with chronic medical conditions. Older adults have many risk factors for depression because of the frequent losses experienced within this age-group. There is a higher incidence of depression in women (21%) than in men (13%). Researchers have studied this phenomenon for decades, but there does not appear to be a single, universal explanation for women's greater susceptibility to depression.

Once a person experiences a depressive episode, he or she is at high risk for a recurrence. As many as 50% of these individuals go on to experience a recurrence; after two episodes, there is an 80% chance of another recurrence.

One out of seven patients with recurrent depressive illness commits suicide, and of those who do, 70% have seen their primary-care provider within 6 weeks before committing suicide, often for somatic complaints. In the absence of systematic screening, usual care by primary-care providers fails to detect between 30% and 50% of depressed patients. This makes it imperative that primary-care practitioners learn to inquire sensitively about depression and to utilize evidence-based screening tools appropriately (see Table 18.4). Risk factors for depression are presented in Risk Factors 18.2.

Depression is also an independent risk factor for morbidity and mortality from cardiac disease. In patients with coexisting atrial fibrillation and congestive heart failure who received optimal treatment, a higher rate of depressive symptoms correlated with increased cardiovascular mortality. The World Health Organization (WHO) estimates that by 2020, depression will rank second only to cardiovascular illness in terms of disease burden and as a worldwide cause of disability. Similarly, patients with comorbid diabetes mellitus and depression face increased mortality in comparison to those patients without concomitant disease.

Risk Factors 18.2 Major Depression

Age	Adolescent or older adult
Gender	Female
Family History	Strong family history of depression, suicide or attempt, alcohol abuse, or other substance abuse
History	History of migraine headaches, back pain, recent myocardial infarction, and/or peptic ulcer disease
Current Medical Condition	Current chronic disease (especially multiple diseases) Insomnia
Lifestyle	Stress Poverty Less than high school education Recent traumatic event Parent or caregiver of a child or children with behavioral disorders, especially hyperactivity Retired

Pathophysiology and Psychopathology

A correlation between the hypersecretion of cortisol and depression is one of the oldest observations in biological psychiatry. Neurovegetative signs and symptoms of depression may correlate with various neuroendocrine abnormalities.

Approximately 5% to 10% of all patients with depression have a coexisting thyroid disorder. Recent research has focused on the theory that a subset of depressed patients may have an unrecognized autoimmune disorder that affects the thyroid gland. Some depressed patients benefit from liothyronine. A thyroid level should be obtained on all depressed patients.

Alterations in sleep, appetite, and sexual behavior, as well as biological changes in endocrine, immunological, and chronobiological measures in depressed patients, all suggest dysregulation of the hypothalamus. The stooped posture of depressed patients, motor slowness, and minor cognitive impairments are similar to the signs of disorder of the basal ganglia, such as Parkinson's disease and other subcortical dementias.

Genetic factors are strongly implicated in the development of depressive disorder, although it is impossible to rule out psychosocial factors, as well as other nongenetic factors. Adoption studies have also provided supporting data to the idea that there is a genetic basis for the inheritance of mood disorder. For major depression, the concordance rate in monozygote twins is about 50%, arguing strongly for a genetic disposition. A recent study indicated that a functional polymorphism in the serotonin transporter gene *(5-HTT)* may interact with stressful life events to markedly increase the risk for depression and suicide.

Psychosocial factors also contribute to depression. Stressful life events have been demonstrated to precede first episodes of mood disorders. Some speculate that the stress accompanying the first episode results in long-lasting changes in the brain's biology. Thus, the person is at high risk for subsequent episodes of mood disorder, unrelated to an external stressor. The external psychosocial factors most often associated with the onset of a major

depressive episode is the loss of a spouse or losing a parent, especially if it occurs before age 11. Another risk factor is unemployment; persons out of work are three times more likely to report symptoms of an episode of major depression than those who are employed. However, what may seem to be a relatively mild stressor from an outside perspective may be devastating to the person because of whatever idiosyncratic meaning that he or she assigns to the event.

Clinical Presentation

Assessment of major depression need not be overly complicated, but the focus of the assessment should include more than the presence or absence of significant sadness or apathy. The sadness and apathy that characterize major depression may be reported by the patient, observed and reported by significant others, or observed by the practitioner. Two quick questions that provide a preliminary screen for depression are recommended by the U.S. Preventive Services Task Force. The patient is first asked if he or she has felt down or hopeless over the past month and then asked if there has been little interest in doing things over the past month. A positive response to one or both questions in this screen indicates possible major depression, but the test has a high false-positive rate. Thus, confirmatory testing should be performed using a validated screening instrument or a clinical interview.

The Patient Health Questionnaire–9 (PHQ-9) consists of a checklist of nine symptoms. The patient is asked to indicate the frequency with which these symptoms have occurred over the preceding 2 weeks. The test is scored based on symptom frequency. This instrument can be filled out quickly either in the waiting room or exam room before a primary-care visit and provides an effective supplementation to the two-question screening. A similar measure of symptom severity, the self-rated Quick Inventory of Depressive Symptomatology (QIDS-SR), can be used for the same purpose and has the additional benefit of including symptom severity and may thus provide a sensitive measure of change with treatment (see Table 18.4).

Programs aimed at enhancing public awareness of depression have been effective, in that more patients are likely to seek professional health care for major depression as a result of having accurately self-assessed their symptoms. Patients may bring in depression self-assessment surveys published in popular magazines or local newspapers. When patients have self-assessed their depression symptoms, practitioners can determine symptom intensity, symptom duration, and symptom impact on functioning. It can also be helpful to ask patients to identify which symptoms they consider treatment priorities.

Some patients with major depression may, as a result of the disorder, find it difficult to list their symptoms. In this case assessment, screening assessment tools such as the Zung Self-Rating Depression Scale (SDS) or Beck Depression Inventory (BDI), checklists, direct observations, or yes-or-no questions may be substituted. When yes-or-no assessment questions are used, all yes responses should be explored. Extremely depressed patients may not tolerate assessment in any form that requires effort on their part. They can become irritable and impatient with the practitioner for asking questions that, to the patient, seem unnecessary. This situation can sometimes be improved by indicating that the purpose of asking questions is to understand fully the patient's depression and not to qualify or disqualify the patient for treatment.

The Geriatric Depression scale (GDS) is a widely validated screening tool for use in older adults (see Table 18.4). Depression is one of the five major health problems confronted by older adults. Clinicians need to be aware of the common presenting symptoms (see Table 18.5).

Diagnostic Reasoning

DSM-5 Symptom Criteria

The DSM-5 symptom criteria for major depression state that five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning. At least one of the symptoms is either (1) depressed mood or (2) anhedonia, meaning loss of interest or pleasure:

- Depressed mood expressed as feelings of sadness or hopelessness. Irritability may be the primary symptom in adolescents and children.
- Markedly diminished interest (apathy) in most activities.
- Change in appetite.
- Insomnia or hypersomnia.
- Behavioral agitation or retardation.
- Loss of energy.
- Feelings of worthlessness or guilt.
- Loss of concentration.
- Recurrent thoughts of death or suicide.
- These symptoms cause significant functional impairment and are not related to a medical illness or from the effects of a substance.

Table 18.5 Components of Depression in Elderly Persons

- Vegetative—poor appetite, disrupted sleep, early morning awakening
- Somatic—pain throughout body or out of proportion with underlying pathology
- Psychological—obsessive feelings of guilt and worry, ruminations throughout the night; suicidal ideation; memory problems
- Psychomotor—anxiety; psychomotor agitation
- Diurnal variation in symptoms—cannot "get moving" in morning, or specific time of day when depression is worst

The depressive episode can be further "specified" as follows: with anxious distress, with mixed features, with melancholic features, with atypical features, with psychotic features, with catatonia, with peripartum onset, and with seasonal pattern.

In patients with comorbid anxiety and depression, the symptom profile may be balanced or either symptom can predominate; in addition, some patients with so-called mixed anxiety and depression may demonstrate symptoms of both disorders but may not meet the full diagnostic criteria for either. Any patient who has symptoms of either depression or anxiety should be evaluated for current symptoms of both disorders. Consensus recommendations from a panel of experts who represent psychiatry, primary care, pharmacy, and managed care state that every patient suspected of having unipolar depression be evaluated for bipolar disorder using a quick screening tool before being treated with antidepressants. It is also necessary initially to rule out other medical conditions and substance use. Then, it must be determined if the patient has ever experienced symptoms of mania or hypomania. Then the patient's depressive symptoms must be assessed for severity, duration, recurrence, and the like to differentiate among the depressive disorders. One consideration is persistent depressive disorder or dysthymia, which is distinguished by time course without episodes of mania or hypomania.

Differential Diagnosis

All patients must be carefully evaluated for underlying medical conditions. Many medical and neurological disorders and pharmacological substances can produce symptoms of depression. Careful medical history and physical examination should be done on all patients, including a neurological exam and routine blood work and urinalysis. The history needs to include the patient's personal as well as family history of depression and suicide. Tests for thyroid and adrenal function should be included because disorders of both of these endocrine systems can mimic depression. Cardiac drugs, antihypertensive agents, sedatives, hypnotics, antipsychotics, antiepileptics, antiparkinsonian drugs, analgesics, antibacterials, steroids, and antineoplastics are all commonly associated with depressive symptomatology. A careful medication review, including over-the-counter drugs and herbal agents, as well as evaluation of alcohol and substance use, is imperative. The most common neurological disorders that may manifest depressive symptoms are Parkinson's disease (50%–75% of patients have depressive symptoms that do not correlate with physical disability), dementing illnesses (including Alzheimer type), epilepsy, cerebrovascular disease, and tumors. The interictal changes associated with temporal lobe epilepsy can mimic a depressive disorder, especially if the epileptic focus is on the right side. There is increasing evidence of linkages between depression and cardiovascular disease, not limited to sequelae but actually preceding the event. In brain tumors, depression is more common in cases of anterior lobe tumor as opposed to posterior lobe lesions, and in both cases it responds to antidepressants. The pseudodementia of MDD can be differentiated from true dementia with regard to onset (sudden in the case of pseudodementia), and guilt and self-reproach are common features of MDD, but not of dementias. Patients with depression will sometimes not answer questions, whereas those with dementia may confabulate. Depressed patients may be "coaxed" into remembering during an interview; those with primary dementia cannot.

In terms of mental disorders, depression can be a feature of virtually any disorder listed in the DSM-5. Depression has a high comorbidity with the anxiety disorders, as well as alcohol-use disorders, eating disorders, schizophrenia, schizophreniform disorder, and somatoform disorder, especially somatization disorder. Bereaved patients also need careful assessment.

Management

Remission of symptoms should be the standard for successful treatment of depression. Remission is defined as an absence of depressive symptoms or a PHQ-9 score of less than 5, and this is the goal of therapy. Alternatively, response can be defined as a reduction on the PHQ-9 score of 25% to 50%. In clinical trials, only 25% to 35% of patients experience complete remission of depressive symptoms. Clinical practice guidelines are available at https://www.icsi.org/_asset/fnhdm3/Depr-Interactive0512b.pdf. Achievement of remission is important because incomplete relief of symptoms may increase the risk of relapse and further impairment. The mainstays of treatment are the use of appropriate antidepressants and/or psychotherapy (Level I; Institute for Clinical Systems Improvement, 1996; Michigan Quality Improvement Consortium, 2012). For mild to moderate depression, either medication or psychotherapy is recommended; if the depression is more severe, evidence-based guidelines support the simultaneous use of both (Level I; Institute for Clinical Systems Improvement, 1996; Michigan Quality Improvement Consortium, 2012). When the patient expresses suicidal intent or plan or has a history of suicidal attempt, consultation with a behavioral specialist or psychiatrist is important. In addition, treatment of a mood disorder such as major depression requires a *Circle of Caring* (see Chapter 2). For patients from differing ethnic groups or cultures, discussion of acceptable treatments should form the basis of therapeutic management (Level I; Institute for Clinical Systems Improvement, 1996; Michigan Quality Improvement Consortium, 2012).

Pharmacological Management

With pharmacological therapy, about 7 out of 10 patients with severe major depression will obtain symptom

relief. Medications that are effective in the front-line treatment of MDD are the selective serotonin reuptake inhibitors (SSRIs), serotonin-norepinephrine reuptake inhibitors (SNRIs), norepinephrine reuptake inhibitors (NRIs), tricyclic antidepressants (TCAs), and dopamine agonists (DAs) (Level I; Kaiser Permanente Care Management Institute, 2012). Prescribing antidepressant medication begins with patient education. Each patient should be given as much information as is necessary to ensure that he or she understands the potential benefits of taking medication, the specific medication being prescribed, anticipated effects, possible adverse effects and how to handle them, and what to do in an emergency. When possible, this information should be made available in writing. Effective patient education makes it possible for patients to participate in their care and decreases the risks of having a patient agree to take medications without being fully informed of the medication risks and benefits.

The process of prescribing medications begins with building a patient symptom profile. A comprehensive list of current and recent patient symptoms is developed. This symptom list includes the symptoms, their intensity, duration, and effects on day-to-day functioning and role performance. From this list, two to four target symptoms are selected. Target symptoms should be identified and used to determine the most appropriate antidepressant medication.

The side-effect profiles for the newer neurotransmitter receptor–specific antidepressant medications are less severe than those for the TCAs. The receptor-specific antidepressants also have a lower risk of lethal overdose, but significant adverse reactions can occur. The advantages of fewer adverse effects and greater patient safety are significant, but many patients will experience initial adverse effects from the newer antidepressants.

Patients who are sensitive to the powerful serotonin activity produced by the SSRIs may be better able to tolerate antidepressants that have serotonin and norepinephrine (NE) activity, NE activity only, less specific serotonin activity, or an atypical antidepressant. Depressed patients who cannot tolerate SSRIs or the atypical antidepressants may be able to obtain excellent symptom relief from TCAs. TCAs are not less effective than newer antidepressant medications, but they can produce more side effects, take longer to work, and are more lethal in overdose.

Antidepressant medications can be prescribed based on their half-life, neurotransmitter activity, side-effect profile, and clinical efficacy. The half-life for newer antidepressant medications ranges from hours to several days. Neurotransmitter activity accounts for the significant differences in medication effects, including sedation, activation, anxiolytic (antianxiety), and anticompulsive effects. Important common side-effect risks with serotonin-specific antidepressants include decreased sexual desire, decreased sexual response, headache, stomach upset, sedation, fatigue, or nervousness. Absolute medication-dose limitations have been defined for patients with seizure disorders, renal disease, and liver disease. Some newer antidepressants are contraindicated for persons with bulimia, and some drugs have significant liver P450-interaction effects. There appear to be fewer age-related dose limitations; thus, newer antidepressants tend to be well tolerated by depressed older adults and adolescents. Ongoing clinical trials with pregnant women suggest that for some women, antidepressant medication can be a safe option.

Individual reactions to antidepressant medications are unique, but in general, antidepressant medications with significant NE effects (e.g., bupropion) tend to be activating. Antidepressant medications with multiple neurotransmitter effects (e.g., venlafaxine) may be effective when serotonin-specific antidepressants are not. Patients who have difficulty adjusting to the short-term side effects of antidepressants with a short half-life (e.g., sertraline, paroxetine) may experience milder short-term side effects with longer half-life antidepressants (e.g., fluoxetine). For some patients, dramatic decreases in adverse effects can be obtained by adjusting the time of day the medication is taken. Patients who are bothered by adverse effects when they take an antidepressant in the morning may experience only mild side effects if they take the same medication with dinner or at bedtime. Extremely low starting doses may be necessary when it is clear that a patient seems able to benefit from an antidepressant but cannot tolerate medication side effects during the early stages of treatment. According to a meta-analysis by Cipriani et al (2009) comparing efficacy and acceptability of second generation antidepressants, sertraline and escitalopram should be considered for initial therapy for adults with moderate to severe depression. Barriers to adherence to pharmacological guidelines can be intolerable side effects, efficacy, and cost. Switching between classes of antidepressants is common. Maximizing the dosage by a systematic stepwise approach is recommended to achieve a full therapeutic effect. When an agent does not seem to be effective, switching agents or classes is recommended. Switching between SSRIs and SNRIs can be done by prescribing the new drug at equivalent dosage. Switching from SSRI to TCA or SNRI can be accomplished through cross-tapering, where SSRI is gradually reduced over a 1- to 2-week period as the new drug is introduced and gradually increased to therapeutic levels. Cross-tapering is also recommended for mirtazapine. Because paroxetine possesses the most distressing discontinuation symptoms, one approach may be to switch to fluoxetine and then slowly taper. Discontinuation symptoms are generally not a problem for bupropion because it does not possess strong serotonergic properties. It is recommended to taper bupropion over a 1-week period while initiating the new drug at full dosage. Paroxetine, fluvoxamine, and fluoxetine are metabolized by the liver

and could potentially increase the blood level of bupropion and increase risk of seizure, especially at high doses of bupropion. Refer to specific prescribing considerations and patient information regarding monoamine oxidase inhibitors. The most important aspect is to warn patients about abrupt cessation and formulate a plan to discontinue by tapering over a 2- to 3-week period.

Providers are advised to identify all supplements or medications the patient is currently taking before starting an antidepressant medication, particularly if the patient has not taken a psychotropic medication before. This list should include all compounds—prescribed and self-administered. Many people now medicate themselves with over-the-counter (OTC) products—vitamins, minerals, herbal remedies—that they may not consider medications. The high number of such products now available makes this information vital. Patient use of megadose vitamin and mineral supplements, weight-loss or weight-gain products, and nutritional supplements should also be noted. At present, the standard of practice regarding the use of prescribed and herbal compounds is that the two treatments should not be used simultaneously. For example, there is no compelling evidence for the efficacy of St. John's wort in either mild or moderate depression; neither is the herb recommended in cases of more serious major depressive disorder (Level I; Institute for Clinical Systems Improvement, 1996; Michigan Quality Improvement Consortium, 2012). For information on specific drugs for major depression, see Drugs Commonly Prescribed 18.2.

Nonpharmacological Management

Both interpersonal and cognitive-behavioral therapy have been shown to be effective for the treatment of depression, and there is evidence that the combination of psychotherapy and pharmacotherapy may be more effective than either alone. Patients with major depression need hope and reassurance. Both are particularly important with patients who may have lived with untreated depression. Informing a person that his or her disorder is major depression and that the disorder can be treated sets the stage for patients to define goals for improvement and begin to combat the secondary demoralization that can develop after months of untreated depression. False reassurances and unrealistic expectations must be avoided, however. The support needs of patients with

Drugs Commonly Prescribed 18.2 Selective Serotonin Reuptake Inhibitors (SSRIs)

Drug	Indication	Adverse Reactions and Prescribing Considerations
All SSRIs		Common to most SSRIs: Response rates—60%–70% Remission rates—20%–35% Lowest risk of overdose Avoid sudden discontinuation Do not prescribe with monoamine oxidase inhibitors (MAOIs) Hepatic excretion: monitor LFTs Agitation, weakness, dizziness, headache, drowsiness (dose in evening), insomnia (dose in morning), nausea/vomiting (self-limiting 1–3 weeks), and xerostomia. SIADH, serotonin syndrome (caution with "triptans") SSRI-induced mania If anxiety/panic disorder develops or history of such, start low and adjust dose slowly. Risk factor for suicide. No to slight weight gain except paroxetine Sexual dysfunction that resolves in 1–3 days after medication discontinued; no MAOIs for 2 weeks after discontinuing SSRIs; wait 2 weeks after discontinuing MAOIs to start (except fluoxetine).
citalopram (Celexa)*	Depression SAD,† panic disorder,† PTSD†/OCD† hot flashes*†/PMDD†	Higher acceptability. Tolerability similar to sertraline. Monitor weight, TSH
escitalopram (Lexapro)*	Depression, generalized anxiety disorder Depression in children ages 12–17	Higher efficacy and acceptability Shortest onset of action 1–2 weeks Monitor TSH, weight Insomnia that increases 50% with 20 mg dose

Drugs Commonly Prescribed 18.2 Selective Serotonin Reuptake Inhibitors (SSRIs)—cont'd

Drug	Indication	Adverse Reactions and Prescribing Considerations
fluoxetine (Prozac)*	Bulimia Depression OCD Panic disorder PMDD Depression and OCD in children	Less severe discontinuation syndrome due to long half-life. Nausea (20%), headache, GI complaints (10%), anxiety, nervousness, insomnia, drowsiness, fatigue, dizziness, tremor Monitoring parameters: Weight, LFTs, thyroid function tests (TFTs), and growth rate Must wait 5 weeks after discontinuing before initiating MAOI
fluvoxamine (Luvox)*	OCD Social anxiety disorder	More side effects than other SSRIs Monitor growth rate and weight
paroxetine (Paxil)*	Depression Generalized anxiety Hot flashes Menopause OCD Panic PTSD PMDD SAD	Most severe discontinuation syndrome Weight gain variable Nausea/vomiting occur in 25%, xerostomia, sedation, insomnia, tremor Monitor renal function and LFTs and TSH
sertraline (Zoloft)*	Depression OCD Panic PTSD PMDD SAD	High efficacy. Nausea, vomiting, diarrhea, drowsiness, headache Monitor LFTs, TSH, weight
fluoxetine/olanzapine (Symbyax)	Bipolar depression Treatment-resistant depression (failed two separate antidepressants)	Remission rate of 25.5% Same as each individual medications
Serotonin-Norepinephrine Reuptake Inhibitors (SNRIs)		
All SNRIs		Common to most SNRIs: Response rates—60%–70% Remission rates—up to 50% Risk of overdose intermediate between low SSRI to high TCA Avoid sudden discontinuation. Do not prescribe with MAOIs Hepatic excretion: Monitor LFTs. Agitation, weakness, dizziness, headache, drowsiness, insomnia, nausea/vomiting (self-limiting 1–3 weeks), and xerostomia. SIADH, serotonin syndrome (caution with "triptans") SNRI-induced mania If anxiety/panic disorder develops or history of such, start low and adjust dose slowly. Contraindicated in uncontrolled closed-angle glaucoma. Sexual dysfunction that resolves in 1–3 days after medication discontinued. Monitor BP for onset induced hypertension and orthostatic hypotension, no MAOIs for 5 days after discontinuing SNRIs; wait 2 weeks after discontinuing MAOIs to start.

Drugs Commonly Prescribed 18.2 Selective Serotonin Reuptake Inhibitors (SSRIs)—cont'd

Drug	Indication	Adverse Reactions and Prescribing Considerations
desvenlafaxine (Pristiq)*	Depression	No monitoring required.
duloxetine (Cymbalta)*	Depression Diabetic neuropathy Fibromyalgia GAD Musculoskeletal pain Osteoarthritis	Do not use with hepatic impairment or seizure disorder. May cause hepatic failure. May cause symptomatic orthostatic hypotension. May cause hypertension.
venlafaxine (Effexor)*	Depression GAD Panic disorder Social anxiety disorder	Monitor BP due to potential emergent hypertension. Insomnia, nervousness. Associated with weight loss. Monitor cholesterol.

*__Black Box Warning:__ Children, suicide ideation.
†Non–FDA approved.
PMDD, premenstrual dysphoric disorder; SAD, social anxiety disorder; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

Tetracyclics

Drug	Indication	Adverse Reactions and Prescribing Considerations
mirtazapine (Remeron)*	Depression	Response and remission rates—53%–63% Somnolence (high incidence) and weight gain. Precautions include dizziness, increased cholesterol levels, elevated liver transaminase, and orthostatic hypotension. Risk of seizures at higher doses. Can cause agranulocytosis. Monitor glucose, liver transaminases, lipids, BUN/creatinine (Cr), and ECG.
maprotiline (Ludiomil)*	Depression	Contraindicated with MAOIs. Seizure precaution; caution with CVD. Monitor liver transaminases, TFTs, and ECG

Serotonin Modulator

Drug	Indication	Adverse Reactions and Prescribing Considerations
nefazodone (Serzone)*	Depression	Risk of hepatic failure. Response rate—35%–67% Remission—35%–52% Modest antidepressant; used mainly for hypnotic and anxiolytic effects. Allow washout period when discontinuing fluoxetine and starting nefazodone (at least 1 week). Monitor liver transaminases
trazodone (Desyrel)*	Depression	Avoid electroconvulsive therapy (ECT); do not give after myocardial infarction; potentiates alcohol, other CNS depressants; sedative effect; avoid use before or after discontinuation of MAOIs without adequate period. Monitor ECG, liver transaminases, BUN/Cr

Miscellaneous: Aminoketone Derivative

Drug	Indication	Adverse Reactions and Prescribing Considerations
bupropion (Wellbutrin)*	Depression Nicotine withdrawal SAD	May decrease weight. Less sexual side effects. Avoid use in known seizure disorders. Avoid use with history of eating disorders. Response rate—52%–70%

Drugs Commonly Prescribed 18.2 Selective Serotonin Reuptake Inhibitors (SSRIs)—cont'd

Drug	Indication	Adverse Reactions and Prescribing Considerations
		Effective in smoking cessation; less sexual dysfunction; safe in overdose Increased risk of seizure
TCAs		
Drug	**Indication**	**Adverse Reactions and Prescribing Considerations**
All TCAs	In addition to major indications may be used in conjunction with mood stabilizers and antipsychotics to treat concomitant depression	Common to most TCAs: Response rates—43%–70%. Remission rates—25%–60% Narrow therapeutic index; high lethality with overdose Analgesic, anticholinergic, and antimuscarine actions; high side-effect burden Risk of cardiotoxicity Variable depending on specific drug Wait 2 weeks after discontinuation of fluoxetine, MAOIs. Do not use with history of seizures, glaucoma, urinary retention. Monitor for suicidality, drug levels helpful to monitor. Monitor ECG and BP. Treat constipation with fiber and exercise.
amitriptyline (Elavil)*	Depression	Monitor TFTs, liver transaminases, ECG, serum concentrations
amoxapine (Asendin)*	Depression	Moderate sedation. Monitor orthostatic BP, may cause tardive dyskinesia and NMS Monitor TFTs, liver transaminases, ECG, serum concentrations
clomipramine (Anafranil)*	OCD	Strong anticholinergic effect and sedation, hypotension Monitor ECG and liver transaminases
desipramine (Norpramin)*	Depression	Less sedating Monitor ECG and liver transaminases, TFTs
doxepin (Sinequan)*	Anxiety Atopic dermatitis Depression Eczema Insomnia Lichen simplex	Strong sedation and orthostatic hypotension Monitor ECG and liver transaminases, serum concentration
imipramine (Tofranil)*	Depression Enuresis	Moderated effect on sedation and hypotension Monitor ECG and liver transaminases, serum concentrations
nortriptyline (Pamelor)*	Depression	Monitor TFTs, liver transaminases, ECG, serum concentrations
protriptyline (Vivactil)*	Depression	Strong anticholinergic effects, mild sedation ECG, liver transaminases
trimipramine (Surmontil)*	Depression	Strong sedation effect, monitor orthostatic blood pressure ECG, liver transaminases, TFTs

major depression can be significant. It is unlikely that, in a primary-care setting, practitioners will be able to meet all of a patient's support needs. For this reason, new sources of support should be identified. Friends, relatives, and spouse or partners are important potential sources of information, comfort, and assistance. Professional-led support groups and peer self-help groups are also highly effective.

Support is an important resource for all depressed patients, but patients who are anxious or irritable may require a great deal of practitioner patience. Anxious, irritable patients can be indecisive, critical, and demanding and can appear uncooperative or uninterested. Every effort must be made to avoid getting into a power struggle or challenging upset patients. In the long run, reassuring acceptance is easier and more effective.

Establishing a routine and focusing on activities and behaviors rather than feelings may be a constructive approach. Massage, relaxation therapies, exercise, good nutrition, and a variety of forms of self-care should be initiated and supported.

For some patients, the only important outcome of treatment for major depression is symptom relief. Normalized sleep, appetite, mood, energy, and concentration should, however, be viewed as minimal patient outcomes. Symptom relief and symptom remission are necessary patient outcomes, but if the patient's risk for future episodes of depression is to be significantly lowered, additional outcomes need to be addressed. Improved patient depression awareness is important. Patients treated for major depression should, as a stated outcome of treatment, increase their understanding of major depression and improve their personal methods of coping with depression. The most important outcome is that the patient will immediately seek help should symptoms of major depression return. Recurrent episodes of major depression or major depression that has continued unrelieved for months or is characterized by extremely high symptom levels requires referral and specialized care, sometimes in an inpatient setting.

Follow-up and Referral

Follow-up during treatment of depression and/or anxiety is absolutely necessary to ensure adherence to therapy. The patient must be monitored to ensure that the prescription was filled and that the medication was taken. Treatment outcome should be assessed regularly using formal diagnostic assessment tools. Target symptoms are used to evaluate the effectiveness of medication during early stages of treatment and until full symptom remission is obtained. In moderate to severe depression, follow-up is determined by the severity of the initial PHQ-9.

A reasonable criterion for extending the initial treatment is to assess whether the patient is experiencing a 25% or greater reduction in baseline symptom severity at 6 weeks of therapeutic dose. If the patient's symptoms are reduced by 25% or more, but the patient is not yet at remission, and if medication has been well tolerated, continue to prescribe. Raising the dose is recommended. In the acute phase of treatment and recovery, the patient should be seen or contacted every 1 to 2 weeks within the first month of therapy and at least once in the succeeding 4 to 8 weeks. For persons who can be treated effectively with antidepressant medication, satisfactory symptom remission often is achieved within 4 to 8 weeks. Many patients begin to feel better in 2 to 3 weeks. When the patient reports target symptom relief or the assessment indicates symptom remission has been achieved, the practitioner and patient develop a treatment and discontinuation plan. The duration of medication treatment

for uncomplicated major depression is at a minimum 6 to 12 months at the treatment dose (Level I; Institute for Clinical Systems Improvement, 1996; Michigan Quality Improvement Consortium, 2012; Kaiser Permanente Care Management Institute, 2012). The treatment duration algorithm is available from https://www.icsi.org/_asset/fnhdm3/Depr.pdf. A longer treatment period is recommended for patients with complicated or multiple disorders or patients who have a history of one or more years of untreated depression. In these instances, treatment duration should extend from 15 months to 5 years. Short half-life antidepressants are discontinued gradually over a period of 2 to 3 weeks. Persons who experience significant serotonin withdrawal syndrome may report flu-like symptoms that last a few days. Consultation with a specialist should be considered if withdrawal symptoms appear to be significant or persistent.

Patient Education

It is vital for the provider to teach the patient and significant other(s) to report signs of increased agitation, irritability, and suicidality. Emergency phone numbers (such as crisis services) and tertiary care sites need to be given to the patient and significant others should such symptoms emerge. It has been known for some time that in some cases, starting a severely depressed patient on antidepressants may, after 1 to 2 weeks of treatment, provide the boost in energy needed for the patient to design and carry out a suicide plan. Danger signs and symptoms include the following:

- Hallucinations or delusions
- Severe adverse effects from antidepressant medications (e.g., severe urinary retention, fluctuation in blood pressure, seizures, cardiac complications)
- Suicidal thoughts
- Extreme self-care deficits (e.g., not able to care for basic needs)

The person and his or her family need to understand that depression generates feelings of helplessness, powerlessness, and pessimism; major decisions should be delayed. The practitioner should reassure the patient that current feelings will change. All side effects of drugs should be clearly understood, and the provider should stress the importance of taking medication daily as ordered for maximum effect. The clinician should advise the patient and family that drugs to offset adverse effects are available, or that medication can be changed. Patients should be encouraged to maintain a schedule of activities and to maintain their regularly scheduled visits with their primary-care clinician.

BIPOLAR AND RELATED DISORDERS

Bipolar disorder (BD) is commonly seen in the primary-care setting and is frequently mistaken for other conditions, most commonly major depressive disorder (MDD). The spectrum of bipolar disorder includes bipolar I (BD I), bipolar II (BD II), cyclothymic disorder, substance/medication-induced bipolar, and bipolar and related disorders due to another medical condition. The three major categories—BD I, BD II, and cyclothymic disorder—will be discussed here.

Defining the length of the manic episode helps to differentiate between the various disorders. Patients with BD I have had at least one episode of true mania preceded by or followed by hypomanic or a major depressive episode. BD II is characterized by recurrent depression and hypomania. Cyclomania involves symptoms of hypomania and depression that do not meet the full criteria for any one disorder. Symptom criteria for BD I, BD II, and cyclomania with descriptions of mania and hypomania are presented in Table 18.6.

Clinicians must be able to distinguish between depressive episodes occurring in the context of unipolar depression and bipolar mood disorders because patients suffering from BD require mood-stabilizing pharmacological therapy, and their symptoms may worsen with antidepressant monotherapy. Emerging data from a variety of sources have confirmed a typical delay between symptom onset and diagnosis of 5 to 10 years, with patients seeing an average of four health-care providers before the correct diagnosis is given. MDD is a common misdiagnosis, the treatment for which (e.g., antidepressant monotherapy) may induce mania in BD patients. Over a 5-year period, 85% of patients with BD will have a relapse after one affective episode. During interepisodic periods, half of the patients may experience subsyndromal symptoms, such as cognitive impairment and impulsivity; the length of interepisode intervals progressively diminishes with each recurrence. Inappropriate pharmacological treatment for BD is associated with increases in morbidity and mortality and with suicide. BD is frequently encountered in primary care; therefore, for optimal outcomes, an accurate history, assessment, and diagnosis are required (see Table 18.6).

Epidemiology and Causes

The pathogenesis of bipolar disorder is as yet unknown, but biological, psychological, and social factors are thought to contribute. Depression and BD differ significantly in their genetics, prognosis, and treatment. BD is the sixth leading cause of disability worldwide in patients aged 15 to 55. The financial burden of this disorder eclipses that of diabetes, and the impact on occupational function due to BD is more extensive than in major depressive disorder. Two-thirds of patients with BD are substantially adversely affected by their illness; but the negative impact of BD goes beyond its morbidity rate. Twenty-five percent to 50% of patients with BD have a lifetime risk of suicide attempt; up to 15% of patients will complete the attempt. Suicide attempts can occur in patients in the manic, hypomanic, depressive, and mixed phases of BD but are most likely to occur in patients in a depressive or mixed state.

Table 18.6 Symptom Criteria for BD I, BD II, and Cyclothymic Disorder

BD I: To meet symptom criteria identification of at least one lifetime mania episode must have occurred (see description below). Often mania episodes are preceded by or followed by hypomania or major depressive episodes. A major depressive episode is not required for the diagnosis. Various specifiers can also be included. Refer to the DSM-5 for further information.

BD II: To meet symptom criteria identification of at least one hypomania episode and one major depressive episode must have occurred (see description below). NO history of a mania episode. Various specifiers can also be included. Refer to the DSM-5 for further information.

Cyclothymic Disorder—numerous episodes of depressed mood that do not meet full criteria for major depression, mania, or hypomania that have occurred over a 2-year period for adults or 1 year in children and adolescents. There have been no symptom-free periods for greater than 2 months. Specifier may include anxious distress. These patients have a 15%–50% chance of developing BD I or BD II.

Mania
A distinct period of abnormally elevated or irritable mood lasting at least 7 days and accompanied by either three of the symptoms below with euphoria **or** four of the symptoms below with irritability: grandiosity, psychomotor agitation or an increased involvement in planning or executing multiple activities, high-risk behavior with adverse consequences, a decreased need for sleep, incessant talking or pressured speech, racing thoughts, and distractibility. In addition, the symptoms cause significant functional impairment and are not related to a medical illness, therapeutic drug, or a drug of abuse. May include psychotic features in as many as 50%–80% of patients, but this is not a necessary criterion. Symptoms are marked and often require hospitalization.
Hypomania
A distinct period of persistently elevated, expansive or irritable mood, lasting for at least 4 days, that is clearly different from the usual nondepressed mood. Symptoms can include grandiosity, psychomotor agitation or an increased involvement in planning or executing multiple activities, high-risk behavior with adverse consequences, a decreased need for sleep, incessant talking or pressured speech, racing thoughts, and distractibility. Symptoms are not severe enough to cause marked impairment in occupational or social functioning and do not require hospitalization, but the changes are noticeable by others and clearly differ from the person's baseline functioning. No psychotic features are present, and the symptoms cause significant functional impairment and are not related to a medical illness, therapeutic drug, or a drug of abuse.
Major Depressive Episode
The symptom criteria for major depression state that five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning. At least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure: Depressed mood expressed by the patient as feelings of sadness or hopelessness. Depressed mood may also be reported by significant others and may be reported as tearfulness. These symptoms need to be present nearly every day and for most of each day. Irritability may be the primary symptom in adolescents and children, markedly diminished interest or pleasure (apathy) in most activities, change in appetite nearly every day or a weight loss defined as greater than 5% of body weight loss over a 1-month period, insomnia or hypersomnia, observable behavioral agitation or retardation, loss of energy nearly every day, feelings of worthlessness or guilt, loss of concentration or indecisiveness, recurrent thoughts of death or suicide. The symptoms cause significant functional impairment and are not related to a medical illness, therapeutic drug, or a drug of abuse.

Adapted from American Psychiatric Association. *Diagnostic and statistical manual of mental disorders, fifth edition* (DSM-5). American Psychiatric Association, Arlington, VA, 2013.

BD I has a lifetime prevalence of 1% to 3%; when the entire spectrum of bipolar disorder is included, the prevalence may approach 7% to 10%. Men and women are equally affected, although BD II is more common in women. The mean age of onset of BD I is 18 years of age, and for BD II it is 20 years of age. It can occur in early childhood, adolescence, or as late as the sixth or seventh decade. New onset of mania after age 40 is rare and should prompt consideration of a medical condition, such as frontotemporal neurocognitive disorder, thyroid dysfunction, or substance abuse or withdrawal.

Genetic components appear to play a significant role in transmitting BD II. On average, there is a 10-fold risk for first-degree relatives with MDD; they are 1.5 to 2.5 times more likely to have BD I than first-degree relatives of control subjects. The fact that about 50% of all BD I patients have at least one parent with a mood disorder (most often MDD) further supports inheritability. If one parent has BD I, the child has a 25% chance of developing a mood disorder. When both parents have BD I, the odds of their child developing a mood disorder range from 50% to 75%. Support of the genetic basis of mood disorder is also found in twin and adoption studies, which show a strong genetic component for the inheritance of BD I. It is unknown how culture affects the expression of bipolar disorder. Transcultural validation

of screening tools is unknown and therefore difficult to evaluate.

Pathophysiology and Psychopathology

Depression and mania are affective states on a continuum of mood disorder. As such, many current biological theories of depression also apply to mania. Several genetic variants were associated with bipolar disorder in genome-wide association studies. Clinical consequences of BD have profound effects on the quality of life for patients living with BD. Understanding of the complex gene–environment interactions is likely to emerge in the future and holds great promise for clearer understanding of affective illness.

Clinical Presentation

BD may be viewed as a disorder of "elevated mood" that may manifest itself as euphoria or irritability or dysphoria, characterized by a depressed mood with or without irritability. Approximately 25% of all patients experience episodes of pure mania, 40% demonstrate mixed (dysphoric) mania, and 10% to 25% are called "rapid cyclers," manifesting rapid shifts from mania to depression. Onset of a BD mood episode typically begins with depression. Descriptions of mania, hypomania, and cyclomania are presented in Table 18.6.

Onset of BD occurs in prepubertal years, in adolescence, or in adulthood. An initial manic episode may be related to an adverse life event or stressor; however, subsequent episodes may occur without an identifiable trigger. Seasonal changes may result in fall or winter depression and spring or summer mania. Light exposure may trigger manic episodes. Many women with BD report mood changes related to the menstrual cycle. Manic episodes usually last 3 to 6 months if untreated, and the symptoms typically escalate rapidly during a period of days. Psychotic symptoms may be present in the acute manic phase or in the depressive phase. Psychotic depression should raise an index of suspicion that the patient may have an underlying bipolar disorder. Older adult patients may manifest irritability rather than elated mood. Untreated depressive episodes may last 6 to 12 months, and some treatment-resistant patients suffering from depression may actually have BD. Almost 90% of all persons with BD experience depression, and most BD patients present for treatment during a depressive episode. In *all* patients presenting with depression, clinicians should inquire specifically about symptoms of past manic or hypomanic episodes, past treatment and responses, and family history. Patients may be asymptomatic during interepisode periods.

Over a 5-year period, 85% of patients with BD will have a relapse after one affective episode. Though some patients experience limited functional recovery despite successful syndrome treatment, early intervention is associated with improved outcomes. Most commonly these patients present for treatment for a depressive episode than for the euphoria associated with a manic or hypomanic episode. Only one lifetime manic or hypomanic episode is required for a patient to be diagnosed with BD. Often patients, for a variety of reasons, may leave out this episode when reviewing their medical history and clinicians may fail to query or recognize previous hypomanic or manic symptoms. Some patients may even identify periods of normal mood as depressed when compared with mania.

Diagnostic Reasoning

DSM-5 Symptom Criteria

The DSM-5 symptom criteria for the spectrum of bipolar disorders are presented in Table 18.6.

The following mnemonic, DIGFAST, is useful for identifying BD:

- Distractibility
- Insomnia (decreased need for sleep)
- Grandiosity (inflated self-esteem)
- Flight of ideas (racing thoughts, negative for rumination)
- Activities (increased, goal directed)
- Speech (pressured, increased talkativeness)
- Thoughtlessness (pleasure-seeking activities that show poor judgment such as spending sprees, sexual indiscretions, reckless driving, arguments if irritable)

Differential Diagnosis

Bipolar I

The differential diagnoses to consider are the following: MDD, other bipolar disorder, anxiety disorders, attention-deficit/hyperactivity disorder (ADHD), personality disorders, and substance use. It is essential to obtain a full psychiatric history and also, if the patient consents, to interview family and friends to corroborate information and establish the diagnosis of BD (Level II; Suppers et al, 2001). Patients with mania often lack insight into their symptoms and often do not report them. They feel euphoric during a manic episode and value their productivity during an episode of hypomania. Family members and friends may be able to report historical clues, personal factors, and suicidal ideation that may be associated with increased suicide risk and may point to a diagnosis of BD that the patient has not revealed to any clinician. As part of the history, ask specifically about the onset, frequency, and duration of symptoms, distractibility, seasonality, and other characteristics of a depressed patient's high and low moods, to help differentiate between bipolar and unipolar depression (see Table 18.7).

Bipolar II

In addition to the differential diagnoses listed for BP I, schizophrenia spectrum disorders need to be considered. It is essential to inquire about suicide, because most suicide attempts are associated with depressive episodes or during depressive features of mixed episodes.

Table 18.7 Distinguishing Between Bipolar and Unipolar Depressive Episodes

- Ask all depressed patients about history of mania and hypomania.
- Ask about family history of bipolar disorder—"loaded" family history is a clue to bipolarity in "unipolar" patients.
- Involve family member and/or significant other in screening process.
- Administer a screening instrument for bipolar disorder, such as the Mood Disorder Questionnaire.
- Early age at onset (<25 years) is another clue for bipolarity.
- Psychotic features are another clinical clue for bipolarity in the seemingly unipolar patient, as is seasonal pattern.
- Adverse and/or inadequate antidepressant response such as treatment-emergent hypomania or agitation, erratic or uneven antidepressant responses, multiple antidepressant failures, or "treatment-resistant depression."

Source: Adapted from Hirschfeld, RM, and Vornik, LA: Recognition and diagnosis of bipolar disorder. *J Clin Psychiatry* 65(Suppl 15):5–9, 2004; and Loganathan, M, et al. When to suspect bipolar disorder. *J Fam Pract* 59(12):682–688, 2010.

Cyclothymic Disorder

Differentiating between the various bipolar disorders can be a major challenge, especially in determining the length of previous episodes. In addition, borderline personality disorders and substance-induced disorders need to be considered.

Overall Considerations for All Bipolar Disorders

The two diagnoses most likely to be confused with bipolar disorders are substance abuse and cluster B personality disorders, and there may be comorbidities with these entities. However, in substance abuse, euphoria/dysphoria is temporally related to drug intoxication and withdrawal state. In cluster B personality disorders, "mood swings" last from minutes to hours to days, not weeks to months, and are typically closely associated to interpersonal disruptions or alliances.

Inquire about chronic or recurrent nonspecific physical symptoms (e.g., fatigue, headache, or gastrointestinal distress) and about depressive or manic feelings and behaviors. Consider medical disorders that may coexist or appear similar to BD. Medical disorders to consider are thyroid dysfunction, vasculitis, chronic infection, malignancies, and metabolic disorders. Clinical and laboratory findings may help to exclude these causes. Review family history, particularly of first-degree relatives. Ask about recent medications, including hormonal contraceptives, and about treatment during prior episodes. Evaluate any suspected temporal association between drugs and symptoms because many drugs can induce or exacerbate manic or depressive symptoms. Levodopa and corticosteroids are the most common causes of drug-induced mania; these agents can also cause depressive symptoms.

Patients with BD may choose to self-medicate with drugs and alcohol to relieve anxiety, insomnia, agitation, and excessive fatigue. Drugs, alcohol, and some medications may also contribute to these symptoms. Over half of those patients who meet the criteria for bipolar disorder have an alcohol or substance-use disorder or other mental health disorder, increasing the risk for suicide attempt. Assess the severity, frequency, and longitudinal course of depressive and manic episodes and determine whether the symptoms meet the specific diagnostic criteria for bipolar or another psychiatric disorder. Ask about deterioration in the baseline level of functioning at work or school or in personal relationships.

Patients with BD appear especially sensitive to sleep deprivation, which may occur in conjunction with stressors such as bereavement, childbirth, vacation, longer work hours, and shift changes. They may experience periods of decreased need for sleep. Specific details about sleep–wake periods, including daytime naps, meal times, social activities, hobbies and other areas of interest, interpersonal attitudes, and ability to work and perform household tasks are helpful. Inquire about a typical day.

Patients with mania or depression usually do not report characteristic psychological descriptors (e.g., elation, grandiosity, inflated self-esteem, racing thoughts, irritability or agitation), so activities may provide diagnostic clues. For example, grandiose thinking may manifest as reckless gambling, spending sprees, or sexual promiscuity. Conversely, increased productivity, enhanced perceptual ability, altered view on interpersonal relationships, and fluctuating symptoms without substantial negative social or occupational consequences suggest hypomania.

Routine screening for depression is advised in primary-care settings, but little attention has been focused on screening for past episodes of hypomania or mania. The Mood Disorder Questionnaire (MDQ) is a validated screening tool for BD (Fig. 18.1). The likelihood of underdiagnosis or a missed diagnosis is greatly lessened by the routine use of a screening instrument such as the MDQ. Use of the MDQ can identify 70% of persons with BD while eliminating the diagnosis for 90% of persons without the predilection. More recently, there has been some question whether the MDQ may underdiagnose BD II disorder because of the requirement for moderate to severe impairment of functioning as many patients feel that during a hypomanic episode they actually function better. The Bipolar Spectrum Diagnostic Scale is better for ruling out the diagnosis of BD than for giving a positive diagnosis. If a patient scores positive for BD on this scale, further clinical evaluation is necessary to make the diagnosis.

Always assess for suicide risk. It is essential to inquire about suicide ideation and intentions, and about extent of plans or preparations for, prior attempts at, family history of, and recent exposure to suicide. This is essential

1. Has there ever been a period of time when you were not your usual self and...	YES	NO
...you felt so good or so hyper that other people thought you were not your normal self, or you were so hyper that you got into trouble?	❑	❑
...you were so irritable that you shouted at people or started fights or arguments?	❑	❑
...you felt much more self-confident than usual?	❑	❑
...you got much less sleep than usual and found that you didn't really miss it?	❑	❑
...you were much more talkative or spoke faster than usual?	❑	❑
...thoughts raced through your head or you couldn't slow your mind down?	❑	❑
...you were so easily distracted by things around you that you had trouble concentrating or staying on track?	❑	❑
...you had much more energy than usual?	❑	❑
...you were much more active or did many more things than usual?	❑	❑
...you were much more social or outgoing than usual; for example, you telephoned friends in the middle of the night?	❑	❑
...you were much more interested in sex than usual?	❑	❑
...you did things that were unusual for you or that other people might have thought were excessive, foolish, or risky?	❑	❑
...spending money got you or your family into trouble?	❑	❑

2. If you checked YES to more than one of the above, have several of these ever happened during the same period of time? ***Please circle one response only.***

YES **NO**

3. How much of a problem did any of these cause you — like being unable to work; having family, money, or legal troubles; getting into arguments or fights? ***Please circle one response only.***

No problem **Minor problem** **Moderate problem** **Serious problem**

Figure 18.1 The Mood Disorder Questionnaire (MDQ). *(Source: Hirschfeld, RM, et al. Development and validation of a screening instrument for bipolar spectrum disorder: The Mood Disorder Questionnaire.* Am J Psychiatry *157:1873–1875, 2000).*

both at presentation and during subsequent mood episodes because the lifetime risk for suicide in patients with BD is up to 15%. Most suicide attempts are associated with depressive episodes or during depressive features of mixed episodes.

Diagnostic Work-up

A complete physical exam is needed, as well as a neurological assessment to exclude other etiologies of mood symptoms or psychosis. The patient's mental status should be assessed, including general appearance, attitude, behaviors, mood, affect, speech, thought processes and content, concentration, and memory. Focus the physical and neurological exam (cranial nerves, reflexes, muscle tone, gait) on identifying or excluding a medical cause of the patient's symptoms, comorbidity, and the possibility of precipitating factors such as thyroid disorder, head injuries, or substance abuse.

Diagnostic testing may include a complete blood count (CBC) with differential, platelet count, comprehensive blood chemistry panel, thyroxine (T_4), thyroid-stimulating hormone (TSH), rapid plasma reagin (RPR), HIV antibody test, urinalysis, urine toxicology screen, and pregnancy test. In the setting of HIV/AIDS, hepatitis C, and other infectious causes, new-onset mood or bipolar-like symptoms require further studies to exclude organic causes of mood changes. Consider conducting a Mini-Mental State Exam to assess cognition. Refer to neurology or infectious disease to assist with diagnosis if indicated. Brain magnetic resonance imaging (MRI) or computed tomography (CT) scans may be helpful if clinical findings suggest an underlying organic central nervous system (CNS) disorder.

Management

Pharmacological Management

The ideal treatment goal for patients with BD is complete remission of current symptoms, prevention of future affective episodes, and return to premorbid function.

Mainstays of therapy are mood-stabilizing medications. Drug therapy is used to achieve symptom remission and return function in patient with BD. Mood stabilizers, second generation antipsychotics, first generation antipsychotics, and adjunctive anxiolytics and antidepressants are used to treat BD. Factors in determining which medication will most likely result in treatment remission depend on the diagnosis—BD I or BD II, manic versus depressed, acute or maintenance, rapid cycling versus nonrapid cycling, and whether psychotic symptoms exist. Attempts should be made to use the lowest possible dose to minimize side effects, particularly with first generation agents.

Considerations before initiating therapy include the patient's age, because the elderly may be more sensitive to side effects of antipsychotic medications. It is essential to prescribe the lowest possible dose and monitor for side effects. Always consider the possibility of pregnancy in women of childbearing age before initiating psychotropic medications. Knowledge of past treatment history, effectiveness, tolerability, failures, and side effect profiles allows the practitioner to provide individualized, patient-centered care. It is likely there will be a need to change treatment modalities over time. Several weeks are required to assess the effects of a new treatment.

Collaboration with a psychiatrist will aid the clinician in selecting appropriate drug therapy to treat acute manic episodes in patients with BD (Levels I, II; Akiskal et al, 2005). The mainstays of BD drug treatment are those with mood-stabilizing properties. Treatment options for patients with BD I and acute hypomania, mania, or mixed episodes should begin with lithium, valproic acid (Depakote), or antipsychotic agents. Carbamazepine (Tegretol) or oxcarbazepine (Trileptal) may also be used. If there is no response or a partial response, combination therapy such as lithium plus valproic acid, lithium plus an atypical antipsychotic, or an atypical antipsychotic plus valproic acid may be considered. If still not effective, clozapine (Clozaril) may be added or electroconvulsive therapy (ECT) may be introduced.

It is important that lithium be prescribed at a therapeutic dose. Valproic acid is now usually preferred, however, for patients with multiple manic episodes, mixed episodes, and rapid cycling. Carbamazepine, another anticonvulsant agent, is a good alternative. Combinations of these agents may be used if patients do not respond to a single agent. If the patient does not respond fully, atypical antipsychotics may be added to one or more mood stabilizers. Lamotrigine (Lamictal) has proved particularly effective for rapid cycling, particularly in patients with severe depression. Lamotrigine should not be initiated in primary care. Long-acting benzodiazepines, such as clonazepam and lorazepam, may be used for rapid treatment of manic symptoms and to calm and sedate patients until acute mania or hypomania has subsided and the mood stabilizer has taken effect. In the case of psychotic symptoms, antipsychotics may be added. ECT may be used for patients with severe BD with drug treatment–resistant mania or psychotic depression.

Episodes of depression pose particular challenges. There are fewer approved treatments for bipolar depression. Overall, antidepressant medications do not control depression as effectively in bipolar as in unipolar depression and may trigger mania. Mood stabilization is still the primary goal, however, and mood stabilization therapy (lithium, carbamazepine, and valproic acid) should be optimized (in the case of lithium, serum level of 0.8 mEq/L or above) before starting antidepressant therapy. If depression persists 2 to 4 weeks after optimization of the mood stabilizer, it is recommended that either bupropion (antidepressant), lamotrigine (anticonvulsant, mood stabilizer), or an SSRI (antidepressant) should be added. These agents are not mood stabilizers. They are effective against depression but can precipitate mania and should not be given to a bipolar patient without a transitional mood stabilizer. Venlafaxine may also be useful in some cases of severe depression that have not responded to other therapy. Any patient developing symptoms of hypomania while taking an antidepressant should stop taking it; in addition, he or she should be slowly tapered after a period of sustained remission. Severely depressed or delusional patients may benefit from an antipsychotic.

Lithium remains the gold standard for treatment of BD and has been shown to be uniquely effective in decreasing suicidal behavior. Lithium appears to be most effective early in the course of the illness, for classic manic symptoms, in patients in whom depression immediately follows mania, and in patients with a strong family history of BD. However, lithium also has a number of potential adverse effects, including a life-threatening neurotoxicity that can occur at serum levels higher than 2.0 mEq/L. Lithium levels should be obtained twice weekly until the patient's clinical status and levels are stable at which time they may be obtained every 1 to 3 months. Serum trough lithium levels are drawn 8 to 12 hours after the last dose.

Adverse drug interactions can occur with such commonly used drugs as thiazide diuretics, NSAIDs, angiotensin-converting enzyme (ACE) inhibitors, diltiazem (Cardizem), verapamil (Calan, Verelan), and antipsychotics. Additional potential adverse effects include nausea, diarrhea, tremor, polyuria, and polydipsia. Lithium may exacerbate psoriasis and acne, cause hypothyroidism (5% to 35%), and in 20% of patients (usually after 15 or more years of treatment) lead to renal insufficiency. Lithium takes several weeks to become effective and may contribute to weight gain of at least 7% of baseline. Owing to potential adverse effects, lithium therapy should be preceded by an evaluation of renal, cardiac, and thyroid function, as well as a pregnancy test. Most patients demonstrate residual symptoms during maintenance therapy. If depression persists,

the patient may need an adjunctive antidepressant. Many patients do not stay on lithium. Some regret the loss of the exhilaration that occurs during a manic episode; some patients are concerned about weight gain or tremor. In one study, 50% of patients acknowledged some degree of medication nonadherence in the previous 2 years, and 32% reported only partial adherence in the preceding month.

Anticonvulsant medications are not mood stabilizers; however, some of these agents have proven effective for the treatment and/or maintenance of mania and/or BD. These agents have become alternative treatments for patients who need a mood-stabilizing agent but who do not fare well with lithium; additionally, these medications also may be used in combination with lithium. Anticonvulsant agents work by enhancing the inhibitory activity of the neurotransmitter gamma-aminobutyric acid (GABA).

Divalproex/valproic acid is considered first-line pharmacological treatment for acute mania or mixed episodes and maintenance. There is some evidence of antidepressant effect as well. Divalproex appears to be most effective for rapid cycling and mixed episodes, in patients who have had more than three manic episodes, and in patients with comorbid alcohol abuse. Valproic acid is comparable to lithium, and generally better tolerated, during the maintenance period. The most frequently observed side effects when valproic acid is used in the treatment of acute mania are nausea, vomiting, weight gain, tremor, dizziness, and sedation. Serious adverse effects include hepatotoxicity, pancreatitis, thrombocytopenia, and teratogenicity. Serum valproate levels, liver function tests, and CBCs should be monitored closely during treatment with valproic acid.

Valproic acid is a cytochrome 450 enzyme inhibitor and may engender metabolic interaction with other drugs. Valproic acid can induce menstrual irregularities and a higher risk for polycystic ovary syndrome (PCOS), which affects 2% to 7% of women in their reproductive years and is characterized by chronic anovulation and hyperandrogenism.

Carbamazepine is approved for the treatment of acute mania and mixed episodes associated with bipolar disorder. Therapeutic serum levels for BD have not been established; usually concentrations used for seizure disorders (4–12 mcg/mL) are applied. Serum levels as well as CBC, platelets, and liver function must all be monitored as potential side effects include agranulocytosis, aplastic anemia, hepatic failure, Stevens-Johnson syndrome, and pancreatitis. Carbamazepine reduces levels of other drugs, however, such as oral contraceptives and dihydropyridine calcium-channel blockers.

Lamotrigine received approval as maintenance therapy for BD in 2003. This agent appears to have antidepressant effects and has been found to be effective in rapid-cycling BD. The most significant adverse effects are Stevens-Johnson syndrome and toxic epidermal necrolysis, both of which can be fatal.

Typical antipsychotic agents such as haloperidol (Haldol) have been frequently used to treat bipolar mania as a class. These agents work well in reducing symptoms such as paranoia, hallucinations, delusions, and thought disturbances. However, they have not been studied for efficacy in treating BD and carry the risk of extrapyramidal symptoms (EPS), such as akathisia, dystonia, torticollis, parkinsonism, and tardive dyskinesia.

Newer second generation, or atypical, antipsychotics have a lower propensity to induce EPS. Both classes of drugs block dopaminergic transmission, but the newer drugs also act through various receptors such as dopamine, histamine, and alpha-adrenergic. These are standard agents for schizophrenia and are approved for use as monotherapy for mania and with mood stabilizers. See the section of this chapter on psychotic disorders for further discussion of typical and atypical antipsychotics.

Maintenance drug therapy should be based on the patient's response to initial treatment and in conjunction with a psychiatrist. Patients at high risk for recurrence should consider lifelong therapy, generally with mood stabilizers. Lithium and valproic acid are first-line agents used in maintenance therapy, alone and in combination. Although there are some differences in side effects, the dropout rates are similar, and both agents demonstrate equal effectiveness. Carbamazepine may be used as an alternative.

Adjunctive drug therapy should be considered for comorbid disorders. For example, if a patient with BD is compliant with medication yet has persistent symptoms, he or she may have a concurrent anxiety or substance use disorder. Antidepressants with mood stabilizers or antipsychotics as adjunctive agents may be used for treatment of depression. If a patient is persistently anxious, most psychiatrists will assess for a mixed state, occult substance abuse, or a medical condition. In summary, management options are based on the patients' primary symptoms of mania, depression, or mixed states (see Table 18.8). In addition, treatment algorithms can be accessed at www.dshs.state.tx.us/mhprograms/pdf/TIMABDman2007.pdf.

Nonpharmacological Management

Patients living with BD may have difficulty discussing unusual events or thoughts and often have poor insight regarding symptoms or the need for treatment. They respond best to proactive, collaborative, and individualized treatment, as exemplified in the *Circle of Caring* model. Developing a therapeutic alliance is imperative, because BD is chronic and needs long-term management. Establishing a trusting relationship with a medical home will provide patients the opportunity to experience continuity of care, to attend to health maintenance and any chronic medical problems, and to maintain a collaborative connection with their behavioral health providers and supports.

Obtain a consultation with a psychiatrist if you suspect BD once you have excluded medical etiologies. Accurate

Table 18.8 Management of Bipolar Disorder

Symptomatology—Manic/Mixed	Management Strategies
First-line	Lithium plus an antipsychotic Valproate plus an antipsychotic (Second generation antipsychotics are preferable) Carbamazepine Electroconvulsive therapy (may be used if preferred by the patient, patients with severe illness, or if patient is pregnant) For less ill patients, monotherapy with lithium, valproate, or an antipsychotic may be preferable
Adjunctive treatments	Benzodiazepine Gabapentin Topiramate
Nonresponse	Optimize the initial medication dose Add or change mood-stabilizing drug Add or change antipsychotic Add lamotrigine
Symptomatology—Depressed	**Management Strategies**
First-line	Lithium or lamotrigine Electroconvulsive therapy (for patients with life-threatening inanition, suicidality, or psychosis; severe depression/pregnancy)
Nonresponse	Optimize the initial medication dose Add another mood stabilizer Add an antipsychotic Add an antidepressant Electroconvulsive therapy

Source: Adapted from American Psychiatric Association. *Diagnostic and statistical manual of mental disorders, fifth edition* (DSM-5). American Psychiatric Association, Arlington, VA, 2013; and St. John, D. Bipolar affective disorder. *Clin Rev* 15(6):47, 2013.

diagnosis can be complicated because other psychiatric disorders may appear similar. Consultation will provide clinicians with a more accurate diagnosis as well as assistance with managing pharmacological regimens and acute crisis should it be necessary. Consider referral to an integrated treatment provider for dual-diagnosed patients with substance and/or alcohol dependence. Hospitalization is necessary for patients with BD who may be a danger to themselves or others or who are unable to care for their needs. Patients with mood disorders, particularly mania, are often unwilling to enter a hospital voluntarily and may require involuntary commitment.

A supportive primary-care provider can help in monitoring the patient's overall status, as well as encouraging adherence to the medication regimen. The clinician can also provide referral for specific psychosocial interventions for patients with BD (Levels I, II; Miklowitz et al, 2003; Colom et al, 2003). Along with a psychiatrist, a behavioral health specialist may aid recovery by relieving depression, delaying episodes, and improving function and treatment adherence. Psychoeducation is aimed at providing information about BD and treatment and is an important resource for patients, families, and supports. The goals of psychoeducation are to increase knowledge and acceptance of the disorder and to address denial and nonadherence to the treatment plan. Meta-analysis has shown that patient education combined with drug treatment helps to improve adherence (Level II; Gonzalez-Pinto et al, 2004).

Psychotherapy, although not effective as monotherapy, can significantly enhance treatment response and prevent relapse. Interpersonal, family-focused, cognitive-behavioral, supportive, and psychoeducational approaches increase illness awareness, improve collaboration with health-care professionals and supportive family and friends, and may assist in lifestyle regulation. There is good evidence that cognitive-behavioral therapy (CBT) protects against relapse. CBT has proved efficacious, resulting in greater acute treatment response and supporting greater maintenance of treatment gains.

The onset of manic and depressive episodes is often associated with psychosocial stress. Patients should be encouraged to pace their activities at work and to maintain a regular schedule. A change in sleep patterns often heralds the onset of a manic or depressive episode. Insomnia may be a precipitant or a prodromal warning sign. Maintenance of regular sleep habits helps prevent escalation of mood symptoms into a full-blown episode. Educate BD patients and their families about the risks of stress, substance abuse, and irregular and inconsistent sleep patterns, meals, and other daily habits.

Follow-up and Referral

Education is a key component to effective adherence to therapy and to family support. Open discussion of all treatment options, side effects, and their management is critical and is a hallmark of patient-centered care. Monitoring and managing symptoms over time, including triggers and early warning signs, is essential. Self-monitoring and better symptom recognition are desirable goals. The prevalence of nonadherence with mood stabilizers ranges from 18% to 52%. Reasons include denial of diagnosis, unwillingness to take medication long term, perceived improvement in health, and adverse side effects of medications. Patient adherence to the

medication regimen can make a difference in patient outcomes. In one 18-month study, 81% of partially adherent patients required hospitalization versus just 9% of adherent patients. Patients may ask if they will need to continue taking the same medication for life. The specific medications prescribed may change as new agents are introduced and as the individual's treatment needs are reassessed. What will remain constant is the need to monitor the patient with BD over his or her lifetime.

The practitioner can help the patient and family develop realistic treatment goals by actively listening and being responsive to patient needs and by regularly addressing mixed feelings about adherence to treatment. Patients with BD struggle with a variety of interpersonal and/or occupational issues. As stabilization management and supervision are lessened after an acute affective episode, patient attendance at follow-ups may decrease. During this postacute period, intensive collaboration with the patient and family can be invaluable for establishing the framework for long-term interactions that build on the therapeutic *Circle of Caring*.

Involvement of family and friends is critical to successful follow-up because progression of BD may be difficult to validate via self-report. Sensitivity to early warning signs of potential mood destabilization is important. Many patients do not try to achieve treatment goals. Symptoms of illness often preclude sound judgment, and patient unwillingness to tolerate medication side effects are some of the causes of apparent nonadherence.

Regularly reviewing with the patient "quality of life" versus "effects of treatment" and emphasizing the improved prognosis associated with maintenance therapy may improve medication compliance. CBT, family therapy, or interpersonal therapy should all target self-monitoring, treatment adherence, communication skills, and coping strategies to complement pharmacotherapy.

If a patient presents with early manifestations of relapse, promptly assess the clinical scenario and review the drug regimen. It is essential to investigate possible medication nonadherence, drug–drug interaction, and substance use and to obtain a drug level before initiating a change in the current regimen. If the cause of relapse is unclear or the symptoms fail to respond to standard treatment, a psychiatrist should be consulted. Periodically the patient should be reevaluated for known or new medical conditions or medication use that may complicate management; at every encounter, he or she should also be assessed for suicide risk.

Patient and Family Education

Educate the family and patient about the nature of bipolar illness and about the importance of medication compliance, regular visits for clinical and laboratory monitoring, and contacting their health-care provider before stopping or starting any medication (prescribed or over the counter). Patients should avoid complementary therapies such as St. John's wort, because they may interfere with some psychotropics. Educating the patient and family about potential side effects of all medications is important, as is informing them of the many options available to minimize or eliminate side effects. Patients and their families need to understand the importance of maintaining adequate blood levels of medication in prevention of relapse and of contacting the health-care provider in the event of unpleasant side effects rather than stopping the medication.

At follow-up visits, the practitioner can counsel the patient and family about coping with stressors that may precipitate manic or depressive episodes, about maintaining a consistent lifestyle, about signs of relapse, and about medication adherence. Written patient instructions can reinforce the following recommendations:

- Limit "everyday" stimulants such as coffee, alcohol, and over-the-counter medications that contain these substances because they can trigger mood episodes.
- Maintain regular sleep patterns.
- Avoid taking unnecessary or illegal drugs because they can trigger mood episodes; they can also prevent the benefits or increase the adverse side effects of necessary medications.
- Try to maintain a regular work schedule. If necessary, take time off rather than "tough it out" if mood symptoms hinder your ability to work.

As patients learn more about the stress of their illness on family members, it may help them reduce both their own stress and the disruption that it can cause. Patients may develop such insights by learning more about bipolar illness and by joining a bipolar support group or a mental health organization for lay people. Educate patients and families to watch for early signs of relapse, including changes in sleep patterns, grooming habits, energy or sexual interest, concentration problems, mood instability, or changes in self-esteem. Most patients experience a change in sleep patterns early in the development of an episode of mania or depression. Even small amounts of stimulants may interfere with sleep patterns or mood and possibly trigger a relapse. Insomnia may be either a precipitant or a warning sign. Early recognition of these signals, promptly followed by contacting the primary-care provider, can help prevent relapse. Maintenance of regular sleep patterns (including a prescription for benzodiazepine to promote regular sleep patterns) may prevent escalation of early symptoms into full episodes.

BD patients tend to minimize their limitations and vulnerabilities and may decide to discontinue treatment. There should be an individual action plan for coping and seeking assistance whenever the patient or family members suspect the patient is experiencing early manifestations of relapse. Knowing their assigned roles in the patient's action plan may be an important resource when the patient is tempted to stop therapy. They should feel free to contact their psychiatrist, counselor,

or primary-care provider for advice whenever necessary, especially in light of self-destructive, aggressive behavior or any changes in daily routine that cause concern.

ACUTE SUICIDE RISK

Annually, more than 30,000 Americans complete a suicide. *Completed suicide* refers to self-inflicted death; *attempted suicide* refers to potentially lethal acts that do not result in death and nonlethal, attention-seeking gestures such as superficial cuts on wrists. Each person who attempts suicide is unique, but if there is a shared personal characteristic, it is likely to be a profound sense of hopelessness—hopelessness in the sense that the individual perceives there is no future, or that the future that he or she envisions is somehow unacceptable. Suicidal patients may be angry, sad, or confused. They may be quite honest about their suicidal plans or may refuse to disclose their true thoughts and feelings. Suicidal thoughts and feelings commonly are associated with mood disorders, principally BD, schizophrenia, and alcoholism. Persons who are overwhelmed by severe psychosocial problems and/or medical problems may also experience suicidal thoughts. Suicidal thoughts can have an acute onset, meaning that for a period of time, the person is at risk for acting on thoughts of suicide. Chronic suicidal thoughts are also common. In this case, the person never feels completely free of thoughts of taking his or her life. Impulsive suicidal behavior is the most difficult to assess, in that—by definition—this type of suicidal behavior is likely to occur without warning. Patients who are troubled by thoughts of suicide but are clear about their determination not to act on their suicidal thoughts may be appropriate candidates for primary-care management. For example, a patient who is in a great deal of pain associated with a serious physical illness may develop acute suicidal thoughts when overwhelmed by physical pain. Any suggestion of impulsive or chronic suicidal thoughts or evidence of actual suicidal behavior is an indicator for emergent evaluation by a specialist. (See The Patient's Voice 18.1.)

The Patient's Voice 18.1

The suffering of the suicidal is private and inexpressible, leaving family members, friends, and colleagues to deal with an almost unfathomable kind of loss, as well as guilt. Suicide carries in its aftermath a level of confusion and devastation that is, for the most part, beyond description.

Kay Redfield Jamison

Epidemiology and Causes

Suicide is the eleventh leading cause of death in the United States and the fourth leading cause of death among adolescents and young adults. Every 17 minutes another life is lost to suicide, as every day 86 Americans take their own lives and more than 1,500 attempt suicide. For every two victims of homicide in the United States, there are three deaths from suicide, and there are now twice as many deaths due to suicide than due to HIV/AIDS. More than half of all suicides occur in adult men aged 25 to 65. In the month before their suicide, 75% of elderly persons had visited a physician. Males are four times more likely to die from suicide than are females, and sadly, many who make suicide attempts never seek professional care immediately after the attempt. About 10% to 20% of all persons who attempt suicide eventually take their own lives.

Older white men who are widowed or unmarried have the highest suicide rate, as they are most likely to commit suicide with a firearm. Usually these men are living alone and lack social support. Unemployment, a fall in economic status, medical illness, family history, previous suicide attempt, and anniversary of a loss are all risk factors for suicide. Males are three times more likely than females to successfully complete a suicide, although elderly women (75 and older) account for 20% of the suicide deaths among those 65 and older; this number is expected to rise as the population of older women increases. Single and widowed persons of both sexes have a higher incidence of suicide. Adolescent (15–24 years) and geriatric (65 years and older) populations are at highest risk, especially Native Americans and Caucasian males. Attempted suicide is 10 times more frequent than completed suicide. One study indicated that 91% of suicide acts involving firearms result in death, whereas drug overdoses—thought the most common method—lead to fatality only 2% of the time. Fatality rates associated with drowning were found to be 84%; hanging, 82%; and poisoning with gases, 64%. The prime suicide site of the world is the Golden Gate Bridge in San Francisco.

Special at-risk occupations include physicians (especially women physicians and/or psychiatrists), musicians, dentists, law enforcement officers, firefighters, lawyers, and insurance agents. Thirty-two percent of persons who commit suicide have sought medical attention within the prior 6 months. A number of CNS diseases increase the risk of suicide, specifically, epilepsy, multiple sclerosis, head injury, cardiovascular disease, Huntington's disease, dementia, and AIDS. All of these diseases are associated with mood disorders. Loss of mobility, disfigurement, and intractable pain are also associated with an increased risk of suicide. Certain drugs such as reserpine (Serpasil), corticosteroids, antihypertensive agents, and some antineoplastic agents can produce depression that may lead to suicide.

Pathophysiology

It is well documented that suicidal behavior, like other psychiatric disorders, tends to run in families. A family history of suicide increases the risk of attempted suicide and of completed suicide in most diagnostic groups. Twin studies suggest a genetic component in suicide. Over several studies, monozygotic twin pairs had a significantly

higher concordance for both attempted and completed suicide than dizygotic twins did. Danish American adoption studies also yielded strong evidence that adoptees who had committed suicide had, on further investigations, a strong family history in biological relatives compared with no evidence of suicide in the adopting relatives. A further study of adoptees with mood disorders demonstrated that adoptee suicide completers with a situational crisis or impulsive suicide attempt, or particularly both, had more biological relatives who had committed suicide than controls had. It was suggested that the genetic factors lowering the threshold for suicidal behavior may lead to an inability to control impulsive behavior. Environmental stress, or the presence of a psychiatric disorder, may be a potentiating mechanism that triggers or fosters the impulsive behavior in the direction of suicide. The risk for suicide in patients with mental disorders is highest for those diagnosed with mood disorder.

Clinical Presentation

Clinicians must assess an individual patient's risk for suicide on the basis of clinical examination. Acute risk factors may include severe psychic anxiety, anxious ruminations, global insomnia, depression with delusions, and recent alcohol or other substance use. Suicidal behavior is multidimensional, with complex factors contributing to the overall risk of a future suicide attempt. Suicide screening tools often focus on previous attempts or intent to commit suicide, with various supportive items such as demographic information, level of social support, and coexisting mental health disorders. Because the goal of a suicide scale is to prevent completion, the sensitivity of the scale must be high so as not to miss a potential suicide. The risk of high sensitivity is overidentification of potential attempts. The Modified SAD PERSONAS Scale (see Risk Factors 18.3) has an administration time of 1 to 2 minutes, and the authors recommend this as a rapid screening tool for nonpsychiatrists to obtain the objective information necessary to make an initial assessment of suicidality.

Hopelessness about the future is a "red flag" for possible suicidal intent, as well as suicidal thoughts, especially if accompanied by a plan and intent. Giving away personal possessions, quitting a job, and an appearance of peace may all signal that the person has made the

Risk Factors 18.3 Acute Suicide Risk

The mnemonic "SAD PERSONAS" (Campbell, 2004; Patterson, 1983) may be used to evaluate a person's suicide risk. Consider risk factors within the context of the clinical presentation.

- S = Sex
- A = Age
- D = Depression
- P = Previous attempt
- E = Ethanol abuse
- R = Rational thinking loss
- S = Social support loss
- O = Organized plan
- N = No spouse
- A = Availability of lethal means
- S = Sickness

The following table presents a detailed description of acute suicide risk factors.

Gender	Males complete suicide (about one-half kill themselves using a gun) at a 3:1 ratio compared with females. Females are more likely to attempt suicide (usually by overdose) and act impulsively without warning than males.
Age	The risk of suicide increases with age, with persons aged 65 and older being more likely than younger persons to take their own lives (women peak at age 55; men at age 75). Older adults tend to use more lethal means and are less likely to voice their suicidal intent to others. Bereavement, social isolation, and deteriorating health status are thought to contribute to the high suicide rate in this group. Recent trends indicate that the suicide rate among young persons, aged 25–34, is increasing. Adolescents are a high-risk group, with suicide the second leading cause of death in this group. Gay adolescents who have been the victims of hate crimes or bullying, who fear social rejection, or who are socially isolated can be at increased risk for developing suicidal thoughts.

Continued

Risk Factors 18.3 Acute Suicide Risk—cont'd

Race and Ethnicity	Caucasians are at the greatest risk for suicide; however, suicide is one of the leading causes of premature death in minority groups.
Employment Status	Unemployed persons are at higher risk, although social class has not been shown to correlate strongly with increased risk for suicide.
Marital Status	Single, divorced, and widowed persons are at a significantly higher risk.
Immigration Status	Persons who migrate within the United States are at higher risk for suicide, as are those who immigrate to the United States. Social isolation appears to be a significant risk factor for immigrants.
Substance Abuse Problems	Persons with alcohol and drug problems are at extremely high risk for suicide, particularly when their substance abuse is complicated by other risk factors. More than one-third of persons who take their own lives are intoxicated at the time of their deaths. Alcoholism and substance abuse problems of a chronic nature account for 25% of all completed suicides.
Comorbidities	Major depression and bipolar disorders account for approximately 50% of all suicides. Schizophrenia and other psychotic disorders account for approximately 10% of completed suicides. Seventy percent of patients with borderline personality disorder will have at least one suicide attempt.
Medical Conditions	Chronic, life-threatening, or painful physical illness is associated with increased risk for suicide. Specific high-risk illnesses include AIDS, Huntington's disease, cancer, peptic ulcer, spinal cord injury, head injury, renal disease requiring dialysis, chronic intractable pain, uncontrolled diabetes with amputation, multiple sclerosis, numerous psychosomatic illnesses.
Medications	Certain medications increase suicidal risk: Steroids, antihypertensives (reserpine, methyldopa, clonidine), corticosteroids, opiates, antituberculosis drugs (isoniazid, ethionamide, cycloserine), anabolic steroid withdrawal, barbiturates, benzodiazepines, antidepressants, cocaine and amphetamine withdrawal.
Other	Additional suicide risk factors include recent bereavement, legal and financial problems, recent arrest or impending court dates, and being a victim of abuse or sexual assault.

*Campbell, WH. Pearls: Revised "SAD PERSONS" helps assess suicide risk. *Curr Psychiatry* 13:3, 2004.

decision to commit suicide. Self-mutilation, suicide threats and attempts, hallucinations, and delusions all indicate high risk for suicide.

Patients who are suicidal may state their intentions, but many will find it hard to volunteer this information. The impulsive person will often appear to be so and will give information that shows a great deal of recent poor judgment. The determined person may refuse to answer questions or may give information freely, thinking that his or her plan cannot be interfered with. The confused patient is more likely to seem unable to protect himself or herself from harm. Confused patients include persons suffering from auditory hallucinations instructing them to commit suicide and patients who are under the influence of drugs and alcohol. Suicidal patients may also express extreme anger and rage and may also have thoughts of homicide, as though taking their own life permits them to consider taking someone else's life first.

Management

Suicide prevention is carried out at two levels—interpersonal and community. Interpersonal prevention includes risk assessment, intervention (e.g., medications, counseling, hospitalization), and referral to a specialist. Community prevention is based on the crisis model of 24-hour community hotline services and walk-in crisis counseling services. Crisis counseling services should include a crisis response team that is dispatched immediately to schools or locations where assistance may be needed. These response teams can intervene to reduce the risk of suicide contracts among peers or "copycat" suicides. One systematic review found that physician education and programs to reduce access to lethal means (especially firearms) were effective in reducing the risk of suicide. In 2001, the Surgeon General organized the National Strategy of Suicide Prevention, under the auspices of the National Institutes of Health (NIH). Because suicide is such a serious public health problem, the *National Strategy* proposes public health methods to address it. The public health approach to suicide prevention represents a rational and organized way to marshal prevention efforts and ensure that they are effective. Only within the last few decades has a public health approach to suicide prevention emerged

with good understanding of the biological and psychosocial factors that contribute to suicidal behaviors. Its five basic steps are to clearly define the problem; identify risk and protective factors; develop and test interventions; implement interventions; and evaluate effectiveness.

Careful assessment of suicide risk factors, willingness to consult with other practitioners and specialists, and planning are the hallmarks of effective suicide risk management. Most completed suicides are associated with psychiatric disorders, and the combination of depression and use of alcohol or other substance abuse is strongly correlated with suicide attempts. Assess suicidal ideation, intent, and risk to determine the severity of depression (Level II; Institute for Clinical Systems Improvement, 2012).

The assessment should cover the patient's recent personal history and pay special attention to recent stressful life events and changes in mental status. Reports of recent losses, humiliations, demoralizing experiences, substance use and abuse, and relationship problems should be explored. Persons who have been abusing drugs and/or alcohol can suddenly become highly motivated to end their lives when they first realize that they are no longer in control of their substance use. Even a person who is recovering from substance abuse and has stopped using the substance can be at high risk for suicide when faced with the painful consequences of substance abuse, including withdrawal or severe drug cravings.

All suicidal statements should be considered *seriously,* but no one can predict the actual behaviors of a suicidal patient. One of the most valuable assessment tools for practitioners is the willingness to question a patient directly about his or her suicide risk. Two good general questions are "How long can you go on the way you are?" and "Are you feeling so badly that you sometimes wish you could go to bed and not wake up?" Examples of more specific questions are "What is your plan for suicide?" and "Have you assembled what you need?" Suicide plans are assessed on their *specificity, availability,* and *lethality* (SAL): The more specific and detailed the plan and the more available and lethal the method, the higher the risk of suicide.

Once it is determined that the patient is suicidal, the level of risk will determine the direction of the intervention. A major decision to be made is whether the patient needs to be hospitalized. The absence of a strong social support system, history of impulsive behavior, a suicidal plan of action, or the availability of weapons are indications for hospitalization. If hospitalization is deemed necessary but the patient has no way of getting there, or if he or she refuses to go, it will be necessary to call 911 to dispatch someone from the police or sheriff's department to escort the patient to the hospital. The primary goal of the intervention is to maintain the patient's safety. Therefore, the following considerations are important:

- Reduce or eliminate imminent danger.
- Never leave a patient alone who is actively suicidal.
- Involve family members or significant others who care so that they can stay with the patient until the crisis has passed.

The best predictor of suicide risk is a history of previous suicide attempt. All persons with suicide gestures, attempts, and threats should be thoroughly screened for suicide risk factors and referred to a specialist for a full mental status exam, as well as psychiatric consultation. It is important to diagnose and treat any underlying psychiatric and/or substance-abuse disorders. The clinician and the patient's family or significant others should ensure the patient's safety by the least restrictive method, starting with removing potentially lethal objects and providing very close supervision. Some patients at acute high risk will require inpatient hospitalization for constant one-to-one supervision (including use of restraints, if indicated) and ongoing treatment. ECT may provide rapid, safe, and effective treatment for severely depressed, acutely suicidal patients.

Sometimes a no-suicide contract can be initiated. In the case of an angry or manipulative patient, this is usually not advisable. If a patient who is considered seriously suicidal cannot make the commitment to abide by a no-suicide contract, immediate hospitalization is necessary. A no-suicide contract is not a guarantee that a suicide will not happen, nor is it a substitute for clinical judgment. A mental health professional should be the person to implement a no-suicide contract. When it is appropriate to use them, no-suicide written contracts should include the following components:

- An agreement from the patient not to harm himself or herself
- An agreement that the patient will contact a mental health professional if the patient's suicidal impulses become unmanageable
- An agreement from the mental health–care provider to be available to the patient for a specified period of time, usually until the patient returns for a follow-up visit or another part of the intervention has taken place (e.g., when the patient has met with a psychotherapist for evaluation or therapy)
- Contact numbers for the mental health–care provider

Both the patient and mental health–care provider sign the contract. A copy is given to the patient, and the original is kept in the agency records.

After this, it is essential to implement an ongoing program of help. This should involve the following:

- Treatment of the presenting symptoms
- Referral for individual or group therapy
- Referral for support groups
- Referral to a community program

If the patient is not hospitalized and until the treatment program is in effect, the clinician must continue to monitor the patient to ascertain his or her safety.

Appropriate documentation is critical. Follow the agency guidelines for documenting situations involving suicidal risk. Records should include statements made by the patient; the decision-making process followed; potential ramifications of nontreatment; what has been shared with the patient and the family; and the consultation process. To avoid malpractice litigation, practitioners need to perform and document a complete assessment addressing both the risk and the precautions taken and follow evidence-based guidelines. A standard of care exists for assessment of suicide risk but not for the prediction of suicide. Complete and accurate documentation is key (Table 18.9).

Follow-up and Referral

Safety plans for patients who are not acutely suicidal include a follow-up appointment within 24 hours of assessment and a follow-up telephone call for missed appointments. Patients and involved family and friends should be given the local 24-hour crisis telephone number and information regarding access to emergency services. Practitioners must take responsibility to ask patients about weapons and pill stashes, and then take steps to have these items located and removed for safekeeping. If medications are prescribed, the amount should not exceed a 1-week supply, with no refills. Patients who are at risk should be seen at least weekly, and social support systems must be mobilized. Be aware that caring for a patient contemplating suicide can be very difficult (see Table 18.10).

Patient Education

Patient and family education includes providing suicide crisis hotline numbers to the patient and/or family members. Patients should be instructed to avoid alcohol. Encourage the patient to seek out adequate treatment for uncomfortable symptoms of physical illness, possibly including a prescription for analgesics to reduce suffering. Teach the patient that options appear narrowed when a person is feeling depressed and suicidal, and review alternative ways of thinking. Encourage the patient to reach out for support and to reach out immediately when feeling the urge to harm himself or herself. Teach the patient to use specific, more constructive outlets for anger rather than self-destructive ones. Mobilize a social support system for the patient and educate significant others regarding suicidal risk and danger signs. Educate the patient and family that as the patient's mood "lifts" in response to antidepressant treatment, there is an increased risk of suicide related to increased energy. At these times, patients must be monitored closely for increased risk.

In the event that the patient does commit suicide, the clinician should prepare the family for a complex grief reaction that may follow. Suicide is particularly tragic because of the fallout that the death bequeaths to survivors. Edward Shneidman coined the term *postvention,* which refers to an intervention strategy that attempts to minimize the impact of patient suicide and to ensure that survivors of suicide have adequate services and support available to them.

Table 18.9 Suicide Assessment and Management

Suicide Assessment

1. Psychiatric evaluation that includes the following:
   - Specific psychiatric signs and symptoms
   - Psychiatric history, including current treatment
   - Past suicidal or other self-injurious behaviors (including intent of such acts)
   - Family history of suicide, mental illness, and dysfunction
   - Current psychosocial situation and nature of crisis
2. Inquire about suicidal thoughts, plans, behaviors (elicit presence of suicidal ideation, suicide plan, intent, and lethality of plan including access to weapons, pills)
3. Suicide risk estimation to include demographic factors, major psychiatric syndromes (primary and comorbid conditions), specific psychiatric symptoms, other aspects of psychiatric history and physical illness

Management

1. Attend to patient's safety.
2. Establish and maintain a therapeutic alliance.
3. Determine a treatment setting (e.g., involuntary hospitalization, partial hospitalization, and intensive outpatient programs, ambulatory settings).
4. Develop a plan of care.
5. Coordinate care and collaborate with other providers.
6. Promote adherence to treatment plan.
7. Provide education to the patient and the family.
8. Reassess safety and suicide risk (include suicide crisis and chronic suicidality).
9. Monitor psychiatric status and response to treatment.
10. Obtain consultation if needed.

Documentation and Risk Management

1. Documentation issues specific to suicide
2. Be aware of own emotions and reactions, particularly when responding to those with severe or recurring suicidality or self-injurious behaviors—for difficult-to-treat patients, consultation and supervision from a colleague, as well as documentation of same, is recommended.
3. Suicide prevention contracts: limitations and clinical usefulness—not recommended in patients who are psychotic, agitated, impulsive, or using intoxicating substances.
4. Management of a suicide in one's practice.
5. Mental health intervention for surviving family and friends after suicide.

Table 18.10 Support for Health-Care Providers Caring for Patients at Risk for Suicide

- Be aware of your personal and professional limits and honor them.
- Know the legal standards about suicide, duty to report, confidentiality, and liability.
- Consult with others so that you are not the only decision-maker assessing the risk of the suicidal patient.

Postsuicide interventions by the clinician include the following:

- Educating the family members about suicide
- Allowing the family members to share their grief, including any burdens or other factors that the family members may feel (e.g., guilt, shame, anger, inability to do anything, situation out of their control)
- Encouraging family members to attend support groups, such as Survivor of Suicide (SOS) groups, which are available in most communities

The typical SOS group is sponsored by a mental health or social services agency and is facilitated by mental health professionals, survivor peers, or a combination of both. Referrals to such groups following a completed suicide are essential.

SCHIZOPHRENIA SPECTRUM DISORDERS

Psychotic disorders are disturbances of thought and signal a departure from reality with some combination of hallucinations and delusions. Abnormalities may occur in one or more of five domains: delusions, hallucinations, disorganized thinking (speech), grossly disorganized or abnormal motor behavior (including catatonia), and negative symptoms. A person with psychosis may exhibit difficulties with communication, insight, behavior, and relationships. Psychosis may be the direct result of medication effects, such as illicit drugs or prescribed steroids. It may also be confused with delirium, which most often signals overwhelming infection or other medical causes. Psychotic disorders may coexist with other psychiatric disorders. Schizoaffective disorder exhibits symptoms of both schizophrenia and mood disorders and most likely represents a continuum of illness within the psychotic grouping. Psychotic disorders can be classified into several categories as outlined in Table 18.11. Schizophrenia is among the most chronic disabling and economically catastrophic medical disorders of the severe

Table 18.11 Psychotic Disorders

Psychotic Disorder	Description
Schizophrenia with several subtypes	Onset: Acute or insidious. Symptoms present for at least 6 months with at least two or more + or – symptoms present for at least 1 month. Social, employment, or self-care impairment.
Mania with psychosis	Onset: Variable. Signs and symptoms must be present for 1 week or if hospitalization is required. Psychotic signs and symptoms present only during mood disorder. Social and employment impairment during episode.
Mixed episode with psychoses	Onset: Variable. Signs and symptoms must be present for 1 week or if hospitalization is required. Meets criteria for depression and mania. + Signs and symptoms only with mood symptoms. Social and employment impairment during episode.
Major depression with psychotic symptoms	Onset: Variable. Lasts 2+ weeks. + Signs and symptoms occur only during mood episode. Impairment during episode (includes postpartum).
Schizoaffective disorder	Often viewed on a continuum of schizophrenia–mood disorder with psychotic symptoms or psychosis without mood disorder. Impairment similar to schizophrenia.
Brief psychotic disorder	Onset: Acute. Full expression within 2 weeks and complete remission 1–3 months, lasts at least 1 day but less than 1 month. May have an acute stressor.
Schizophreniform	Usually acute onset of symptoms. Criteria of schizophrenia are met, but <6 months symptoms.
Delusional disorder	Criteria for schizophrenia are not met. Onset subtle, nonbizarre delusions, symptoms last >1 month.

Sources: American Psychiatric Association. *Diagnostic and statistical manual of mental disorders, fifth edition* (DSM-5). American Psychiatric Association, Arlington, VA, 2013; and Fochtmann, LJ, et al. Other psychotic disorders. In Sadock, BJ, et al, *Kaplan and Sadock's comprehensive textbook of psychiatry.* Lippincott Williams & Wilkins, Philadelphia, 2009.

mental illnesses. The WHO ranks it as one of the top 10 illnesses contributing to the global burden of disease. People with schizophrenia often suffer terrifying symptoms such as hearing internal voices not heard by others, or believing that other people are reading their minds, controlling their thoughts, or plotting to harm them. These symptoms may leave them fearful and withdrawn. Because of its disconcerting symptoms, a diagnosis of schizophrenia has serious implications for patients and families and can lead to significant medical comorbidities secondary to pharmacological treatments and unhealthy lifestyles.

Epidemiology and Causes

The lifetime risk for schizophrenia is estimated between 0.3% and 0.7%, although there are reported variations related to race and ethnicity, immigration status, and socioeconomic and geographical factors. In the Epidemiologic Catchment Area Study, the lifetime prevalence of schizophrenia among adults aged 30 to 44 years was 2.3%; persons older than age 65 years have a lifetime prevalence of 0.3%. Age at onset occurs earlier in men, commonly in the early twenties; women may present in their late 20s to early 30s. However, in both males and females, subtle symptoms may occur long before a definitive diagnosis is made, and males tend to have a worse prognosis and more difficult course. The prevalence of schizophrenia in adolescents is low, but it can occur in childhood before age 13. Early onset points to a poor prognosis although research is evolving. Developmental pathways are poorly understood. Family history of schizophrenia, obstetric complications and developmental difficulties, abuse, major life events, and parental loss may contribute to the development of the disease.

The disease course is variable, with some patients exhibiting mild symptoms only; but the majority of patients with schizophrenia follow a chronic course with some signs of functional impairment. These characteristics are barriers for employment and financial stability; moreover, they may interfere with stable housing and the patient's ability to navigate and maintain access to quality medical care. Poor engagement in health maintenance initiatives such as cancer screenings, exercise, nutrition, tobacco cessation, and identification of other comorbid chronic medical diseases play a role in poor outcomes.

Pathophysiology and Psychodynamics

A certain cause of schizophrenia is not known. It is most likely a multifactorial disorder consisting of biological, psychological, and social factors. Urban birth and rearing, social adversity and trauma, heavy cannabis use, migration, and stressful life events all suggest increased risk of schizophrenia. Migrant populations experience raised rates of schizophrenia. Increased rates of social adversity and family disruption experienced by some migrant populations may be thought to contribute to increased occurrence.

Clinical Presentation

The onset of schizophrenia may be abrupt or insidious. The majority of individuals have a slow and gradual development of clinical symptoms. Depressive symptoms occur in approximately half of cases. Schizophrenia presents with four symptom clusters that are used to describe the disorder, and each has implications for therapeutic treatment. Positive symptoms, negative symptoms, cognitive impairments, and affective disturbances comprise these clusters.

Positive symptoms refer to the "active" qualities of these symptoms that are abnormal and are synonymous with psychosis. Positive symptoms include delusions, hallucinations, disorganized thinking (speech), and grossly disorganized or abnormal behavior (catatonia). Delusions are the hallmark of positive symptoms, occurring in more than half of patients. Delusions are fixed beliefs not amenable to change despite conflicting evidence. They can include persecutory, referential, somatic, religious, or grandiose themes. Hallucinations are sensory impressions without basis of reality, prompting thought disorganization. They are vivid and clear to the individual experiencing them and may occur in any sensory modality such as auditory, visual, somatic, olfactory, or gustatory. Auditory hallucinations are distinct from the individual's own thoughts and are the most common type of hallucination. They must occur in the context of a clear sensorium. Disorganization is seen in behavior and/or thinking. Disorganized thinking is typically inferred from speech and must substantially impair effective communications. Commonly observed forms of abnormal speech are as follows:

- Tangentiality—getting off topic without answering questions appropriately
- Circumstantiality—will answer question in markedly roundabout manner
- Derailment—switching topics without a logic sequence
- Neologisms—creation of new, idiosyncratic words
- Word salad—words are placed together without any sensible meaning.

Grossly disorganized or abnormal motor behavior (including catatonia) may occur with schizophrenia with problems noted in goal-directed activities and activities of daily living. Positive symptoms can be experienced in combination, and most do respond to pharmacological treatment, although remission may be incomplete.

Negative symptoms represent a diminished or lack of normal characteristics—diminished emotional expression and avolition. *Diminished emotional expression* encompasses reductions in expression of the face, eye contact, intonation of speech, and movements of the hands, head, and face that contribute to emotion of

speech. *Avolition* represents decline in motivated self-initiated purposeful activities. This encompasses loss of affective responsiveness, verbal expression, and communication, personal and social motivation, and enjoyment. Primary negative symptoms can be resistant to treatment and closely related to functional outcome. Secondary negative symptoms may be routed in other manifestations of the illness or treatment.

Cognitive impairments in schizophrenia often are seen early in life, with steady decline after the onset of the illness, and correlate with functional impairment. Affective disturbances, which are difficulties with mood and affect, are seen with schizophrenia and affect how society perceives patients. Depression and anxiety can be detected during or after a psychotic episode, and providers must be alert for risk of suicide, particularly at the initiation of treatment, immediately after an acute psychotic crisis, and throughout outpatient encounters (see Table 18.12).

The DSM-5 symptom criteria for schizophrenia are as follows:

- Two or more of the characteristic *positive symptoms* (delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior) or *negative symptoms* (diminished emotional expression or avolition). At least one of the *positive symptoms* must be delusions, hallucinations, or disorganized speech. Must be present for the greater part of 1 month or less if treated.
- Difficulties experienced with social skills such as interpersonal relationships, work, or self-care.
- Continuous symptoms for 6 months and at least 1 month of characteristic symptoms.
- Exclusion of other medical or psychiatric disorders.
- Disturbance not attributed to effects of substance abuse or other medication.
- If there is a history of autism spectrum disorder or childhood communication disorder, the diagnosis of schizophrenia is made only if prominent delusions or hallucinations in addition to the other required symptoms for schizophrenia are present for at least 1 month.

Table 18.12 Symptom Clusters of Schizophrenia

Positive Symptoms—exaggeration of normal processes
• Hallucinations: Perception of a sensory process in the absence of an external source; can be auditory, visual, somatic, olfactory, or gustatory, alone or in combination.
• Delusions: Fixed false belief despite evidence that it is not true. Classified as bizarre delusion—clearly implausible; or nonbizarre delusions—although not true, is understandable with possibility of being true. Categorized as grandiose, paranoid, nihilistic, and erotomanic.
• Disorganization: Manifested in speech and behavior, loose or illogical thoughts lacking connectivity.
• Movement disorders: Grossly disorganized or abnormal motor behavior including catatonia.
Negative Symptoms—absence or diminution of normal processes
• Flat or blunted affect
• Alogia: Poverty of speech, thought blocking, increased latency of response
• Asociality/anhedonia: Loss of pleasurable feelings, failure to engage with peers socially
• Apathy: Lack of self-motivation, poor grooming and hygiene, anergy
Cognitive Impairments
• Poor executive functioning, concrete thoughts, diminished processing speed
• Difficulty focusing, maintaining attention
• Verbal and visual learning and memory deficits
• Verbal comprehension
• Social cognition
Affective Disturbances
• Blunt, odd expressions or actions that are interpreted as such and affect societal impression of the individual
• Stigmatization, poor self-esteem
• Depression and anxiety
• Increased risk of suicide

Source: American Psychiatric Association. *Diagnostic and statistical manual of mental disorders, fifth edition* (DSM-5). American Psychiatric Association, Arlington, VA, 2013. Adapted from www.surgeongeneral.gov/library/mentalhealth/chapter2/sec2.html#manifest

Schizoaffective disorder appears to be one-third as common as schizophrenia with an estimated prevalence of 0.3%. The incidence is higher in females than in males. Age of onset is typically early adulthood, although it may occur in adolescence to adulthood. The basis of a diagnosis of schizoaffective disorder entails an uninterrupted period of illness during which the individual continues to display active or residual symptoms of psychotic illness. During this period of psychosis, symptom criteria for schizophrenia have to be met. Social dysfunction and exclusion of autism spectrum disorder or other communication disorders of childhood onset required for schizophrenia do not have to be met. Occupational function and social functioning is often impaired but need not be a defining criterion for diagnosis. This is in contrast to schizophrenia. There may be restricted social contact, anosognosia (poor insight), and difficulties with self-care; however, *negative symptoms* may be less severe and less persistent. Alcohol and substance abuse can be associated with schizoaffective disorder. Individuals may go on to a diagnosis of schizophrenia, major depressive disorder, or bipolar disorder. As with schizophrenia, schizoaffective disorder carries a 5% lifetime risk of suicide, and assessment regarding suicide lethality must be always addressed.

The DSM-5 symptom criteria for schizoaffective disorder are as follows:

- Uninterrupted period of illness during which there is a major mood episode (depressive or manic).
- Delusions or hallucinations for 2 or more weeks in the absence of a major mood episode (depressive or manic) during the lifetime duration of the illness.
- Symptoms that meet criteria for a major mood episode are present for the majority of the active and residual portions of the illness.
- Disturbance not attributed to effects of substance abuse or medical condition.

Table 18.11 briefly identifies other psychotic disorders for consideration.

Initial presentation may occur in the primary-care setting. The role of the primary-care provider is to identify and refer any suspected or new cases of schizophrenia for urgent psychiatric evaluation. In some settings, especially in rural settings, this may be difficult owing to a paucity of mental health services and psychiatric providers. The primary-care provider is responsible to evaluate the patient's current risk to self and others. Any person presenting with psychosis for the initial or "first break" should be fully evaluated for underlying medical conditions. Consideration of substance abuse should be one of the primary differentials, and toxicology testing should be performed. Alcohol, opioids, cocaine, amphetamines, barbiturates, and hallucinogens are some of the most common offenders. In addition, it is not only consumption of these agents, but also withdrawal from them, that may precipitate symptoms. Commonly prescribed medications such as anticholinergic agents, phenytoin, steroids, H_2 blockers (cimetidine), and anxiolytics may produce similar symptoms. Other differentials to consider include delirium, in which the onset of symptoms occurs more rapidly and in which visual hallucinations are more common, versus schizophrenia, in which symptoms occur over a longer time period and auditory hallucinations occur more frequently. Medical illnesses such as hepatic encephalopathy, hyponatremia, hypoglycemia, hypoxia, intracranial bleed, infection, meningitis/encephalitis, and so forth should also be considered. A complete history and physical exam with attention to neurological and mental status exam are essential. Laboratory evaluation should include CBC with differential, electrolytes, renal function, liver profile, thyroid function, drug and alcohol toxicology, and pregnancy. Attention should be paid to potential infectious diseases processes with screening for syphilis, HIV, and hepatitis C. It may be determined that further testing for heavy metals, EEG, or brain imaging with MRI or CT is warranted.

Management

Schizophrenia is a chronic illness that influences virtually all aspects of life for patients and their families. Treatment goals should address reducing or eliminating symptoms, maximizing quality of life, improving function, and promoting and maintaining recovery within the context of an early intervention model of care. Treatment involves a multidisciplinary approach: assertive outreach approaches, family involvement and interventions, psychological interventions and psychologically informed care, vocational and educational interventions, and antipsychotic medication and monitoring (Level I; Scottish Intercollegiate Guidelines Network, 2013).

Pharmacological intervention is the mainstay for treatment of schizophrenia (Level I; Scottish Intercollegiate Guidelines Network, 2013; American Psychiatric Association, 2006). Early therapeutic intervention is important. Pharmacological intervention is quite effective in addressing the *positive symptoms* of schizophrenia. The negative symptoms are best addressed in a more multifaceted approach including cognitive-behavioral therapy (CBT) (Level I; Pitschel-Walz et al, 2001). Strategies to prevent relapse and encourage medication adherence are essential. The Expert Consensus Guideline Series determined that adherence problems in patients with serious mental illness primarily stem from poor insight and lack of illness awareness or distress associated with specific side effects or a general fear of potential side effects.

The *Circle of Caring* (see Chapter 2) is essential in helping the patient navigate the complex system of primary care and mental health services, as well as providing education for patients and significant others to access available community resources. Understanding the lived experience of the patient, family, and community of those living with schizophrenia, as well as their definition of wellness and recovery, helps to foster insight and adherence to the treatment plan. Of critical importance is the establishment of the therapeutic alliance, providing a supportive environment, maintaining continuity of provider when possible, and developing a trusting relationship where the patient is the active participant in his or her care. Recovery includes wellness and provision of primary care. Management of comorbid conditions is central to that effort.

Targets of Treatment

The goals of therapy include management of the positive and negative symptoms; evaluation of community issues such as employment, homelessness, justice issues, and victimization; and assessment of co-occurring illnesses such as PTSD, substance abuse, and depression (Level I; Scottish Intercollegiate Guidelines Network, 2013; American Psychiatric Association, 2006). In addition, it is essential to provide education to significant others in an attempt to enhance the therapeutic alliance and compliance with the treatment plan (Level I; Scottish Intercollegiate Guidelines Network, 2013).

Pharmacological Management

Antipsychotic medications are considered primary treatment for psychotic symptoms (Level I; Scottish Intercollegiate Guidelines Network, 2013; American Psychiatric Association, 2006; National Institute for Health and Clinical Excellence, 2009). These medications help to alleviate the positive symptoms and decrease hospital days and relapse rates. In addition, a greater response to medication is often seen when it is started early in the course of the disease (Level I; American Psychiatric Association, 2006; National Institute for Health and Clinical Excellence, 2009). Initiation of early and effective doses of antipsychotic medication is important, because it may influence the effect on the patient and family, as well as the risk of injury to self or others.

Because medication-naive patients are more sensitive to the psychotropic effects of medications (they respond to lower doses), initiation at the lower end of standard dose is recommended. Response rates are variable; slow titration of antipsychotic medication is recommended to help reduce the risk of intolerable side effects that may affect long-term adherence. Patients who experience a first episode are very responsive to treatment; remission is achieved within 3 to 4 months for 70% of patients, and 83% have a stable remission by 1 year. Accessing treatment may be difficult due to the alarming symptoms and the impaired thinking process.

The antipsychotic medications can be divided into two categories: (1) first generation, conventional, or "typical"; and (2) the second generation "atypical" antipsychotic medications. The typical, or conventional, antipsychotics have been used since the 1950s. These medications are very effective; however, the side effects can be troubling, and nonadherence has been attributed to these side effects (see Table 18.13). All antipsychotic medications work to reduce the positive symptoms. The negative symptoms have not diminished with the use of the conventional antipsychotics, but the "atypicals" seem to address some of these issues. The Clinical Antipsychotic Trials of Intervention Effectiveness project (CATIE) sponsored by the National Institute of Mental Health looked at the various drug regimens, comparing the conventional antipsychotic perphenazine and various "atypicals." This study found no difference in discontinuation rates for the conventional versus the atypical antipsychotics. Depot medications are particularly important for patients with compliance issues. Adjunctive medications help with controlling side effects and assisting with comorbid illnesses such as anxiety and depression.

Extrapyramidal symptoms (EPS) are among the most troubling for the conventional agents and can occur in 75% of patients prescribed these agents. It is theorized that these symptoms are related to blockage of the dopamine receptors and thus the decreased availability of dopamine. This reduction can generate alteration in a person's movement and functioning. These symptoms can be categorized as akathisia, dystonia, pseudoparkinsonism, and tardive dyskinesia and are summarized in Table 18.14. Anticholinergic medications are utilized to manage the symptoms experienced by many patients treated with antipsychotic medications. Prophylactic treatment with anticholinergics may be utilized to diminish EPS. Patient education is essential in discussing EPS in order to identify and treat these symptoms and to ensure adherence to the pharmacological regimen. In addition, if anxiety and/or assaultive behaviors are present, treatment with benzodiazepines may be used. Clozapine has been found to be helpful in management of suicidal behaviors and treatment-resistant symptoms (Level I; American Psychiatric Association, 2006; National Institute for Health and Clinical Excellence, 2009). Treatment of coexisting depression with antidepressants may prevent worsening of psychotic symptoms and improve overall functioning.

Individuals with serious mental illness particularly benefit from a consistent source of care, a comprehensive medical record, and continuity of provider. Primary care

Table 18.13 Comparison of the First Generation Antipsychotics and Risk of Side Effects

High Potency	Low Potency	Shared Side Effects
High risk of extrapyramidal effects	Lower risk of extrapyramidal effects	Moderate risk of weight gain
Moderate risk of sedation	High risk of sedation	Low risk of metabolic effects
Low risk of orthostatic hypotension and tachycardia	High risk of orthostatic hypotension and tachycardia	High risk of sexual dysfunction
Low risk of anticholinergic and antiadrenergic effects	High risk of anticholinergic and antiadrenergic effects	Seizures
Higher risk of neuroleptic malignant syndrome	Lower risk of neuroleptic malignant syndrome	Allergic and dermatological effects

Table 18.14 Extrapyramidal Symptoms, Description, and Treatment

Movement Disorder/Timing	Description	Treatment
Akathisia		
Occurs a few days to a few weeks after initiation of medication.	Restlessness Subjective: Impaired concentration, unable to remain calm Objective: Pacing, foot-tapping, shifting weight from foot to foot	Discontinue medication Benzodiazepines: lorazepam, diazepam, alprazolam Beta blockers such as propranolol
Dystonia		
May occur after a single dose of medication to several days later.	Involuntary muscle contractions affecting the head and neck (hoarseness, laryngeal spasms, oculogyric crisis) May involve the torso and extremities (torticollis, opisthotonos)	Anticholinergics Antiparkinsonian medication
Pseudoparkinsonism		
May occur after a single dose, but typically usually seen a few weeks later as the dosage is increased.	Slow pill-rolling movement of hands, cogwheel rigidity, shuffling gait, mask-like facies, loss of arm swing, and bradyphrenia After prolonged use "rabbit syndrome": tremor of lips characterized by constant chewing motion	Anticholinergics
Tardive Dyskinesia		
Late appearing manifestation, months to years.	Involuntary rapid movements of the face (lip smacking, grimacing, facial distortions), torso and extremities 6% irreversible	Prevention and screening tools for movement disorders every 3–6 months Anticholinergic agents Antiparkinsonian agents Removal of agent

Adapted from Courey, TC. Detection, prevention, and management of extrapyramidal symptoms. *J Nurse Pract* 3(7):464–469, 2007; and Schultz, SH, et al. Schizophrenia: A review. *Am Fam Physician* 75:1821–1829, 2007.

plays a fundamental role in promoting healthy behaviors such as physical activity, smoking cessation, and health maintenance screening. The primary-care provider should evaluate cardiac risk factors including hypertension, hyperlipidemia, and QT prolongation, as well as endocrine disorders such as metabolic syndrome, diabetes, and hyperprolactinemia. The weight gain seen with the "atypical" antipsychotics can be modified by lifestyle interventions such as exercise, dietary education, psychoeducation, and the administration of metformin (Glucophage). In a randomized controlled trial, metformin was more effective, but lifestyle intervention also reduced weight gain; the strongest effect was seen in patients who combined lifestyle intervention and metformin (Level I; Scottish Intercollegiate Guidelines Network, 2013). Myocarditis is a potential adverse reaction to clozapine (Clozaril). Patients presenting with fatigue, tachypnea, chest pain, fever, and dyspnea need emergent evaluation with an electrocardiogram, white blood cell count, and serum troponin levels. If myocarditis is diagnosed, clozapine must be stopped. Currently the manufacturer recommends evaluation of cataracts at baseline and every 6 months for patients taking quetiapine (Seroquel). Ongoing education that builds on previous medical encounters is essential to assist the patient and family with methods to reduce the increased risk of cardiac- and pulmonary-related events. An increased risk of mortality from cancer has been demonstrated in patients with schizophrenia, especially for women with breast cancer and for men with lung cancer.

Monitoring for diabetes and dyslipidemia is especially important in patients with a positive family history of those conditions and in those receiving a second generation antipsychotic (Level II; American Psychiatric Association, 2006; National Institute for Health and Clinical Excellence, 2009). Recommendations include sequential measurement of body mass index, waist circumference, blood pressure, fasting glucose, and fasting lipid profile at baseline, 1 month, 3 months, and annually. Assess individual and family medical history at baseline and annually.

In addition, the clinician can help encourage the patient to remain compliant with the antipsychotic medication regimen, as well as all nonpharmacological therapies, to prevent relapse (Level I; American Psychiatric Association, 2006; National Institute for Health and Clinical Excellence, 2009). Persons experiencing a first episode should remain on the antipsychotic medication for at least 18 months. Olanzapine (Zyprexa) has been shown to be slightly more effective than haloperidol although the difference is only slight statistically. Discontinuation rates for haloperidol are slightly higher due to side effects (Level I; Scottish Intercollegiate Guidelines Network, 2013). Generally the second generation antipsychotics have a lower risk of tardive dyskinesia. It is important to note that each medication carries its own side-effect profile and metabolic risks. Adverse effects of medications should be discussed as choice of medication is agreed on. (See Drugs Commonly Prescribed 18.3 and 18.4.)

Drugs Commonly Prescribed 18.3 Typical Antipsychotics

Drug	Indication	Adverse Reactions and Prescribing Considerations
High Potency		
perphenazine*	Psychosis Severe behavioral disturbances due to cognitive impairment Nausea/vomiting	Highest risk for neuroleptic malignant syndrome Monitor for movement disorder (AIMS), CBC, LFTs, annual eye exam, renal function, serum prolactin, photosensitivity Administration 2–3×/day
fluphenazine (Prolixin)*	Psychosis	Monitor for movement disorder, CBC, LFTs, annual eye exam, serum prolactin, skin exanthems Administration 2–3×/day
trifluoperazine (Stelazine)*	Psychosis Anxiety disorder	Monitor for movement disorder, CBC, LFTs, annual eye exam, serum prolactin Administration 2–3×/day
haloperidol (Haldol)*	Acute psychosis Schizophrenia ADHD Tourette's disorder	Significant EPS, prolactinemia QT prolongation risk: Mild if oral, high if IV administration. Sedation, weight gain, rare photosensitivity. Monitor for movement disorder, CBC, LFTs, annual eye exam, serum prolactin, and urinalysis
thiothixene (Navane)*	Schizophrenia	Monitor for movement disorder, CBC, LFTs, annual eye exam, serum prolactin, TFTs and urinalysis Photosensitivity CBC, ophthalmological exam, TFTs, and urinalysis
Medium Potency		
loxapine (Loxitane)*	Bipolar Schizophrenia	Photosensitivity, seizures CBC, ophthalmological exam, TFTs and urinalysis
molindone (Moban)*	Schizophrenia	AIMS assessment
Low Potency		
chlorpromazine (Thorazine)*	Acute intermittent porphyria Acute psychosis Nausea/vomiting Tetanus Schizophrenia Hiccups	Photosensitivity, sulfite sensitivity AIMS assessment, CBC, ophthalmological exam, and prolactin

*Dementia: Black Box.

Drugs Commonly Prescribed 18.4 Atypical Antipsychotics

Drug	Indication	Adverse Reactions and Prescribing Considerations
clozapine (Clozaril)*	Schizophrenia Schizoaffective disorder	Agranulocytosis, lowered seizure threshold† Rare myocarditis Anticholinergic effects, no EPS, postural hypotension, prolong QT interval, sedation Metabolic effects: monitor weight gain++, increased lipids++, FPG++ CBC with differential, LFTs and AIMS
olanzapine (Zyprexa)*	Bipolar depression Bipolar disorder Depression Mania Schizophrenia	Anticholinergic effects, dizziness/hypotension Sedation Metabolic effect: weight gain++ Monitor AIMS assessment, glucose, LFTs, neurological function, lipid profile
quetiapine (Seroquel)*	Bipolar depression Bipolar disorder Depression Mania Schizophrenia	Anticholinergic effects, postural hypotension somnolence Metabolic effects: weight gain+, FPG+ Ophthalmological exam Monitor AIMS assessment, glucose, LFTs, neurological function, lipid profile
risperidone (Risperdal)*	Autism Bipolar disorder Mania Schizophrenia	Anxiety, agitation, hypotension, sedation EPS+++ Metabolic effects: Weight gain+, increased lipids +, FPG+, hyperprolactinemia++ Monitor: AIMS assessment, glucose, LFTs, neurological function, lipid profile
aripiprazole (Abilify)*	Autism Bipolar disorder Depression Mania Schizophrenia	Rarely significant side effects of EPS, weight gain, or prolactin elevation Monitor: AIMS assessment, glucose, LFTs, neurological function, lipid profile
ziprasidone (Geodon)*	Bipolar disorder Mania Schizophrenia	May prolong QT interval Rarely significant side effects of EPS, weight gain, or prolactin elevation Monitor: ECG, AIMS assessment, glucose, LFTs, neurological function, lipid profile
paliperidone (Invega)*	Schizoaffective disorder Schizophrenia	May prolong QT interval, EPS, tachycardia Metabolic effects: weight gain+, prolactinemia Monitor AIMS, ECG
iloperidone (Fanapt)*	Schizophrenia	Anticholinergic+, dizziness, tachycardia, orthostatic hypotension+, sedation, EPS+ Prolong QT interval+++ Metabolic effects: Weight gain++, prolactinemia+ Monitor AIMS and ECG

Nonpharmacological Management

Because schizophrenia is characterized by remissions and relapses, looking at a variety of strategies to optimize functional status is important. Stigmatization, which represents a chronic negative interaction with the environment that most persons living with schizophrenia deal with on a regular basis, must be recognized. Stigmatization reduces schizophrenia to a stereotyped set of negative attitudes, fears, and incorrect beliefs that affects how the disease is understood. Harmful effects of stigma may increase the schizophrenia liability and have negative effects on the clinical course of the disease. Labels and social disapproval may result in patient anxiety and contribute to negative discrimination. This negativity can influence health-care access, damage self-esteem and self-efficacy, and increase depressive symptoms. Increased likelihood of the misuse of alcohol and drugs may be related to the prejudice and discrimination related to schizophrenia.

The *Circle of Caring* model, encompassing the concepts of authentic presence, advocacy, knowing, commitment, and patience, is the essence of humanistic, quality, medical care for all populations but is critically important for those living with schizophrenia and other serious mental illnesses. This model must be fostered in staff training and incorporated into the culture of your health-care setting to reduce the negative effects of stigma.

There is some evidence that practicing active coping strategies and sharing stories with peers may reduce stigma and facilitate attendance at primary care. Peers have the unique lived experience of being mental health consumers themselves who are in recovery. With peer support training, they are able to share experiences and coping strategies that support recovery for those living with mental illness. Services run by trained peers also include assistance with housing and benefits advisement, employment and career counseling, justice issues, advocacy, and independent living skills. Peer-delivered services have been shown to diminish feelings of isolation, to improve coping skills, and often to decrease the need for hospitalization.

Social skill training improves social adjustment and coping skills (Level I; American Psychiatric Association, 2006; National Institute for Health and Clinical Excellence, 2009). Supportive individual and group psychotherapy along with medications can reduce relapses and enhance occupational and vocational functioning (Level II; American Psychiatric Association, 2006; National Institute for Health and Clinical Excellence, 2009). Employment may destigmatize a person coping with both psychiatric disability and a criminal record, and paid employment may aid in community integration. Family education helps to improve communication between the patient and mental health services and subsequently helps to reduce relapse rates and improve family functioning (Level I; American Psychiatric Association, 2006; National Institute for Health and Clinical Excellence, 2009). Social centers aim to address isolation experienced by most patients. Social centers, sometimes called "club houses," provide a voluntary semistructured program wherein patients can meet in a safe environment to share conversation and participate in activities with others having similar concerns. For patients with persistent positive symptoms, CBT has been found to be helpful in the reduction of both symptoms and relapse rates (Level I; American Psychiatric Association, 2006; National Institute for Health and Clinical Excellence, 2009). Patients who have experienced a high incidence of relapse may benefit from an assertive community treatment (ACT) team approach (Level I; Scottish Intercollegiate Guidelines Network, 2013). ACT is an evidence-based program that provides culturally sensitive services for individuals with severe and persistent mental illnesses who have not benefited from traditional outpatient mental health programming and who also have a significant history of hospitalizations for mental health reasons. ACT is a comprehensive, multidisciplinary, team-based approach to treatment, with a strong emphasis on recovery principles individualized to meet the patient's needs. Services include case management, medication management, vocational counseling and placement, family counseling and psychoeducation, mental health and substance abuse counseling, and wellness management education. Services are provided in the community in the consumers' natural settings. Services are provided 24 hours a day, 7 days a week, for as long as needed. ACT participation is either voluntary or court mandated. The team approach includes a psychiatrist, psychiatric nurse, counselors, case manager, and peer support. The original ACT model included a nurse practitioner who provided medical care, but this is no longer an integral part of the ACT model. A hallmark of ACT is to develop a positive, trusting relationship with each client to improve his or her compliance with mental health treatment and focus on mental health and recovery.

CARE IN PREGNANCY FOR PATIENTS WITH PSYCHIATRIC DISORDERS

When pregnancy coexists with a psychiatric disorder, women need to be informed of all pharmacological and nonpharmacological treatment options so that they may make informed decisions. The decision to continue or withhold pharmacological treatment can pose a risk to the mother, the developing fetus, and the pregnancy outcome. Shared decision making between the woman, her primary-care provider, her obstetrician or midwife, and her mental health provider should be undertaken to minimize risk to the developing fetus and to enable the mother to have few or no psychiatric symptoms during pregnancy and the postnatal and lactation periods. A key concept is to treat these women as individuals, taking into consideration each woman's particular history,

personal situation, and all available resources. All women of childbearing age should be encouraged to take appropriate daily amounts of folic acid; not only is this routinely recommended for prevention of neural tube defects in the fetus, but it may also serve to mitigate the effects of other medications taken during prepregnancy and gestational phases.

Limitations exist in the current evidence-based literature regarding pregnancy outcomes and psychiatric disorders. For example, not all studies on the use of antidepressants have included analysis of the mothers' psychiatric condition; further, confounding variables, such as poor prenatal care and use of tobacco or illicit substances, may alter study findings if not adequately controlled for. It has been documented that use of tobacco and alcohol by pregnant women can result in psychotic symptomatology in their offspring. In general, the mother's history of any psychiatric disorder and severity of symptom expression should be a guiding principle regarding observation and treatment during pregnancy. In addition, the primary-care clinician has in his or her armamentarium not only pharmacological treatment but also person-centered modalities ranging from cognitive-behavioral therapy (CBT) to social supportive care. When the mother's psychiatric condition is intractable to treatment and/or her symptoms place her or the fetus in jeopardy, electroconvulsant therapy (ECT) may be the treatment of choice and is approved for use during pregnancy and postpartum.

Epidemiology

The incidence of depression in pregnancy is estimated between 15% and 25%, but there is insufficient evidence to recommend routine depression screening. A joint report from the American College of Obstetricians and Gynecologists (ACOG) and the American Psychiatric Association advises close monitoring of a woman's emotional health during the prenatal and postnatal periods.

Management

For women who have an existing psychiatric diagnosis, treatment should be guided by the woman's prior pregnancy and medical history, as well as by the safety of pharmacological agents. Studies on the use of pharmacological agents during pregnancy offer the basis for treatment guidelines covering specific pharmacological agents and drug classes. There are pharmacological guidelines for depression in pregnancy endorsed by the American Psychiatric Association and ACOG, as well as available through the governmental National Clearinghouse Guidelines. One set of guidelines can be accessed at www.guideline.gov/content.aspx?id=36811&search=depression+and+pregnancy. Guidelines suggest that providers use a standardized tool for assessment of depression in pregnancy. Tools that have been validated in pregnancy are the PHQ-9 and the Edinburgh Postnatal Depression Scale. Screening should minimally occur at the initial prenatal visit, at the four to 6-week postpartum visit, and again at three to 4 months after delivery. For women who have an active diagnosis of depression or a previous history of depression, evaluation for depression should occur at each visit. Positive screening requires further evaluation. This evaluation includes the duration and intensity of symptoms, suicide ideation, anxiety, substance use, and psychotic symptoms. Treating depressive disorders in pregnancy can affect the health of the mother and fetus. Untreated depression has been linked to altered fetal growth, interrupted prenatal care, miscarriage, preterm birth, substance use and abuse, infant temperament and behavioral issues, and mother-attachment issues. Women with a history of mania or hypomania are at risk for severe postpartum depression. Treatment of depression in the perinatal period involves a multidisciplinary, stepped-care approach based on the depression severity. For mild depression, CBT or interpersonal psychotherapy is indicated. For moderate depression, CBT (individual, group, or computer-assisted) or interpersonal psychotherapy is recommended. For women with symptoms that persist for greater than 8 weeks, an antidepressant should be considered. Psychiatric referral is indicated for women with severe depression, suicide ideation, psychotic symptoms, bipolar disorder (or a history of mania or hypomania), a current or recent episode of severe depression, no response to pharmacotherapy or psychotherapy, a history of schizophrenia or postpartum psychosis, severe coexisting anxiety, obsessive-compulsive disorder, panic disorder, eating, disorder, or substance abuse. In addition, ECT may be indicated for resistant depression during both the prenatal and postpartum periods.

Several psychiatric/psychotropic medications appear safe in pregnancy. For mood disorders, neither the tricyclic agents (TCAs) nor fluoxetine (an SSRI) has proven teratogenic, based on observational studies. There are limited data on the use of other SSRIs and SNRIs in pregnancy; most have shown no adverse outcomes, except for paroxetine, which has been associated with cardiac malformations. Guidance regarding the safety of medications during lactation is also limited. Generally, it is recommended to use agents that have shorter half-lives and greater protein-binding. Low infant serum levels of paroxetine and sertraline have been reported. Doxepin and clozapine should be avoided in lactating women. Women should be informed of the potential risks of the pharmacological agents, as well as the risks of untreated depression.

If a patient exhibits signs and symptoms of anxiety or panic disorder, the first choice of pharmacological agent during pregnancy should be an SSRI, because benzodiazepines are associated with an increased risk of orofacial clefting and cardiac malformations. In the case of bipolar disorder, a major problem occurs when considering the use of mood-stabilizing drugs. All of these agents are associated with teratogenesis, including valproic acid

and carbamazepine (neural tube defects) and lithium (Ebstein's anomaly or hypoplasia of the right ventricle).

In women who suffer from psychotic disorders during pregnancy, a first generation agent with higher potency, such as haloperidol, should be used. Although this may seem paradoxical, use of lower-potency drugs, such as chlorpromazine, has been associated with teratogenicity during the first trimester. Newer "atypical" agents such as risperidone and olanzapine have not yet been adequately studied in pregnancy to offer any recommendations as to their use.

A further consideration is the postpartum period, when rapid transitioning of hormones may influence psychiatric presentations. Women with bipolar disorder are at highest risk postpartum for relapse into depression, mania, or rapid cycling. Other conditions with a higher risk of recurrent symptoms include women newly diagnosed with major depression during pregnancy, with recurrent major depression, or with a history of psychosis. There is limited evidence to guide the recognition and management of postpartum psychosis. A Cochrane review in 2013 concluded that further research is necessary before concrete guidelines can be developed. In these cases, medication should be considered immediately postpartum, whether it be an antidepressant or a mood-stabilizing agent. In addition, all providers should discuss medication effects on lactation and carefully explore with the woman her feelings about and experience with breastfeeding. Here as well, the *Circle of Caring* and nonpharmacological therapies can be offered.

Management of psychiatric disorders during pregnancy can be challenging but can be achieved with person-centered care, attention to available evidence, and well-coordinated, shared care with obstetric and mental health professionals.

GRIEF

Grief, mourning, and *bereavement* are terms that define a universal human response to loss.

Pathophysiology and Psychodynamics of Grief

Grieving is both an emotional and a physiological response. In acute grief, as in cases of other stressful events, there may be a disruption of biological rhythms. It is well documented that grief is accompanied by impaired immune function, specifically decreased lymphocyte proliferation and impaired functioning of natural killer cells, although it is not known how clinically significant these changes are. Manifestations of grief reflect cultural context, the individual's personality, previous life experiences, the significance of the loss, past psychological history, the relationship with the deceased, existing family and social networks, other life events, resources, educational level, and general state of health.

The stages of grieving, identified in the classic work of Elisabeth Kübler-Ross, are as follows:

- Denial
- Anger
- Bargaining
- Depression
- Acceptance

Grief is identified when the onset of a patient's symptoms is associated with the death of a loved one, either recent or past. Grief, however, may not be limited to the physical death of a loved one. Grief can also result from the loss of a significant relationship or the loss of an important aspect of one's identity.

Clinical Presentations

Each person grieves in a manner that is, for him or her, meaningful and effective. With normal grief, there is consistent progress toward acceptance.

Grief consists of three distinct phases: avoidance, confrontation, and accommodation.

- Acknowledging the loss
- Reacting to the separation—feeling the pain, expressing reactions
- Recollecting and reexperiencing the deceased and the relationship—realistically reviewing and remembering the deceased
- Relinquishing attachment to the deceased while still acknowledging a loving connection to the deceased
- Readjusting to move adaptively into the new reality without forgetting the old
- Reinvesting; redirecting one's energy to new goals, pursuits, hopes, causes, beliefs, activities

Grief can be understood as a journey along a well-marked psychological path: Each person travels in his or her own way and at his or her own speed. The way a person grieves, and, consequently, the amount of time a person needs to move from agony to acceptance is heavily influenced by personal, social, cultural, religious, and spiritual norms.

Lifestyle is also a factor to be considered. Individuals who live in social isolation may find it more difficult to grieve a loss without close significant others who can offer comfort and assistance. Grieving for a loss alone can drain psychosocial resources that are needed for day-to-day functioning. An equally difficult modern problem is the overvaluation of immediacy. Living with technology has increased our cultural expectations for speed. Human experiences that require time may appear suspect in this context. Busy employers, families, and friends may support grieving, as long as (in their perceptions) it does not take too long—the implication being that personal grief should not take too much time, or demand too many valuable social resources. After a year has passed, family and friends may begin to ask why the grieving person is not "over" his or her loss yet.

Grief can present in a number of different ways. It can range from absent or delayed grief to excessively intense and prolonged emotions, or to complicated grief associated with suicidal ideation or frank psychosis. The risk factors for a more complicated grief reaction include (1) sudden and/or violent death, (2) social isolation, (3) individuals who believe that they are in some way responsible for the death (real or imagined), (4) individuals with a history of traumatic losses, and (5) individuals who had an intensely ambivalent or dependent relationship with the deceased. In some instances, reduced or absent grief may be an appropriate reaction.

Differential Diagnosis

Cultural, ethnic, religious, and social beliefs, community and family traditions, and personal characteristics all determine how and when a person, a couple, or a family will mourn a loss. For some people, grieving is a well-defined, highly satisfying ritual. For others, particularly those who have never suffered a major loss before, grief can be confusing and disturbing. In terms of psychosocial health and well-being, the process of mourning should allow the person to experience pain but achieve acceptance. Grief reactions that are harmful to self or others or that persist without progressing toward acceptance require specialized care. Because of the pain and disturbance associated with extreme grief, some individuals may present their mourning as an illness that requires treatment rather than as a process.

Grief and depression share many of the same characteristics, and it can sometimes be difficult to evaluate exactly when the scope of normal grieving has slipped into a pathological realm. It is important to distinguish the grieving process from a major depressive episode. DSM-5 points out several features that help to define each process.

An individual with a history of depression is at risk for becoming depressed at times of major loss. The mood disturbance in depression is typically pervasive and unrelenting, whereas fluctuations of mood in grief are common. Grief is often described as "coming in waves, washing over" the individual affected; even in intense grief, moments of happy reminiscence can surface. In contrast, people suffering from major depression feel hopeless—they cannot imagine ever feeling better. Nonpathological grief, on the other hand, is a normal, although intensely painful, state that is responsive to support, empathy, and the passage of time. The emergence of a major depressive disorder associated with grief is a medical emergency and should be treated as such.

Management

All too often, treatment for bereavement occurs within the realm of tertiary intervention, when grief has already emerged as complicated. Early detection and preventive interventions could alleviate suffering and lead to earlier and more effective treatment. Primary-care clinicians can assist in the attainment of those goals by doing the following:

- Validating pain and distress related to loss
- Providing appropriate pharmacological therapy
- Making bereaved patients aware of the many supportive therapies available and having ready a list of referrals

In the case of terminal illness, early and ongoing bereavement assessment and a collaborative process are essential components of a preventive approach to bereavement care. Interventions include bereavement education and counseling that assist in facilitating communication with the dying person. There is strong evidence that involvement and caregiving benefits survivors.

Management of grief includes preparing (if possible) the person and family for the normal stages of grieving—normalizing grief. The practitioner should let the person know that feelings of guilt and anger are normal and counsel patience. Encouraging expression of feelings may be helpful. Offering comfort is important, but the practitioner must recognize that he or she cannot "fix" things for the patient—efforts to remove emotional pain can actually hinder the grieving process. Utilizing the *Circle of Caring* model, community services that focus on grief, especially traumatic grief (miscarriage, death of a child at birth, death from violence or war), church resources, family support, and other support services to deal with special issues, for example, single parenting, may all be beneficial. Provide medical therapy as indicated depending on symptomatology and past history. A brief course of a short-acting sedative may be appropriate during acute grief to induce sleep or to get through the funeral and burial, especially when supportive interventions have not succeeded. The use of drugs such as tranquilizers or alcohol, which numb emotions, should be discouraged over time. Narcotizing patients with drugs interferes with the normal process of grieving. Antidepressant therapy may be considered for patients with particularly prolonged or complex grief reactions, even when it may be difficult to differentiate depression from a normal grief response. Clinical data suggest that SSRIs may be beneficial and assist the patient to mobilize the energy necessary to progress through the stages of mourning and grief.

Specific counseling sessions for the bereaved may be extremely valuable and may assist in the prevention of pathological mourning or depressive reactions. These sessions, with trained counselors, can assist the grieving person in recognizing and expressing angry or ambivalent feelings toward a deceased person. Group counseling, as well as self-help groups, can be important adjunctive therapies. More than 30% of widows and widowers reported feeling isolated from friends and withdrawing from social activities; self-help groups offer companionship, social contact, and emotional support.

This is particularly important given the contraction of the family unit in modern times. Have a referral list available to assist the patient in seeking such psychosocial support.

The goals for treating complicated grief reactions include facilitating mourning and helping the patient to find new activities and relationships to substitute for the loss. Studies have found that effective treatment of depressive syndromes, even as early as 6 to 8 weeks after the death of a loved one, reduces suffering and facilitates the work of grief. The outworn notion that medications or psychotherapy impede the process of grief is unsubstantiated and may, at times, serve to prolong suffering and disability. Obviously, elements of psychosis clearly indicate a need for more aggressive treatment: Some patients may even become suicidal and should be monitored closely.

Follow-up

The manifestations of grief usually subside over time. Typically, acute grief reactions gradually lessen and within 1 to 2 months the grieving person is able to eat and sleep normally, beginning to return to normal functioning. Traditionally, grief lasts from 6 months to 1 year as the grieving person experiences the calendar year at least once without the lost person. This varies from person to person and is dependent on circumstances. The normal grieving process can extend up to 2 years.

Patient Education

It is important to prepare the person and family for the emotional "triggers" that will exacerbate the sense of loss—holidays, birthdays, or the anniversary of the death or traumatic event. The clinician should encourage good nutrition and health habits, especially in elderly patients. Grieving persons should be encouraged to maintain self-care and not to neglect any active medical problems of their own. The clinician can encourage physical activity as a positive way of dealing with the stress of grieving.

SUBSTANCE-RELATED AND ADDICTIVE DISORDERS

The chapter for substance-related and additive disorders in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) has undergone several changes. To eliminate the confusion between the terms *substance abuse* and *dependence,* these terms were removed and replaced with specific symptom criteria for each disorder. One important deletion is the criterion for recurrent legal issues. In addition, several behavioral addictions were added. These additions include gambling and Internet gambling. Evidence for other behavioral addictions such as hypersexuality, shopping, or exercise is less clear and is not included.

The primary-care provider has an obligation to inquire about, provide information about, and make appropriate referrals for substance-related or behavioral addictions. All agents in the substance-use disorder (SUD) category can cause tolerance, habituation, and physical dependence. The legal substances that fall into this category include tobacco and alcohol; illicit substances including cannabis, cocaine, opioids, hallucinogens, inhalants, stimulants, sedatives, hypnotics, and anxiolytics. Caffeine is unique in that it is not classified as an SUD agent, but symptom criteria for intoxication and withdrawal are provided. The science of addictions has grown over the last 20 years, and it appears that a neurophysiological basis is common to all addictive behaviors. These disorders are considered chronic and relapsing because despite significant negative consequences, the behaviors continue. It is now recognized that dopamine is vital in this process, and thus pharmacological agents have been introduced to target certain areas of the brain. Targeted treatments for tobacco, alcohol, and opioids are now available.

Substance-Related Disorders

It is important to note that in the United States, the term *addiction* has been replaced by the term *substance-use disorder.* The core features of SUDs include a triad of behavioral, physiological, and cognitive symptoms. A basic understanding of several terms is essential. Soon after consuming an agent, *intoxication* occurs. This process is considered reversible; as the effect of the substance wears off, a return to baseline generally occurs. Intoxication can occur in individuals without an SUD as well as in individuals with an SUD. Several symptoms of intoxication include impaired judgment, psychomotor and interpersonal behavioral changes, and alertness. Substance *withdrawal* is characterized by functional impairment related to the cessation or reduction of a substance, which is demonstrated in physiological, cognitive, and behavioral symptoms.

Use is defined as sporadic or intermittent utilization of alcohol or drugs with no adverse consequences. *Abuse* is defined as utilization of drugs or alcohol that causes the user some type of adverse consequence. *Dependence* involves physiological and/or psychological components. *Physical dependence* refers to the physiological effects of withdrawal from rapid dose reduction, abrupt cessation of the drug, or administration of an antagonist. *Psychological* or *behavioral dependence* emphasizes pathological use patterns and substance-seeking activities; it is a subjective need for the substance. *SUD* is a chronic illness characterized by impaired control, social impairment, and use despite significant consequences, tolerance, and withdrawal.

The risk of SUD is directly related to the properties of the drug of choice, such as availability, cost, how quickly the brain perceives the substance, and its ability to produce gratification or pleasure, as well as various environmental factors. A person may initially consume a drug for any number of reasons. However, people continue using a drug based on the actual or perceived

rewards of substance use. Denial and rationalization of substance use, substance effects, or consequences of substance use make it possible for an individual to continue to use a substance as though he or she is immune to unexpected or dangerous consequences. Substance-related disorders that may be seen in a primary-care setting and that are included in this chapter are nicotine, alcohol, cannabis, hallucinogen, inhalant, opioid, sedative and hypnotic, and stimulant disorders. Caffeine is discussed in the intoxication and withdrawal section.

Epidemiology and Causes

The highest prevalence rates for substance use occur in persons aged 18 to 24 years. The current statistics are derived from the 2012 National Survey on Alcohol and Drug Dependence, which can be accessed from www.samhsa.gov/data/NSDUH/2012SummNatFindDetTables/NationalFindings/NSDUHresults2012.htm. In 2012, 26.7% of adults in the United States reported tobacco use. Use over the last 10 years has declined slightly. Tobacco use is the leading preventable cause of death and disability. The total direct and indirect costs incurred by the United States are nearly $200 billion. Nicotine and tobacco contribute to deaths from cancer, heart and lung disease, and infant mortality attributable to maternal smoking. More than 52% or 135.5 million persons aged 12 and older reported current alcohol use (one or more drink in the last month). Alcohol remains the primary substance of abuse and dependence; 14.9 million persons are dependent on or abuse alcohol alone, and 2.8 million persons are dependent on or abuse alcohol plus illicit drugs. For persons aged 12 years and older, 23.9 million persons had utilized an illicit substance in the previous month. Current illicit drug use among persons aged 12 years and older increased from 8.1% in 2008 to 9.2% in 2012. Substance dependence or abuse is estimated at 8.5% or 22.2 million in persons aged 12 or older. The total annual cost to society of substance use problems is estimated at almost $559 billion (health costs, loss of productivity, and crime-related costs).

Among all classifications—alcohol, alcohol plus illicit drugs, and illicit drugs alone—levels of dependence and abuse have remained stable from 2002 to 2012. The survey further identified that male sex, ethnicity, and education level seem to correlate with current alcohol use. Caucasians (57.4%) followed by individuals belonging to more than two races (51.9%) reported the highest alcohol use. The rates of alcohol use for other groups, in declining order, were as follows: African Americans 43.2%, American Indians or Native Alaskans 41.8%, Hispanics 41.7%, and Asians 36.9%. With increasing levels of education in adults age 18 or older, alcohol use increased; in addition, among adults with less than 12 years of education only 36.6% currently used alcohol versus 68.6% of college graduates. College students were more likely to use alcohol, binge drink, and drink heavily than their peers who were not full-time students and those not in college; these rates did not change from 2002 to 2012. Binge alcohol use peaks in 21- to 25-year-olds with rates of 45%. More men aged 18 to 25 years (62.9% of males) reported alcohol use than women (57.5%). Increased volume of alcohol consumption correlates with increased use of illicit substances and tobacco use. Drinking and driving has declined over the last 10 years but was essentially unchanged from 2011 to 2012. The number of persons who drove under the influence of alcohol at least once in the past year was estimated to be 11.2%. Underage drinking (aged 12–20) is of particular concern, with current drinking rates estimated to be 9.3 million persons. These values have slowly declined over the past 10 years.

Marijuana was found to be the number one illicit substance used in 2012, followed by psychotherapeutic agents (pain relievers, stimulants, tranquilizers, and sedatives), cocaine, hallucinogens, and inhalants. The least used illicit substance was heroin. Marijuana's current use increased from 5.8% to 7.3% from 2007 to 2012. It is estimated that 4.3 million persons aged 12 years or older were classified as dependent on or an abuser of marijuana; 2.1 million persons aged 12 years and older were classified as dependent on or an abuser of pain relievers; and 1.1 million persons were classified as dependent on or an abuser of cocaine.

Age is a factor. In youths aged 12 to 17 years, concurrent use of illicit substances was greater in those who used tobacco or alcohol. The rate for substance dependence or abuse is highest for adults aged 18 to 25 years at nearly 18.9%, compared with youth aged 12 to 17 years at 6.1% and adults older than age 26 years at 7.0%. In addition, rates of nonmedical use of prescription drugs increased from 4.1% to 4.6% in young adults aged 18 to 25 years. In adults aged 26 to 59 years, there has been a gradual increase in illicit use, with marijuana and nonmedical use of prescription drugs being the most prevalent. This increase is suspected to be related to the aging baby boomers, who are known to have had increased exposure. Male sex, ethnicity, education, employment status, and criminal justice population seem to correlate with illicit substance use. In summary, national statistics indicate that the most commonly used legal substances are caffeine, alcohol, and nicotine; the most commonly used illegal substances are marijuana, prescription pain relievers, and cocaine.

Different population-based causes for substance abuse have been described. As with all psychiatric disorders, the initial causative theories evolved from psychodynamic models; subsequent models include behavioral, genetic, and neurochemical explanations. According to one National Institute on Drug Abuse (NIDA) survey, family transmission is a core risk factor for substance abuse. Both social learning and genetic models have been developed to explain the increased risk and incidence of substance abuse in the children of

substance-abusing parents. Compared with earlier generations, however, Americans today are more likely to seek the immediate gratification and immediate solutions offered by drugs.

Comorbidities (also known as "dual diagnosis") are common in persons with substance abuse. The most common comorbidities are substance abuse with more than one substance and mood disorders including bipolar disorder, anxiety disorders, antisocial personality, and schizophrenia. People who abuse substances are about 20 times more likely to die from suicide than are those in the general population. About 15% of people with alcohol abuse or dependency commit suicide. The frequency of suicide among individuals in this group is second only to that among patients with major depression; many individuals with alcohol abuse or dependency may have underlying depression, further increasing their suicide risk.

Neurophysiological Basis of Addiction

Knowledge of the basic neurophysiological concepts of addiction is essential. Deleterious effects are seen in all individuals exposed to substance abuse. In infants exposed in utero, prematurity and developmental issues are seen; adolescents demonstrate poor school performance and high dropout rates, as well as an increased risk of violence and infectious diseases. Further, adults demonstrate poor concentration, coping, and interpersonal skills, which adversely affects employment, family dynamics, and parenting skills. In the past, many clinicians felt that addiction was a moral weakness, and this engendered negative perceptions about the patient; however, current knowledge helps to identify the differences in the brains of those with addiction and those without addiction. This research has helped to provide targeted treatments for specific diseases.

Anatomical pathways, neurotransmitter dysregulation, and imbalance and neuroadaptation are important neurophysiological components of addiction. The dopaminergic pathways located in this area of the brain are believed to be essential for the feelings of pleasure, reward, motivation, and incentive salience (whereby exposure to a stimulus is transformed from a pure sensory experience to one that brings it to the forefront of consciousness and causes it to be sought out). In addition, this area is essential for learning and memory, executive decision making, and behavior control.

Tolerance and dependence are believed to be related to the alteration of the neurochemical pathways, as well as overall cellular changes of the brain. This process of neuroadaptation can be persistent and permanent. These changes affect how the brain functions and have been the focus of research to describe the compulsive and harmful effects of addiction.

Diagnostic Reasoning

DSM-5 Symptom Criteria

The DSM-5 divides the substance-related disorders into two groups: *Substance Use Disorders* (those pathological behaviors associated with substance seeking activities) and *Substance-Induced Disorders* (intoxication, withdrawal, and mental disorders caused by a medication or a substance). The severity of substance-use disorders is identified as mild, moderate, or severe. Mild SUD occurs when there is a presence of two to three symptoms; moderate SUD is when there are four to five symptoms; and severe SUD is identified by six or more symptoms.

Substance-Use Disorders

The substance-use disorders are identified by the major symptom criteria listed below, taking into account the inherent properties of the specific substance. These behaviors need to occur within the previous 12 months with at least two of the following symptoms:

Impaired Control

- Use of a substance in greater amounts than intended or for more prolonged periods of time
- Persistent desire to use a substance or unsuccessful efforts aimed at decreasing or controlling substance use
- Extensive amounts of time spent obtaining, using, or recovering from the substance
- Intense desire or craving for the substance

Social Impairment

- Recurrent substance use results in work, school, or home obligation failures
- Continued substance use despite persistent interpersonal or social problems
- Continued substance use results in social isolation and/or withdrawal from recreational and family activities

Risky Use

- Recurrent substance use in physically hazardous situations
- Continued use despite physical or psychological problems

Tolerance

- Characterized by a marked increase in the amount needed to achieve the desired effect or intoxication, or a marked decrease in the effect achieved with the same amount of substance

Withdrawal

- Symptoms that occur when a substance has not been used; or the substance is used to relieve the symptoms of withdrawal

The existence and prevalence of significant comorbidities may make the "primary" disorder difficult to identify.

However, it is always necessary to concurrently treat the substance-abuse and dependence issues, regardless of the comorbidity. Evidence shows that unless the comorbid condition is also addressed and treated, recurrence of the substance abuse is likely.

Nicotine Disorders

Nicotine is the addictive substance in tobacco and is present in cigarettes, cigars, chewing tobacco, pipes, and snuff. Nicotine is readily absorbed and causes the adrenal glands to produce epinephrine. The epinephrine then stimulates the central nervous system (CNS), producing increases in heart rate, blood pressure, and respiration. At the same time, nicotine suppresses insulin output from the pancreas, leading to chronically high levels of blood glucose. Nicotine increases levels of the neurotransmitter dopamine as well, which accounts for a feeling of pleasure and relaxation. Thus, the immediate effects of nicotine are a brief period of stimulation and mild improvements in alertness, mood, and memory. The immediate brain dopaminergic and acetylcholine effects make the drug highly self-reinforcing. The half-life of nicotine is approximately 2 hours. Two hours after smoking, the chronic smoker experiences irritable nicotine cravings. As a mild stimulant, nicotine causes alterations in metabolism that can suppress appetite. Adolescent girls may intentionally become smokers with the hope that using nicotine will help them to stop the normal weight gain associated with puberty or improve their ability to control their appetite. Fear of weight gain keeps many young female smokers from stopping: A temporary weight gain of about 10 pounds is not uncommon when smokers first quit.

The biochemistry of nicotine withdrawal is complex, and nicotine withdrawal symptoms make quitting difficult. Management of withdrawal symptoms is the first and foremost goal of smoking cessation treatment. Nicotine withdrawal symptoms start within 2 hours of the last dose of nicotine, peak within 48 hours, and can last for weeks. Symptoms include severe cravings, irritability, decreased concentration, drowsiness, insomnia, decreased heart rate, decreased blood pressure, impaired motor skills, muscle tension, and increased appetite.

Treatment for tobacco dependence is effective, so all patients presenting for care should be asked about use of tobacco on a regular basis (Level I; U.S. Department of Health and Human Services, 2008). This should include regular questioning of and discussion with children and adolescents. Advice about smoking cessation increases rates of abstinence when done by primary-care providers (Level II; U.S. Department of Health and Human Services, 2008). Telephone, personal, and group counseling about tobacco cessation are all effective. There is a dose response seen for the clinical interventions and abstinence. Higher abstinence rates are associated with session length (more than 10 minutes), face-to-face treatment sessions (4–8 sessions OR 1.9; more than 8 sessions OR 2.3), and the total amount of intervention contact time up to 90 minutes (Level I; U.S. Department of Health and Human Services, 2008). It is crucial that clinicians continue to provide guidance and counseling as patients move through their abstinence journey. The reference guide to utilizing the five As (ask, advise, assess, assist, and arrange) for treating tobacco use and dependence is available at www.surgeongeneral.gov/tobacco/tobaqrg.htm. Pharmacotherapy should be encouraged, and first-line effective therapies include nicotine replacement agents (gum, inhaler, nasal spray, and patch), bupropion SR (Wellbutrin SR), and varenicline (Chantix) (Level I; U.S. Department of Health and Human Services, 2008). There is evidence also suggesting that combination nicotine therapy is more effective than a single form of nicotine replacement (Level II; U.S. Department of Health and Human Services, 2008). Second-line therapies for tobacco cessation include clonidine (Catapres) (Level I; U.S. Department of Health and Human Services, 2008) and nortriptyline (Pamelor, Aventyl) (Level II; U.S. Department of Health and Human Services, 2008). At this time, there is not sufficient evidence available to rate the long-term efficacy of varenicline. See Drugs Commonly Prescribed 18.5 for available pharmacological agents.

Alcohol Disorders

According to the National Institute on Alcohol Abuse and Alcoholism (NIAAA), the younger the age at drinking onset, the greater the chance that at some point in life an individual will develop an alcohol disorder. The person who begins drinking before age 15 is four times more likely to develop an alcohol disorder as an adult. Researchers have found that the risk of adult alcohol disorders *decreases* by 14% for each additional year of age drinking onset is delayed. Individuals who start drinking at age 21 to 22 years have significantly lower risks for developing adult alcohol dependence. Alcohol disorders are family disorders. It is estimated that one in five adults in the United States has lived with an alcoholic while growing up. Children who grow up with alcoholism are at risk for being abused and becoming adult problem drinkers. Concurrent depression, anxiety, or personality disorder; evidence of a family history of alcohol disorder; or evidence of early age at drinking onset are critical risk factors for alcohol disorder. Although there is little debate that alcohol is an addictive drug, there is a great deal of debate regarding the nature of alcoholism. The core of the debate has to do with significant evidence of alcoholism as a genetic disorder, a biological disease, and as a maladaptive behavior. Alcoholism cannot be fully explained by any one of these models. What is not clear is how these different factors interact. What is clear, however, is that significant exposure to high blood alcohol levels increases the risk of uncontrolled, compulsive, or problem drinking.

The unique biochemical effects of alcohol are related to the drug's ability to produce both short-term and

Drugs Commonly Prescribed 18.5 Smoking Cessation

Drug	Indication	Adverse Reactions and Prescribing Considerations
Nicotine Replacements	Smoking cessation	Do not use concurrently with other nicotine products. Not indicated immediately after myocardial infarction, significant arrhythmias, or unstable angina. Not recommended for pregnant or nursing mothers; attempt nondrug treatment first. Pregnancy Category D for patch and inhalers and Category C for gum. Common side effects include tachycardia, nausea.
Transdermal patch		Apply topically to trunk or upper outer arm. Firmly press patch for at least 10 seconds (may need to shave area). Apply one patch per day for 16–24 hours, usually in the a.m. Use for 24 hours if symptoms of withdrawal occur in a.m. If vivid dreams occur, remove at bedtime and reapply on awakening. Skin reaction may be reduced by rotating sites.
Gum/lozenges		Gum must be chewed until a "tingling" sensation is felt and then "parked" in the buccal mucosa until the sensation dissipates and then chewed again. Repeat process; usually total of 30 minutes. Lozenge is to be sucked slowly over 30 minutes and not swallowed. For success with either agent: Use at least 9 pieces a day. Do not drink anything other than water for 15 minutes before and during gum chewing. Use in response to nicotine craving and decrease over time.
Nasal spray		Nasal spray: Prime pump, and administer intranasally by tilting head back and spraying into each nostril with meter-dose pump. Do not sniff, inhale, or swallow.
Inhalers		Inhaler method mimics smoking behavior. Must insert cartridge for each use. With the inhaler in place, use rapid shallow sucking method (preferred) or inhale slowly and deeply (requires effort). Cartridge used up in 20 minutes of active puffing.
Bupropion		Prescribe at 150 mg/day for 3 days; then increase to 150 mg twice daily. Do not take second dose sooner than 8 hours, and do not take later than 5:00 p.m. Do not use in patients with seizure disorder or eating disorder. Monitor for hypertension, especially if used with nicotine replacement. **Black Box Warning:** Increased risk of suicidal thinking and behavior. Counsel patients to stop medication if any changes in mood or behavior occur. Pregnancy Category C
Varenicline		If symptoms of depressed mood, agitation, or suicide occur, discontinue. **Black Box Warning: bipolar disorder, depression, schizophrenia, suicidal ideation.** Pregnancy Category C

long-term changes in neuron membranes and the enhancement and inhibition of critical ion channels. As a CNS depressant, alcohol compares to drugs such as barbiturates and benzodiazepines. Alcohol is readily absorbed from the stomach and small intestine into the bloodstream and is metabolized by the liver.

Alcohol intoxication is greatest when blood alcohol levels are increasing. In other words, alcohol intoxication is a manifestation of the rate at which alcohol is consumed.

- A blood alcohol level of 0.05 causes disruptions in thinking, judgment, and inhibition.
- A blood alcohol level of 0.1 produces obvious intoxication.
- A blood alcohol level of 0.2 results in depression of motor functioning and emotional/behavioral dyscontrol.
- A blood alcohol level of 0.3 produces stupor and confusion. Blood alcohol levels of 0.4 and higher produce coma.

Several terms are utilized in the literature to describe alcohol disorders, and it is important to have an understanding of the various definitions. The NIAAA defines *low-risk drinking* for men as less than 4 drinks per day and no more than 14 drinks per week, and for all women and men aged 65 and older no more than 3 drinks per day and no more than 7 drinks per week. *At-risk drinking* is consuming volumes greater than these guidelines. *Harmful drinking,* on the other hand, occurs when alcohol is causing physical, psychological, or social harm exhibited by zero to two dependence criteria and zero to one abuse criteria. The DSM-5 categorizes disorders as alcohol-use disorder, alcohol intoxication, and alcohol withdrawal (see Diagnostic Reasoning).

Other terms are frequently seen in the literature. The term *problem drinker* refers to persons who do not meet the diagnostic criteria for abuse or dependence but who experience problems related to alcohol, and the World Health Organization (WHO) uses the term *harmful use,* which can be defined as drinking that is causing either physical or psychological harm. In addition, the term *hazardous drinking* is characterized by the risk of harmful consequences (physical, mental, or social) related to alcohol use. Binge drinking (i.e., consuming 5 or more alcoholic beverages within 2 hours for men and more than 4 alcoholic beverages for women) often results in acute impairment and causes a large portion of alcohol-related deaths.

Alcohol affects circulation and cardiac functioning and dilates skin blood vessels, thereby producing flushing and a drop in body temperature. Reduction in risk of coronary artery disease has been proposed as a benefit of light to moderate consumption. The rationale for this proposal is based on the finding that in low doses, alcohol can increase high-density lipoprotein and decrease low-density lipoprotein. This benefit is canceled out, however, by common unhealthy behaviors such as poor diet or smoking or excessive use.

Alcohol-use disorder typically has a slow, progressive course; persons generally present for care after 10 to 20 years of use. At-risk drinking may progress to an alcohol-use disorder with its attendant morbidity and mortality. Components of the history can include driving under the influence (DUI), work issues, and relationship issues. Alcohol disorders have several deleterious health consequences. Manifestations of involvement of the cardiovascular system include hypertension, arrhythmias, dyslipidemia, cardiomyopathy, and stroke; gastrointestinal system involvement can be seen initially with dyspepsia and progress to gastritis, peptic ulcers, abnormalities of the liver enzymes, alcoholic hepatitis, fatty liver, pancreatitis, esophageal varices, and cirrhosis. Neuropsychiatric changes include peripheral neuropathy, memory impairment, suicidality, cortical atrophy, and dementia. Cancer risk is also increased, with oral, pharyngeal, laryngeal, esophageal, and possibly breast and colon cancers being the most prevalent. Safety issues are substantiated by an increased number of motor vehicles accidents, falls, burns, episodes of violence, and risky sexual behaviors.

It is important to understand that gender plays a part in alcohol disorders. Recommendations on daily use of alcohol for women are less than for men because of women's smaller body mass and less efficient ability to metabolize alcohol. Among heavy drinkers (men and women), women develop problems with alcohol at an accelerated rate and are at greater risk for cirrhosis; in addition, increased rates of miscarriage are seen.

Knowledge of alcohol withdrawal symptoms and appropriate therapy is essential. Abrupt cessation of alcohol in dependent persons can range from mild (characterized by symptoms such as irritability, tremulousness, and insomnia) to severe symptoms (characterized by withdrawal seizures, delirium tremens [disorientation, diaphoresis, visual hallucinations, tachycardia, hypertension, and agitation]); if left untreated, death is a potential complication. Treatment may occur in both the outpatient setting and the inpatient setting. Pharmacological therapy of withdrawal includes the intermediate- or long-acting benzodiazepines such as lorazepam, oxazepam, diazepam, or chlordiazepoxide. Carbamazepine has also been shown to be effective in mild to moderate symptoms of withdrawal and has the added advantage to decrease craving. In addition, adjunctive medications include antipsychotic medications such as haloperidol, which is utilized in patients with significant hallucinations and agitation. Cardiovascular stabilization with beta blockers needs to be considered in patients with coronary heart disease. When beta blockers are used with oxazepam, stabilization of vital signs and decreased craving have been demonstrated. In addition, clonidine has been found helpful in controlling hypertension and tachycardia. Phenytoin may be appropriate for patients with an underlying seizure disorder, but it is not effective for withdrawal seizures.

Screening It has been estimated that one in five patients presenting to primary care has a current problem or past problem with alcohol abuse. Primary care provides an excellent opportunity to address alcohol-related issues, provide education and information, and offer therapeutic modalities. Screening and behavioral interventions for alcohol disorders are recommended by the U.S. Preventive Services Task Force (USPSTF) (Level II; USPSTF, 2013) for all adults. NIAAA recommends screening as part of routine evaluations and in response to medical conditions that are affected by alcohol, as well as before prescribing medications that may interact with alcohol.

Several screening tools are available such as CAGE, Audit, and so forth (see Table 18.4). More recently, asking one question, "How often in the past year have you exceeded the maximum daily limit (specific for men and women as previously identified)?" has been found to be comparable in sensitivity and specificity to more involved tools. This question not only provides information to the clinician, but it also informs the patient of safe amounts of alcohol consumption. The clinician may use a more specific tool or refer the patient to a specialist to properly identify the severity of the disorder. Proper identification of at-risk drinking and alcohol abuse is important so that proper treatment can be initiated. Brief counseling is recommended for at-risk drinkers (Level II; USPSTF, 2013). Pharmacological therapy has been found to be helpful for dependent and chronic dependent drinking.

Cannabis Disorders

The psychoactive effects of marijuana are produced by cannabinoids, of which tetrahydrocannabinol (THC) is the active ingredient. Specific receptors for cannabis have been identified in the brain, particularly in the basal ganglia, hippocampus, and cerebellum. Tolerance and psychological dependence on cannabis have been reported, and abrupt discontinuation of high daily doses can produce withdrawal symptoms that include irritability, insomnia, and mild nausea. The euphoric effects of marijuana can last for hours. These effects include distortions of time, sound, color, and taste; changes in the ability to concentrate; and dreamlike states. Studies of the mental status changes produced by smoking marijuana indicate that the drug affects behavior by increasing brain cell–receptor sensitivity to dopamine. THC can create a mellow mood state by increasing gamma-aminobutyric acid (GABA) activity. THC impairs short-term memory by decreasing brain acetylcholine activity. High doses of marijuana are associated with red eye; mild increases in heart rate; orthostatic hypotension; increased appetite; dry mouth; and disruptions in recall, memory storage, and sensory-input coding. Memory impairment appears to be the most significant long-term effect of marijuana use.

Marijuana is most commonly smoked either through cigarettes (joints, nails, and reefer) or pipes (bongs or bowls); a potent marijuana resin (hashish) is also smoked. Ingestion is not as common but may be seen in foods and teas. Because marijuana is commonly smoked, it is very well absorbed from the pulmonary system to the circulatory system to the brain. Behavioral effects tend to develop immediately. Absorbed THC is distributed throughout the body but concentrates in body fat. THC crosses the blood–brain barrier with ease and efficiency. THC also crosses the placenta and affects the fetus. Ingested THC is slowly metabolized and eliminated by the liver over a period of 1 to 4 days. Chronic marijuana smokers can test positive for THC metabolites for weeks, despite brief drug-free periods.

Smoked marijuana has been shown to improve appetite in persons with HIV and AIDS and to reduce nausea and vomiting in chemotherapy patients. In recent years, the potency of THC in marijuana has increased from a low of 0.5% in the 1970s to levels from 6% to 10% in 2000. No longer a "Sixties symbol" of social rebellion, marijuana today may be equated by smokers with tobacco, alcohol, and caffeine. As with long-term users of nicotine, alcohol, and caffeine, long-term marijuana smokers who wish to stop usually find it extremely difficult to do so. Heavy daily users of marijuana experience significant withdrawal symptoms and cravings.

Significant health risks are associated with inhalation of marijuana. Fifty to seventy percent more carcinogens are present in cannabis than in tobacco, and thus patients may present to primary care with common respiratory complaints of cough, asthma, and respiratory infections. In addition, there is an increased incidence of head and neck cancers (twofold to threefold increase), as well as lung cancer. Circulatory changes seen include variability of blood pressure, arrhythmias, and cerebellar infarction. Immune system dysfunction and fertility issues of erratic ovulation and reduced sperm count have also been reported. Overall the most significant changes are in mood and cognition. Exacerbation of panic attacks, anxiety, and depression has also been reported. Other behavior changes may include a lack of desire to participate in activities; persistent cognitive and memory impairment, especially if abuse began in adolescence; and psychotic symptoms. In genetically predisposed adolescents, exposure to cannabis has been associated with onset of psychosis and worsening outcomes of schizophrenia. Medical marijuana use for various conditions such as glaucoma, AIDS wasting, neuropathic pain, spasticity, and nausea from chemotherapy has been proposed, but the Food and Drug Administration (FDA) and Drug Enforcement Administration (DEA) do not support its use at this time, although marijuana use for medical purposes is legal in some states. Limitations currently are related to a lack of valid studies with consistent THC dosage. In addition, the physical risks related to inhalation may further limit its use.

Hallucinogen-Related Disorders

The phencyclidines are synthetic agents that produce a range of feelings from dissociation to stupor and death. The dissociative agents can be smoked, consumed orally, or snorted. These agents include PCP, or angel dust. In addition, several other substances produce similar effects: ketamine (vitamin K, Special K, and Valium K) and *Salvia divinorum*. Persons taking these substances may present with various injuries from falls and accidents. Memory loss and deficits in cognition can last for months with chronic use.

The "other" hallucinogen use disorders involve the following substances: LSD, or lysergic acid diethylamide (acid, blotter, cubes, microdot yellow sunshine, blue heaven); mescaline (buttons, cactus, mesc, peyote); MDMA or ecstasy; and psilocybin (magic mushrooms, purple passion, shrooms, little smoke). These agents can produce hallucinations, nausea, and altered perceptions. These substances are usually taken orally but can be smoked, snorted, or taken by injection. Duration of effect can vary from hours to days depending on the substance. Flashbacks can occur with LSD. Ecstasy possesses stimulant properties and long-term neurotoxic effects in addition to the hallucinogenic properties. Withdrawal symptom criteria have not been established for any of the hallucinogenic agents.

Inhalant-Related Disorders

The exposure to volatile hydrocarbons from solvents (paint thinners, gasoline, glues); gases (butane, propane, aerosol propellants, nitrous oxide); nitrites (isoamyl, isobutyl, cyclohexyl) with street names such as laughing gas, poppers, snappers, and whippets comprise these disorders. These substances can produce neurocognitive problems, as well as pulmonary and cardiac issues. Inhalants have been associated with sudden death related to cardiac arrhythmias but also through respiratory depression and aspiration.

Opioid-Related Disorders

Opioid abuse can include both prescription and/or illicit drugs such as heroin. The most frequent prescription drugs of abuse include hydrocodone, fentanyl, oxycodone, oxymorphone, morphine, and methadone. Opioids can both relieve pain and cause euphoria. The pain relief effect by opioids is achieved by the drug attaching to the opioid receptor and thus blocking the subjective feeling of pain. The statistics of prescription abuse continue to escalate. Particular populations at risk for prescription opioid abuse include women, adolescents and young adults, and older adults. Attention to adequate pain management has become recognized as the standard of care. It is the clinician's responsibility to adequately evaluate, assess, and prescribe appropriate therapy for pain. This can be a daunting task in primary care. Several strategies may be helpful. Current guidelines are available in dealing with chronic nonmalignant pain (see www.jpain.org/article/S1526-5900%2808%2900831-6/abstract).

Heroin (also known as smack, H, ska, junk) abuse results in significant costs related to medical care, criminal justice, and lost productivity; it is estimated to cost the United States billions of dollars annually. Heroin can be injected, snorted, or smoked. Medical issues related to heroin use involve HIV/AIDS, hepatitis B and C, and tuberculosis, to name a few; social issues involve justice issues, the interference with education and employment, and significant family distress. More information about heroin abuse and addiction may be obtained at www.drugabuse.gov/publications/research-reports/heroin-abuse-addiction. Neonatal issues such as low birth weight and abstinence (withdrawal) symptoms can be addressed during pregnancy, with the mother receiving prenatal care in addition to comprehensive drug treatment and methadone maintenance.

Overall the number of new nonmedical users of pain relievers has not changed over the last 10 years. In 2012, 2.1 million persons were dependent on or abusers of prescription pain relievers. For the most recent use, over 54% of users obtained pain relievers free from family or friends, followed by 14.9% who bought the substance from a friend or relative.

Sedative-Hypnotic– or Anxiolytic-Related Disorders

The substances used in this disorder include barbiturates, carbamates such as muscle relaxers, and benzodiazepine and benzodiazepine-like agents. These substances are CNS depressants that can be utilized for legitimate medical conditions, but the behaviors of early refills and obtaining prescriptions from multiple providers helps to define this disorder. These agents can cause various neurological deficits in memory, coordination, autonomic depression, and cognition, and they produce many of the same effects as alcohol.

Stimulant-Related Disorders

Cocaine and amphetamine-related substances are included in this disorder. These substances are typically smoked, snorted, or injected. Diversion of stimulant attention-deficit/hyperactivity disorder medications also contributes to this disorder.

Cocaine Disorders

Cocaine acts as a CNS stimulant by blocking the reuptake of dopamine, thereby increasing dopamine activity in several areas of the brain. Cocaine may also have dopamine-agonist effects. The dopamine effects of cocaine account for most of the immediate and long-term effects of the drug. Biochemical studies of cocaine have shown that cocaine has extremely self-reinforcing, self-rewarding properties, and thus is highly addictive. The euphoria of cocaine intoxication, combined with the

dysphoria of cocaine crashing and craving, can lead to compulsive consumption.

Cocaine is available in several forms: the hydrochloride salt that is inhaled or injected; the alkaloid solid, rock crystal (crack) made by combining the salt with baking soda or ammonia that is usually smoked; and freebase that is manufactured by heating the salt form and combining it with ether and then inhaling (freebasing). Intravenous administration and smoking have the most rapid pharmacological and euphoric onset of action (within 10–30 minutes), as well as discontinuation effect, whereas the onset for intranasal usage is 30 to 60 minutes. Compulsive and abusive use is associated with IV and smoking routes of administration.

One of the most important studies of cocaine's effects on the brain and emotional states successfully used functional magnetic resonance imaging (fMRI) to study the rush, high, low, and craving experiences of cocaine-dependent adults. Maximum cocaine blood levels were reached in an average of 7 minutes after infusion, dysphoria and paranoia developed about 11 minutes after infusion, and cravings for more cocaine occurred about 12 minutes after infusion. One of the most impressive indicators of the speed and scope of cocaine's effects on the brain was that subjects reported maximal feelings of euphoria as cocaine was being infused, before maximal cocaine blood levels had been reached. Cocaine intoxication is characterized by elation, significant increases in self-esteem, and the perception of improved task performance. Intoxication can also produce agitation, irritability, impaired judgment, impulsive sexual behavior, aggression, hyperactivity, and mania. Chronic cocaine use has been associated with the onset of symptoms of thought, personality, and mood disorders and with paranoid psychosis.

Tolerance to cocaine occurs as users are unable to achieve the euphoric effects of the first episode of use and subsequently escalate the dosage. In addition to its stimulant effect, cocaine also has anesthetic and convulsant effects; and sensitization develops even without a change in dosage. It is believed that this has contributed to deaths by cardiac arrest or seizure followed by respiratory arrest that may occur with the first use episode and precipitately with any use thereafter. Cardiovascular conditions such as hypertension, angina, myocardial infarction, and cerebrovascular accident may also be seen. In addition, pulmonary edema and respiratory depression may occur. Potential complications of pregnancy include abruptio placentae, uterine rupture, and hypertension. Higher rates of sudden infant death syndrome have been reported in infants exposed to cocaine prenatally.

Cocaine withdrawal is typically characterized by irritability, depression, and anxiety and generally decreases after the first few weeks of abstinence. Currently, there are no FDA-approved pharmacological agents to assist withdrawal. In early abstinence, insomnia may be problematic, as evidenced by memory and attention deficits that may place the individual at higher risk of relapse. Some infants manifest symptoms such as tremulousness and irritability during the neonatal period.

Over the past few decades, smoked cocaine (crack), an extremely rapid-acting form of the drug, became cheap and easy to obtain. Cocaine has consistently been linked with severe social problems and antisocial behavior, such as gang violence and prostitution. Harmful behaviors such as driving while impaired, sexually transmitted disease exposure, and violence are also reported.

Amphetamine-Type Disorders

Substances include amphetamines, dextroamphetamine, methamphetamine, and methylphenidate. After having been a relatively popular and cheap drug of abuse, amphetamines quickly came to be associated with violent, bizarre behavior at a time when mellow "highs" were more socially acceptable. Decades later, amphetamines, particularly methamphetamine ("crank"), have once again become popular among older adolescents and young adults.

Methamphetamine is a synthetic agent also known as speed, meth, chalk, ice, and crystal. Users describe being high as being "amped" (amplified) or "tweaked." Methamphetamine is a potent, easy-to-make, inexpensive stimulant, which can be snorted or injected. "Crystal-meth" is methamphetamine in a free-base form; "ice" is a high-grade form of "crystal-meth" that is sold in rocks, like crack cocaine. Because of its purity and potency, "ice" is expensive; one hit can deliver an extreme amphetamine high that can last for hours. A methamphetamine rush is intense. Intoxication includes elation, increased self-esteem, increased physical endurance, insensitivity to fatigue, and feelings of being invulnerable. Methamphetamine half-life is 11 hours or more, which far exceeds that of cocaine. This long half-life contributes to the longer neurological changes. But like cocaine, amphetamine increases dopamine activity, is self-reinforcing, and is a highly efficient addictive agent. Several side effects of methamphetamine use are hyperthermia, dehydration, a significant anxiety, insomnia, mood disturbances, and violent behavior, as well as psychosis. These symptoms can persist even after the behavior of abuse has stopped. Additional physical signs and symptoms include dermatological changes such as sores and dental issues, including tooth decay and tooth loss.

Chronic users experience acute episodes of euphoria and dysphoria that can mimic bipolar disorder. Other medical issues that can occur with stimulant use include nasal septum perforation, respiratory and cardiovascular issues such as chest pain, myocardial infarction, arrhythmias, and stroke. Stimulant use produces several adverse pregnancy outcomes.

Clinical Presentation

Patients who ask questions about their personal substance use may have used substances for a relatively short

period of time; but more often, patient questions are motivated by having recently suffered negative consequences from long-standing substance use. Routine substance use and abuse screening has become a standard of practice in primary care. The most consistent identifier for substance abuse may be the numerous health consequences of abusing drugs and alcohol. Personal characteristics are not reliable indicators. Persons of all ages, races, religions, and every socioeconomic status are susceptible to substance abuse, and substance dependence typically follows substance abuse.

Substance-Induced Disorders

Substance-induced disorders are divided into intoxication, withdrawal, and mental disorders caused by a medication or a substance. The clinical presentation of a person with substance intoxication, abuse, or withdrawal will vary depending on the substance abused. Table 18.15 presents a summary of the clinical presentation of an individual with cannabis, cocaine, amphetamine, nicotine, caffeine, or alcohol intoxication and withdrawal. The DSM-5 symptom criteria are listed below.

Substance Intoxication

- Symptoms are reversible and are directly related to recent ingestion of a substance.
- The substance causes substance-specific induced behavioral or psychological changes. These behaviors can include issues associated with judgment, wakefulness, interpersonal skills, and the like.
- The symptoms cannot be explained by another medical or psychological problem.

Withdrawal

- Substance-specific physiological, psychological, and cognitive changes associated with the absence of or decreased use of the substance usually associated with intense craving to diminish the symptoms.
- The syndrome causes functional impairment.
- The symptoms cannot be explained by another medical or psychological problem.

Caffeine-Related Disorders

Caffeine is present in many products. The average daily U.S. consumption over the last 10 years has remained

Table 18.15 Clinical Presentation: Selected Substance Intoxication and Withdrawal

Cannabis-Related Disorders

- *Cannabis-Use Disorder:* Two or more of the symptom criteria should be present within the previous 12 months.
- *Intoxication:* Intoxication typically includes euphoria, grandiosity, impairment of complex mental processes; user perceives self and experiences as occurring in slow motion. Symptoms occur within **2 hours** of cannabis use. Two or more of the following should also be present: conjunctiva injection (red eye), increased appetite, dry mouth, and tachycardia. The above symptoms are not attributable to any other substance or medical condition.
- *Cannabis Withdrawal:* Occurs after stopping cannabis after prolonged use. Within 1 week three or more of the following symptoms are present: anxiety, depression, anorexia, irritability, insomnia or disturbing dreams, agitation, or various physical symptoms such as headache, tremors, fever, or chills. The above symptoms cause significant sociocognitive impairment and are not attributable to any other substance or medical condition.

Stimulant-Related Disorders

- *Stimulant-Use Disorders:* Two or more of the symptom criteria should be present within the previous 12 months.
- *Intoxication:* Intoxication typically includes a sudden change in behavior, which can include hypervigilance, euphoria, etc., accompanied by two or more of the following: pupil dilation, either an increase or decrease in heart rate, blood pressure, or motor activity. Chest pain, nausea and/or vomiting, weight loss, or neurological changes such as seizures, dystonias, or confusion. Symptoms occur either during or shortly after use. The above symptoms are not attributable to any other substance or medical condition.
- *Withdrawal:* Occurs within hours or days of last use. There is intense dysphoria and weariness. Suicidal thoughts and behavior can develop. Characteristic withdrawal includes severe dysphoria and two or more of the following: fatigue, vivid nightmares, insomnia or hypersomnia, increased appetite, and psychomotor retardation or agitation. Some people may have only mild withdrawal symptoms. Experienced heavy users may plan their drug use to include substances that can prevent or minimize withdrawal. The above symptoms cause significant sociocognitive impairment and are not attributable to any other substance or medical condition.

Tobacco-Related Disorders

- *Tobacco-Use Disorder:* Two or more of the symptom criteria should be present within the previous 12 months.
- *Tobacco Intoxication:* No characteristics for intoxication.
- *Tobacco Withdrawal:* Cessation of daily tobacco use will produce symptoms within 24 hours. Four or more of the following symptoms must be present: depressed mood, sleep disturbances, impaired concentration, anxiety, restlessness, appetite increase, and irritability. The above symptoms cause significant sociocognitive impairment and are not attributable to any other substance or medical condition.

Table 18.15 Clinical Presentation: Selected Substance Intoxication and Withdrawal—cont'd

Hallucinogen-Related Disorders

- *Phencyclidine- or Other Hallucinogen-Use Disorder:* Two or more of the symptom criteria should be present within the previous 12 months.
- *Phencyclidine or Other Hallucinogen Intoxication:* Several behavioral symptoms occur shortly after use of phencyclidine. These symptoms can include impulsiveness, aggressiveness, confrontational and psychomotor agitation, etc. Two of the following signs and symptoms will generally occur within 1 or 2 hours following ingestion of the substance: nystagmus, increased heart rate or blood pressure, decreased sensitivity to pain, ataxia, sensitivity to sound, muscle rigidity, and seizures or coma. For other hallucinogens the psychological symptoms that occur shortly after use include significant depression, anxiety or paranoia, "fear of losing one's mind," accompanied by significant perceptual changes. Shortly after use, two or more of the following signs and symptoms will occur: pupil dilation, increased heart rate and blood pressure, tremors, sweating, and incoordination. The above symptoms are not related to any other substance or medical condition.
- *Phencyclidine or Other Hallucinogen Withdrawal:* There are no established withdrawal symptoms.

Inhalant-Related Disorders

- *Inhalant-Use Disorders:* Two or more of the symptom criteria should be present within the previous 12 months.
- *Inhalant Intoxication:* Problematic behaviors occur after exposure to an inhalant. Intoxication typically includes a sudden change in behavior, which can include belligerence and impaired judgment accompanied by two or more of the following: neurological symptoms such as nystagmus, dizziness, slurred speech, incoordination, unsteady gait, tremor, muscle weakness and decreased reflexes, vision changes, lethargy, and euphoria. The above symptoms are not related to any other substance or medical condition.
- *Inhalant Withdrawal:* Generally mild and not recognized as a specific disorder.

Opioid-Related Disorders

- *Opioid-Use Disorder:* Two or more of the symptom criteria should be present within the previous 12 months.
- *Opioid Intoxication:* Intoxication typically includes a sudden change in behavior, which can include euphoria, change in motor activity, indifference, etc., with pupillary constriction and accompanied by either slurred speech, impaired concentration, or altered mental alertness. Symptoms occur either during or shortly after use. If hallucinations are present, a specifier with perceptual disturbances is required. The above symptoms are not related to any other substance or medical condition.
- *Opioid Withdrawal:* Can occur either on interruption in use or with the administration of an opioid antagonist. Characteristic withdrawal begins within minutes to days after last use. At least three of the following symptoms need to be present: severe dysphoria, gastrointestinal symptoms of nausea and/or vomiting or diarrhea, eye tearing or rhinorrhea, diaphoresis or pupillary dilation, fever, yawning, and sleep disturbances. The above symptoms cause significant sociocognitive impairment and are not related to any other substance or medical condition.

Sedative, Hypnotic, or Anxiolytic Disorders

- *Sedative-, Hypnotic-, or Anxiolytic-Use Disorders:* Two or more of the symptom criteria should be present within the previous 12 months.
- *Sedative, Hypnotic, or Anxiolytic Intoxication:* Intoxication typically includes a sudden change in behavior, which can include significant and frequent changes in mood, aggression, or impaired judgment. In addition, one or more of the following symptoms: nystagmus, change in sensorium, change in gait, garbled speech, or coma. Symptoms occur either during or shortly after use. The above symptoms are not related to any other substance or medical condition.
- *Sedative, Hypnotic, or Anxiolytic Withdrawal:* Symptoms can occur within hours to days of last use. Symptoms can include tremor, palpitations, increased blood pressure, nausea and vomiting, motor hyperactivity/restlessness, nervousness, insomnia, hallucinations, and grand mal seizures. At least two of the above symptoms must be present. The above symptoms cause significant sociocognitive impairment and are not related to any other substance or medical condition.

Caffeine-Related Disorders

- *Caffeine Intoxication:* Recent ingestion of a caffeinated product (usually greater than 250 mg). In addition, five of the following symptoms occur shortly after ingestion: agitation, excitability, diuresis, facial flushing, an increase in motor activity, insomnia, tachycardia, etc. The above symptoms cause significant sociocognitive impairment and are not related to any other substance or medical condition.
- *Caffeine Withdrawal:* Sudden cessation or decreased use of daily caffeine generally results in symptoms within 24 hours. Three or more of the following symptoms must be present: headache, fatigue, impaired concentration, mood changes, and various physical symptoms such as muscle aches and nausea and vomiting. The above symptoms cause significant sociocognitive impairment and are not related to any other substance or medical condition.

Source: American Psychiatric Association. *Diagnostic and statistical manual of mental disorders, fifth edition* (DSM-5). American Psychiatric Association, Arlington, VA, 2013.

stable at 300 mg per person per day. At low doses, caffeine causes symptoms such as insomnia and restlessness. At high doses (greater than 1,000 mg/day), caffeine may induce arrhythmias, and psychomotor agitation can occur. Death from caffeine can occur with ingestion of 5 to 10 g. Well-known products that contain caffeine are coffee, tea, soft drinks, over-the-counter medications, energy drinks, some snack foods, some ice creams and yogurts, and chocolate. There is great variability in the amount of caffeine present in products as well as the individual's response to a particular dosage. The primary source of caffeine for adults and youths comes from beverages. The caffeine content of coffee can range from 95 to 330 mg depending on the size of the beverage. Even decaffeinated coffee contains small amounts of caffeine ranging from 3 to 12 mg/serving. The caffeine content of tea ranges from 15 to 74 mg/serving. Caffeinated soft drinks include colas, Mountain Dew, and some root beers. The caffeine content of these beverages can range from 22 to 69 mg per 12 ounce serving. Energy drinks can contain anywhere between 33 and 400 mg of caffeine per serving. Over-the-counter medications that contain caffeine include analgesic and weight loss products, as well as agents used to inhibit sleep; caffeine contained in these products can range from 30 to 130 mg/serving. For further information on various or specific products, see the FDA report at www.fda.gov/downloads/AboutFDA/CentersOffices/OfficeofFoods/CFSAN/CFSANFOIA-ElectronicReadingRoom/UCM333191.pdf. Nowadays, youth are exposed to caffeine products at younger ages. The impact of long-term, higher caffeine exposure at younger ages poses many unanswered questions.

Gambling Disorder

To meet the DSM-5 criteria for a gambling disorder, four of following symptom criteria need to be present for 12 months and the disorder must be causing significant distress:

- The amount of money used to gamble increases to achieve same level of excitement
- Displays symptoms of irritability when attempting to decrease or stop gambling
- Attempts to stop or decrease gambling have failed
- Spends significant amount of time trying to figure out how to get money to gamble or planning next episode
- Gambling often occurs when feeling distressed
- Attempts to break even by returning to gamble after a loss
- Lies to others
- The behavior has harmed relationships with significant others (family, friends, employer, etc.)
- Is unable to manage financial responsibilities independently

Severity of the disorder is rated as mild with 4 to 5 criteria met, moderate with 6 to 7 criteria met, and severe with 8 to 9 criteria met.

Management

The first treatment goal in substance abuse is abstinence. Research for many years has shown that moderation in usage is rarely effective for those with a substance abuse problem. The second goal is restoring the physical, psychological, and social well-being of the person and family. Significant damage has often been done to the patient's support system. The family may have additional codependent and enabling issues to address and also may need treatment. Sometimes relationships that have remained intact during the substance-abuse phase ultimately falter and disintegrate when one partner becomes engaged in treatment.

Although some patients with substance-related problems recover without formal treatment, especially as they age, most require a variety of interventions. Approaches include specific procedures or techniques such as individual therapy, family therapy, group therapy, relapse prevention, pharmacotherapy, and treatment programs. Treatment programs tend to be multidisciplinary and often include a specific set of procedures. However, there is no standardization of terminology for categorizing treatment programs and procedures, and their effects are difficult to measure. Broadly, some programs focus on controlling acute withdrawal (detoxification), and others aim at long-term behavioral change. Some use pharmacological interventions, and others are based on individual psychotherapy, Alcoholics Anonymous (AA) or other 12-step principles, or therapeutic community principles. Publicly funded treatment programs for drug dependence are categorized as methadone maintenance (mostly outpatient), outpatient drug-free programs, therapeutic communities, or short-term inpatient programs. Substantial reduction in illicit drug use, antisocial behaviors, and psychiatric distress among patients dependent on cocaine or heroin are much more likely following treatment lasting at least 3 months. Such a time-in-treatment effect is seen across very different modalities, from residential therapeutic communities to ambulatory methadone maintenance programs.

After an initial period of detoxification, persons in treatment for substance abuse will need a period of sustained rehabilitation that includes education, support, and, in some cases, psychotropic drugs to discourage them from using the substance involved or to treat any underlying psychiatric disorder.

Patients with substance-use disorders may be resistant and fearful or lack the will and motivation to confront their behavior. In addition to primary care, specialized substance treatment services are needed if the patient's disorder is to be addressed adequately and his or her risk for substance-related disability, morbidity, and mortality are to be decreased. Primary-care practitioners are often the first health-care professionals to observe the health and psychosocial impact of substance abuse; sometimes the practitioner is the only health-care professional the

patient is willing to talk to. Clinicians can take advantage of this by striving to help patients recognize their substance abuse and take the first steps toward improvement. Several options are available from brief advice, printed information, brief intervention (FRAMES) (see Resources), professional intervention, peer intervention, and referral to treatment and/or self-help groups. Brief intervention has been most helpful for the "at-risk" drinker; for the dependent drinker, its role is less clear.

An *intervention* is a strategy to get a person who has been resistant to treatment to confront the reality of his or her drug and/or alcohol problem. In a private location, close family and friends confront the individual with the facts of his or her substance abuse and the consequences of actions the individual has taken or failed to take. The intervention is an attempt to hold the person accountable for his or her actions, using a "tough love" approach. The end result sought is for the person to willingly choose to seek treatment. Patients with poor physical health or severe legal and interpersonal problems will need improvement in these areas in order to feel able to change their substance-abuse behaviors. Substance-related mental disorders should be treated as well. Patients often already have a great deal of information about their substance abuse and the benefits of stopping. The most useful patient education will address the process of stopping. Some people are able to stop on their first try, but the more typical pattern is repeated efforts to stop until the individual is finally substance free.

Specific management of each case will depend on the substance being abused. General indications for the need for inpatient treatment of substance abuse are presented in Table 18.16. Specific interventions and assessment tools the clinician may use for nicotine or alcohol disorders can be accessed from www.surgeongeneral.gov/tobacco/tobaqrg.htm and www.ahrq.gov/legacy/clinic/tobacco/tobaqrg.htm. Clinical tools can be accessed at www.projectcork.org.

Pharmacological therapies are available for nicotine, alcohol, and opioid disorders. Nicotine agents are listed in Drugs Commonly Prescribed 18.5. Pharmacological options for maintenance of alcohol abstinence in dependent drinkers include disulfiram (Antabuse), oral and extended-release injectable naltrexone (Revia), and acamprosate (Campral) (Level I; Anton et al, 2006). For most, naltrexone is the primary drug choice unless co-occurring opioid use is present (Level II; Rösner et al, 2010).

Treatment options for opioid disorders may include detoxification (managed opiate withdrawal), behavioral strategies, and pharmacological intervention. Long-term maintenance of abstinence can be achieved by methadone maintenance and buprenorphine (Subutex, Buprenex) alone or with naltrexone. It is imperative for all disorders that behavioral therapies are ongoing

Table 18.16 Indications for Inpatient Treatment of Substance Abuse

Several factors need to be considered when identifying the best treatment placement for patients with substance-use disorders. Of particular concern is withdrawal from alcohol and from the sedative, hypnotic, and anxiolytic agents. Withdrawal from these agents can cause cardiovascular collapse, delirium, and death. Withdrawal from opiates does not impart the same risk. Cardiac monitoring may be indicated in cocaine intoxication. Assessing medical stability requires evaluation of several factors. These factors include the following:

Current Situation

- Severe illness—unable to tolerate oral medications
- Suicidal and homicidal ideation—either in ideation or intent
- Lengthy and heavy substance abuse
- Prior unsuccessful attempts at ambulatory medically supervised withdrawal
- Social conditions such as homelessness with decreased chance to complete ambulatory medically supervised withdrawal
- Active psychosis or severe cognitive impairment
- Medical conditions—cardiovascular disease, pregnancy, liver disease
- Withdrawal symptoms for the substance *OR* taking the same (or closely related) substance to relieve symptoms of withdrawal
- Alcohol withdrawal symptoms as defined by DSM-5. Objective measurement of alcohol withdrawal symptoms is recommended. The Clinical Institute Withdrawal Assessment of Alcohol (CIWA-Ar) is commonly utilized. Scores of greater than 20 are considered severe; 10–19 moderate withdrawal; and scores less than 10 are interpreted as mild. Consider inpatient management for scores greater than or equal to 10.
- Severely dependent on sedative, hypnotic, and anxiolytic agents

Past History

- History of withdrawal
- History of withdrawal seizures or delirium tremens

VHA/DoD clinical practice guideline for the management of substance use disorders. 2009. Retrieved from www.guideline.gov/summary/summary.aspx?doc_id=3169&nbr=002395&string=VHA%2fDoD.

(Level II; Lieber et al, 2003; Willenbring et al, 1995; Willenbring & Olson, 1999).

Treatment of the severely mentally ill who are also drug dependent continues to pose problems; specialized addiction agencies have trouble treating such patients. Generally, integrated treatment of both the psychiatric disorder and the addiction is more effective than either parallel or sequential treatment. Integrated models of care are limited but increasingly recognized in local and state mental health agencies. A related issue is the funding of treatment programs for substance-related disorders in general. Managed care organizations tend to assume that the relatively brief course of outpatient counseling will be effective with patients who are dependent on illicit drugs, perhaps suffer from significant comorbidities, and who have minimal social supports. At present, the trend is a short-term view that provides the care that costs the least, ignoring studies that show that more services can produce better long-term outcomes.

Follow-up and Referral

In addition to primary care, patients being treated for substance abuse will need access to several information and support resources, which should include education services, treatment programs, and support groups. It is unlikely that any single program or support group will be sufficient, so patients are encouraged to make repeated contact with several different types of programs and groups (see Case Study 18.2).

Referral to a specialist should be made immediately when the patient's behavior represents a danger to self or others. Substance abuse, particularly alcohol abuse, is a factor in motor vehicle accidents, family violence, and suicide. It can also be very helpful for patients to have at least one appointment with a specialist, in order to develop a comprehensive assessment of the patient's substance use and abuse. For the patient, this assessment is a critical source of information that can reduce his or her ambivalence toward making needed changes in substance-related behaviors. Seeing a specialist can also be motivational, in that one of the most common reasons for failing to try to make required changes in behavior is the patient's unspoken fears of failure.

Patient Education

Individuals who have developed psychological and physical needs for a substance often have also formed strong attachments to their substance-use lifestyle and substance-based relationships. It may be impossible to effectively address a person's substance abuse without taking into account his or her substance-based relationships and attachments. A person can become strongly attached to the people, places, and community that make up his or her substance-abuse lifestyle. From friendships among coworkers that develop at designated smoking areas to football parties and alternative lifestyles, for many people, the thought of giving up their attachments may be more painful than the thought of giving up their actual substances of abuse. The fear of losing these valued attachments is frequently used to rationalize continued substance abuse.

Personal losses may increase or decrease the motivation to significantly change substance-use behaviors. Individuals who have not suffered substance-abuse–related losses may nevertheless have to deal with significant interpersonal conflicts related to their substance-abuse behaviors. Years of substance abuse can result in the loss of all non–substance-based relationships, significant loss of self-esteem, financial losses, and loss of physical and mental health. These personal losses can have a devastating psychological impact on the individual. The patient may feel that he or she is in a no-win situation: Feelings of hopelessness may manifest as ambivalence about making needed changes in substance-use behaviors or bravado about continued substance abuse.

CASE STUDY 18.2 Substance Abuse and the *Circle of Caring*

The following vignette, abstracted from L. Smith-Battle, M.A. Drake, and M. Diekemper, "The Responsive Use of Self in Community Health Nursing Practice," *Advances in Nursing Science* 20(2):85, 1997, addresses a person with substance abuse. It is a story that highlights the skills of involvement, coordination, and advocacy that helped to reintegrate this mother into the community and the child into the family. The mother's eventual reintegration was contingent on the APRN's responsiveness and perseverance in a situation with an uncertain outcome, which demonstrates practice within a *Circle of Caring*.

In this situation, an unreceptive new mother tested positive at the birth of her baby for cocaine abuse. The infant was severely injured at 2 months of age in a car accident when, unrestrained, he hit his head against the dashboard. The infant was removed from the mother's care and placed with an aunt. The following account is from a nurse involved with the family:

> [In the year after the accident], I saw the baby at the aunt's house and we got him involved with developmental programs . . . I hooked them up with all that . . . Meanwhile, I was visiting mom. [Describes how the mother was in and out of treatment programs.]

CASE STUDY 18.2 Substance Abuse and the *Circle of Caring*—cont'd

I got a phone call from her one morning. She told me that a drug dealer had beat her up and put a gun to her head over a 5-dollar debt. "I'm going to die. I'm either going to get killed or I'm going to die of using cocaine." So I worked with the social worker and we got her into a long-term, 3-month treatment [program] away from the entire environment. And when she came back, I will never forget, I cried when I called her. She had make-up on. She had gained weight . . . I didn't even recognize her . . .

A year later, when she came back, she started visiting with her son at the aunt's house, and gradually the whole team, the social worker, myself, the aunt, and all other interventionists, we had huge meetings and we basically started reintegrating the child into the home. And now she has him full-time. And she's been clean . . . She keeps up with all [her son's appointments] and she goes to Narcotics Anonymous three times a week. She wants to become a treatment counselor and . . . she finished her GED. She's just a total success story . . .

. . . She told me once, "Everyone that ever cared about me has left me or treated me like crap." . . . [it] was the first time in her life where [although] she was down-right obnoxious and hateful [to me], I never bit back or quit coming. I mean, I accepted her behavior because I knew it was the drug use and it wasn't her.

The clinician should educate patients regarding the effects of drugs, especially during pregnancy, and provide information on substance abuse and treatment to patients and their families. Practitioners should provide information regarding danger of exposure to HIV, hepatitis, and other infections, and to obtain appropriate testing if there is suspicion of exposure. Care providers should teach family members about the dynamics that may continue to enable substance abuse; often they are unaware of these. The clinician can give family members specific feedback in this area about behaviors that he or she has observed; it is also important to discuss the strategy of using an intervention with the family and how to set up one if indicated.

Codependence is a term that has come to mean the behavioral patterns of family members who have been significantly affected by another family member's substance use or addiction. Related concepts of enabling and denial may characterize family members of patients who abuse substances. Twelve-step programs should be encouraged—for example, Narcotics Anonymous (NA) or Alcoholics Anonymous (AA) for the individual with the substance-abuse problem and Al Anon for family members. As noted earlier, family members and significant others need treatment also. The *Circle of Caring* model may be utilized in caring for those with addictions.

SLEEP–WAKE DISORDERS

Description and classification of sleep–wake disorders has been expanded in DSM-5 to reflect the important diagnostic overlay of medical conditions that affect normal sleep patterns. Of particular importance to primary care are Insomnia Disorder, Obstructive Sleep Apnea Hypopnea Syndrome (OSAHS), Substance/Medication Induced Disorder, and Restless Legs Syndrome (RLS). Insomnia disorder will be presented in detail, because insomnia is an underpinning of each of these disorders. The criteria and important contributing factors for OSA, RLS, and substance-induced sleep disorder will be discussed.

Insomnia disorder, or difficulty sleeping, is an extremely common problem, yet it is one that is etiologically complex. It is defined as difficulty in falling asleep or maintaining sleep, early morning wakefulness, or any combination of these. It must cause clinically significant distress or functional impairment, occur at least 3 nights per week, be present for at least 3 months, and not be a consequence of a substance.

Epidemiology and Causes

It is estimated that 10% to 17% of the primary-care population report daytime insomnia symptoms and that 6% to 10% meet criteria for the disorder. Women appear to be slightly more affected than men are, and up to 50% of sufferers have a comorbid mental disorder.

Acute insomnia may be precipitated by physical or emotional discomfort. Examples include pain, acute illness, and environmental disturbances such as noise, light, and temperature. Sleeping at a time that is inconsistent with daily biological (circadian) rhythms because of plane travel across time zones (jet lag) or shift work may also precipitate acute insomnia. Any number of underlying medical conditions may contribute to insomnia. Pain may contribute to wakefulness; indeed, often the question, "Does the pain awaken you at night?" is an important piece of information in determining the severity of pain. Examples of painful conditions that commonly affect sleep are arthritis and muscle cramps. Insomnia is also associated with some types of delirium and dementias (e.g., "sundowning"). Acid reflux and duodenal ulcers may also cause insomnia. Fibromyalgia is closely associated with insomnia and is classified by

some as a sleep disorder. Additional risk factors for insomnia include chronic illnesses, thyroid disorders, obesity (also correlated with sleep apnea), and drug usage. Insomnia related to discomfort in certain sleeping positions is common during pregnancy; it may also occur during the postpartum period because of caregiving that interrupts sleep, along with postpartum hormonal shifts.

A variety of psychosocial problems may also contribute to insomnia: Anxiety, mania, and schizophrenia specifically are associated with insomnia. Traumatic events can precipitate an acute, transient insomnia that may become chronic if not properly managed. Chronic stress, hyperarousal of the type associated with PTSD, poor sleep hygiene, and behavioral conditioning may contribute to primary insomnia—insomnia that cannot be related to any specific underlying factors.

Pathophysiology

Normal sleep is a periodic state of rest accompanied by varying degrees of unconsciousness and relative inactivity. It is normally an easily reversible, regular, recurrent state. The functions of sleep are restorative and hemostatic, critical for normal thermoregulation and energy conservation. Sleep disturbance is often an early symptom of impending mental illness.

Two physiological states compose sleep: non–rapid eye movement (NREM) and rapid eye movement (REM) sleep. In NREM sleep most physiological functions are markedly lower than in wakefulness although there may be episodic, involuntary body movements during NREM sleep. In contrast, REM sleep is characterized by physiological activity levels similar to those in wakefulness and a high level of brain activity and is sometimes called *paradoxical sleep.* NREM sleep is composed of stages 1 through 4, with stages 3 and 4 being the deepest portions. Typically, NREM sleep is punctuated with an REM cycle typically every 90 to 100 minutes during the night. The first REM period tends to be the shortest, lasting less than 10 minutes; later REM periods may last 15 to 40 minutes each. Most REM periods occur in the last third of the night; most stage 4 sleep occurs in the first third of the night.

These sleep patterns change over the course of a person's life. In young adulthood, REM comprises about 25% of sleep, and NREM approximately 75%. These figures remain fairly constant in normal sleep, although there is a reduction in both slow-wave sleep and REM sleep in older persons. NREM sleep increases after exercise and starvation and is thus thought to be associated with satisfying metabolic needs.

Daily variations in a variety of physiological functions affecting the endocrine, thermoregulatory, cardiac, pulmonary, renal, gastrointestinal, and neurobehavioral systems, as well as sleep–wake cycles, are governed by the 24-hour rhythm in humans. The timing and internal architecture of sleep are coupled directly to the output of the endogenous circadian pacemaker. Misalignment of the output of the endogenous circadian pacemaker with the desired sleep–wake cycle can, therefore, induce insomnia, decrease alertness, and impair performance of shift workers, and accounts for the phenomenon of jet lag. Sleep deprivation for prolonged periods can lead also to hallucinations, ego disorganization, and delusions, and REM-deprived patients may exhibit irritability and lethargy.

Clinical Presentation

Insomnia may not be the chief reason for an office visit. It may be detected, however, by incorporating sleep-related questions into the general review of systems. Direct inquiry is important because patients with chronic insomnia often have never discussed their problem or have lived with it for so long that they do not think that anything can be done about it. The primary consequences of acute insomnia are sleepiness, negative mood, and impairment of performance. The severity of the components is related to the amount of sleep lost on one or more nights. Patients with chronic insomnia frequently complain of fatigue, mood changes (e.g., depression, irritability), difficulty concentrating, and impaired daytime functioning.

The assessment should include questions about sleep, as well as questions about daytime functioning, where the full effects of altered sleep are manifested. The actual number of hours of sleep required for each individual to subjectively feel refreshed varies markedly. Although the ability to maintain sleep alters with age, the individual's need for sleep does not change significantly. The patient's medical history and comorbidities are other important parameters that should be documented. Many medical problems, such as gastroesophageal reflux disease (GERD), worsen at night because they may be aggravated by recumbency.

It is necessary to rule out all underlying causes, for example, pain and the disease or condition that is the cause of the pain. A thorough drug history must be taken, including all over-the-counter drugs such as decongestants and cough syrups that contain decongestants, which act as stimulants. In addition, a complete history of all herbal remedies used, especially teas that may contain caffeine or ginseng and a variety of other CNS stimulants, should be obtained. When patients buy products in health food stores, they often do not think of them as "drugs." Screen for any illicit drug and alcohol use. (See Focus on History 18.1).

It may also be helpful for the patient to keep a sleep diary (see www.sleepeducation.com/EvaluateSleep.aspx). A sleep diary is a useful tool to track exactly when and under what conditions the patient sleeps, as well as diet, exercise, and drug habits that may help reveal the underlying problem. In addition, a record of all exercise and physical activity may prove helpful. The sleep diary also helps to further define the nature of the sleep problem. The delayed sleep phase type of circadian

Focus on History 18.1 Insomnia

Questions to ask:

- How has the person been sleeping recently?
- How long has the problem existed?
- Does the person have any underlying psychiatric or medical conditions?
- Is the person's sleep environment conducive to sleep? For example, are there any problems that would make sleeping difficult, such as noise, temperature, light, or space?
- Does the person work shift work or odd hours? What time does the person usually go to sleep? Get up? Are these hours the same on the weekday as well as the weekend?
- Does the person travel frequently?
- Does the person use caffeine, alcohol, drugs, or tobacco? If so, how much, and what are the specifics concerning the patient's use?
- Does the person have difficulty staying awake or report dozing off during normal daily activities?
- Does the person report any daytime consequences of not sleeping?
- Does the person (or partner) report:
  - Loud snoring, gasping, or stop breathing at night? (Suggests sleep apnea)
  - Legs or arms jerking during sleep? (Suggests periodic limb movement)
  - Creeping, crawling, or uncomfortable feelings in the legs that are relieved by moving them? (Suggests restless legs syndrome)

rhythm sleep disorder, for example, manifests itself with difficulty falling asleep at the desired time and difficulty waking at the desired time. The advanced sleep phase pattern, in contrast, is characterized by difficulty staying awake in the evening and by early awakening. Some persons awaken during the night and cannot fall back to sleep. Consider screening for insomnia as part of regular patient care (Level II; Schutte-Rodin et al, 2008).

Diagnostic Reasoning

DSM-5 Symptom Criteria

The DSM-5 symptom criteria for insomnia disorder are as follows:

1. Dissatisfaction with sleep quantity or quality associated with
   - Difficulty initiating sleep.
   - Difficulty maintaining sleep
   - Early-morning awakening with inability to return to sleep.
2. The sleep disturbance occurs at least three times per week for at least 3 months and causes clinically significant distress or impairment in social, occupational, educational, academic, behavioral, or other important areas of functioning.
3. Co-occurring mental disorders and medical conditions do not adequately explain the predominant complaint of insomnia.

There may be objective corroboration by a family member of acute or chronic insomnia, but basically insomnia is a subjective complaint. In cases of suspected sleep apnea, it may be necessary for the patient to undergo polysomnography. Reserve laboratory evaluation for confirmation of medical or other sleep disorders that may underlie insomnia, such as obstructive sleep apnea (Level II; Schutte-Rodin et al, 2008).

Management

Nonpharmacological Management

The first National Institute of Health "state of the science" conference on insomnia since 1983 was held in June 2005. One important finding was recognition of the tendency of insomnia to be a chronic, potentially lifelong illness. Given the chronic nature of this problem, long-term treatment is often advisable. The panel stated that evidence supports the efficacy of cognitive-behavioral therapy (CBT) for the treatment of chronic insomnia (Level I; Schutte-Rodin et al, 2008), but it noted that there is very little evidence to support the efficacy of other treatments (including antidepressants, antipsychotics, and antihistamines), despite their widespread use.

Nonpharmacological treatment is therefore recommended in the initial management of insomnia (Levels I, II; Schutte-Rodin et al, 2008). The clinician should review and explain sleep hygiene "violations" expressed by patients (Level I; Schutte-Rodin et al, 2008). Recommendations include keeping sleeping and waking times regular, spending less than 8 hours in bed, maintaining adequate nutrition and exercise regimens, and avoiding sleep-altering substances such as caffeine and alcohol. All underlying causes of insomnia, such as pain, must be treated. Any drugs and/or herbal supplements that may be contributory should be discontinued. The patient should be encouraged to avoid daytime napping and to develop bedtime rituals that are conducive to sleep. Recommendations for appropriate sleep parameters include associating the bedroom with "sleepiness," not staying in bed for longer than 20 minutes when wakeful, and leaving the bedroom until tired, before returning (Level II; Schutte-Rodin et al, 2008). An exercise schedule may prove beneficial, although evening exercise may be stimulating. Alcohol should be avoided after 5:00 p.m., as should heavy evening meals (a light evening snack may sometimes be conducive to sleep). Reassurance and supportive counseling are essential; insomnia is not a complaint that should be taken lightly. Issues of caregiving for young children or older adults living in the home

may be a part of the clinical picture. Again, diversionary lifestyle changes and situational support may be more effective than pharmacological measures for these patients. Sleep parameters can be reviewed and reemphasized several times during return visits before resorting to pharmacological measures. (See Advanced Practice Nursing Interventions 18.2.)

Pharmacological Management

Some evidence suggests that for some patients with persistent insomnia, adding a short course of a medication to CBT produced an additive benefit. Advantages of the sedative-hypnotics are that they hasten sleep onset, decrease the number of nighttime awakenings, increase total amount of sleep time (varies with medication duration of action), and make sleep more refreshing. Some of the disadvantages are that they may alter sleep architecture over time by decreasing slow-wave sleep and REM sleep and that they may cause residual sedation, psychomotor and cognitive impairment, psychological dependence in vulnerable individuals, and rebound insomnia. Medications indicated for insomnia include five older benzodiazepines (estazolam, flurazepam, quazepam, temazepam, and triazolam) and three newer nonbenzodiazepine medications (eszopiclone, zaleplon, and zolpidem). The elimination half-lives of the sedative-hypnotics (see Drugs Commonly Prescribed 18.6) vary tremendously, and as a result, so does their duration of action. The advantages and disadvantages of a given duration of action must be assessed in light of each patient's individual needs. All agents in this class have some potential for abuse although the newer agents may have less. All are classified as Schedule IV by the DEA. Clinical trials have provided some evidence that sleep can improve to some degree without the use of any medication, because patients receiving placebo often reported as much improvement during the study as those taking medication. In sleep studies, a placebo is not an "inactive" treatment in that all study participants must adhere to nonpharmacological regimens (such as going to bed and getting up at regular hours, not napping, avoiding caffeine and alcohol) that are recognized as effective remedies for insomnia. Depression is the most common comorbid psychiatric diagnosis with chronic insomnia; however, medications such as the SSRIs should be utilized only in the setting of depression and not solely for the treatment of insomnia (Level II; Schutte-Rodin et al, 2008). Concurrent treatment of both insomnia and an underlying psychiatric comorbidity may result in greater improvements for the patient.

Advanced Practice Nursing Interventions 18.2 Insomnia

Behavioral Treatment	Relaxation therapy (progressive muscle relaxation therapy), autogenic training, electromyogram, biofeedback.
Sleep Restriction Therapy	Poor sleepers often increase their time in bed. Sleep restriction therapy curtails this time. For example, if a person reports sleeping only 5 hours per night, he or she should be counseled to stay in bed only 5 hours per night. As sleep improves, increase time in bed in 15- to 30-minute intervals. It works best to alter bedtime and keep rising time constant. Do not reduce sleep to less than 5 hours per night.
Stimulus Control Therapy	Functions on premise that insomnia is a conditioned response to temporal (bedtime) and environmental (bed/bedroom cues). Objective is to reassociate the bed and bedroom with rapid sleep onset. Stimulus control therapy counsels: (1) Go to bed only when sleepy. (2) Use the bed only for sleep. (3) Get out of bed and go into another room when awake; go back into the bedroom only when sleepy. (4) Maintain a regular rise time, regardless of sleep deprivation during the night. (5) Avoid daytime napping.
Cognitive Therapy	Identify dysfunctional ideas about sleep and replace them with more functional approaches, e.g., 8 hours of sleep is not necessary for everyone; insomnia and less sleep does not have to destroy one's life. This approach helps minimize anticipatory anxiety around sleep.
Physical Therapy	Exercise: Regular physical activity will assist with sleep. Advise the patient not to exercise too close to bedtime. Massage: Weekly massage may assist with relaxation.
Pharmacological Therapy	Hypnotics, antidepressants, antihistamines, melatonin.
Reassurance and Support	Active listening and patience; encourage ventilation of feelings, especially if stress is a component of the insomnia.

Drugs Commonly Prescribed 18.6 Sedatives and Hypnotics

Drug	Indication	Adverse Reactions and Prescribing Considerations
Benzodiazepines		C-IV controlled substance. All benzodiazepines are associated with potential anterograde amnesia, CNS depression, and paradoxical reactions. Sedation, memory deficits, ataxia. Caution with narrow-angle glaucoma. Association with falls and injury in the elderly. Caution with depressed patients and substance abuse, impaired hepatic or renal function. Most contraindicated in obstructive sleep apnea (OSA). Many drug–drug interactions (CYP pathways). Withdrawal symptoms with abrupt discontinuation. The onset of withdrawal symptoms is usually seen on the first day without drug and lasts 5–7 days—slow taper. Treatment longer than 4 months should be reevaluated to determine the patient's need for the drug. Avoid valerian, St. John's wort, kava kava, gotu kola. Potential severe allergic reactions (anaphylaxis, angioedema) and complex sleep-related behaviors, which may include sleep-driving, cooking and eating food while asleep, and making phone calls while asleep.
estazolam (ProSom)	Insomnia, short-term	Intermediate acting. No active metabolites
flurazepam (Dalmane)	Insomnia, short-term	Long acting. Avoid in elderly and debilitated. Active metabolites with extended half-lives may lead to delayed accumulation and adverse effects.
temazepam (Restoril)	Insomnia, short-term	Intermediate acting. Administer 30 minutes before bedtime. Lack of active metabolites—excellent option for the elderly.
triazolam (Halcion)	Insomnia, short-term	Short acting. In elderly, higher incidence of CNS adverse reactions; not a drug of first choice.
quazepam (Doral)	Insomnia	Long-acting daytime sedation and fatigue, but may prevent withdrawal symptoms when stopped.
Benzodiazepine Like		CV IV controlled substance. Daytime sedation, anterograde amnesia, rebound insomnia. Less anxiolytic properties than the benzodiazepines. All patients should be advised of residual morning effects and of complex sleep-related behaviors. This may include sleep-driving, cooking and eating food while asleep, and making phone calls while asleep. All patients should be advised to get at least 4 hours of sleep after taking a short-acting agent and at least 7 hours of sleep with a long-acting agent.
eszopiclone (Lunesta)	Insomnia, long-term	Long half-life of 6 hours; good for sleep initiation and maintenance. Advise to get 8 or more hours of sleep. No hangover effect; may have metallic taste. Headache, dizziness, and somnolence. Potentiates CNS depressants.
zaleplon (Sonata)	Insomnia, short-term	Short half-life, about 1 hour. Good for patients that have difficulty falling asleep, not for sleep maintenance. Advise to get at least 4 hours of sleep. Dosage adjustment for hepatic impairment.
zolpidem (Ambien)	Insomnia, short-term	Half-life 1.4–2.4 hours. Good for patients that have difficulty with falling asleep. Headache, dizziness, and somnolence. Take with liquid—food can delay absorption; CNS depression. No known rebound insomnia or hangover effect. Reduced dosage in women and geriatric populations.

Continued

Drugs Commonly Prescribed 18.6 Sedatives and Hypnotics—cont'd

Drug	Indication	Adverse Reactions and Prescribing Considerations
zolpidem CR (Ambien CR [extended release])	Insomnia, long-term	Half-life 1.4–2.4 hours, but released over a longer duration. Headache, dizziness, and somnolence. Sleep may be impaired after discontinuation. Abuse potential low. Reduced dosage in women and geriatric populations. Complex sleep-related behaviors, which may include sleep-driving, cooking and eating food while asleep, and making phone calls while asleep.
Melatonin Receptor Agonist		
Insomnia	Ramelteon (Rozerem)	Indicated to promote sleep onset. Peak concentrations within 1 hour if fasting, avoid high fat meal. No withdrawal or rebound insomnia. Does not affect REM sleep. May affect testosterone and prolactin levels. Somnolence, dizziness, fatigue, nausea, and exacerbated insomnia. Monitor liver transaminases.
OTC		
diphenhydramine (Benadryl)	Insomnia, short-term use less than 2 weeks	May have next day sedation, dry mouth, decreased cognitive function. Potentiates CNS depression; caution with asthma, other respiratory disorders; glaucoma; hyperthyroidism.

Source: Clinical pharmacology [database online]. Gold Standard, Inc., Tampa, FL, 2012. http://cp.gsm.com.

Follow-up and Referral

Transient insomnia may turn into chronic insomnia. For this reason, treatment is essential. Insomnia should resolve with patience, counseling, and treatment, and patients should be followed until the situation is resolved (Level II; Schutte-Rodin et al, 2008). A concern is daytime sleepiness (sleep apnea, for example, is highly correlated with car accidents). The patient may need to be referred for supportive counseling, especially if insomnia is related to a traumatic event. The entire environmental situation of the patient and family should be assessed. Are there caregiver issues involved, and can external and additional support be provided or arranged for? Is there a need for diversionary activities, or a need to increase the individual's physical activity level? If sleep apnea is suspected, a polysomnogram should be ordered.

OBSTRUCTIVE SLEEP APNEA/HYPOPNEA

This is the most common sleep-related manifestation of medical illness, defined as repeated episodes of upper pharyngeal obstruction during sleep. *Hypopnea* refers to reduced airflow, and *apnea* to a total restriction of airflow. Symptoms are most prominently daytime sleepiness and nighttime snoring. Associated medical conditions include GERD, hypertension, headache, reduced libido, and erectile dysfunction.

Epidemiology

Obstructive sleep apnea (OSA) is a common disorder, occurring in 1% to 2% of children, 2% to 15% of middle-aged adults, and in over 20% of older adults. The condition is very strongly associated with obesity and with male gender. There is also a genetic basis, with a twofold risk among first-degree relatives of probands.

Diagnosis and Management

The differential diagnosis includes ruling out other sleep-related disorders such as narcolepsy, hypersomnia, and circadian rhythm disorders. Polysomnography (PSG) is the hallmark of diagnosis and treatment of OSA. The test uses respiratory effort and peripheral pulse oximetry to quantify episodes of hypopnea and apnea. This is reported as the apnea-hypopnea index (AHI). PSG records brain electrical activity, eye movements, and muscle potentials, indices that may help to identify and diagnose restless legs syndrome and other disturbances of the sleep–wake cycle.

Continuous positive airway pressure (CPAP) machines tend to mitigate symptoms and enhance patients' quality of life, but no long-term studies have demonstrated a long-term reduction in mortality. Individuals with OSA have an increased risk of occupational accidents and an almost sevenfold increase in motor vehicle accidents. There may be state-by-state restrictions for commercial drivers suffering from OSA. Associated morbidities range from hypertension and heart failure to neurological disease and depression. Lifestyle modifications most important to the long-term control of symptoms secondary to OSA include weight control, tobacco cessation, exercise, and avoidance of sleep-disruptive agents such as sedatives and alcohol.

DSM-5 Symptom Criteria

The DSM-5 symptom criteria for OSA include either of the following:

1. Evidence by PSG of at least five obstructive apneas or hypopneas per hour of sleep and either of the following sleep symptoms:
   - Nocturnal breathing disturbances: snoring, snorting/gasping, or breathing pauses during sleep.
   - Daytime sleepiness, fatigue, or unrefreshing sleep despite sufficient opportunities to sleep that is not better explained by another mental disorder (including a sleep disorder) and is not attributable to another medical condition.
2. Evidence by PSG of 15 or more obstructive apneas and/or hypopneas per hour of sleep regardless of accompanying symptoms.

RESTLESS LEGS SYNDROME

RLS is a neurological, sensorimotor condition that is typified by uncomfortable sensations in the lower extremities such as burning, tingling, crawling, or itching and an uncontrollable desire to move the legs. One result is the inability to obtain or maintain an appropriate sleep pattern.

Usually a development in older adults, the syndrome does have a familial component, which manifests at younger ages. Important differential diagnoses are arthritis, peripheral neuropathy, ischemia, and radiculopathy. A complete neurological examination and appropriate laboratory testing will help to focus the diagnosis.

Diagnosis is difficult because it is mainly by self-report of symptomatology. There is an overlay of comorbidities including depression, anxiety, panic, and PTSD.

Patient Education

The patient and family members need to be reassured and counseled regarding the transient nature of RLS, including the lifestyle measures that can be instituted to assist with sleep. The establishment of healthful sleep rituals, increasing physical activity and regular exercise, the need to refrain from alcohol consumption and smoking later in the day, and the need to eat lighter in the evening should be discussed. Care should be used with all pharmacological therapies because of the possible adverse effects and their potential for drug dependency, especially in elderly patients.

EATING DISORDERS

Eating disorders, which include both anorexia nervosa and bulimia nervosa, are not routinely assessed in primary care, although they can be a significant health problem. Eating disorders occur on a continuum; the number of individuals with subclinical symptoms exceeds those with full disorder symptomatology. Being female is a risk factor for developing an eating disorder. At present the incidence of eating disorders among males is low, but there is evidence of persistent increases. DSM-5 characterizes feeding and eating disorders as persistent disturbances from altered consumption or restriction of food intake, resulting in significant functional impairment. Included in the DSM-5 classification are Rumination Disorder, Avoidant Food Intake Disorder, Anorexia Nervosa, Bulimia Nervosa, and Binge-Eating Disorder.

Bulimia Nervosa

Recurrent episodes of binge eating, followed by compensatory methods to prevent weight gain, and self-evaluation unduly influenced by body shape are the three essential features of *bulimia nervosa* (BN). Persons with BN undergo feelings of loss of control during bingeing episodes, and their self-esteem is excessively influenced by their body shape and weight.

There are two types of bulimia—purging and nonpurging. A person with BN who purges regularly will engage in self-induced vomiting and/or misuse of diuretics, laxatives, or enemas. With nonpurging BN, persons compensate for their food intake with excessive exercise or fasting. In extreme cases, individuals may abuse thyroid hormone replacement medication or try other types of stimulant medication.

Some individuals with BN alternate between cycles of strict dieting or fasting and cycles of binge eating and purging, whereas others may compensate for binges with excessive (several hours every day) exercise patterns. Persons with BN who cycle between bingeing and fasting or extreme food restricting have a poorer prognosis. The daily number of times the person with BN purges tends to increase over time and can lead to serious medical complications. In the primary-care setting, it is not unusual for persons with BN to refuse to disclose their symptoms.

Individuals with BN experience a sense of lack of control over eating during an episode and tend to misperceive themselves on the basis of their body weight and shape. Comorbidity with other psychological disorders is common, especially depression, anxiety, and substance abuse. Periods of food, calorie, and fat restrictions are often followed by bingeing and purging. The individual may feel an intense sense of shame about this behavior and may go to great lengths to keep it secret from others, including health-care providers.

Anorexia Nervosa

Anorexia nervosa (AN) is characterized by a refusal to maintain a minimally normal body weight and an intense fear of gaining weight. In early adolescence, the patient may also fail to achieve expected weight and height gains. There are two types of AN—restricting and binge-eating/purging AN. With restricting AN, weight loss is usually accomplished by reducing or restricting all food intake or restricting dietary fat. With binge-eating/purging AN, there is binge eating followed by self-induced vomiting and chronic and excessive use of laxatives or diuretics. Providers can expect patients to resist changes in their diet or weight, and patients may put a great deal of effort toward frustrating the practitioner's efforts to help.

Anorexia can be accompanied by serious physiological consequences, including amenorrhea, signs and symptoms of starvation, and electrolyte abnormalities.

One in 10 patients with AN dies suddenly from starvation, cardiac arrest, or suicide. AN is associated with depression in 65% of cases; social phobia in 34%; and obsessive-compulsive disorder in 26% of cases. AN is a serious medical disorder, with estimates of mortality ranging up to 20%. Patients with anorexia nervosa rarely self-identify and often demonstrate poor insight into their condition. Clinicians therefore have a responsibility to help patients recognize their diagnosis and work with them to assess their readiness to change and their integration with additional elements of care.

Epidemiology and Causes

The lifetime prevalence estimate for AN is 0.6% and for BN is 1.0%. For each disorder, the risk is up to three times higher in women than in men, with a median age at onset between 18 and 21 years. An exact cause of eating disorders is not known but is considered to be a possible multifactorial combination of genetic, neurochemical, and sociocultural factors. Recent work indicates that childhood obesity may be a risk factor for bulimia, and there is evidence that familial transmission may occur. The state of starvation itself initiates dramatic physiological changes in a variety of body systems leading to a cascade-like cycle that makes it difficult to discern which biological change may have precipitated the process; nonetheless, it becomes self-perpetuating.

Pathophysiology and Psychopathology

There appears to be a constellation of factors that include biological, social, and cultural forces that contribute to eating disorders. Recent studies point to some genetic differences in the major groups of eating disorders, AN and BN. When families of individuals with a high incidence of bulimia are examined, family members with an increased risk for obesity are found; however, in families of individuals with the restricting subtype of anorexia, there is no increased risk for obesity. So although these are two genetically related disorders, there clearly may be important differences between them. There is an increased frequency of BN in first-degree relatives of patients with this disorder. Some evidence points to higher concordance rates in monozygotic twins than in dizygotic. Sisters of patients with AN are more likely to be affected, but the causality involved may be more social than genetic. Cultural factors may be difficult to ascertain, because few studies have looked at eating disorders and their occurrence in different countries. Certain populations who may not have appropriate access to care may therefore not be accurately diagnosed.

Clinical Presentation

Eating disorders are characterized by intense feelings of shame, guilt, and embarrassment. It is important to know key warning signs of eating disorders to provide care early in the disease process; early intervention has a better prognosis. (See Focus on History 18.2.)

Focus on History 18.2 Anorexia and Bulimia

Anorexia Nervosa	
Warning signs	To assess for warning signs of anorexia, it is important to obtain answers to the following questions: • Has the patient had any *substantial weight loss*? • Does the patient have signs or symptoms of *depression or mood swings*? • Does the patient have a *preoccupation with weight, calories, and food*? • Does the patient *wear baggy clothes*? • Does the patient have a history of *excessive exercise*?
Signs	Hypotension, hypothermia, dry skin, bradycardia, edema, lanugo
Symptoms	Amenorrhea, constipation, abdominal pain, hypothermia, lethargy or fatigue, anxious energy, headaches
Bulimia Nervosa	
Warning signs	To assess for warning signs of bulimia nervosa, it is important to obtain answers to the following questions: • Has the patient had any significant *weight loss or gain*? • Does the patient have signs or symptoms of *depression*? • Does the patient have a *great concern for weight*? • Does the patient *visit the bathroom after meals*? • Has the patient alluded to *strict dieting/bingeing cycles*? • Does the patient have *marked criticism of his or her body*?
Signs	Tooth enamel erosion, enlarged parotid glands, periodontal disease
Symptoms	Irregular menses, abdominal pain, fatigue or lethargy, peripheral edema, bloating, depression

Individuals with eating disorders typically do not present with that as a key symptom or problem but with other somatic complaints. Therefore, the clinician must be alert to screen for these disorders among adolescents and young adults, particularly those thought to be at high risk. Assessment should be comprehensive and include physical, psychological, and social needs and a comprehensive assessment of risk to self. The primary-care provider should take responsibility for initial assessment and the initial coordination of care. This includes the determination of the need for emergency medical or psychiatric assessment. Where management is shared between primary and secondary care, there should be a clear agreement in writing as to who should be monitoring the patient on a regular basis. It should be shared with patient and family so all lines of responsibility are clear.

Screening for eating disorders may use brief screening methods such as questionnaires and clinical presentation. Available screening instruments include the SCOFF Questionnaire, the Eating Disorder Screen for Primary Care (ESP), Eating Attitudes Test (EAT-26), and Eating Disorders Inventory–Second Edition (EDI-2). The SCOFF consists of five questions designed to assess the core features of anorexia nervosa and bulimia. It is a mnemonic, with each letter based on a keyword in each question of the screening tool: **S**ick, **C**ontrol, **O**ne, **F**at, and **F**ood. It was designed to be brief, to be administered in primary care, and to be answered with yes-and-no responses. The EAT-26 is better validated but takes longer to administer and score. The EDI-2 is a standardized measure of symptoms associated with anorexia, bulimia, and other eating disorders. Although reliable and valid with good psychometrics, it does not yield a specific diagnosis but has utility as a screening instrument. Assessment of body mass index (BMI), height, weight, and centile charts for age should be done on all patients. When AN or BN is suspected, a complete physical examination is needed to rule out other diseases or disorders that could produce severe weight loss.

Other physical assessments such as pulse, blood pressure, core temperature, cardiovascular and peripheral examination, and sit-ups/squat test for muscle power should be done on all patients. Laboratory investigations include complete blood count, endocrine testing, erythrocyte sedimentation rate, blood urea nitrogen (BUN) and electrolytes, creatinine, liver function tests (LFTs), random blood glucose, urinalysis, and electrocardiogram.

Anorexia Nervosa

Assessment for AN should include a weight history, including highest and lowest weight, and the frequency with which the person experiences significant weight fluctuations. Ask about ideal weight goals. Persons with AN tend to have extremely unrealistic goals for a low ideal weight. Excessive weight loss is often the most obvious sign of AN, but individuals with AN rarely complain of weight loss. Persons with AN are likely to deny that a problem exists although as they lose more weight, their fear of becoming fat intensifies. Severe weight loss eventually results in electrolyte imbalance and dehydration, with significant risks of serious medical complications such as cardiac arrhythmias. Individuals with AN who purge may experience electrolyte imbalances, edema, and enlarged parotid glands. Long-standing amenorrhea can leave females at risk for developing osteopenia and osteoporosis.

Individuals with AN may complain of hypothermia, constipation, lethargy, or excess nervous energy. APRNs may find evidence of significant hypotension, dry skin, and dull hair. Hypertrophy of the salivary glands may be present if the person with AN purges. Chronic dehydration can result in impaired renal function, cardiovascular problems, and osteoporosis. Positive laboratory findings in AN include leukopenia, anemia, elevated BUN, elevated LFTs, hypomagnesemia, hypophosphatemia, and elevated thyroid-stimulating hormone. Hypercholesterolemia and sinus bradycardia are also common findings in patients with AN.

Bulimia Nervosa

Persons with BN vary in their weight and appearance, but most have a normal BMI score. Many persons with BN have an extensive history of dieting. Assessment of dieting history, including both weight gain and loss as well as dieting, is important. BN is considered less life-threatening than AN; however, serious health complications can also develop with BN.

Dental erosion (from gastric acid) and periodontal disease are common in patients with BN, as are complaints of swollen salivary glands, especially the parotid glands, GERD, sore throat, and esophageal irritation. Persons who regularly engage in self-induced vomiting can develop scars or calluses on the backs of their hands from repeated trauma from the teeth.

Laboratory findings may indicate many abnormalities, including hypokalemia, hyponatremia, hypochloremia, increased serum bicarbonate, and/or elevated levels of serum amylase. In severe cases of purging, electrolyte imbalance and dehydration may lead to cardiac arrhythmias, which can lead to heart failure and sudden death. Esophageal bleeding, tears, and gastric rupture can also occur.

Diagnostic Reasoning

DSM-5 Symptom Criteria

The DSM-5 symptom criteria for anorexia nervosa are as follows:

- Restriction of energy intake resulting in *significantly low weight.*
- Intense fear of gaining weight or of becoming fat.
- Lack of recognition of the seriousness of the current low body weight.

DSM-5 Symptom Criteria

The DSM-5 symptom criteria for bulimia nervosa are as follows:

- Recurrent episodes of binge eating.
- Recurrent inappropriate compensatory behaviors (self-induced vomiting; misuse of laxatives, diuretics, or other medications; fasting; or excessive exercise).

Management

The therapeutic relationship is central to management of the person with an eating disorder. Using the readiness to change model can help the patient and their family set realistic and safe goals. If the patient's condition does not require hospitalization, outpatient treatment of eating disorders can be effective. A multidisciplinary team, including the primary-care practitioner, nutritionist, and a psychiatric nurse specialist, is needed. Good communication between team members is essential because even motivated patients will have strong urges to resist treatment.

There are certain danger signals that mandate hospitalization. These include the following:

- Weight less than 85% of healthy body weight for that individual
- Signs that the person is suicidal
- Evidence of physiological instability such as hypokalemia or dehydration
- Lack of response to outpatient treatment

Evidence of psychotic thinking, hallucinations, or severe obsessions is also grounds for inpatient treatment, as are signs of other addictive behaviors, such as substance abuse. When there is severe family and/or staff conflict over the proposed treatment plan, hospitalization might also be indicated, preferably at a specialty treatment center.

Inpatient Management

Goals for the patient who is hospitalized are fairly specific and include the following:

- Prescribed bedrest with supervised meals until the person has obtained a weight greater than 80% to 85% of his or her healthy body weight.
- A 300-calorie stepwise gradual increase in calories consumed (as the calories consumed are increased and weight increases, there is a stepwise increase in activity as well).
- Work to establish the target weight.
- Weigh daily at first; as the weight gain progresses, this may be reduced to three times per week.
- Medicate for symptom relief.
- For the patient with AN, the goal is to achieve a weight gain of 1 to 2 pounds (0.45–0.91 kg) per week, with tube feedings used only as a last resort.
- For the patient with BN, meals and bathroom privileges should be supervised, with no access to the bathroom for 2 hours after eating.

The patient's psychological and nutritional status should be continuously assessed. A supportive, structured environment and programs should be provided, preferably in a specialized center, or the patient should be admitted to a specialized eating disorder unit. If purging is involved, the clinician should identify the triggers and precipitants and help the patient work to establish alternative behaviors. Focused individual, group, and family therapies are also indicated.

Outpatient Management

On an outpatient basis, therapy revolves around building trust and a therapeutic alliance. The practitioner should involve the person with AN or BN in setting the target weight. The weight gain can be achieved gradually unless any danger signals surface.

The clinician should weigh the patient weekly at first and later monthly if progress is being made. The focus should be on overall indices of health, not just on weight. The practitioner should prescribe medication if necessary for symptom relief and challenge any fear of uncontrollable weight gain. If purging is involved, precipitants should be identified and alternative behaviors should be established. A cognitive-behavioral approach combined with education is often effective. Interpersonal therapy or CBT should be offered to patients with BN and binge-eating disorder (Level I; William et al, 2008), although self-help programs are helpful for some patients (Level II; William et al, 2008).

Family therapy as well as individual therapy may be necessary; the person should be referred to specialists in these areas. These may be APRNs who specialize in eating disorders and/or family therapy and social workers, psychologists, or psychiatrists who have expertise in those areas. The primary-care provider can, however, continue to play an important role on the interdisciplinary team and should maintain contact with the person being treated for an eating disorder.

Pharmacological therapy has been found to be effective in some cases, slightly more so with patients with BN (Level II; William et al, 2008). Antidepressant medications (especially SSRIs) have become mainstays of treatment of eating disorders. Fluoxetine (Prozac) 10 to 80 mg daily is the only FDA-approved drug for bulimia. It is sometimes necessary to use higher than normal doses for effective treatment of bulimia.

Follow-up and Referral

Treatment of AN and BN requires specialized care. Providers play the key role in helping patients to accept referral to an eating disorders program. Making this decision is extremely difficult; patients may fail to follow through repeatedly before they actually accept treatment. Persons may appear to wish to have this decision made for them, but this is rarely the case. Involuntary treatment for an eating disorder is rarely effective. Persons

who are dangerously malnourished and in need of emergency weight regain must be hospitalized.

The course of illness with an eating disorder is long and highly variable. In a recent study of AN patients, about 50% achieved complete recovery, 21% had an intermediate outcome, and 26% had an outcome that was poor, with an overall mortality rate of 9.8%. Half of BN patients were reported to have recovered fully, 30% experienced occasional relapse, and almost 20% maintained the full criteria for BN. Relapse is common, especially during times of stress (e.g., marriage, childbearing). There is significant morbidity from cardiac arrest and eventual suicide. Poor prognosis is indicated by repeated hospitalizations, initial low weight, being married, and poor maturation. Depression is often a sequela of recovery. Both eating disorders are best approached as chronic conditions marked by improvement and relapse. Older women appear to reach a stage of development at which they have the psychological skill to establish control over their food and weight-related behaviors. Recovered persons may continue to have complex feelings about food and their weight, but their self-care behaviors are more effective.

Patient Education

Information must be provided on the long-term effects of anorexia and/or bulimia. This may be especially important for the person with the disorder, because she (or he) may simply be unaware of some of the long-term health consequences. The provider can take the following steps: (1) Provide information on appropriate programs if dealing with addictions is involved in the treatment plan. (2) Review nutritional information and recommended dietary program. (3) Teach stress management and relaxation techniques for persons and families involved, especially at mealtimes, which are always tense. (4) Provide education on health effects of laxatives and diuretics. (5) Reinforce the long-term nature of these disorders and the need for long-term follow-up and treatment. (6) Point out that under stress, regressive behaviors occur. Involve the family in what symptoms to identify and report. For persons who have used self-induced vomiting, encourage better dental care. It is important to teach strategies for dealing with self-destructive behaviors in ways that do not reinforce them.

ATTENTION-DEFICIT/ HYPERACTIVITY DISORDER

Attention-deficit/hyperactivity disorder (ADHD) is a persistent pattern of inattention, gross motor hyperactivity, and impulsivity that interferes with social, school, and work functioning. The disorder typically manifests itself in childhood, but symptoms may continue into adolescence and adulthood. Adults must show a childhood onset of symptoms to receive a diagnosis of ADHD.

Inattentiveness in school and work activities is evidenced in difficulty following through on instructions, as well as distractibility, performing work carelessly, and moving from one uncompleted task to another. In social activities, inattentiveness is expressed as frequent shifts in conversation, inability to concentrate, and not following the rules of games or activities.

Hyperactivity is usually expressed through fidgetiness or squirming while seated, not remaining seated when expected to do so, and excessive running or climbing in situations when it is inappropriate. In adolescents and adults, symptoms of hyperactivity take the form of feelings of restlessness and difficulty engaging in quiet sedentary activities. Impulsivity manifests itself as impatience, difficulty in delaying responses, blurting out answers before questions have been completed, difficulty awaiting one's turn, and frequently interrupting or intruding on others to the point of causing difficulties in social, academic, or occupational settings. Impulsivity may lead to accidents and engagement in potentially dangerous activities without consideration of possible consequences.

Symptoms typically worsen in situations that require sustained attention or mental effort or that lack intrinsic appeal or novelty. Signs of the disorder may be minimal or absent when the person is under very strict control or in a one-to-one situation. The behaviors of ADHD are more likely to occur during group situations.

Epidemiology and Causes

The prevalence of ADHD is estimated at 5% in school-age children and 2.5% of adults. The disorder is much more frequent in males than in females. In children the male-to-female ratio is 2:1 and for adults the male-to-female ratio is 1.6:1. Although early onset is common (50% meet diagnostic criteria for ADHD by age 4), some patients have later onset, and it is not uncommon for the disorder to persist into adulthood. There are limited data on prevalence in adolescence and adulthood, but the persistence of symptoms into adulthood has been estimated from 30% to as high as 70% of children who were diagnosed with ADHD.

To date, no single etiology for ADHD has been identified. Data from biological, environmental, and psychosocial research suggest several risk factors or causes for the disorder. Data from various family, twin, and adoption studies suggest a genetic origin for some forms of this disorder. In addition, children with parents or siblings with ADHD are at increased risk.

Recent work suggests that maternal smoking, alcohol abuse, and exposure to toxins during pregnancy are related to hyperkinetic-impulsive behavior in children. Perinatal influences that are thought to contribute to ADHD include prematurity, intrauterine growth retardation, precipitous or prolonged labor, and perinatal asphyxia. In addition, postnatal CNS abnormalities resulting from trauma, infections, cerebral palsy, and

lead exposure have been linked to the development of ADHD in childhood. Common comorbidities include Tourette's syndrome, learning disability, genetic disorders, and other psychiatric disorders. There is no strong scientific evidence that food additives, colorings, preservatives, or sugar contributes to ADHD.

Pathophysiology

Currently, there is no known neurophysiological or neurochemical basis for the disorder. Imbalances among the levels of norepinephrine, dopamine, and epinephrine all seem to be involved. Behavior and attention are best controlled when optimal balance is achieved. Computed tomography head scans of children with ADHD showed no consistent pathological findings. Studies using positron emission tomography have found diminished cerebral blood flow and lower metabolic rates in the frontal lobe areas of children with ADHD than in controls. It is theorized that the frontal lobes are not adequately performing their inhibitory function.

Clinical Presentation

Parents may be the first to note excessive motor activity (hyperactivity) during the toddler years. The disorder is not usually diagnosed during this time, however, because that is the normative developmental stage. Toddlers and preschoolers may have difficulty participating in sedentary activities, such as sitting still while listening to a story in preschool. Parents may describe the child as "always on the go," and the child may appear to constantly run, jump, and not sit still. There may also be excessive talking and interrupting of others.

ADHD is most often diagnosed during the childhood years (especially during elementary school) when the child's decreased attention span affects classroom work and academic performance. The school-age child with ADHD will usually have difficulty remaining seated, be unable to complete assignments and turn them in, and talk out of turn. Hyperactive behaviors in these children may include constantly tapping their hands; shaking of their feet or legs; getting up during meals; and talking excessively while watching television, doing homework, or in other quiet activities.

In childhood and adolescence, impulsive symptoms associated with ADHD often lead the individual to break family, interpersonal, and educational rules. Disruptive behaviors and few social skills can make bonding with peers difficult and may lead to association with deviant peer groups and substance and tobacco abuse. In adulthood, restlessness may lead to difficulty in participating in sedentary activities, as well as to avoiding occupations, such as desk jobs, that provide limited opportunity for spontaneous movement. Adults with ADHD often complain of boredom and frustration with job and life routines.

Various medical, psychological, and genetic conditions need to be assessed. Medical disorders such as thyroid disease, lead toxicity, and iron deficiencies (ferritin levels less than 30 ng/mL) have been associated with increased behavioral symptoms. Physical findings of microcephaly, growth retardation, and facial anomalies coupled with the behavioral findings may suggest fetal alcohol syndrome. Although patients and family may report a history of a higher rate of physical injury (because of excessive motor activities and impulsivity), there are no specific physical features associated with ADHD. It is important for the clinician to be able to distinguish symptoms of ADHD from developmentally age-appropriate behaviors in active children. It is also important to differentiate ADHD from symptoms of inattention in children with learning disabilities or those with pervasive developmental disorders. The clinician should be aware that ADHD may not be the sole diagnosis; comorbid problems such as learning disorders, autism, conduct disorders, oppositional defiant disorders, genetic disorders, mood disorders, anxiety, and substance abuse, particularly in adults and adolescents, can coexist. Genetic conditions to consider include neurofibromatosis and fragile X, Turner, Prader-Willi, and Williams syndromes.

During a structured assessment in the practitioner's office, symptoms may not be evident, because they are most often seen in a less structured environment, such as school or work. Children with ADHD may not be able to report their own symptoms accurately because of their age; therefore, information should be gathered from parents or guardians and supplemented by reports from teachers. The DSM-5 provides guidance for diagnosis of ADHD for individuals aged 17 and older. It may be necessary to review early academic records or report cards for the presence of impulsivity, hyperactivity, and inattentive symptoms during the early school years. Additional questions related to family history of ADHD should be conducted. Adult patients may need to question their parents regarding ADHD behaviors that were evident from childhood. Key areas for questioning relate to complaints of boredom, disorganization or frustration in work, and a tendency for impulsive, impatient, and restless behavior.

Generally, diagnostic tests are not indicated, but a serum lead, ferritin, and/or thyroid level may be considered. Electroencephalography (EEG), diagnostic imaging, and genetic testing may be indicated for those patients who present with anomalies or soft neurological signs.

Diagnostic Reasoning/Differential Diagnosis

DSM-5 Symptom Criteria

Some hyperactive and impulsive or inattentive symptoms must have been present before 12 years of age, and some impairment from the symptoms is present in one or more settings (home, work, school, or social interaction). In addition, there must be clear evidence of

clinically significant impairment in social, academic, or occupational functioning, as well as evidence that the symptoms are not caused by another disorder.

ADHD is characterized by six or more of the following symptoms of inattention that have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level.

Inattentive
- Pattern of careless mistakes
- Difficulty sustaining attention in tasks or play activities
- Does not listen when spoken to
- Does not follow through on instructions
- Has difficulty organizing tasks and activities
- Loses things necessary to complete tasks
- Avoids, dislikes, or is reluctant to engage in sustained mental activity
- Easily distracted by external stimuli
- Forgetful

Hyperactivity and impulsivity can occur with or without inattentive symptoms. When six or more of the following symptoms are present and have persisted for at least 6 months to a degree that is maladaptive and inconsistent with developmental level, the diagnostic criteria are met for hyperactivity/impulsivity disorder.

Hyperactivity
- Often fidgets with hands and feet, squirms
- Leaves classroom or refuses to remain seated when it is expected
- Runs or climbs excessively
- Difficulty playing or engaging in quiet activities
- Acts as if "driven by a motor"
- Talks excessively

Impulsivity
- Blurts out answers
- Difficulty waiting turn
- Interrupts, intrudes

For individuals aged 17 and older, at least five (not six) of the inattention and/or hyperactivity-impulsivity symptom criteria listed must be present.

Screening

Screening for psychosocial issues has become more common as providers become increasingly aware that 13% of preschoolers and 12% to 25% of school-age children exhibit emotional/behavioral problems. Utilizing a tool at regular well-child visits may help to identify this chronic condition, particularly in children with academic and behavioral issues (Level II; Wolraich et al, 2011). The Pediatric Symptom Checklist is a one-page questionnaire that is completed by the parent. This tool is free and is available in multiple languages and a pictorial format. The tool and scoring instructions are available from www2.massgeneral.org/allpsych/psc/psc_forms.htm. If screening is positive, assessment with an ADHD-specific tool should occur (Level II; Wolraich et al, 2011). Various tools are available and need to be completed by both the parents or guardians and the teacher (Level I; Wolraich et al, 2011) (see Table 18.4).

Early diagnosis and treatment are associated with improved school performance, behavior, and social interaction (Level I; MTA Cooperative Group, 1999). For adults, assess prior history of ADHD, previous school performance, history of mental health diagnoses, substance abuse, and current or past medication use. Assess current symptoms with inquiry into their effect on current school performance, work, and home. Various adult screening tools are readily available (see Table 18.4). For patients who do not specifically meet the criteria for ADHD or whose history and behavior are not consistent with ADHD, referral to a neurodevelopmental specialist, behavioral health specialist, or neurologist is warranted. (See Nursing Research–Based Practice Box 18.2.)

Management

A comprehensive plan needs to address the chronic nature of the disorder, including developmental challenges throughout the life span, treatment options (pharmacological and nonpharmacological), and community and school resources (Level II; Wolraich et al, 2011). Reappraisal of the plan with medication reassessment needs to be done periodically and appropriate changes made.

Pharmacological Management

Pharmacotherapy is generally not recommended for preschool children unless the symptoms have not responded to behavioral therapy, the symptoms have persisted for more than 9 months, and the symptoms are present in more than one setting. Pharmacotherapy can help improve symptoms in the areas of school, work, social interaction, and family life. If the diagnostic criteria are met, it is recommended to initiate pharmacological treatment with an FDA-approved medication for ADHD for individuals aged 6 to 11 years (Level I; Wolraich et al, 2011). The evidence is strongest for use of dextroamphetamine (DEX), D- and D,L-methylphenidate (MPH), mixed salts amphetamine, and less for atomoxetine (Strattera), extended-release guanfacine (Intuniv), and extended-release clonidine (Kapvay) (Level I; Wolraich et al, 2011). For adolescents aged 12 to 18 years, pharmacological treatment should be offered with the assent of the teen (Level I; Wolraich et al, 2011).

The core symptoms are best managed by stimulant medications, which have shown response rates of 75% to 80%. The stimulant agents (MPH or amphetamine) should be considered first-line therapy (Level I; Wolraich et al, 2011). Both immediate-release and sustained-release formulations are available. The advantages for once-daily dosing include compliance, convenience, and confidentiality (school). Management includes beginning the stimulant at a low dose and titrating upward until symptoms are controlled, generally every 1 to 3 weeks, until optimal treatment outcome is achieved or

Nursing Research–Based Practice 18.2 Attention-Deficit/Hyperactivity Disorder

Lobar, SL, et al. Parents', physicians', and nurse practitioners' perceptions of behaviors associated with attention deficit hyperactivity disorder. *J Am Acad Nurse Pract* 11(6):237–242, 1999.

This exploratory descriptive study conducted a survey to identify parents', nurse practitioners', and physicians' perceptions of behaviors most commonly associated with attention-deficit/hyperactivity disorder (ADHD). A convenience sample of 29 physicians, 23 nurse practitioners, and 41 parents who were members of a parent support group was obtained. The study utilized the ADHD Rating Scale, which highlights symptomatology consistent with hyperactivity, inattention, and impulsivity. In addition, qualitative data were collected from parents regarding their reasons for seeking health care for their children. This study arose in part because of the recurrent changes and revisions in nomenclature and defining criteria and the use of multiple subjective observers in a child's behavioral evaluation that may confound the identification of ADHD. It was important to assess whether there was consistency in perceptions of ADHD in the varied reports.

This study found that there was no significant difference between nurse practitioners, parents, and physicians in their perceptions. All respondents were familiar with ADHD and were aware of the DSM criteria for the disorder. The researchers note that the similarity in responses may have been a function of shared knowledge. The parents in the support group were all well educated as to the definitions of ADHD. The addition of teachers, who are often involved in the observation of children with ADHD, might have been useful. The study supported the fact that collaboration between parents and health-care providers was important in enhancing the accurate formulation of a diagnosis of ADHD, which is based largely on subjective criteria.

the side-effect profile prohibits further titration (Level II; Wolraich et al, 2011). It is not necessary to begin with a short-acting agent before using a sustained-release agent. If the maximum dosage does not control the symptoms, switching to another stimulant is indicated. Stimulants may increase levels of seizure drugs, SSRIs, tricyclics, and warfarin. (See Drugs Commonly Prescribed 18.7.)

Atomoxetine is not a stimulant and may be used if the stimulant drugs are not tolerated or contraindicated. Atomoxetine has an effect both on ADHD and on comorbid anxiety. Some situations where this may be the drug of choice are active substance abuse, tics, comorbid anxiety, or mood lability. Less appetite (weight loss) and less insomnia are seen with atomoxetine. Full clinical

Drugs Commonly Prescribed 18.7 Attention-Deficit/Hyperactivity Disorder (ADHD) Medications

Drug	Indication	Adverse Reactions and Prescribing Considerations
methylphenidate		
D,L-methylphenidate D-methylphenidate (MPH)	ADHD: Age 6 years and older Narcolepsy	C-II controlled substance. Available in short and extended-release formulations. Age 6 years and older. Caution administration with history of drug or alcohol dependence. Administer short-acting forms every 4 hours during daytime hours only because administration after late afternoon is associated with insomnia. Extended-release typical duration 8–12 hours Monitor growth parameters and weight Laboratory testing: CBC with differential and platelet count. Long-acting formulations available. 2009 FDA notification of potential of sudden death in healthy children treated with stimulants. Do not use in severe cardiac disease. May improve driving performance in adolescents and adults Transdermal preparation and OROS methylphenidate (Concerta) less abuse potential

Drugs Commonly Prescribed 18.7 Attention-Deficit/Hyperactivity Disorder (ADHD) Medications—cont'd

Drug	Indication	Adverse Reactions and Prescribing Considerations
Amphetamine		
d-amphetamine (DEX) mixed amphetamine salts lisdexamfetamine dimesylate	ADHD Narcolepsy Age 3 years and older (mixed amphetamine salts) Extended-release age 6 years and older *Lisdexamfetamine age 6 years and older	C-II-controlled substance. **Black Box Warning:** High potential for abuse Sudden death and CVD events Available in short-acting and extended-release formulations Insomnia, weight loss, tics, tachycardia, and elevated BP Give on awakening Stop slowly, not suddenly Stimulant medication with less abuse potential May cause anorexia, insomnia, GI upset, emotional lability Avoid in cardiovascular disease Rare cardiomyopathy 2009 FDA notification of potential of sudden death in healthy children treated with stimulants. Monitor height and weight for all agents
SNRI		
Atomoxetine (Strattera)	ADHD: Age 6 years and older *FDA approved indication for adults	Once daily in a.m.; interacts with MAOIs; GI upset; weight loss; mood swings Sedation, GI distress Decreased appetite Potential CYP2D6 interactions Black Box for suicide ideation

The following medications are approved by the U.S. Food and Drug Administration (FDA) for the treatment of ADHD: dextroamphetamine (DEX), D- and DL-methylphenidate (MPH), mixed salts amphetamine, and atomoxetine.

*Stimulants do not have an indication in adults, and dosing guidelines are based on clinical studies rather than FDA-reviewed material. Doses of stimulants should advance slowly every several days until appropriate response is obtained.

Alpha-agonist		
clonidine (Catapres) guanfacine (Tenex, Intuniv)	ADHD ADHD	More effective in treatment of impulsivity/hyperactive symptoms vs. inattention symptoms; must be tapered on discontinuation Beneficial in comorbid Tourette's and tics Sedation, dizziness Monitor BP and heart rate Treatment of stimulant-induced insomnia Treatment of tics and insomnia Advantages of guanfacine over clonidine: less sedation and longer duration of action
TCAs*		
imipramine (Tofranil)* desipramine (Norpramin)*	ADHD ADHD	ECG recommended at baseline and with dose increases Monitoring blood levels is useful in guiding dosing Black Box warning suicide ideation Anticholinergic effect Sudden death; use only if other TCAs not effective
Other		
bupropion (Wellbutrin)*	ADHD	Insomnia, decreased appetite Seizure risk

*Off-label use.

effect may take up to 6 weeks, and thus educating the child, parent, and teachers is essential. Considerable attention has been given to the comorbid occurrence of SUD and ADHD and whether it is related to the use of amphetamines. Meta-analysis has shown that stimulant use in childhood actually reduced the risk of SUD by 50%. Medication diversion among adolescents, especially to improve academic performance, is a consideration when prescribing for patients with ADHD. The alpha-2 agonists, such as clonidine and guanfacine, can be utilized for ADHD treatment, as well as used adjunctive to the other stimulant medications. Clonidine is particularly helpful for insomnia.

Stimulant medications may not be effective in up to 30% of children, or adverse drug reactions prevent compliance. Side effects are common, occurring in about 70% to 90% of patients, but are usually mild and transient. Common side effects include weight loss, appetite suppression, abdominal pain, insomnia, and headache. Irritability and tics may develop. The practitioner needs to be aware of the common side effects and have strategies to offset them, including dose reduction, changing medication, and prescribing adjunctive medications. Insomnia can be managed with clonidine, antihistamines, and trazodone (Desyrel). Other agents that may be helpful for insomnia include melatonin and cyproheptadine (Periactin). Randomized controlled studies regarding tics have shown that patients with comorbid disease (tic plus ADHD), the tic disorder actually decreased with stimulant medications. For patients with medication-induced tics, reduction of dose or alternative medication may be necessary. Consideration of comorbidities is important because it may alter the treatment regimen, especially with cardiac disease. Congenital heart disease including hypertrophic cardiomyopathy or significant cardiac-related symptoms should prompt cardiac evaluation before initiating pharmacological therapy. Stimulants are contraindicated in Tourette's syndrome, monoamine oxidase inhibitor use, hereditary fructose intolerance, and glaucoma.

If all FDA-approved agents have been utilized without response, reevaluation of the diagnosis, as well as consultation, is essential. Non–FDA-approved drugs utilized are bupropion and tricyclic antidepressants.

For adults, three medications are FDA approved for treatment of ADHD. These three medications are extended-release amphetamine (Adderall), extended-release methylphenidate (Focalin XT), and nonstimulant atomoxetine. In adults, multimodal therapy is more effective than pharmacological therapy alone. Considerations in females of childbearing age and pregnancy must be also considered. See Drugs Commonly Prescribed 18.7.

Nonpharmacological Management

Behavioral techniques can include parental training, classroom management techniques, and peer interventions. Evidence-based group parent training programs and early educational programs are recommended as the initial step for children ages 4 to 5 years. In children aged 6 years and older, behavioral therapy may be initiated alone or adjunctively with medications (Level II; Wolraich et al, 2011). Combined therapy seems to be helpful in patients with comorbid anxiety and conduct disorders, as well as those who are economically disadvantaged and members of minority groups (Level I; MTA Cooperative Group, 1999). Patients who receive both medications and behavioral therapy have shown improvement in social interaction and academic achievement, but not in ADHD symptoms. Adolescents without comorbid conditions who respond well to pharmacological therapy (ADHD tool assessment) may not need additional therapy (Level I; Wolraich et al, 2011; MTA Cooperative Group, 1999). In addition, children with other psychosocial issues are more likely to benefit from combined therapy (Level I; MTA Cooperative Group, 1999). Information on parental education about ADHD, behavioral management, public behavior management, school reports, and dealing with persistent behavioral issues can be accessed at www.aacap.org/galleries/PracticeParameters/JAACAP_ADHD_2007.pdf.

There is no evidence to support the use of CBT, play therapy, dietary modifications, or EEG feedback in the treatment of ADHD in children (Level II; Wolraich et al, 2011). Involvement of the educational system is imperative. Teachers need to implement classroom behavior management strategies to help children with ADHD improve their focus and find modalities that enhance self-control (Levels I, II; Daly et al, 2007). Another strategy to improve academic performance is peer tutoring. Peer tutoring allows immediate feedback, one-to-one as well as continuous interface, and shows improved test scores and engagement in learning. Many other resources are available (see Resources).

ADHD may persist into adolescence and adulthood. Reevaluation and continued support educationally and occupationally may be needed. Adults can benefit from CBT in addition to drug therapy (Level I; Safren et al, 2005). Organizational skills training including time management, study strategies, and empowerment to minimize distractions may increase function.

Follow-up and Referral

Follow-up for patients diagnosed with ADHD includes performing a validated ADHD rating and monitoring scale for core symptoms (see Table 18.4) and a behavioral report or teacher narrative report for target symptoms. A 40% to 50% reduction in core symptoms or achieving targeted goals is considered an adequate response. Titration of medications can occur every 1 to 3 weeks. Medications used for ADHD may cause headaches, abdominal pain (which can be avoided by taking medication with meals), and growth delay. Office visits should be scheduled initially at 2 to 4 weeks, followed by every month for 6 months and then every 3 to

6 months thereafter. The focus of these visits includes physical parameters (height, weight, cardiac evaluation including blood pressure and pulse), assessment on behavioral progress (utilizing an ADHD scale helps to objectively identify behavioral changes from the parent and teacher), monitoring of medication compliance and side effects, and continued education and referral to support services if indicated. A reduction in growth of 2% as seen on the growth chart signifies a potential problem, and adjustment of the treatment plan can include a drug holiday or changing the medication. Specific laboratory tests are not generally indicated. Targeted endpoints include improved grades and ADHD rating scales, acceptable family interactions, and improved peer interactions.

Children with ADHD are at increased risk for abuse, depression, and social isolation and should be monitored for these. Parents will need regular support and advice and may need referral for family therapy to cope with the added demands. The provider should establish contact with the child's teacher every school year. Parents, teachers, and advisors should encourage career choices that allow autonomy and mobility. There is no increased frequency of delinquency unless other comorbid features (such as oppositional defiant disorder or conduct disorder) exist.

Adolescence offers new challenges, and the practitioner needs to address these issues both with the adolescent and the family. Increased independence, decision-making, and risk-taking behaviors need to be addressed. In addition, discussion about the continued need for and benefit of medication may ensue. In general, if the patient has been symptom free for longer than 1 year with no adjustment in medication dosage despite increases in weight and height, consideration about remission should occur. Summer vacation or prolonged vacation may be a good time to trial a drug holiday. Several concerns arise during adolescence. Driving needs to be discussed, stressing the importance of symptom control. Monitoring for diversion of controlled substances is essential. If there are concerns regarding this, use of atomoxetine, extended-release guanfacine, or extended-release clonidine should be considered. In some situations, treatment with a stimulant agent that possesses a smaller risk for abuse could be utilized.

Patient Education

Adherence to the treatment plan is improved when the patient and family understand the chronic nature of ADHD and its potential impact on school, social life, and occupational functioning. Continued education about medications and management of side effects may improve adherence. Utilization of various community support groups may also assist families and adults to deal with developmental challenges. There are a number of interventions that parents, family members, and teachers can do in addition to administering medication (Table 18.17). They must be educated to be aware of all potential adverse effects of medications but also should be counseled extensively in behavioral techniques. Parents should be educated regarding realistic expectations and should be made aware of support groups for themselves as well as child advocate groups. They must be helped to deal with whatever negative feelings may emerge as a result of the diagnosis of ADHD.

Table 18.17 Patient Education: Attention-Deficit/Hyperactivity Disorder (ADHD)

Teach parents to do the following:
- Have the child do one task at a time.
- Use "time-out" periods for bad behavior.
- Make eye contact each time they are making a request.
- Reinforce good behavior or tasks the child does well with rewards and attention.
- Use behavior therapy such as token systems.
- Stop unacceptable behavior before it escalates.
- Make use of parent support and advocacy groups.
- Deal with negative feelings and unrealistic expectations.
- Incorporate family therapy, anger-management training, and social training.
- Coordinate homework with teachers.
- Work closely with teachers for consistent behavioral plan.

Teach teachers to do the following:
- Make sure the child has a second set of books at home.
- Make work sessions short.
- Help the child deal constructively with negative feelings.
- Provide immediate consequences for bad behavior.
- Reinforce good behavior.
- Coordinate homework with parents.
- Work closely with parents for a consistent behavioral plan.

INTIMATE PARTNER VIOLENCE

Intimate partner violence (IPV) is defined as a pattern of assaultive and coercive behaviors that may include inflicted physical injury, psychological abuse, sexual assault, progressive social isolation, stalking, deprivation, intimidation, and threats perpetrated by someone who is, was, or wishes to be involved in an intimate relationship with an adult or adolescent, and aimed at establishing control by one partner over the other. IPV is not associated with any ethnic group, religion, income level, level of education, employment, or sexual orientation. However, typically the victim is a child, a woman, or an elderly person, and the typical perpetrator is a man (in the case of partner abuse), a parent or other trusted adult (in the case of child abuse), or an adult child or other caregiver (in the case of elder abuse). More than one type of violence may occur in any given family; for example, in one study, 45% to 70% of battered women reported that their batterer also abused their children. In 2013, the World Health Organization (WHO), the U.S. Preventive Services Task Force (USPSTF), and Cochrane Reviews released identification and treatment

recommendations for IPV. All guidelines encourage clinicians to be alert to physical and behavioral signs of abuse such as trauma or somatic symptoms.

Epidemiology and Causes

Estimates of the prevalence of IPV in the United States are that 1 to 4 million women per year are physically, sexually, or emotionally abused by their partners. Thirty-one percent of women report IPV at some point in their life. Violence by women against men also occurs although women are 7 to 14 times more likely to be battered. More than 1 million children are abused each year, and approximately 550,000 elderly individuals suffer abuse and/or neglect. Thousands of women and children die as a result of IPV each year. Annual health-care costs are estimated to be $44 million annually, not including money lost from work absenteeism, turnover, and decreased productivity.

Examples of IPV include punching, slapping, kicking, burning, pushing, dragging, choking, restraining, and sexual assault. In one study, 68% of domestic assault incidents involved weapons; in 15% of these cases the assault resulted in serious injury. Recent research indicates that 82% of women killed in their homes are killed by someone they knew, 55% in the context of a quarrel, physical domestic fight, or assault by a spouse, lover, or close relative. Statistics on violent crime indicate that three out of every four American women murdered die at the hands of their male partners. Recurrent violence is common; in one study, 89% of victims reported previous episodes of injury; 34% of these victims were battered on a daily basis.

Additional risk factors that increase the potential for violence include financial instability, pregnancy (15%–25% of pregnant women are abused physically while pregnant, with the abuse often leading to birth defects), the birth of a child, and job loss by either partner. Women are at great risk when they leave an abusive relationship. They have a 75% greater chance of being killed by their batterers than women who stay.

Numerous studies have documented that women with a history of IPV have greater rates of physical symptoms, a higher prevalence of unexplained physical symptoms, a greater number of symptoms, and poorer overall health status than nonabused controls. Similarly, IPV survivors have higher rates of mental health problems, including major depressive disorders, depressive symptoms, dysthymia, generalized anxiety disorder, phobias, PTSD, suicidality, and substance abuse. IPV survivors have been found to have higher health-care costs and increased utilization.

Psychodynamics and Pathophysiology

Intimate partner violence occurs in families of every racial and religious background and in every socioeconomic stratum. Although alcohol/substance abuse and a history of childhood abuse are important correlates of IPV, they do not cause or explain IPV.

Violent individuals use fear, pain, injury, humiliation, and suffering to establish power and control over their victims. The pattern for IPV is often unpredictable. In some cases, the only predictable element of the violence may be the offender's use of violence to establish power and control over the person he or she wants to dominate. This includes stalking behaviors that are intended to display the violent person's skill, strength, and determination. In other cases, with no warning at all, or after repeated threats, a violent individual can become intent on killing his or her victim. The abused individual often is forced into isolation, which prevents anyone from observing the violence or assisting the victim. The psychologically isolated victim typically is convinced that he or she is alone and that no one cares or is willing to help. A common pattern, known as the *cycle of violence,* starts with an episode of violence, followed by reconciliation, increasing tension, and the next episode of violence. Typically, the periods of tension and episodes of violence increase in duration while the reconciliation periods become shorter.

Victims of IPV often develop strong dependency needs and may deny the violence. About 50% of battered wives grew up in violent homes, and their most common trait is dependency. Victims may rationalize the violence by thinking that they can change the violent individual's behavior by making changes in their own behavior. For example, women with small children and women who are unemployed may deny the violence exists because they feel escape is impossible. Victims of domestic violence, particularly adolescents who feel they cannot escape, may first try to escape psychologically by abusing alcohol or drugs. However, all too often the violence is then blamed on the victim's substance abuse.

Clinical Presentation

Routine screening for IPV is recommended by the USPSTF for all women of childbearing age at initial visits and periodically (Level II; Moyer, 2013); this is in contrast to the WHO and Cochrane recommendations in which universal screening is not recommended. The USPSTF found insufficient evidence to routinely screen the elderly or other vulnerable populations. The WHO's premise for not recommending universal screening is based on studies that demonstrate that although an increased number of women experiencing IPV were identified, the outcomes were unchanged. Of utmost importance is that safety and confidentiality are established before asking questions about abuse (Level II; Moyer, 2013). Always preface IPV questioning with an appropriate and nonthreatening explanation such as, "I ask all of my patients these questions because these problems affect many people's health." Avoid using stigmatizing words such as *domestic violence* or *abuse.* In some instances, a patient may disclose a past experience with violence that may provide useful information in providing appropriate care.

Women who end an abusive relationship are usually at greater risk for serious injury—and therefore in greater need of intervention—than women who are still involved in an abusive relationship, but these individuals are less likely to seek help. Men should also be screened if signs of abuse are evident (Level II; Moyer, 2013). Men who have sex with men and men who are disabled may be at a higher risk and should be screened as part of the social and sexual history.

It is difficult to know when to include violence in the differential diagnosis. Recognition of IPV continues to be difficult because the victim and the abuser often conspire to conceal it. The partner, if present, may be suspicious. Look for symptoms or behaviors that may signal abuse such as exacerbation or poor control of chronic illness, sleep disturbances, chronic pain, or frequent unexplained appointment changes. Behavioral red flags are (1) a patient who is reluctant to speak in front of her partner or gives evasive answers and (2) an overly protective or controlling partner. Any patient presenting with multiple complaints or whose symptoms are not consistent with her history should be assessed for violence at least once and reassessed if she fails to respond to therapy appropriately. Exposure to IPV is frequently linked with mental health issues such as depression, anxiety, suicide attempts, and/or substance abuse. Problems or injuries during pregnancy should raise the level of suspicion, as should delays in seeking medical care. The first goal of assessment is to determine whether or not an individual is a target of violence. The second goal is to evaluate the level of danger. The patient must be seen alone. Ask the partner, children, and family members to leave the room. If an interpreter is needed, use a gender concordant professional interpreter rather than a family member. If the partner refuses to leave, do not confront him or her; instead, strategize a way to get the patient alone later. Requesting a urinalysis or chest x-ray exam is often an effective approach.

The clinician must communicate concern and caring and tell each woman that all women are assessed for abuse. The seriousness of the issue cannot be underscored enough. Although it may be necessary to obtain specific information, the clinician should try to limit data-gathering to essentials. Some sources suggest "funneling," beginning with innocuous questions and progressing to more directed approach. Consider the utilization of a validated instrument. (See Focus on History 18.3.) Many patients will disclose emotional abuse long before they are comfortable disclosing physical abuse, even if both are occurring. A key component of the abuse experience is intrusion; many patients who are in an abusive relationship may perceive questioning as intrusive. Again, sensitivity is crucial.

Do not jump to conclusions too quickly. One sign or symptom alone is not sufficient to make a "diagnosis" of abuse. The clinician should be aware that a traumatic experience such as abuse, especially over an extended period of time, will have an impact on the victim's thought processes and belief systems. This must be taken into consideration during the assessment. It is imperative for clinicians to remain objective and nonjudgmental. Maintaining contact with a patient in the primary-care

Focus on History 18.3 Intimate Partner Violence (IPV): Three Questions to Ask

By asking the following three questions, the APRN may be able to identify approximately 75% of women at risk for IPV. A positive response to any of the three questions represents a positive screen.

- Have you been hit, kicked, punched, forced to have sex, or otherwise hurt by someone within the past year? If so, by whom?
- Do you feel safe in your current relationship?
- Do you feel threatened or controlled by a partner or ex-partner or anyone else in your life?

(Source: Reprinted with permission from Feldman, K, et al. Accuracy of three brief screening questions for detecting partner violence in the emergency department. *JAMA* 277:1357–1361, 1997.)

At this point, ask the patient what change, if any, he or she wants to make. Do *not* expect or even try to "fix" the situation. An abusive relationship is most often a chronic condition. As with any condition that threatens a patient's health, an important step is to determine the urgency of the situation. If there is any recent violence or threat, it is essential to assess the level of danger. Listen first to the women's own assessment; if she feels she is in danger, she most likely is. But her assessment that she is not in danger may be a misperception. There are a variety of Danger Assessment tools such as the Danger Assessment–2 (DA-2), which is a 20-question instrument; another validated tool is the Spouse Abuse: Assessing Level of Violence in the Home, which includes a revised form of that instrument and its use. Ask if the patient feels safe in the primary-care office; if the abuser is in the waiting room or likely to return, ask the patient what she would like you to do. Inquiring whether the abuser has access to weapons is critical. The clinician should aid patients in assessing the risk of future harm (Level II; Moyer, 2013).

If the patient responds with a "no" to all questions but there is still a suspicion of abuse, avoid confrontation. Make a note of the concerns on the chart, offer resources, and leave the issue open for future discussion. Ask again on future visits. Note that this is a "concern for possible abuse," not the leading diagnosis if unconfirmed.

environment and working within a *Circle of Caring* may help the clinician make this difficult assessment, as well as a viable plan for dealing with the difficult situation.

Management

The overarching goals of therapy include safety, empowerment, perpetrator accountability, and social policy change. Careful documentation of assessment findings is critical to effective management of the health-care needs of victims of domestic violence. The clinician should record the history using specific, plain language, in the patient's own words when possible. Record all physical findings, use a body map, and take photographs only if the patient consents. The clinician should preserve physical evidence, if appropriate. Thorough, well-documented medical records may prove to be crucial in a legal case. Psychiatric hospitalization may be indicated if the patient is actively suicidal, acutely psychotic, unable to care for herself, and does not have any safe alternatives for care.

Treatment for a victim of abuse involves more than treating the injuries and providing telephone numbers and referrals. Developing a caring relationship with the patient is essential. It is important to validate the lived experiences of IPV, offer support, and assist in safety planning. This is truly a patient who needs a *Circle of Caring*. Advanced Practice Nursing Interventions 18.3 lists some general interventions clinicians can make, including a danger assessment and counseling concerning the individual danger assessed. For some patients, even accepting printed material about domestic violence or abuse can be a dangerous act. False reassurance is to be avoided. Victims of IPV typically look for professionals they feel they can trust, and individuals who are planning their escape may require a great deal of time and support before they act.

Refer to appropriate law enforcement or social services agencies and develop a patient "safety plan," although there is no guarantee that the patient will comply with the plan or be willing to contact law enforcement or social services. In some practice settings, the health-care provider may need to take these actions unilaterally; in others, a team approach is more facilitative.

Follow-up and Referral

Any evidence of IPV requires full compliance with local reporting and referral laws. Local and state agencies for victims have established protocols and systems for providing services that include emergency housing, health care, foster care, and displacement counseling. Despite the significant incidence of IPV, there is still a shortage of referral services for violent offenders. Violent individuals who are motivated to stop their violence may benefit from community support groups. Local crisis services and police hotlines should be contacted to protect victims of domestic violence. Victims of IPV should have the phone number and address for local emergency services, legal advocacy programs, and support groups, or at least be informed regarding how to obtain this information.

Advanced Practice Nursing Interventions 18.3
Intimate Partner Violence

Prevention:

- Teach conflict resolution skills.
- Create a safety plan to remove the individual(s) from the violent situation.
- Inquire about the abuse. Questions to ask include the following:
  1. Has the physical violence increased in frequency/severity over the past year?
  2. Have you ever been choked?
  3. Has a weapon or threat with a weapon been used?
  4. Have you been threatened with death, or do you believe the individual could kill you?
  5. Is there a gun in the house?
  6. Have you ever been forced to have sex when you did not wish to?
  7. For women, have you ever been abused while you were pregnant?
  8. Is alcohol or substance abuse a factor? How often is the alcohol or substance used?
  9. Have your daily activities been controlled?
  10. Is the individual violent and constantly jealous of you?
- Provide community resources.
- Provide counseling and other therapy as indicated (for example, crisis intervention, post-traumatic stress disorder therapy, physical rehabilitation).
- Document findings and interventions.

Source: Adapted from Jezierski, M. Abuse of women by male partners: Basic knowledge for emergency nurses. *J Emerg Nurs* 20(5):361–368, 1994.

Consider referral for mental health evaluation for associated psychiatric problems. Those living with abuse may have associated major depression, panic disorder, PTSD, suicidal thoughts, and co-occurring substance abuse. A patient who may refuse referrals for domestic violence services may accept a referral to obtain help with abuse-related depression and anxiety.

Participate in prevention by working with local and state coalitions against domestic violence, child abuse, and elder abuse. In addition, the work environment should have clear policies and procedures defining abuse-reporting procedures. This is important in every office, because primary-care clinicians are often the "first stop" for victims of abuse.

Patient Education

Education regarding who is at risk and information about the cycle of violence is a crucial step. One way to initiate dialog is to display information about IPV in your practice site, including waiting areas, exam rooms, and restrooms. Local, state, and national agencies have available

patient education materials that are also available in many languages. Professional development on domestic violence in many states is mandated on an annual basis. It is important to remember that much knowledge in this area is new. The concept of battering as a social problem did not become widely accepted until the 1960s.

Overcome clinician barriers to addressing IPV. Professional development should include the provision of knowledge and skills to address IPV (Level I; Moyer, 2013). Establish a referral base with local providers with expertise in IPV. Include training for support staff about IPV. Incorporate screening for IPV into primary care by creating a safe environment and integrating routine inquiry.

Education about the fact that a woman may be *more* at risk *after* she leaves an abusive relationship is also very important (Level II; Moyer, 2013). Options for help need to be made available and accessible to the individual at risk. Instrumental support for new mothers, for example, may be important in limiting child abuse or other forms of domestic violence. Careful attention to the risk factors for violence in a relationship is necessary, and most important, the practitioner should provide information on where and how to get help.

SEXUAL ASSAULT

Sexual assault (SA) is defined by the National Crime Victimization Survey (NCVS) (www.nida.nih.gov/DirReports/DirRep906/DirectorReport11a.html) as forced sexual intercourse involving physical force or psychological coercion, with vaginal, anal, or oral penetration by the offender(s), including the use of foreign objects. The three key components of sexual assault are these:

- Lack of consent
- Threat or use of force
- Vaginal, anal, or oral penetration by body part or object

Sexual assault is a violent act, one of conquest and control. The offender's intent is to dominate, humiliate, and degrade the victim. For the victim, sexual assault is a highly traumatic event that can have long-term effects on the physiological and psychological well-being of the survivor. It is important to note that victims of sexual assault can be female or male.

Rape can be a life-threatening situation. The victim experiences shock and panic. Rapists may urinate or defecate on their victims, ejaculate into their faces and hair, force anal intercourse, insert foreign objects into the vagina and/or rectum, and cause other physical injury, including death. After the rape, the victim experiences shame, confusion, humiliation, fear, and rage. Many become phobic about sex. Few emerge from the assault completely unscathed. The degree of damage usually depends on the violence of the attack, the vulnerability of the victim, and the support system available to him or her immediately after the attack. Many victims go on to develop post-traumatic stress disorder (PTSD), depression, or alcohol and/or drug abuse and are more likely to contemplate suicide.

Date rape, or acquaintance rape, is far more common than rape by strangers and may lead to serious health and adjustment problems for girls and women. Research has suggested that more than 50% of the women who have vaginal, oral, or anal intercourse against their will do not label these experiences as sexual assault or rape. Other forms of sexual assault and rape include child sexual abuse, sexual hate crimes, incest, male sexual assault, sexual harassment, stalking, partner rape, and sexual exploitation by trusted professionals including health-care clinicians, therapists, teachers, priests, and police officers.

Epidemiology and Causes

It has been estimated that every minute in the United States, an adult woman is sexually assaulted. According to the Federal Bureau of Investigation, over the last decade there has been a 15% decrease in the number of forcible rapes reported to local police departments. In 2010, there were 84,767 forcible sexual assaults reported to local police departments. The U.S. study of sexual assault titled "Rape in America" estimated that only one in six sexual assaults is actually reported to law enforcement. Prevalence of sexual assault has been reported at 255,630 incidents in the 2006 NCVS by the U.S. Department of Justice (www.nida.nih.gov/DirReports/DirRep906/DirectorReport11a.html). Of those incidents, 39.1% were committed by strangers, whereas 60.9% were committed by perpetrators known to the survivors. One out of 6 women and 1 out of 33 men will experience an attempted or completed sexually assault or rape at some point in their lifetimes. The vast majority of sexual assaults occur before age 18. In 2008, according to the U.S. Department of Justice, the number of forcible rapes was 89,000, which represented a 1.6% decline from 2007 estimates. This is an estimated 57.7 offenses per 100,000 females (www.ovw.usdoj.gov/sasp.htm).

According to the NCVS, women who are young, unmarried, and in a low-income group are the most frequent victims of sexual assault. The highest victimization rate for women is in the 16- to 19-year-old age-group, with the second highest rate occurring in the 20- to 24-year-old age-group. Divorced and single women experience higher rates of sexual assault than married or widowed women, and women in low-income groups experience higher rates of assault than women in moderate or high-income groups. In addition, women of color report sexual assault twice as frequently as do white American women, with African American, American Indian/Alaskan women, and women of mixed race reporting the highest lifetime rates of rape or attempted rape. Sexual assault is more likely to occur in the survivor's home (43%) or in the home of a friend (15%). Most sexual assaults (65%) occur in the evening and during the summer months. Finally, most sexual assault survivors

(78%) know their rapists. When the sexual assault is committed by a stranger, 31% of the time the sexual assault takes place in the home of the survivor or a friend's home. In some cases, sexual assault is part of the larger picture of intimate partner violence.

Men who commit rape, according to crime statistics, are typically between 25 and 44 years of age; 51% are white and tend to rape white victims; 47% are black and tend to rape black victims; the remainder are mixed. Thirty-four percent of all forcible rapes involve alcohol. The Violence Against Women Act of 2005 created the Sexual Assault Services Program (SASP; www.ovw.usdoj.gov/sexassault.htm), which is federally funded and dedicated to direct intervention and related assistance for survivors of sexual assault. State and local communities have responded as well to combat sexual assault.

Pathophysiology and Psychopathology

Sexual assault, typically a rape, is an act of violence and humiliation that happens to be expressed through sexual means. Power and anger are expressed through rape and are often part of another crime. Rapists typically threaten their victims with fists, a knife, a gun, and frequently harm them in other ways. Victims may experience beatings, sustain injuries emotionally and physically, and may be killed.

Clinical Presentation

Through their work with sexual assault survivors, experts have identified a set of immediate and long-term effects of sexual assault called the *rape trauma syndrome*. Rape trauma syndrome is considered a normal response to sexual assault. There are two identified phases of survivor responses—the *initial* or *acute phase,* characterized by a period of disorganization, and the *long-term phase,* characterized by a period of reorganization.

Initial or Acute Phase

During the initial or acute phase, many sexual assault survivors experience both physical symptoms and emotions such as fear, shock, and disbelief. Four major categories of physical symptoms have been identified:

- Physical trauma: Symptoms include soreness and bruising from the physical attack on the hands, throat, neck, breasts, thighs, legs, arms, back, buttocks, head, and face.
- Skeletal muscle tension: Symptoms include tension headaches, fatigue, and sleep disturbances.
- Gastrointestinal irritability: Symptoms include stomach pains, nausea, and a decreased appetite.
- Genitourinary disturbance: Symptoms include vaginal and/or anal bleeding and bladder and vaginal infections.

In the first few hours after the assault, survivors of a sexual assault often experience shock or disbelief. Several researchers have observed in their study of sexual assault survivors that survivors tended to have one of two emotional response patterns—expressed or controlled. The expressed style is the expression of fear, anger, and anxiety through behaviors such as crying, sobbing, paradoxical smiling, restlessness, and tenseness. The controlled style masks the psychological distress with a calm, composed, subdued affect. There were equal numbers of both expressed and controlled response styles among sexual assault survivors.

Long-Term Phase

In the long-term phase, psychological symptoms such as depression, anxiety, and fear are prominent. This phase has three components:

- Motor activity: Sexual assault survivors often exhibit an increase in motor activity with a range of activities, such as changing their residence and telephone number and adopting a variety of personal safety and security measures. They may turn to family and friends for assistance with these activities. Survivors may make special trips home or to some location that symbolizes safety and social acceptance.
- Nightmares: Nightmares after sexual assault are often upsetting, and violent dreams can occur for months after the sexual assault. The nightmares may contain images that are clearly connected to the sexual assault, but nightmare content may also fail to be obviously related to the sexual assault.
- Trauma-phobia: As the term implies, *trauma-phobia* is a phobic reaction to trauma in which the phobia develops as a psychological defense against the sexual assault experience. The more common phobias are fear of being indoors, fear of being outdoors, fear of being alone, fear of being in crowds, fear of having people behind the individual, and sexual fears. Fear of sexually transmitted disease (STD), including HIV, is also a powerful source of psychological trauma. It has been estimated that 4% to 30% of sexual assault survivors are diagnosed with an STD as a result of the sexual assault.

Some victims of sexual assault have what has been called a "silent rape reaction"; these survivors have not reported the assault to anyone. They experience psychological burdening and are not able to resolve their thoughts and feelings about the sexual assault. Consider unreported sexual assault as a basis for atypical psychological symptoms such as atypical anxiety; abdominal pain not otherwise specified; sexual relationship problems; significant changes in sexual behavior patterns; unexplained, sudden onset of phobias; and chronic low self-esteem.

Diagnostic Reasoning

The diagnosis of sexual assault is made by patient complaint and confirmed by forensic evidence.

Management

During the initial or acute phase, sexual assault survivors may be seen in emergency departments, rape crisis centers, primary-care offices, or police stations. If the sexual assault has occurred within the last 72 hours, forensic physical evidence should be collected. If the survivor chooses to remain anonymous, a "Jane Doe Rape Kit" enables forensic evidence to be collected without revealing identifying information. Survivors are given a code number that can be used to identify themselves if they choose to report later. The Violence Against Women and Department of Justice Reauthorization Act of 2005 (and reauthorized in 2013) provides that states may not require those who have experienced sexual assault to participate in the criminal justice system or cooperate with law enforcement in order to be provided with a forensic medical exam. Under this provision, a state must ensure access to an exam free of charge even if the survivor chooses not to report to the police or otherwise cooperate with the criminal justice system.

The use of a Sexual Assault Nurse Examiner (SANE), if one is available, is highly recommended. These nurses receive special training in collecting forensic evidence and providing crisis intervention and offer a number of advantages over emergency department practitioners. For example, the survivor is seen by one specialist rather than by several practitioners, which decreases the time a sexual assault survivor spends in the emergency department and ensures that she (or he) receives sensitive, nonjudgmental care by a practitioner who is an SA specialist. Equally important, the nurse is skilled in the collection of forensic evidence, resulting in higher conviction rates of sexual assault.

Care for survivors is not always consistent when they present to emergency departments. A retrospective study of care received in the emergency department from the 2003 National Hospital Medical Care Survey showed that the majority of sexual assault patients did not receive sufficient care in accordance with national treatment guidelines. Consider consultation with an expert in forensic examination (Level II; Sievers et al, 2003). Law enforcement should be involved; however, patients may decline to discuss the assault with police. Conversely, in some cases, patients may choose to cooperate so that testing costs will be paid by law enforcement. Initial treatment for sexual assault survivors includes the sexual assault interview, physical exam for physical assessment and forensic evidence collection, and crisis intervention.

The Sexual Assault Interview

Ascertain the capacity of the patient to consent to a forensic examination. Evaluate understanding and appropriate responses when obtaining the diagnostic history. Drugs, alcohol, developmental disability, or young age may cause a delay in obtaining the patient's consent. In the case of severe head or critical injury, law enforcement may provide a court order to proceed with forensic evidence collection. Before doing a diagnostic physical exam, it is imperative to address psychological issues related to the examination itself (Level II; Campbell & Raja, 1999). Patients presenting after sexual assault have undergone an experience that denied them the right to consent. There are important psychological and legal implications with obtaining forensic evidence, and the patient's consent and opportunity for a family member, friend, or patient advocate to be present should not be undervalued.

The sexual assault interview is performed in a room away from the waiting areas and exam rooms, while the survivor is still fully clothed, often with a police officer present. It should be done unrushed and with sensitivity. The sexual assault interview begins with general health information, including drug allergies, current medications including birth control, surgical history, tetanus and hepatitis B immunization if relevant, major health problems, pregnancy status if known, first day of last menstrual period, gravidity, parity, history of STDs, and most recent consensual sexual contact.

Questions about the sexual assault follow the general health information questions. Although this history is difficult for the patient to report, it is important to obtain an accurate history for collection of forensic evidence in order for the examiner to locate all points of physical contact and penetration, as well as documenting the survivor's activity immediately following the sexual assault.

The sexual assault survivor is asked the date, time, and place of the sexual assault and all events surrounding the sexual assault. Inquire about the use of force or threats of force, including threats of future harm to the patient or acquaintance, presence of a weapon, or threats to expose a personal secret. Notation of the type of force; use of restraints; number of assailants; and type of assault such as fondling, kissing, licking, penetration or attempted penetration of the mouth, vagina, or anus by finger, object, or penis need to be documented. "Drug-facilitated sexual abuse" associated with gamma-hydroxybutyrate (GHB) or alcohol may be suspected when the patient also reports lapses in consciousness, and GHB may be detected in urine up to 96 hours after consumption. Ask whether a condom was used. Ask about activities since the assault such as bathing, urinating, defecating, douching, gargling, eating, brushing teeth, and washing or wiping self.

A complete physical exam should be performed, assessing for injury and potential evidence. All physical exam and forensic evidence collection procedures should be fully explained with ample opportunities for clarification if needed. The physical examination can be traumatic for survivors; thus, survivors should be allowed to control the exam as much as possible. This can be accomplished by letting the survivors know they can refuse any part of the exam or stop the procedure at any time.

Sexual assault survivors should also be encouraged to have a support person such as a friend, spouse, or family member with them during the exam. In addition, a counselor or patient advocate from the local rape crisis center may also be available to support the sexual assault survivor during the exam. Although sexual assault survivors may decline such support, they should be offered and encouraged to accept it.

Physical Examination and Forensic Evidence Collection

The practitioner needs to be aware of state guidelines for evidence collection. The physical exam begins with the removal of all items of clothing. Each item of clothing worn at the time of the sexual assault is placed in a separate bag and then signed over to a law enforcement officer as forensic evidence. Physical forensic evidence that can be found on clothing includes hair, blood, semen, and saliva. Gloves should be worn throughout the physical exam to preserve evidence.

The sexual assault kit, available in most states, should contain all materials needed. Become familiar with the forms before doing the sexual assault exam. Document the general appearance of the patient and complete a head-to-toe assessment for signs of trauma, including an oral exam, skin exam for lacerations, swelling, broken fingernails, and foreign material such as leaves, grass, fibers, dried blood, and dried secretions anywhere on the body. Forensic evidence includes samples of the individual's hair (head and pubic) and saliva; oral, vaginal, and rectal swabs; and fingernail scrapings. It is important to label specimens accurately, noting the collection time and date and the signature of each person who provided and received them.

A detailed anogenital exam is performed to assess for injury (Level II; Sugar et al, 2004; Read et al, 2005). Pelvic, vaginal, and rectal exams are completed at the end of the exam. Colposcope and/or toluidine blue dye can be used to assess genital injury and provides permanent documentation of injuries that may heal very quickly and avoids having the patient subjected to reexamination or potential loss of evidence. Toluidine blue dye is a nuclear stain that adheres to the areas of injury on subepithelial nucleated cells but not to intact epithelial cells; therefore, it is not useful for mucosal surfaces such as the vagina or anus. Almost half of genital exams done with a colposcope of women who have been raped will have a normal exam. Anoscopy is utilized to view extent of rectal injuries. Genital injuries can also be detected when women participate in consensual intercourse. Although forensic evidence should be collected as soon as possible, exams performed several days after the sexual assault can still produce findings.

Laboratory testing for STDs is recommended only if treatment is deferred. STD testing at this time would detect only preassault infection. Consider testing in minors, because they are unable to give consent to engage in intercourse. However, serological testing for HIV, hepatitis B, and syphilis is recommended, because the efficacy of prophylactic treatment is not complete. Seroconversion that is attributed to the assault may be covered by the Victims of Violent Crimes Fund. Further collection of blood, buccal, and urine specimens is recommended for crime lab testing for DNA, pregnancy testing for all women of childbearing age, and toxicology analysis if indicated (Level II; Nelson et al, 1996). A 6-year, retrospective study of 1,421 sexual assault patients who presented to the emergency department found that 12% reported drug-facilitated sexual assault. This group had a longer delay in presentation to the emergency department, less often had police involvement, and had a decreased occurrence of genital and other injury. Hospitalization may be necessary to treat unstable medical conditions or to provide surgical intervention or psychiatric stabilization.

Nonpharmacological Treatment

Crisis intervention with sexual assault survivors includes encouraging them to talk about their feelings, validating these feelings, educating survivors about rape trauma syndrome, and identifying concerns related to the sexual assault. Psychological support is necessary to address the patient's needs and should be done before the sexual assault interview. These concerns include prevention of pregnancy and/or STDs, physical safety, and the need for specialized sexual assault psychotherapy and community support groups. Physical safety becomes a focus of concern for anyone who has just been assaulted. Sexual assault survivors can become preoccupied with the fear that their attacker will try to hurt them again. This is especially true when the survivor knows the identity of the attacker or the assault occurred in the survivor's home. Clinicians can help survivors start to problem-solve safety concerns and help to meet the survivor's immediate needs for safety. Some individuals may elect to live with friends or family until they begin to feel safe again.

A supportive approach and focusing on restoring the victim's sense of adequacy and control over his or her life are the best means for supporting the survivor provided there is no severe underlying pathology that might warrant a different treatment plan. Group therapy with homogeneous groups has been found to be effective for many. A rape victim fares best when he or she receives immediate support and can ventilate her feelings of rage and fear to loving family members and to supportive clinicians and law enforcement officials. A longitudinal study of sexual assault survivors showed that negative social reactions and blame of the victim were associated with worsened PTSD symptoms. Socially acceptable means of recourse, such as the arrest and conviction of the rapist, can help the victim. (See Advanced Practice Nursing Interventions 18.4.)

Advanced Practice Nursing Interventions 18.4 Crisis Intervention

Persons Amenable to Crisis Intervention	• History of recent, specific crisis situation (may be an event, e.g., sexual assault, natural disaster; or developmental, e.g., death, divorce, job loss). • Clear-cut evidence of psychological incapacitation, specifically, severe anxiety related to the event. • High motivation to overcome the crisis. • Previously demonstrated ability to cope.
Processes	• Practitioner must rapidly establish psychological rapport with the person and develop psychological insight on part of the person; speed is essential. • Person must actively participate. • Person and practitioner must work together to overcome the crisis.
Methods	• Main task is to decrease anxiety through reassurance, suggestion, environmental manipulation, psychotropics. • Review steps that have led to crisis and promote understanding of the maladaptive response to the crisis. • Focus on developing more adaptive ways of coping with the crisis situation. • Length of intervention may vary from 1–2 sessions to 1–2 months. • Brief hospitalization may be part of the plan.
Outcomes	• Patient better equipped to deal with future stressors. • Intervention ended as soon as possible, hopefully at a higher developmental level than before crisis. • Intervention may be viewed as both therapeutic and preventive.

Pharmacological Therapy

Medications to treat STDs and pregnancy should be offered. A tetanus booster is necessary if patients who experienced lacerations or abrasions have not been adequately immunized. HIV counseling, as well as testing and prophylaxis, should be offered to all survivors. Provider encouragement was shown to have an association with the patient's decision to start HIV prophylaxis treatment. Consider referral to an infectious disease specialist to guide antiretroviral therapy. Offer hepatitis surface antibody testing with vaccination. Administer HBIG if there is a high risk of exposure by a known hepatitis B–positive assailant. Emergency contraception should be offered to female patients after penile-vaginal assault, especially to those patients who have not had a tubal ligation or do not have an intrauterine device (Levels I, II; von Hertzen et al, 2002). Referral to an obstetrician/gynecologist and a urology specialist may be needed for treatment for specific traumatic injuries that require further care.

Follow-up and Referral

Sexual assault survivors should be encouraged to use the support services available from community rape counseling centers, such as individual therapy, group therapy, and self-defense training, as well as legal follow-up. The majority of rape counseling centers offer 24-hour crisis hotlines. Many individuals may not feel they need this support or that their family and friends are there for them. Survivors continue to be at risk for long-term problems, however, and to have grief and mourning needs long after the immediate crisis has passed and significant others have come to believe that the crisis is over. Rape counseling center personnel understand the long-term course of events of sexual assault. Some rape counseling centers are also able to provide advocates to support survivors as they deal with the legal and judicial systems. These services are often offered free of charge or at greatly reduced rates.

Medical follow-up after the initial visit is important to reassess any traumatic injuries, review laboratories, advise post-HIV test counseling, and reassess psychological status and recovery. Consider retesting for pregnancy if the patient has not had the expected menstrual cycle. Repeat HIV, hepatitis B, and STD testing as indicated.

Patient Education

Education begins with the first patient encounter, allowing the survivor to regain control and become an active participant in her recovery, incorporating patient-centered care. Include education about the diagnostic work-up, management, psychological and medical recovery, and advice about community support services, as well as discussion of the long-term effects of sexual assault. Impress on the patient the need to engage with psychological evaluation early on. The most common long-term effect of sexual assault is the development of PTSD. Recent research has indicated that sexual assault

survivors may be the largest single group of PTSD sufferers. PTSD was originally defined to explain the set of symptoms observed in survivors of natural disasters and military combat and includes symptoms such as anxiety, depression, nightmares, flashbacks, and sleep disturbances. Researchers have found that 94% of the women who had been sexually assaulted met the criteria for PTSD 12 days after the sexual assault and that 46% of these women still met the criteria 3 months later.

In addition to having higher rates of PTSD, sexual assault survivors reported higher rates of drug and alcohol problems, depression, attempted suicide, anxiety, obsessive-compulsive disorder, and medical care use. Sexual assault survivors were 13.4 times more likely to have had alcohol-related problems and 26 times more likely to have had problems with drug abuse, compared with women who were not sexually assaulted. Survivors were three times more likely to have had a major episode of depression, four times more likely to have had thoughts about suicide, and 13 times more likely to have attempted suicide compared with other women. Finally, survivors of sexual assault report more symptoms of illness across all body systems and perceive their health less favorably than do other women. Symptoms that are diagnosed at a much higher rate in sexual assault survivors include chronic pelvic pain, gastrointestinal disorders, headaches, general pain, and premenstrual symptoms. Every effort should be made to encourage the patient to initiate long-term support for dealing with the trauma of sexual assault. The health-care provider, practicing within a *Circle of Caring,* may be in the best position to maintain contact with the patient and facilitate growth and healing.

Emergency Problems

Jill E. Winland-Brown, EdD, APRN, FNP-BC •
Brian Oscar Porter, MD, PhD, MPH

Chapter 19

In the United States in a typical year, there are approximately 130 million emergency department (ED) visits. Thirty-eight million of those are injury-related visits. Falls are the most common reason for an injury-related visit. Almost 43% of all Americans will visit an ED this year; 35% of ED visits will involve a patient being x-rayed, and 17% will involve computed tomography or magnetic resonance imaging scans.

COMMON PROBLEMS

PNEUMOTHORAX AND HEMOTHORAX

Pneumothorax refers to the abnormal presence of air in the potential space between the parietal and visceral pleura in the thorax. *Hemothorax* refers to the abnormal presence of blood in the same region. For this potential space to become occupied by air or blood, there must be an injury to one of the pleurae. A pneumothorax is described as *closed* if the chest wall is intact or *open* if the chest is violated and communicates with the atmosphere.

Epidemiology and Causes

Pneumothorax and hemothorax are usually the result of a trauma that penetrates the chest wall and violates the parietal pleura or of a blunt force trauma that fractures ribs, which violate the parietal or visceral pleura. Pneumothorax may be procedurally related; for example, during placement, a central line or arterial catheter may accidentally puncture the lung. Most patients (60%) who have suffered a penetrating or high-energy blunt trauma to the chest will have a hemothorax and/or pneumothorax. A pneumothorax (in 25% of patients) or other extrathoracic injuries (in 13%) will usually accompany a hemothorax. The etiology of pneumothorax can be traumatic (ribs piercing the pleura as a result of a motor vehicle accident, for instance), iatrogenic (as a complication of a central-line insertion), idiopathic (spontaneous), or related to an underlying disease process (such as a ruptured emphysematous bleb in the lung apices in a patient with chronic obstructive pulmonary disease [COPD]). With the increased incidence of COPD, pneumothorax is becoming more common in the primary-care setting.

A spontaneous pneumothorax, which accounts for two-thirds of all pneumothoraces, occurs most commonly, and this type is more prevalent in tall, slender young men. It is usually the result of a rupture of a superficial bleb. A *bleb* is a defect on the lung surface that appears as an outpouching. Such defects may be inherited or related to forces placed on the lung during growth, development, and remodeling of inflammatory lung tissue. Cigarette smoking clearly predisposes an individual to bleb formation and spontaneous pneumothorax with a clear dose–response relationship, likely due to repeated inflammatory insults to the lung parenchyma. Patients with connective tissue disorders, such as Marfan syndrome or homocystinuria, are also susceptible to spontaneous pneumothoraces. In addition, women with thoracic endometriosis may suffer from recurrent catamenial pneumothoraces or hemothoraces, which are related to their menstrual cycles and bleeding from extrauterine endometrial implants. Catamenial pneumothorax occurs within 72 hours before or after the menstrual cycle. Surgical exploration of the diaphragm should be done in females with repeated pneumothorax. Rare, heritable genetic conditions also exist that predispose individuals to primary pneumothorax, such as the familial cancer condition characterized by renal cancer and benign skin tumors known as Birt-Hogg-Dube syndrome. However, such conditions are typically not suspected without a strong family history. Thirty percent to 50% of patients with a history of spontaneous pneumothorax will have a recurrence of this condition.

Secondary pneumothoraces are most often due to underlying emphysematous COPD or HIV-associated *Pneumocystis jiroveci* (formerly known as *Pneumocystis carinii*) pneumonia. Other etiologies for the clinician to consider include asthma, neoplasms, as well as pulmonary infarction.

Other common predisposing conditions include cystic fibrosis and other conditions that cause significant bronchiectasis, as well as any cavitary lung infection, such as tuberculosis, in which cavities may rupture through the parietal pleura, leading to gas escape into the pleural space. Hemothoraces may similarly result

when cavitary lung lesions invade both blood vessels and the parietal pleura; however, penetrating chest trauma remains the primary cause of hemothorax.

Pathophysiology

Although the underlying etiology of pneumothorax and hemothorax varies widely as described in the preceding text, the collection of either gas or blood within the pleural space ultimately results from a similar pathophysiological mechanism. The thorax contains the lungs, heart, and major blood vessels. A visceral pleural layer surrounds the outer surface of the lungs, and the chest wall is lined with a parietal pleural layer. The pleural space is a potential space resulting from the apposition of the two pleural membranes. The pleural cells that line the lungs and chest wall continually absorb any gas or fluid that collects in the pleural space, which maintains a negative pressure of –10 to –12 mm Hg. This thoracic pressure differential allows the lungs to expand during inspiration. Any trauma or membrane rupture that results in violation of either pleura can eliminate this negative pressure and allow fluid or air to collect in this space. In turn, this will have a negative impact on the ability of the lungs to expand effectively.

Clinical Presentation

Subjective

The most frequent presenting symptoms of patients with pneumothorax and hemothorax are dyspnea and chest pain. The severity of the symptoms depends on the size of the pneumothorax or hemothorax. Typically, these conditions are associated with other injuries, which may mask the dyspnea or chest pain. For example, a patient who has a head injury or is unconscious may have altered breathing patterns related to a cerebral event. If the clinician is not alert to the possibility of chest pathology, a pneumothorax or hemothorax may be missed. Fractured ribs may mimic the type of pain encountered with a pneumothorax or hemothorax. If rib x-ray studies are the only type (view) ordered, the technique used to perform this type of x-ray exam correctly will obscure the subtle radiographic findings of a pneumothorax. A chest x-ray film with both posterior-anterior and lateral views should be ordered for any patient who may have suffered chest trauma. A high index of suspicion is needed when considering a pneumothorax or hemothorax.

Objective

Because of decreased lung volume, patients with pneumothorax or hemothorax will usually have a lower than normal oxygen saturation and may present with cyanosis and varying levels of tachypnea and tachycardia. Lung sounds can be used to help determine the presence of a pneumothorax or hemothorax: Auscultation of absent breath sounds on the affected side has a high-positive predictive value for these conditions, but a normal auscultation does not rule out the presence of pneumothorax or hemothorax. A patient with a large hemothorax can present with frank hypovolemic shock.

Diagnostic Reasoning

Diagnostic Tests

Any patient who has sustained blunt chest trauma and/or penetrating chest trauma must have an upright chest x-ray film to rule out pneumothorax or hemothorax. A supine chest x-ray film can miss many significant thoracic injuries and should not be relied on to rule out these conditions. The clinician should review the x-ray film, comparing the lung fields bilaterally and looking for any differences in lung markings on one side. When a pneumothorax is present, a subtle light line will be noted—this is the edge of the lung tissue. Beyond that point, the pleural cavity will have absent lung marking. Depending on the technique used, the amount of fat, clothing, or other objects visible on the film, the difference in the pathological and normal pleural cavity can be very difficult to visualize. It is helpful to use a bright viewing box, position the x-ray film horizontally, and focus on the lateral and lateral-superior aspects of the pleural cavity, where most pathology is found.

If a pneumothorax is suspected but not found on an inspiratory chest x-ray study, the clinician should request an expiratory chest x-ray exam. During the expiratory phase, the thoracic volume is decreased; the relative size of the pneumothorax is increased and thus may be more easily detected.

If a hemothorax is suspected, the clinician should order a lateral decubitus view, which will reveal the shifting of blood to the lowest part of the pleural cavity. If doubt still exists or a more accurate determination of size of the defect is required, a computed tomography (CT) scan is the definitive test.

Differential Diagnosis

Differential diagnoses for pneumothorax and/or hemothorax include pneumonia, pulmonary embolism, myocardial infarction, angina, and intercostal muscle strain.

Management

Emergency Management

The patient with a pneumothorax or hemothorax is usually cared for and managed in the ED; therefore, if the clinician suspects that a patient presenting to a primary-care setting has a pneumothorax and/or hemothorax, emergency medical services (EMS) should be called, the patient's respiratory and cardiovascular status should be evaluated and supported as indicated, and then the patient should be transported to the ED immediately.

General Management

A pneumothorax is measured as a percentage of thoracic volume. A mild pneumothorax is less than 15%, a moderate one is 15% to 60%, and a severe one is more than

60%. Most mild and some small to moderate pneumothoraces (fewer than 20%–30%) can be treated conservatively with observation if the patient is not experiencing any untoward effects. The patient should be admitted for continuous observation and serial chest x-ray films. Patients should be placed on supplemental oxygen (up to 100% for a significant pneumothorax), even if the O_2 saturation is normal on room air, as this helps resorption of the pneumothorax. If the size of the pneumothorax remains unchanged over 8 hours, it is usually safe to allow the body to absorb the air. Any patient with a moderate or severe pneumothorax will require a tube thoracostomy (chest tube).

A hemothorax of even mild to moderate size requires insertion of a chest tube. Any patient who presents with significant dyspnea or who is too unstable for ancillary studies and has a high risk of having a pneumothorax or hemothorax should receive a chest tube immediately. The tube should be inserted in the fourth to fifth intercostal space, at the anterior or midaxillary line. Directing the tube posteriorly and toward the apex can effectively remove both air and fluid. Because 2% to 20% of patients with chest tubes usually have infectious complications, antibiotic prophylaxis may be warranted in some patients.

Most pneumothoraces can be treated in a nonurgent manner. Patients with significant respiratory distress will respond quickly to insertion of a chest tube. Patients with a tension pneumothorax, however, require immediate stabilizing treatment (Box 19.1).

Follow-up and Referral

After a period of observation, patients with a mild pneumothorax who do not require a chest tube can be discharged with continued follow-up in 1 to 2 days. Patients with a large pneumothorax, a tension pneumothorax, or a hemothorax requiring a chest tube should not be discharged until the pleura has been drained of blood, and the lung has been reexpanded for at least 24 hours. Strenuous exercise should be limited until the patient has fully recovered; it is possible to reopen and aggravate the pleural defect until it has fully healed. The patient should be advised to follow up with a primary-care provider in 1 week for repeat chest radiograph to evaluate for percent of reexpansion. If the pneumothorax is not fully expanded at this time, the clinician should consult a cardiothoracic surgeon.

Patient Education

Patients who have been diagnosed with a spontaneous pneumothorax should be counseled that up to 23% to 30% will have a recurrence at some point. An explanation of the signs and symptoms to watch for—dyspnea, persistent cough, and chest pain—should be given to all patients, regardless of the type of pneumothorax. The clinician should consider consulting respiratory therapy before discharge for incentive spirometry teaching, as an aid in recurrence prevention.

POISONING

Because most adult poisonings are intentional and self-inflicted (the second highest cause of suicide at 24%), the goal is to treat the immediate event and get the patient into counseling as soon as possible to determine precipitating factors and prevent recurrence. During childhood, poisonings are most often due to accidental ingestions.

Epidemiology and Causes

It has been estimated that more than 2 million poisoning accidents occur each year. The majority of these involve children. More than 90% of all poisonings occur in the home. Children younger than age 6 years account for approximately 60% of all poisonings reported. Adult poisonings account for 80% to 90% of all hospital admissions from poisoning. Most adult poisonings involve intentional ingestions, such as recreational drug exposures or suicidal gestures or attempts by overdose. Table 19.1 presents common poisonings. The American Association of Poison Control Centers

Box 19.1 Tension Pneumothorax

Patients with a tension pneumothorax usually have some type of penetrating trauma such as a gunshot or knife wound. A *tension pneumothorax* develops when air in the potential space between the parietal and visceral pleura is under pressure. The defect in the pleura allows air to enter the potential space during inspiration, but because of a flap mechanism (which functions like a one-way valve), air does not escape. This mechanism increases the pressure on the affected lung and, if not corrected, will lead to a complete collapse of that lung. If the defect is left untreated, the pressure will continue to increase and force the mediastinum to the unaffected side. This will cause the major blood vessels to kink and restrict normal blood flow to and from the heart, which can cause death within minutes.

A tension pneumothorax is a true medical emergency and must be treated immediately. There is no time for x-ray exams to diagnose this condition. The emergent stabilizing treatment involves performing a needle thoracostomy. This is accomplished by inserting a large-bore (18-gauge or larger) needle into the chest. The needle should be inserted between the second and third rib intracostal space at the midclavicular line. The needle should be inserted just over the third rib to avoid penetrating the neurovascular bundle that runs parallel to the rib on the inferior border.

Table 19.1 Common Poisonings

Name/Type	Signs and Symptoms	Diagnosis	Management
Drugs			
acetaminophen (Tylenol)	Nausea, vomiting After 24–48 hours postingestion—hepatic necrosis with jaundice, hepatic encephalopathy, renal failure, possible death	Acetaminophen level	Activated charcoal acetylcysteine (Acetadote) for 36 hours after ingestion
Barbiturates: phenobarbital (Phenobarb) pentobarbital sodium (Nembutal)	Decreased level of consciousness Drowsiness Confusion Ataxia Vertigo Slurred speech Shallow respirations Bradycardia Headache Cyanosis Hypothermia Cardiovascular collapse	Toxicology screen	Gastric lavage with activated charcoal and cathartic Airway maintenance Ventilatory assistance
Benzodiazepines: clorazepate potassium (Tranxene) diazepam (Valium) alprazolam (Xanax)	CNS depression Drowsiness Dizziness Headache Ataxia Hypotension Memory impairment Salivation changes	Toxicology screen	Gastric lavage Symptomatic treatment Airway maintenance Ventilatory assistance
CNS stimulants: methylphenidate (Ritalin, Concerta), amphetamine mixture (Adderall)	Vomiting, emotional lability, nervousness, fever, dizziness, hypertension, tachycardia, psychosis, dyskinesias, Tourette's syndrome, seizures	Toxicology screen	
Cocaine	Nervous system stimulation Restlessness Hallucinations Tachycardia Dilated pupils Chills Fever Abdominal pain Vomiting Muscle spasms Irregular respirations, progressing to death	History of cocaine use Toxicology screen	diazepam (Valium) IV Emetic Gastric lavage Oxygen Symptomatic treatment
Heroin	Euphoria Flushing Pruritus Miosis	History of heroin use Toxicology screen	Maintain patent airway Oxygen Symptomatic treatment naloxone (Narcan) 2 mg IV

Table 19.1 Common Poisonings—cont'd

Name/Type	Signs and Symptoms	Diagnosis	Management
	Decreased level of consciousness Bradycardia Shallow, slow respirations Hypotension Hypothermia		nalorphine HCl IV Respiratory stimulant: 3–5 mL doxapram hydrochloride
lithium (Lithobid, Lithotabs, Duralith)	Vomiting, diarrhea, slurred speech, decreased coordination, drowsiness, muscle weakness or twitching	CSF lithium level Toxicology screen	Induced emesis Gastric lavage Osmotic and saline diuresis (if renal function is normal) Urine alkalization Hemodialysis
Salicylates (aspirin, methylsalicylate)	Nausea, vomiting, gastritis, hypercapnia, tachycardia, tinnitus, agitation, confusion, coma, seizures, cardiovascular collapse, pulmonary edema, hyperthermia, possible death	Elevated prothrombin time Toxicology screen with a level >100 mg/dL Arterial blood gases reveal respiratory alkalosis with an underlying metabolic acidosis	Activated charcoal Gastric lavage IV NaBicarb Possible hemodialysis
Tricyclic antidepressants (SSRIs are relatively safe, even in overdose): amitriptyline (Elavil) imipramine (Tofranil) nortriptyline (Pamelor)	Confusion Dizziness Decreased level of consciousness Hypotension Tachycardia Hyperthermia Mydriasis Dry mucous membranes Cardiac dysrhythmias Seizures	Toxicology screen	Gastric decontamination with activated charcoal and cathartic Symptomatic treatment
Foods			
General food poisoning: Foods consumed with toxins present	Vomiting, afebrile, abdominal cramping	Toxins: *Staphylococcus aureus, Bacillus cereus, Clostridium perfringens, Shigella, Salmonella.* Toxin can be detected in food or stool specimens.	Fluids and electrolyte replacement Ciprofloxacin (use with caution) Disease usually self-limiting Antimotility drugs
Poisonous fish	Abdominal cramps Nausea Vomiting Diarrhea Paresthesia Hypotension Respiratory paralysis	History of ingesting fish	Supportive treatment for symptoms

Continued

Table 19.1 Common Poisonings—cont'd

Name/Type	Signs and Symptoms	Diagnosis	Management
Scombroid fish poisoning (bacteria producing scombrotoxin)	30 minutes to 2 hours after ingestion: Peppery sensation on tongue Urticarial pruritic rash Headache Dizziness Periorbital edema Nausea Vomiting	History of ingesting fish	Gastric lavage Antihistamines Symptomatic treatment
Other Substances			
Arsenic	Metallic taste Garlic odor to breath Burning pain throughout GI tract Vomiting Dehydration Shock Seizures	Order toxicology screen and/or attempt to discover type of material ingested by investigating all suspect containers	Gastric lavage Fluid and electrolyte management Treat shock and pulmonary edema Possible blood transfusions
Carbon monoxide	Deep respirations Pink (cherry red) tissues and skin (with COHb ↑ 30%) Initial bradycardia, progressing to tachycardia Pounding pulse Dizziness Paresis Tinnitus Headache Faintness Nausea Dilated pupils	Carboxyhemoglobin (COHb) ↑	100% oxygen, under hyperbaric pressure Symptomatic treatment
Corrosive materials: Lysol, tincture of iodine, carbolic acid (phenol)	Burned tissues along GI tract Brownish stains on lips and tongue Stridor from laryngeal swelling Nausea Vomiting Abdominal cramps Hematemesis Watery, mucoid, or bloody stools Violet or black mucous membranes Carbolic acid—white or gray mucous membranes Hydrochloric acid—grayish mucous membranes Nitric acid—yellowish mucous membranes Sulfuric acid—tan or dark-stained mucous membranes	As above	Opiates for pain Possible tracheostomy Aggressive fluid and electrolyte resuscitation Antibiotics and corticosteroids

Table 19.1 Common Poisonings—cont'd

Name/Type	Signs and Symptoms	Diagnosis	Management
Iodine	Brown stains on lips and mouth Burning pain in mouth and throat Yellow emesis (blue if starch is present)	Diagnosis based on symptoms and open or empty container found at scene	Cornstarch or flour solution: 15 g in 2 cups of water given orally if patient is conscious, or gastric lavage if patient is comatose Morphine sulfate for pain
Lead: lead-based paints, lead-contaminated dust, hobbies (e.g., stained-glass windows)	Colicky abdominal pain, constipation, headache, irritability, coma, convulsions Chronic poisoning—learning disorders in children, motor neuropathy (wrist drop)	Blood levels: 10–50 mcg/dL—mild toxicity 50–70 mcg/dL—moderate toxicity 70–100 mcg/dL—severe toxicity Microcytic anemia	*Up to moderate toxicity:* Edetate calcium disodium (EDTA) Oral chelator—succimer (dimercaptosuccinic acid, DMSA) *Severe toxicity:* Edetate calcium disodium continuous IV, dimercaprol (BAL) IM
Strychnine	Sense of suffocation Cyanosis Dyspnea Tachycardia Muscle rigidity Contractions Seizures	As above	Gastric lavage Oxygen Sedatives

has a Toxic Exposure Surveillance System (TESS), which is a database of detailed toxicological information on more than 24 million poison exposures reported to U.S. poison control centers. The Web address where annual reports are published is listed at the end of the chapter.

Pathophysiology

The pathophysiology of poisonings varies widely, depending on the substance inhaled or ingested. Most poisonings are dose related, and the diagnosis is usually clinically based. However, the clinician should consider the toxicity of the poison and utilize blood and urine toxicity screens when indicated. Discussion of a representative sample of potential toxins emphasizes this point. For example, with the inhalation of motor vehicle exhaust, the chemical binding of carbon monoxide (CO) to the hemoglobin component in blood results in the formation of carboxyhemoglobin (COHb), which prevents the binding of oxygen to hemoglobin with subsequent transport to bodily tissues. In contrast, with a tricyclic antidepressant overdose (e.g., amitriptyline, nortriptyline, imipramine), the toxic cardiovascular and central nervous system (CNS) effects are secondary to the anticholinergic effects of the medication and the alteration in cardiac cells, which results in conduction disturbances such as QTc prolongation.

With a barbiturate overdose (e.g., phenobarbital), there is decreased neuronal activity, depressed central sympathetic tone, and inhibition of cardiac contractility. These medications act directly on inhibitory gamma-aminobutyric acid (GABA) receptors by increasing the affinity of the GABA ligand to its cognate receptor and increasing the average opening time of chloride ion channels. Benzodiazepines such as lorazepam (Ativan), alprazolam (Xanax), and diazepam (Valium) are also CNS depressants that enhance GABA receptor activity but at a molecularly distinct portion of the receptor. Benzodiazepines increase ligand affinity and the frequency of ion channel opening, but not the duration of open channel time. Thus, given this difference in mechanism, benzodiazepines have less potential for toxicity than barbiturates because their effects are saturable.

Clinical Presentation

Signs and symptoms of various types of poisoning are listed in Table 19.1.

Subjective

The history is an essential component of the diagnosis and treatment plan when a patient is being evaluated for a possible ingestion of a poisonous substance. Interviewing the patient, family, and significant others will give the practitioner valuable information regarding what may have been ingested, as well as the amount ingested and time since the exposure. A lack of symptoms does not preclude the possibility that ingestion has occurred. The history may be very unreliable because poison ingestion

is usually associated with the pediatric population and suicidal gestures.

Objective

The physical exam should include an assessment for evidence of trauma and neurological symptoms. The clinician should also assess for odors that may give a clue as to what was ingested. The neurological exam should include a mental status exam; an assessment for seizure activity; and assessments of pupils, the gag reflex, and any focal signs. Additional cardiac, respiratory, gastrointestinal (GI), and renal assessments may be required, depending on the type of poison ingested.

Diagnostic Reasoning

Diagnostic Tests

The diagnostic tests ordered will vary depending on the poisoning situation. Laboratory testing should include toxicology screening. If the specific drug ingested is known, quantitative levels of that agent should be obtained (mg/kg of body weight), along with routine chemistry testing, which includes electrolyte levels. COHb levels should be monitored to detect evidence of carbon monoxide poisoning.

Differential Diagnosis

Differentials for poisoning may range from a bipolar disorder to a transient ischemic attack. Because many substances produce GI symptoms, GI tract disorders should also be ruled out. In addition, overdose of many substances produce CNS symptoms, so vascular and cerebral pathology must also be ruled out. The clinician should always consider head injury in any patient arriving in the ED with altered mental status.

Management

Emergency Management

Poisonings are usually managed in the ED; therefore, if the patient presenting to a primary-care setting has a complaint of poisoning, emergency medical services should be called, the patient's respiratory and cardiovascular status should be evaluated and supported as indicated, and then the patient should be transported to the ED immediately. Emergency management in this scenario includes the A, B, C, Ds, for airway control, breathing, circulation, and drugs.

Because aspirin and acetaminophen are commonly overdosed substances, many clinicians check acetylsalicylic acid and acetaminophen levels with any overdose or potentially intentional toxin ingestion so as not to miss this diagnosis.

General Management

For management of common poisonings, refer to Table 19.1. If there is any question about treatment, the local poison control center should be consulted. The Poison Help Line (1-800-222-1222) of the American Association of Poison Control Centers can direct individuals to local control centers.

Management may also include gastric lavage and the administration of activated charcoal. A protected airway is essential before initiating lavage and is contraindicated in the presence of caustic ingestions. Gastric lavage may be performed to prevent the poison from reaching the stomach or intestinal tract, where many chemicals are commonly absorbed. Gastric lavage is accomplished by the insertion of a large-bore orogastric tube and lavaging the stomach with normal saline solution. Gastric lavage should be performed only in a conscious patient in order to avoid aspiration of stomach contents. Activated charcoal is often given after gastric lavage, especially after acute ingestions, to absorb the toxins. However, it does not absorb heavy metals, alcohol, caustics, or cyanide. The dose of activated charcoal for children is 1 to 2 g/kg; for adults, the dose is 50 to 100 g/kg. The activated charcoal may be given with or without sorbitol. Sorbitol is a cathartic and may produce dehydration and electrolyte imbalance in young children; therefore, it should be used with caution.

Aside from gastric lavage and GI decontamination, another method of eliminating toxins from the body is whole bowel irrigation by administering cathartic solutions such as Go-Lytely. Forced diuresis and alteration of urine pH can be used to remove certain toxins. Acidic toxins can be trapped in alkaline urine, and alkaline toxins trapped in acidic urine. Sodium bicarbonate administration can be used to alkalinize urine to a pH greater than 7.0.

Extracorporeal removal—for example, through dialysis, plasmapheresis, and exchange transfusion—is capable of removing almost any toxin from the bloodstream. Chelation is used to remove heavy metals such as lead, and hyperbaric oxygen is used for carbon monoxide poisoning.

Adults who are comatose should be given dextrose, thiamine, and naloxone. If hypoglycemia can be diagnosed, 50 to 100 mL of 50% dextrose should be given by IV bolus, as hypoglycemia can cause irreversible brain damage. In malnourished patients or patients with suspected alcohol abuse, 100 mg of thiamine should be given. Naloxone, 0.4 to 2 mg given intravenously may reverse opioid-induced respiratory depression and coma. Additional doses of up to 5 to 10 mg may be required.

Follow-up and Referral

Follow-up and referral will depend on the nature of the poisoning or overdose and the patient's response. If the poisoning or overdose was a suicide attempt or a call for attention, a psychiatric referral is indicated. The patient with suicidal ideation or attempts should never be discharged home without having a psychiatric evaluation clearly documented.

Patient Education

When teaching the patient's family about poisonings, the clinician should advise parents to call the Poison Help Line (1-800-222-1222) of the American Association of Poison Control Centers if a poisoning occurs. Historically, syrup of ipecac was used by parents to induce vomiting, but it is no longer recommended by the American Academy of Pediatricians owing to its potential for misuse and the regurgitation of corrosive ingested substances, which may cause more damage.

General teaching points for preventing poisonings include the following:

- Keep all medications and hazardous products locked up and out of the reach of children.
- Keep all medications in child-resistant containers.
- Never call medication "candy."
- Dispose carefully of all unused or old medications.
- Do not leave medications on countertops or tables, especially if children are present.
- Never transfer a hazardous material into another container.
- Do not mix chemicals unless you know what the reaction will be.

HEAT-RELATED ILLNESSES

Heat-related illnesses include heat cramps, heat syncope, heat exhaustion, and heat stroke. It is important to understand that heat-related illnesses are actually a continuum of conditions that range from mild to severe. Heat-related deaths are preventable. Heat response plans should be established before they are needed.

Heat cramps occur in hot weather when a person performs strenuous tasks and drinks large volumes of water, causing an electrolyte imbalance. Sodium chloride is lost from excessive perspiration.

Heat syncope is a heat-related fainting episode. This may occur because of vasodilation and peripheral pooling of blood, volume deficit, and sluggish vasomotor tone. Venous return does not support the required cardiac output, and syncope occurs. Heat syncope can result from inadequate cardiac output and postural hypotension. Recovery is immediate once the patient faints and lies flat.

Heat exhaustion occurs when there is a prolonged period of fluid loss (e.g., perspiration, diarrhea, or use of diuretics) and exposure to warm ambient temperatures without adequate fluid and electrolyte replacement. It is more common in younger persons and older adults.

A core body temperature of at least 104.9°F (40.5°C) characterizes *heat stroke.* Heat stroke occurs when heat production is greater than heat loss. There may be damage to multiple organ systems, and mortality may be as high as 10%. Heat stroke may be classic or exertional and is a true medical emergency. It must be rapidly assessed and treated.

Epidemiology and Causes

On average, 650 persons die each year of heat-related illnesses in the United States. Heat stroke is ranked third—behind head and neck trauma and cardiac disorders—as a cause of death among high school athletes in the United States. Factors associated with an increased risk of heat-related illnesses include age (both very young children and older adults are at higher risk); a history of a chronic illness, such as a cardiovascular, endocrine, nervous system, or psychiatric disease; use of certain medications, such as antihistamines, beta blockers, and diuretics, to name a few; fever or dehydration; a previous history of heat stroke; and heavy clothing. Many drugs possess anticholinergic side effects that may result in the inability to perspire. Individuals on beta blockers may have a diminished ability to cope with heat, thus resulting in a heat-related illness. Monoamine oxidase inhibitors and sympathomimetics can cause core temperature disturbance, leading to rapidly occurring muscle rigidity, extensive rhabdomyolysis, and electrolyte disorders that can prove fatal. Autonomic neuropathy of diabetes cause heat-related illnesses. Because diabetes is prevalent within the population, this is an important cause of faulty heat dissipation. The conditions of autonomic neuropathy of diabetes and beta-adrenergic and cholinergic blockade are often unrecognized contributors to heat-related illness that clinicians need to be alert to. Certain living conditions, such as living in an urban setting, living alone, and not using air conditioning during hot weather, are other risk factors. Exertion-related heat stroke may be a complication of unconditioned amateurs involved in strenuous athletic competitions.

Pathophysiology

Human beings are homeothermic, with a core temperature ranging from 97.0°F (36.1°C) to 99.5°F (37.5°C). When the body temperature reaches 107.6°F (42°C), oxidative phosphorylation occurs, and multiple key enzymes cease to function. Thermal regulation is controlled in the anterior hypothalamus, which receives information from the temperature of the circulating blood and from skin sensors. When the hypothalamus is stimulated, the respiratory rate increases to enhance heat loss via expired air; cardiac output is increased to facilitate cutaneous and muscular blood flow, which helps dissipate heat; and sweat glands become active in their role of sustaining evaporative heat loss.

Heat loss is dependent on radiation, convection, conduction, and evaporation. Radiation and conduction result in direct transfer of heat to the environment. When environmental temperatures reach 95°F (35°C), these mechanisms for heat transfer are no longer effective.

Convection is heat loss related to air circulation. This process relies on wind velocity. Evaporation of sweat is

the only physiological mechanism for eliminating heat in an environment hotter than 95°F. The body's ability to sweat is affected by skin conditions (such as sunburn), systemic diseases that affect sweating (such as cystic fibrosis), and drugs that inhibit sweating (such as phenothiazines). Increased core temperatures stimulate peripheral vasodilation and sweating. Venous return to the heart increases, resulting in increased cardiac output and heart rate. A concurrent sympathetic response is decreased blood flow to the kidneys. The kidneys are damaged if this process continues; myoglobin is produced as a by-product. If this condition is not aggressively treated, it will lead to rhabdomyolysis. Respiratory function may be compromised by pulmonary edema. Hepatic function is often decreased because of the general decrease in perfusion. Clotting abnormalities can range from thrombocytopenia to disseminated intravascular coagulation. Such abnormalities usually occur in severe heat illness. The metabolic rate increases and sweat production can increase to 1.5 L/hr, which may result in dehydration.

Acclimatization is a term that refers to the body's ability to adapt to heat stress. This adaptation primarily involves the sweating mechanism. In the unacclimatized person, each liter of sweat contains 30 to 50 mEq of sodium. This sodium level decreases to as little as 5 mEq/L in the fully acclimatized person, and the rate of sweating can be increased to 1.5 to 3 L/hr. This means that the acclimatized person doubles sweat production, losing one-third to one-fifth the total amount of sodium. Potassium wasting compensates for sodium loss. Therefore, a fluid and electrolyte imbalance can develop quickly in an unacclimatized person. Cardiac output increases with acclimatization, as does muscle aerobic metabolism, which is more efficient. As the heart muscle responds, cutaneous circulation improves, and heat dissipation is augmented. The body develops a new, lower point at which sweating begins. Finally, increased secretion of aldosterone aids in sodium conservation by the kidneys and sweat glands. The additional sodium enhances extracellular fluid volume, which plays a part in the accelerated cutaneous blood flow and heat dissipation.

Clinical Presentation

Subjective

For any heat-related illness, a complete history of the circumstances preceding the incident should be obtained. Any past history that may assist with the differential diagnosis is crucial. Medications that the patient is currently taking should be reviewed.

Objective

A complete physical examination, including monitoring the patient's cardiac status, vital signs, and core temperature, should be performed.

The clinical presentation may include hot dry skin, decreased level of consciousness, tachycardia, tachypnea, decreased urinary output, hyperpyrexia of greater than 104.9°F (40.5°C), hypotension, seizures, nausea and vomiting, decerebrate posturing, diarrhea, and dilated, nonresponsive pupils.

Table 19.2 describes the signs and symptoms and recommended management of the various types of heat-related illnesses.

Diagnostic Reasoning

Diagnostic Tests

There are no specific diagnostic tests performed. Management follows good assessment techniques (see Table 19.2).

Differential Diagnosis

The differential diagnosis of heat stroke should include CNS infections, cerebrovascular accident, and diabetic ketoacidosis. If the patient has recently traveled outside the country, the clinician should consider malaria or typhoid fever. In addition, the clinician should consider thyroid storm, meningitis, encephalitis, or brain abscess. Some toxicological issues to consider include salicylate, anticholinergic, phencyclidine (PCP), cocaine, or amphetamine toxicity.

Management

Emergency Management

Heat stroke is a medical emergency, with core body temperature reaching greater than 105°F (40.5°C). If the patient presenting to a primary-care setting has heat stroke, emergency medical services should be called, the patient's respiratory and cardiovascular status should be evaluated and supported as indicated, and then the patient must be transported to the ED immediately.

General Management

Specific management of heat-related illnesses is presented in Table 19.2. General management includes cooling the patient. The safest and most practical method is to remove all clothing and spray warm water over the body surface. Evaporation can be increased with fans, which should circulate air over as much body surface as possible. If ice packs are used, they should be placed in the axilla and groin, with the skin protected from local injury by a wrapping over the pack. Extremities should not be packed in ice, especially in older patients, because this treatment is poorly tolerated in older adults. Cooling of the internal core temperature can also be achieved by gastric or peritoneal lavage with cold saline. In extreme cases, hemodialysis can be used to cool blood. The goal is to reduce the temperature to 102°F (38.8°C) within the first hour. To avoid hypothermia, further active cooling should cease when a

Table 19.2 Types of Heat-Related Illnesses

Type of Illness	Signs and Symptoms	Management
Heat Cramps Heat cramps occur in hot weather when a person performs strenuous tasks and drinks large volumes of water, causing an electrolyte imbalance. Sodium chloride is lost from excessive perspiration.	Cramps, especially in the large muscle groups, such as shoulders, thighs, and abdominal wall muscles; weakness; nausea; tachycardia; pallor; profuse diaphoresis; cool, moist skin; and/or a history of ingestion of large amounts of hypotonic solution	Sodium chloride PO or IV (depending on the degree of discomfort and the clinical status of the patient). An oral saline solution of 4 tsp of salt per gallon of water may be used. Salt tablets are absorbed very slowly and should not be given. If IV therapy is indicated, 1,000 mL 0.9% NaCl infused over 1–3 hours is preferred. Cool environment Rest
Heat Syncope Heat syncope is a heat-related fainting episode. This may occur because of vasodilation and peripheral pooling of blood, volume deficit, and sluggish vasomotor tone. Venous return does not support the required cardiac output, and syncope occurs. Heat syncope can result from inadequate cardiac output and postural hypotension. Recovery is immediate once the patient faints and lies flat.	Orthostatic syncopal episode, dizziness	Place the patient in a supine position. Oral fluid replacement Cool environment Rest
Heat Exhaustion Heat exhaustion occurs when there is a prolonged period of fluid loss (e.g., from perspiration, diarrhea, or use of diuretics) and exposure to warm ambient temperatures without adequate fluid and electrolyte replacement. Heat exhaustion is more common in young patients and older adults.	Thirst, anxiety, anorexia, cramps in muscles, malaise, syncope, headache, dehydration, tachycardia, muscle weakness, orthostatic hypotension, nausea and vomiting, cutaneous flushing and/or possible elevated temperature above 37.8°C	Remove the patient from the hot environment into an air-conditioned room or a shady or cool place. Treat symptomatically; for example, elevate legs for postural hypotension Oral fluid replacement if no GI symptoms are present and if patient is alert and oriented; replace fluids and electrolytes at about 1 L/hr for several hours. Recovery should be rapid, within 2–3 hours. If not, patient may need additional interventions.
Heat Stroke Heat stroke occurs when heat production is greater than heat loss. Mortality rates from heat stroke may be as high as 10%. There may be damage to multiple organ systems. Heat stroke may be divided into classic and exertional. Heat stroke is a true medical emergency—it must be rapidly assessed and treated.	Core body temperature of at least 104.9°F (40.5°C), acute mental status changes, absent sweat, tachypnea, decreased urinary output, hypotension, seizures, nausea and vomiting, diarrhea, dilated nonresponsive pupils, decerebrate posturing	Rapid cooling; if ice packs are used, place them in groin and axillary region. Monitor rectal temperature. Supplemental oxygen, including possible intubation, may be necessary. IV fluids (usually 0.9% normal saline).

core temperature of 101°F (38.3°C) is achieved. Antipyretics are ineffective in lowering the temperature in heat-related illnesses. IV fluids, such as normal saline or dextrose and half normal saline are usually given. Chlorpromazine (Thorazine) 25 to 50 mg IV or diazepam (Valium) 5 to 10 mg IV may be given initially to control shivering and then every 4 hours. In addition, the patient's urinary output, rectal temperature, and cardiac status should be monitored. Supplemental oxygen is also often administered.

Follow-up and Referral

A patient is discharged after a complete recovery. Other than teaching to prevent further episodes (see next section), no special follow-up or referral is necessary.

Patient Education

Heat-related illnesses, with their devastating effects, can be avoided or at least reduced in severity through simple preventive measures. These include the following:

- Becoming acclimatized
- Avoiding alcohol consumption during exposure in hot, humid areas
- Wearing protective, light-colored clothes and a hat when outdoors in hot weather
- Ingesting adequate amounts of balanced liquids (e.g., Gatorade) to maintain fluids, electrolytes, and homeostasis
- Pacing personal activities

If a patient has suffered from a heat-related illness in the past, he or she will be more prone to heat-related illnesses in the future.

Patients should be taught to gradually build up time spent in hotter conditions (acclimatization). It should be stressed that the higher the temperature and greater the humidity, the greater the risk for heat injury. Fluids must be consumed before there is an urge to drink. If exercising, prehydration is important. The best fluids are simply water or a low-sugar electrolyte drink.

Education about heat-related illnesses should be a part of health maintenance. The clinician should remind parents not to leave children in cars unattended. Older adults should be cautioned about the increased risk of heat-related illnesses, especially if they have medical conditions or are taking medications that increase the risk of heat-related illnesses. Athletes should drink more fluids and exercise during the coolest part of the day.

COLD-RELATED ILLNESSES

FROSTBITE

Because of the growing number of homeless persons and the increasing numbers of individuals participating in outdoor activities during cold weather, frostbite is becoming a growing concern.

Frostbite is freezing of an exposed area, usually the ears, cheeks, nose, fingers, and toes. If a previously frostbitten area becomes frostbitten again after it has healed, permanent tissue damage can occur, resulting in necrosis to that body part.

Epidemiology and Causes

The individuals at greatest risk for frostbite are adults aged 30 to 49. The anatomical regions at greatest risk for injury are the hands and feet, which account for 90% of frostbite injuries. The ears, nose, cheeks, and penis are also prone to frostbite.

There are many predisposing factors that can contribute to frostbite. Cold is the most prevalent factor, but it is not the only factor. In addition, the duration of contact, humidity, wind, clothing, and preexisting medical conditions also contribute to the incidence of frostbite. Although both the actual temperature and duration of exposure affect frostbite severity and resultant tissue injury, it is the duration of exposure that has the greater impact.

Although prolonged contact with a cold object can produce frostbite, it is the cold humidity that contributes to evaporative heat loss. Wet skin is more conducive to ice crystal formation. Wind contributes to an increasing loss of heat (exposure in relation to the wind-chill factor). Inadequate clothing or overly constrictive clothing can contribute to an increased incidence of frostbite. Constrictive clothing can reduce circulation to extremities. Diseases such as atherosclerosis, diabetes, and previous cold-related injuries predispose individuals to frostbite. In addition, individual behaviors such as alcohol consumption and smoking, poor self-care, immobility, drug abuse, and altered mental status increase the risk of frostbite.

Pathophysiology

The pathophysiology of frostbite occurs in several stages: tissue freezing, hypoxia, and release of inflammatory mediators. As tissues cool, the circulation slows, allowing ice crystals to form, first extracellularly and then intracellularly, which damages the cell membrane. Crystals that form extracellularly exert osmotic force and pull fluid from the intracellular space, resulting in cellular dehydration. As this process continues, the cell membrane is damaged. Intracellular crystals cause more damage to the cell as they expand within it.

Hypoxia results from cold-induced local vasoconstriction. This vasoconstriction leads to acidosis and increased local blood viscosity as well as hypoxia. Although the body has a natural defensive mechanism against the cold (called *cold-induced vasodilation*—the "hunting response," which prevents rapid freezing of the skin), prolonged exposure to cold eventually causes this response to fail, and freezing takes place. As capillary blood

flow ceases, arterioles and venules thrombose, leading to the release of inflammatory mediators. The release of prostaglandins and thromboxane promotes vasoconstriction, platelet aggregation, and blood vessel thrombosis, which worsen endothelial damage. If left unchecked, this process will lead to cell death and widespread tissue necrosis.

Clinical Presentation

Subjective

Initially, the patient complains of a tingling sensation of the body part, followed by pain and eventual numbness.

Objective

Classically, the clinical presentation of frostbite has been categorized according to four degrees of injury. The classification should be applied after some rewarming has been done because all victims of frostbite present similarly at first, with tingling and redness followed by pallor and numbness.

- **First-degree frostbite (partial skin freezing):** Erythema, edema, hyperemia, no blisters or necrosis, occasional skin desquamation (5–10 days later), transient stinging and burning, and possible throbbing and aching; the patient may also have hyperhidrosis (excessive sweating).
- **Second-degree frostbite (full-thickness injury):** Erythema, substantial edema, vesicles with clear fluid, blisters that desquamate and form blackened eschar, numbness, and vasomotor disturbances (in severe cases).
- **Third-degree frostbite (full-thickness injury and subcutaneous freezing):** Violaceous/hemorrhagic blisters; skin necrosis and blue-gray discoloration; initially, no sensation (tissue feels like a block of wood) but shooting pains, burning, throbbing, and aching develop later.
- **Fourth-degree frostbite (full-thickness injury and subcutaneous tissue, muscle, tendon, and bone freezing):** Little edema is present. Initially, skin is mottled, deep red, or cyanotic; later, skin becomes dry, black, and mummified; possible joint discomfort.

Diagnostic Reasoning

Diagnostic Tests

There are no definitive diagnostic studies for frostbite, especially within the first week of injury. Doppler studies may be helpful to assess blood flow.

Differential Diagnosis

Differential diagnoses for frostbite may include the following:

- Frostnip—a mild form of cold injury.
- Chilblain (erythema pernio)—tender red to red-blue itchy nodules on extremities triggered by cold weather and thought to result from chronic vasospasm. There is no actual freezing of the tissue.
- Immersion foot—hyperhidrosis (excessive perspiration) of the feet causing thickening, maceration, and tenderness of the skin due to prolonged submersion in water or cold (also called trench foot, because it affected soldiers camped for days in trenches during times of war).
- Hypothermia.

Management

Emergency Management

Frostbite is a medical emergency because of the potential for extensive tissue necrosis and loss of limb. If the patient presenting to a primary-care setting has frostbite, the area should be rewarmed as stated below. Hot liquids such as coffee, tea, or broth should be administered.

General Management

The basis of treatment for frostbite is reversing the pathological effects of the ice-crystal formation, vasoconstriction, and the release of inflammatory mediators. Treatment should not be started if there is a possibility of refreezing. If it is suspected that the patient has second- to fourth-degree frostbite, hospitalization should be considered.

The first measure is to rewarm the affected area. Rewarming is accomplished by using warm water (104°F [40°C] to 108°F [42.2°C]). Care must be taken not to rub the affected area. The affected part should be placed in water for 10 to 30 minutes until the tissue is pliable and red. This process can be very painful; therefore, narcotics should be administered and titrated for comfort.

Blister management in patients with frostbite is somewhat controversial. Blisters containing clear or milky fluid should be debrided and covered with aloe vera every 6 hours. Aloe vera is a potent antiprostaglandin agent. Hemorrhagic blisters should be left intact and covered with aloe vera. The affected area should be wrapped with a sterile dressing, splinted, and elevated. Silvadene and Bacitracin have proved to be effective as antibacterials; however, use of these topical ointments may interfere with the aloe vera.

It is unclear whether prophylactic antibiotic use is warranted for frostbite. The use of penicillin G 500,000 units IV every 6 hours for the first 72 hours has proven effective. Ibuprofen 400 mg PO every 4 to 6 hours should be administered for its antiprostaglandin activity. Ibuprofen is a potential inhibitor of thromboxane—more potent than other anti-inflammatory drugs. The patient's tetanus status should also be assessed. Patients who are being treated for frostbite should not be allowed to smoke.

Patients may need daily hydrotherapy to debride devitalized tissue. In some instances, referral to a surgeon

for a fasciotomy or escharotomy may be needed if there is limited range of motion in an extremity or if the possibility of "compartment syndrome" develops. Compartment syndrome occurs when any structure such as a nerve or tendon is being constricted in a space. The sheath or tendon is enlarged because of the inflammation and no longer able to move freely in the compartment. This results in a cut-off of the circulation, a critical condition, and may result in loss of a limb. It may take up to 3 to 4 weeks for full demarcation of the tissue damage to occur; therefore, amputation should not be considered before this time.

Follow-up and Referral

The majority of patients with frostbite injuries should be admitted to the hospital for 2 to 4 days. If dressings are in place, the patient should be monitored every 2 to 3 days to assess the healing potential. If debridement or grafting is necessary, the patient should be referred to a dermatologist or a vascular surgeon.

Patient Education

Patients should be taught to watch for signs of infection, to take medication as prescribed, and to use extreme care regarding further exposure to cold. The following preventive measures should also be recommended:

- Do not go outdoors for prolonged periods of time.
- Wear a hat or earmuffs, mittens, and dress in layers.
- Keep dry and change out of wet clothing.
- Dress in natural materials such as cotton or wool.
- Avoid caffeine, tobacco, and alcohol when going out in the cold, because these substances leave the skin more prone to thermal injury.
- Check the skin every 12 to 20 minutes for signs of frostbite.

HYPOTHERMIA

Accidental hypothermia is a medical emergency that can threaten life and limb and is defined by a core temperature of less than 95°F (35°C). If not treated promptly and accurately, the diagnosis carries a high mortality rate. In the United States alone, hypothermia is responsible for hundreds of deaths each year. The outcome depends on the underlying medical conditions and length of exposure to the elements.

Epidemiology and Causes

The incidence and prevalence of hypothermia are difficult to quantify, because not all cases are reported. The hypothermic patient is more likely to be older (with a mean age of 45 years), to be uninsured, and to consume more critical care than most other ED diagnoses. Approximately 700 people die in the United States from accidental primary hypothermia each year (Level I; Li et al, 2013). The condition of hypothermia tends to affect disadvantaged patients and is preventable with community involvement. Problems with alcoholism, homelessness, and mental illness are common to patients in this category. The other category of affected individuals includes adventure-seekers, including hunters, skiers, climbers, boaters, and swimmers. Despite treatment in a hospital, 40% of patients with moderate to severe hypothermia die.

Pathophysiology

The reduction in body core temperature starts with a cascade of events. First, there is a loss of heat from the body. This can involve evaporation, convection, conduction, respiration, and, most importantly, radiation through which 50% of the body heat is lost rapidly. Common causes of hypothermia are prolonged exposure to lower extremes of outdoor temperature without protective clothing. Alcohol, drug abuse, homeless status, and being elderly are all potential contributing factors. The prognosis is highly dependent on the length of exposure, as well as the provider's recognition of and rapid intervention for the condition. For example, progressive organ failure increases as the core body temperature decreases; however, this situation is potentially reversible with adequate rewarming. The clinician should be aware of the pathophysiological changes in acid–base balance; during rewarming, the pH remains constant until the core body temperature reaches 89.6°F (32°C). At this temperature, there is a decline in calcium (Ca^{2+}) and magnesium (Mg^{2+}), accompanied by an increase in the pH. Observation of arterial blood gases (ABGs) and electrolytes is essential to monitor acid–base balance.

Clinical Presentation

Subjective

The hypothermic patient may arrive with a core body temperature ranging from less than 82.4 to 95°F (28–35°C). Depending on the core temperature, the patient may or may not be conscious enough to give a subjective history. If conscious, the primary complaint is coldness accompanied with a feeling of exhaustion.

Objective

Typically, the initial presentation consists of evolving signs and symptoms of hypothermia. Moreover, it is usually categorized by the level of the core body temperature.

1. ***Mild hypothermia*** **is defined as a core temperature of 89.6 to 95°F (32–35°C).**
   - The cardiopulmonary response is by vasoconstriction, hypertension, tachycardia, and tachypnea.
   - The renal response is cold diuresis and defective distal tubular absorption of water and sodium.
   - The neurological response involves shivering, ataxia, slowed mental processes, and an apathetic affect.

2. ***Moderate hypothermia*** **is defined as a core temperature of 82.4 to 89.6°F (28–32°C).**
   - The cardiopulmonary response is evidenced by hypotension, bradycardia, respiratory depression, and a J-wave on the electrocardiogram (ECG). Atrial fibrillation and junctional bradycardia are both associated with a high mortality rate, as noted in a prospective multicenter study by researchers.
   - The renal system clamps down, and urine output decreases.
   - The neurological responses are now diminished level of consciousness, dilated pupils, decreased reflexes (including gag reflex), and an inability to mount a shivering reflex.
3. ***Severe hypothermia*** **is defined as a core temperature of less than 82.4°F (28°C).**
   - The cardiopulmonary response may now reveal profound bradycardia with ventricular dysrhythmias or asystole, accompanied by pulmonary edema and/or apnea.
   - Renal blood flow is greatly diminished, leading to oliguria.
   - Neurologically, the patient loses consciousness, and coma rapidly ensues; pupils are nonreactive.

Diagnostic Reasoning

Diagnostic Tests

Initial laboratory tests consist of ABGs, complete blood count (CBC), basic metabolic panel with blood urea nitrogen (BUN) and creatinine, alcohol and drug levels along with coagulation studies, prothrombin time (PT), partial thromboplastin time (PTT) and international normalized ratio (INR), chest x-ray, and ECG. The advanced practice registered nurse (APRN) should also consider that all tests might need to be repeated frequently during rewarming because the pathophysiology may change.

Differential Diagnosis

The clinician should consider head injury, stroke, myocardial infarction, diabetic hypoglycemia or hyperglycemia, drug or alcohol involvement, sepsis, and hypothyroidism.

Management

Emergency Management

The initial management consists of assessing airway, affirming breathing, and monitoring circulation. The clinician should intubate and ventilate if needed. In addition, warmed IV fluids of normal saline and rewarming the body at 1° to 2°C (1.8°–3.6°F) an hour should be initiated. Caution should be taken to prevent shivering because this action depletes glycogen stores. Further treatment should consist of gradually rewarming the internal and external temperatures, supportive treatment with warm fluids and oxygen, and monitoring acid–base balance with treatment accordingly.

General Management

General management should include gradually rewarming the body, supportive care with warm IV fluids, cardiac monitoring, frequent vital signs, and repeating electrolytes, ABGs, and ECG as needed.

Follow-up and Referral

The clinician will need to consider the patient's age, psychological and medical status, and his or her living situation to plan appropriate follow-up care. If the patient is homeless, a wide social network must be cast to prevent recurrence of hypothermia, and a case manager should be consulted. The clinician may have to discern if the patient has a home or a shelter during the winter and whether he or she has a coat to wear and food to eat.

Patient Education

Each patient will have different needs for education from the clinician, who must consider the audience or receiver of the educational information. Basic education is best and includes advice on dressing appropriately for winter weather, keeping the body dry and well covered when outdoors. The clinician should warn the patient to avoid alcohol and overexertion during extremely cold temperatures.

COMMON INJURIES

WOUNDS AND LACERATIONS

Wounds and lacerations result in a disruption of the continuity of the skin commonly related to trauma. The mechanism and energy of the force causing the defect determines the type and severity of the wound. Wounds can range from trivial lacerations or abrasions, which occur daily in children on playgrounds, to more severe injuries such as stabbings or shootings that may require immediate surgical care. All wounds have the potential of becoming infected and should be evaluated for occult injury and retained foreign bodies. Proper evaluation and care will reduce the morbidity associated with wounds.

Epidemiology and Causes

In a recent year, 12% of all visits to the emergency department (ED)—that is, 11.5 million visits—were related to wounds. The average laceration seen in the ED is 1 to 3 cm in length; 13% of the wounds seen are considered "dirty." In one study, scalp and face lacerations accounted for 51% of wounds seen in the ED, upper extremity lacerations accounted for 34%, and lower extremity lacerations accounted for 13%. Adult wounds become infected about 5% of the time, whereas wounds in children become infected 1.2% of the time. Almost 75% of the patients with wounds were men with an average age in the early 20s.

Wound care is a highly litigious area of health care. Missed fractures, missed foreign bodies, and wound infections are common reasons for medical practitioners to be named in a lawsuit. Although wound-care litigation is not associated with the highest payouts, it is prudent in any case for the clinician to perform a thorough assessment and maintain complete documentation of wound care. Wound management accounts for 5% to 20% of ED malpractice claims. Although culturing the wound can subsequently guide the treatment and identify infectious complications, it is essential that the clinician visually appraise the wound for signs of infection before more invasive action and stronger antibiotics are required.

Pathophysiology

The skin is made up of several layers, which are divided into the epidermis and dermis. The skin acts as a barrier, regulates body temperature, aids in elimination of waste, and helps prevent dehydration. It also contains the cutaneous nerves, is a reservoir for nutritional stores and water, and is a source of vitamin D when exposed to sunlight. The ability of bacteria and other substances to penetrate the skin is related to the depth of the wound. Wounds that do not penetrate the stratum germinativum—the basement layer of the skin—do not leave scars.

The healing process is a complicated one and involves many processes that occur simultaneously:

- *Injury phase.* This phase involves coagulation and platelet release. This process enhances the inflammatory response in the wound.
- *Inflammatory phase.* This phase is characterized by increased capillary permeability, which allows white blood cells (WBCs) to migrate into the wound. Neutrophils and monocytes act as scavengers and rid the wound of debris and bacteria. In addition to providing wound defenses, inflammation stimulates other monocytes to promote fibroblast replication and neovascularization.
- *Epithelialization phase.* This phase involves migration of fibrils across the wound. These fibrils are a result of collagen synthesis. This process requires tissue lactate and ascorbic acid and is directly related to local arterial PO_2. Of note, lacerations may heal by primary intention when the edges of the wound are approximated with sutures and allowed to heal together. Suturing techniques that allow for maximal eversion of the wound edges once approximated facilitate healing by primary intention. Alternatively, open wounds may heal by secondary intention, as granulation tissue fills in open lacerations whose edges are not approximated. Collagen synthesis in the healing wound peaks at day 7 post-trauma, and the tensile strength (which determines the ability of the wound to remain intact) increases rapidly at this stage. Typically, the wound will have only 15% to 20% of its normal tensile strength at 3 weeks and 60% by 4 months.
- *Remodeling phase.* In this final phase, the process involves wound contraction and tissue formation. This process begins on the third day after the injury and continues for up to 6 months. The appearance of the wound can change during this period; for this reason, plastic surgeons will usually wait 6 months before considering revising a scar.

Clinical Presentation

Subjective

A thorough history of the injury must be obtained and documented. Information regarding how the wound occurred is important. The mechanism of wounding is useful in determining the likelihood of deep structure injury, infection risk, extent of tissue damage, and likelihood of associated injuries. For example, a laceration that occurred when a glass shattered in the hand has a high likelihood of having a retained foreign body. A wound that occurred when a hand became caught in a machine has a high likelihood of having an associated fracture. Questions regarding medical history should also be included. For example, a patient with diabetes or a history of vascular problems has a higher possibility of infection (see Focus on History 19.1).

Focus on History 19.1 Wounds and Lacerations

History

- Mechanism of injury
- Potential for foreign body
- Potential for underlying injury
- Potential for infection
- Type of injury
- Age of wound
- Delayed or immediate presentation
- Tetanus immunization status
- Allergies
- Comorbidities (especially vascular problems)

Physical Examination

- Vital signs
- General examination
- Vascular injury
- Nerve involvement
- Located over joint
- Tendon damage
- Associated with fracture (open or closed)
- Range of motion
- Wound contamination
- Foreign body
- Avulsion injury
- Puncture

Objective

A description of any wound should include the length and depth (in centimeters) and the type of defect found. The depth of the wound is described as *partial thickness* if all layers of the skin have not been violated. If any subdermal tissue can be seen in the wound, it is considered a *full-thickness* defect. Wounds this deep may involve injuries to deeper structures; further evaluation is necessary.

Different types of wounds are associated with specific types of associated injuries and special considerations. Refer to Advanced Assessment 19.1 for various types of wounds and special considerations associated with their assessment and treatment.

Any wound to an extremity should be evaluated for distal circulation and sensation. Circulation should be assessed by determining if the distal extremity has a strong pulse. For fingers or toes, the clinician should

Advanced Assessment 19.1 Wounds and Lacerations

Type	Special Considerations
Abrasion	
A partial-thickness defect to the skin, usually associated with an abrasive force being applied to the skin.	• Ensure that the wound is thoroughly cleansed (this may require anesthesia). For cleansing larger areas of abrasion, consider using topical viscous lidocaine. Use caution with children because the amount of medication applied to large wounds may cause lidocaine toxicity. Allow about 10–15 minutes after administration of lidocaine for sufficient absorption. • Remove all embedded dirt because it can lead to "tattooing" of the skin. Tattooing can occur when the skin has healed and the epidermis has grown over the embedded dirt—the dirt is visible through the thin epidermis layer of skin. • Examine the entire area of the wound. Look for any deep lacerations, which may be hard to find because of the size of the wound. Any deep lacerations within an abrasion must be closed with sutures after thorough exploration, debridement, and irrigation. The goal of closure is to loosely approximate the edges. If the wound is deep, use a subcutaneous suture to allow the wound to heal without having to disturb the granulation tissue to remove the stitches later.
Stellate or Flap Laceration	
When the defect in the skin involves a flap or stellate defect; this usually occurs with a ripping mechanism or blunt trauma to a bony structure such as the skull.	• During exploration, fully retract the flap to allow for visualization to the base of the defect. Typically, this is the deepest part of the laceration. It is important to examine the area under the flap carefully for possible injuries to deeper structures. • Scalp lacerations should be explored for galeal injury. The galea is a fibrous fascia that covers the skull. If the galea has a large defect (more than 3 cm), it should be closed with deep sutures. • If a flap laceration has a nonviable portion, it should be excised. When closing these types of defects, the first suture should bring all the sections of the flap or star together. Following the initial stitch, closure of the remaining defect can be accomplished using normal interrupted sutures.
Linear Laceration	
Single linear or near-linear defect in the skin; usually caused by a sharp instrument.	• Thorough wound exploration is required to ascertain deep structure involvement. If tendons are involved, orthopedic consultation is recommended. • If muscular fascia are violated, these defects must be closed with deep sutures. If these wounds are not repaired, the possibility of muscular herniation is increased.

Continued

Advanced Assessment 19.1 Wounds and Lacerations—cont'd

Type	Special Considerations
	• If a joint is violated, an orthopedic consultation is highly recommended. Depending on the mechanism of injury and how dirty the wound is, surgical exploration and irrigation may be necessary. • Wounds in regions with low cosmetic significance, such as the scalp, can be closed using staples, which are faster and easier to place and remove than conventional sutures. Staples have a lower tissue inflammatory response and are well tolerated. Staples must be removed with special instruments, however, so follow-up must be considered when the decision regarding type of wound closure is made. If the patient's primary-care provider is not familiar with staple removal or does not have the correct instrument, placement of stitches is recommended. • Wounds with low tension that do not cross a joint can be closed using tissue adhesive. This eliminates the need for suture removal and has been found to have similar or better cosmetic results than stitches. Using tissue adhesive to close wounds is much faster and decreases the amount of pain associated with wound closure. Before closing the wound, it is important to make sure that the wound has been thoroughly explored and cleaned. This may require infiltration with local anesthesia. Tissue adhesive can be used over wounds that have had subcutaneous sutures placed. Tissue adhesive can also be used to hold fingernails and toenails in place after nailbed repair. • Wounds under high tension must be closed with subcutaneous stitches or mattress sutures to reduce the tension on the skin edge. High-tension wounds will produce a larger scar and have a higher risk of dehiscence. To avoid this, sutures should remain in place longer in these types of wounds.
Crush Injury	
A defect caused by a high-pressure force, such as a dog bite.	• These wounds have diminished vascularization related to the tissue disruption and swelling. Debriding devitalized tissue is necessary to decrease the bacterial load and eliminate that potential nidus of infection. • The practitioner should consider whether delayed primary closure or allowing the wound to heal by secondary intention is appropriate. Consultation with the referring primary-care provider is recommended.
Tendon Injury	
A force applied that is great enough to cause a disruption to a tendon; this could be a penetrating or blunt force.	• All wounds near tendons must be explored for possible tendon injuries. If tendon damage is found, consultation with an orthopedist is recommended. • Extensor tendon injuries may be closed by the primary-care practitioner, providing he or she has been properly trained in the technique. Early antibiotic prophylaxis is indicated. • Flexor tendon injuries usually require primary wound closure by an orthopedic specialist. There is a high morbidity associated with flexor tendon injuries. Early antibiotic prophylaxis is indicated.

Advanced Assessment 19.1 Wounds and Lacerations—cont'd

Type	Special Considerations
Joint Violation	
A force, usually applied by a sharp, penetrating injury, that disrupts the joint capsule.	• All wounds near joints must be explored for potential violations of the joint capsule. If any such injury is found, consultation with an orthopedist is recommended. • If the wound is near a joint and a violation of the joint capsule cannot be ruled out, the saline-load test can be used to assess whether penetration of the capsule has occurred. • If the metacarpophalangeal (MCP) joint is injured and any possibility of an injury from a bite (open mouth) exists, immediate follow-up by an orthopedist is needed. The area should be surgically irrigated to avoid joint morbidity.
Cellulitis	
An infection of deeper tissue, usually caused by a defect to the integrity of the skin that was inoculated by bacteria. The infection usually involves *Staphylococcus aureus* and/or *Streptococcus* bacteria.	• Placing patients with simple, noncomplex wounds on antibiotic prophylaxis does not affect the incidence of infection. Typically, 2%–10% of wounds in adults will be infected. • Mild cellulitis should be treated with an oral course of a first or second generation cephalosporin. Although the infection can be treated on an outpatient basis, it is important to have the patient return for wound check within 24–48 hours, depending on the extent of cellulitis, to determine if the antibiotic therapy is effective. The region of erythema should be outlined with a tissue marker on initial examination; this demarcation can be used to assess treatment effectiveness or failure if the erythema continues to increase. Wounds that exhibit fluctuance (palpable fluid under the skin) should be incised and drained to reduce the tension on the wound and decrease the bacterial load. • Patients with diabetes or other conditions that may involve vascular compromise need to be treated more aggressively. Treat the initial findings of cellulitis or wounds that appear dirty with parenteral antibiotics and place the patient on oral antibiotics. Close follow-up is required. These patients may need to be seen daily in the office, depending on the extent of cellulitis. • Patients who present with cellulitis should receive a thorough history and physical to determine the possible mechanism of injury. All hand and foot wounds that become infected should be x-rayed to rule out foreign bodies. Any wound that, based on the history and/or physical exam, has a high potential of having a foreign body should be x-rayed. • If fluctuance is felt, the wound should be incised and drained. The placement of a drain or packing is dictated by the size of the site and clinical judgment. • Patients with wound infections involving angioedema or accompanied by fever or chills should receive parenteral antibiotics. Inpatient treatment should be considered for these patients.

assess blanching. A normal blanch response (capillary refill time) is considered to be less than 2 seconds. Distal sensation should be checked to rule out nerve injury. A gross neurological screening exam should be done on all patients who present with wounds to the extremities: This involves lightly touching the extremity or digit distal to the injury and comparing the response with sensation in uninjured extremities or digits. If the patient states that the sensation is similar, the clinician should document it. If the sensation is decreased, different, or if the patient complains of paresthesias, a two-point discrimination test should be performed to rule out nerve injury.

All wounds must be explored to identify any deep structure injuries or foreign bodies and to help determine the type of closure required. After the wound is anesthetized, a bright light should be used to illuminate the wound. Wound edges should be retracted, but it is important not to cause trauma to the tissue that may impede normal healing. Blindly probing a wound can cause additional tissue destruction or nerve or vascular injury. Using an Adson forceps with teeth or tissue retractors, the clinician should hook the wound edge and retract it to expose deep structures. The clinician should probe the wound with gloved fingers only.

For large wounds, it is important to examine the full length of the wound because only a small section of the wound may be deep enough to cause deep structure injury. The defect should be examined for any tendon injury. Exposed tendon will appear as a shiny white structure in the wound. Any wound that involves the extremities must be assessed for tendon and nerve injuries. The range of motion of the affected extremity or digit should be tested carefully against resistance in all planes in which the extremity can be moved. During the movement, the clinician should ask the patient if the resistance causes a pain in the wound. If a partial tendon laceration is present, movement against resistance will cause pain at the site. The wound needs to be explored, and deep structures should be examined during the full range of motion to the involved extremity. A tendon injury may be hidden because the defect may not be visible in the wound at the position in which it is being examined. The injury may have occurred at a different degree of flexion.

Examination for injuries to underlying muscular fascia is required. If a large defect is found, the fascia must be closed to prevent herniation of the muscle in the future.

If the wound is near a joint, violation of the joint capsule must be ruled out. The joint capsule is lined with a synovial membrane and contains synovial fluid, which lubricates the joint and also provides cushioning for the joint. If the synovial capsule is violated, the joint is seeded (contaminated) with bacteria, and the possibility of developing a septic joint is likely. The joint capsule is a shiny white structure; if it has been penetrated, bone ends are palpable and can be visualized. Again, the joint must be examined through the full range of motion to look for a defect. If a joint violation is suspected but cannot be confirmed by visualization, the clinician should order an x-ray film, which may show air in the affected joint. This is a rare finding, however, and should not be relied on to rule out the presence of joint violation.

A *saline-load test* can be performed to accurately determine if a joint violation has occurred. The practitioner should (using sterile technique) inject sterile saline in the joint, in a place away from the defect, and assess whether any saline escapes through the wound. The amount of saline to be injected is dictated by the size of the joint. Findings are considered negative when the saline injection causes distention of the joint without evidence of leakage or, in a conscious patient, distends the joint capsule to the point of discomfort.

Diagnostic Reasoning

Diagnostic Tests

X-ray films should be taken of wounds that may be associated with a bony abnormality or that raise suspicion of a retained foreign body. Wounds that may have a retained foreign body should be assessed before anesthesia by palpating over the defect and margin of the wound to determine whether the patient can feel a foreign body in the wound. This sensation should be documented. X-ray studies can help to rule out foreign bodies, even fragments of glass of 1 mm in size. Foreign bodies will appear either radiopaque (white) or radiolucent (black), depending on the substance. Some materials, specifically plant-type material (including wood and thorns), will not be visible on x-ray film. As an alternative imaging modality, the clinician may consider ultrasound to rule out radiopaque or radiolucent foreign bodies. Most x-ray exams are now digital, just as mist cameras are being replaced with digital technology. With digital cameras, there is no film to process, which involves noxious chemicals and requires vast amounts of expensive storage areas. The benefit of this technology is that the images can be examined within seconds of completion of the radiograph and the view can be greatly enlarged for better viewing. The images are in a computer database and can be instantly viewed by the clinician or a radiologist on the other side of the world. The clinician can consult with an orthopedist regarding the treatment of a complicated fracture while both providers view the x-ray from their different locations.

The presence of a fracture near the wound defect must be treated as an open fracture. Treatment requires consultation with an orthopedic surgeon and close follow-up. Depending on the type of wound and its size and location, surgical irrigation and closure may be necessary. Prompt antibiotic prophylaxis is indicated—within 2 to 3 hours of injury, if possible. All open fractures

require prophylactic antibiotics to prevent infection and osteomyelitis, and antibiotics should be utilized in all closed long bone fractures as well. There is no indication for laboratory studies in the initial treatment of wounds and lacerations. One caveat is that if the patient is taking anticoagulants and the wound is bleeding profusely, the clinician should consider PT and INR, as the bleeding may be related to hypocoagulopathy. Moreover, a CBC would be indicated if the clinician suspects excessive blood loss. If the patient presents with cellulitis or if an abscess develops, a wound culture is indicated.

Differential Diagnosis

A differential diagnosis for wounds is usually not indicated because the diagnosis is usually obvious. Associated injuries include fractures, foreign bodies, sprains, and strains.

Management

Emergency Management

If the primary-care setting has suturing capabilities, a simple wound or laceration may be treated in the office. A patient with a large wound, however, especially one that needs major debridement or appears to be infected, should be referred to the ED. All patients with wounds should be asked about prior tetanus immunization. If more than 5 years have elapsed, a tetanus booster should be administered.

General Management

Wound Cleansing After a thorough history and physical examination, all wounds must be cleansed. The most effective way to lower the bacterial count in a wound is through irrigation with a high-pressure stream of solution aimed directly into the wound. Irrigation with a syringe and needle/catheter is more effective than bulb syringe irrigation for laceration cleansing and irrigation. (Level I; ENA Emergency Nursing Resources Development Committee, 2011). Although traditionally, most providers use normal saline, potable tap water is equivalent and may be superior to normal saline for laceration cleansing and irrigation. (Level I; ENA Emergency Nursing Resources Development Committee, 2011). The amount of solution needed is dictated by the size and level of contamination of the wound. A good rule of thumb is to infuse 50 to 100 mL of solution per centimeter of wound length.

The clinician may want to consider the use of a splash shield. The device has a luer-lock for any size syringe and allows for a high-pressure stream of fluids to irrigate the wound effectively, while protecting the clinician.

Saline irrigation or even soapy water is preferred to a dilute povidone-iodine (Betadine) solution, because Betadine can be irritating and cytotoxic to lacerated tissue. The clinician should avoid hydrogen peroxide (H_2O_2), because it can be very irritating to the wound. Scrubbing, if employed, needs to be done gently to ensure that the mechanical force applied does not cause damage to the tissue. Scrubbing with an ionic polymer solution such as Shur Cleanse may also be done because it has been shown to loosen up debris and remove superficial foreign bodies.

Wound Debridement The wound needs to be debrided of devitalized tissue. Devitalized tissue is any tissue that is devascularized or extremely macerated. This type of tissue is a nidus for bacterial growth and disrupts tissue defenses. Debridement should be done using a sharp scalpel or scissors so that the debrided edge will be clean and sharp. Using a sharp instrument will cause less tissue trauma and vascular damage at the wound margin. It is important to remove only devitalized tissue. A wound with jagged edges should not be debrided unless the edges are devitalized tissue. Jagged wound margins give the clinician landmarks to use when closing the defect. The jagged edges also increase the surface area of the wound edge and decrease the amount of tension on the wound margin, which can decrease the size of the scar.

Wound Closure Wound closure is done to reduce the size of scarring and decrease the risk of infection or other morbidity. The closure technique used is dictated by the type of wound. Depending on the size and location of the wound, the clinician should consider using sutures, staples, Steri-strips, or 2-octylcyanoacrylate tissue adhesives, such as Dermabond.

2-Octylcyanoacrylate tissue adhesives can be utilized for superficial lacerations less than 6 cm long and in low tension areas. It should not be used over a joint or on any grossly contaminated wounds. Caution should be exercised when repairing wounds near the eye because the adhesive is very fluid and can run into the eye, essentially gluing it shut. If this happens, the clinician must apply an antibiotic eye ointment to aid in slowly dissolving the adhesive. If it cannot be removed for an eye examination, the patient should see an ophthalmologist immediately.

For 2-octylcyanoacrylate tissue adhesive application, the skin must be clean and dry. The wound is approximated with sterile fingers or tissue forceps, taking care not to injure the tissue with the forceps. Once the wound is well approximated, and the fingers are at least 1 cm away, apply the adhesive in concentric circles, allowing 15 seconds in between applications. Advise the patient not to scrub the adhesive and not to apply any antibiotic ointment, because this can dissolve the adhesive. Adhesive tape should not be placed directly over the site.

Another application for the cyanoacrylate tissue adhesive is in the repair of skin tears. Once the skin tear has been cleansed, the torn skin should be unfurled, which is teasing the curled up pieces of skin back to their previous locations. Under no circumstances should the clinician cut the torn skin off because it actually can be used as an allograft. Then the cyanoacrylate adhesive can

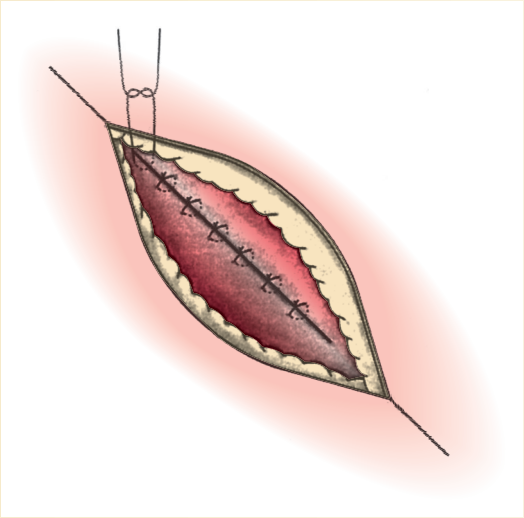
be applied with excellent results. This tissue adhesive can also be a barrier against common bacterial microbes, including certain staphylococci, pseudomonads, and *Escherichia coli* (Level I; Gaffey et al, 2012).

To decrease tension in high-tension areas, subcutaneous stitches or a mattress technique will be helpful. To close a flap or stellate laceration, the half-buried horizontal mattress technique should be used. To avoid obvious scars and poor cosmetic results, landmarks must be meticulously aligned and skin layers placed in good alignment, with the first suture being placed in the center of the wound. Suturing techniques are illustrated in Therapeutic Procedure 19.1. Remember to "approximate, not strangulate."

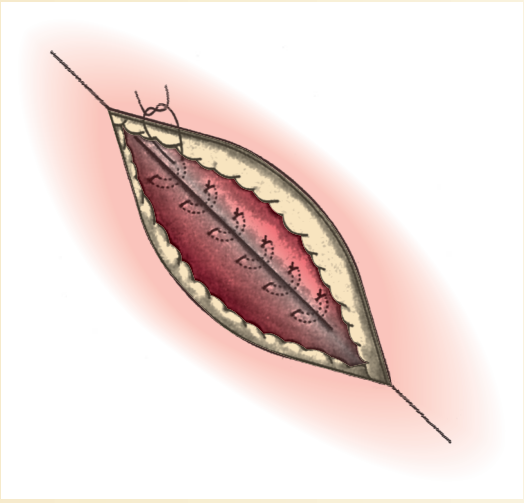
Wound Dressings The wound should be kept clean, dry, and covered. For sites that are difficult to keep bandaged, a thin layer of antibiotic ointment should be applied to provide protection to the wound. The bandage should be changed daily or if it becomes wet or dirty. It is helpful to apply antibiotic ointment to the wound when the dressing is changed.

Antibiotic Therapy Antibiotic prophylaxis for most wounds is not indicated. A clean, recently injured wound in a well-vascularized area has a very low chance (only 3%–5%) of becoming infected. Antibiotic prophylaxis does not affect the infection rate. Dog, cat, or human bite wounds, however, have been shown to respond to antibiotic prophylaxis. Early antibiotic therapy, especially if initiated within 2 hours of wounding, has been shown to decrease the chance of infection from bite wounds. Typically, animal bites have a high rate of infection and are not closed with sutures unless they are

Therapeutic Procedure 19.1 Suturing Techniques

Technique	Advantages	Disadvantages
Buried suture	Allows good approximation of wound edges.	Minimal eversion occurs.
		


Buried vertical mattress suture	Has prolonged eversion; allows early removal of top layers of sutures.	If too superficial, more likely to split.
		



Therapeutic Procedure 19.1 Suturing Techniques—cont'd

Technique	Advantages	Disadvantages
Running continuous suture 	Quick, good for children; even tension.	Entire suture must be removed.
Interrupted suture 	Permits precise adjustments between sutures; allows selection of sutures.	Increased risk of uneven tension over the suture line; higher incidence of "railroad track" scarring.
Vertical mattress suture 	Good dead-space wound closure; increased wound eversions; increases wound strength.	Time consuming; increased risk of suture marking; difficult to approximate wound edges.
Corner (half-buried) suture 	Used in skin-flap suturing; decreases risk of obstruction of blood supply to sutured skin flap.	Edge approximation more difficult; risk of trauma to skin flap; increased risk of dead space.

Continued

Therapeutic Procedure 19.1 Suturing Techniques—cont'd

Technique	Advantages	Disadvantages
Subcuticular suture 	Lower incidence of scarring; best for edge approximation.	Poor tensile strength; time consuming; poor wound eversion.
Horizontal mattress suture 	Good for dead-space closure; good wound eversion; some hemostasis occurs.	Increased risk of scarring; increased risk of epidermal necrosis.
Wound-closure strips 	Minimal wound trauma; more resistant to wound infections.	Poor wound eversion; more difficult wound-edge approximation.

Suture Materials

Nonabsorbable

Silk	Not recommended due to frequent tissue reaction
Nylon	Most common
Polypropylene	Best for subcuticular and continuous type suturing Easiest to pull out

Therapeutic Procedure 19.1 Suturing Techniques—cont'd

Suture Materials

Absorbable (metabolized after about 3 weeks—used in inner tissues)

Synthetic polymers	Synthetic for deep layers
	Absorbed by hydrolysis (not for skin)
Surgical catgut	Dissolves in an unpredictable time frame
	Excites tissue reaction during its destruction

Tissue Adhesives

A "glue"-type adhesive of *n*-butyl 2-cyanoacrylate monomers is used in combination with, or as an alternative to, sutures in wound closure.

Suture Size

Smallest size Largest size

10/0—9/0—8/0—7/0—6/0—5/0—4/0—3/0—2/0–0—1—2—3—4—5—6—7—8—9—10

6/0 is thinner than a human hair; use, for example, in eye surgery.

Family practice clinicians use primarily 3/0 and 4/0.

Suture Choices

Fine sizes	Plastic surgery
	Ophthalmic surgery
	Pediatric surgery
	Vascular surgery
Medium sizes	All other kinds of surgery
Heavy sizes	Retention
	Anchoring bone

disfiguring. If sutures are placed, they should be loose to allow for drainage. Grossly contaminated wounds or wounds that involve areas of diminished vascular supply, such as fingers, toes, and ears, may also benefit from prophylactic antibiotics. Wounds that have an increased risk of infection include the following:

- Crushing injuries
- Dirty wounds
- Jagged wounds
- Wounds with devitalized tissue
- Wounds that are more than 12 to 19 hours old
- Bite wounds, especially from humans (if they are meat eaters), cats, and dogs
- Wounds with retained foreign bodies
- Wounds closed with subcutaneous stitches

Patients with diabetes or a history of vascular compromise should be started on antibiotics prophylactically. Parenteral administration of ampicillin/sulbactam, cephalexin, or ceftriaxone is the initial treatment of choice. This should be followed by oral therapy with amoxicillin/clavulanate, cephalexin, or cefadroxil. If the patient has allergies to penicillin or cephalosporins, the practitioner should consider prescribing doxycycline, with or without clindamycin, or ciprofloxacin.

When treating cellulitis or established infections, the clinician should consider initial parenteral therapy with ampicillin/sulbactam, cefoxitin, cephalexin, or ceftriaxone. The clinician should consider wound cultures before starting antibiotics on grossly infected wounds. If the bacterial cultures prove to be resistant to the prescribed antibiotic, it should be changed to one to which the bacterium is sensitive. If the patient has allergies to penicillin and cephalosporins, the clinician should consider using doxycycline, clindamycin, or ciprofloxacin. All parenteral therapy should be followed with oral antibiotic therapy for 7 to 10 days. Appropriate choices for oral therapy include cephalexin or cefadroxil for most infections. Wounds that have a high chance of being infected with anaerobic bacteria (i.e., wounds involving contamination with mucus or feces) need to have additional antibiotic coverage with clindamycin or amoxicillin-clavulanate. Close follow-up is important for the first 8 to 24 hours after therapy has been started. If the infection appears to be responding to the therapy, the clinician should continue oral therapy, with additional follow-up as indicated by the extent of the injury and infection. Severe infections require inpatient IV therapy. Outlining the area of erythema with a tissue marker during the initial visit will allow subsequent practitioners to assess treatment response more easily. Any extremity or digit that is infected should be immobilized to reduce the inflammatory response related to mechanical movement of the cellulitic region.

Follow-up and Referral

Patients should be followed up in the office every few days to check the status of wound healing. Home health-care nursing is an effective mode of wound care follow-up in the outpatient setting. Many hospitals also have wound management clinics that have board-certified wound specialist RNs, clinicians, and physicians who are well equipped to care for difficult wounds or patients with many comorbidities, such as insulin-dependent diabetes mellitus and peripheral vascular disease.

Suture or Staple Removal Sutures must remain in place long enough to allow adequate tensile strength to develop during the healing process. The amount of time before suture removal varies with the location of the wound and the cosmetic importance of the wound site. Sutures that are left in too long can cause scarring, and the healing tissue can cover the sutures if left in too long; however, sutures over joints or areas of high skin tension must remain in longer. If staples are used, follow-up will need to be with a clinician who has a staple remover.

The following are the recommended times for suture removal:

- Face: 4 to 6 days; after suture removal, reinforce wound closure with Steri-strips
- Scalp: 6 to 10 days
- Trunk: 7 to 10 days
- Arms and legs: 10 to 14 days
- Joints: 14 days

Patient Education

The patient may take a shower 12 to 24 hours after the initial wound repair. Studies have shown that wound healing has formed a protective barrier that will prevent bacterial invasion after as little as 8 hours. The wound should not be submersed in water, however, until after suture removal or scar formation.

The clinician should explain to the patient that up to 6% of wounds do become infected. Patients should watch for signs of infection, including redness surrounding the area (cellulitis), red streaks coming from the wound (angioedema), and any purulent discharge from the wound (wound infection). Other secondary signs of infection include increasing pain, fever, and chills. Patients with high-risk wounds should be instructed to follow up with the clinician who treated the wound or another provider in 1 to 2 days so that the wound can be evaluated for healing and signs of infection. As of September 2014, 15% of Americans still lack health insurance. These individuals will not be able to afford to go anywhere but back to the ED for follow-up and suture removal.

Patients may ask whether placing vitamin E ointment on the wound will promote healing. Topical vitamin E should be avoided because it is a weak steroid that can delay healing and cause dehiscence in high-tension wounds. Oral intake of vitamin E during the healing process is beneficial; a good diet will provide the needed amounts.

Aloe vera is a weak salicylate-containing gel. Patients may ask if applying this compound is useful to wound healing. Aloe vera may provide mild pain relief, but it does not improve wound healing or help reduce wound infections. Patients should be advised that taking ibuprofen (Motrin) or another NSAID will serve the same function.

Box 19.2 presents discharge instructions for patients with wounds and lacerations.

BURNS

Approximately 450,000 patients with burn injuries receive medical treatment each year in EDs. According to the 2012 Fact Sheet of the American Burn Association, there was an average per year of 40,000 hospitalizations related to burn injury, with 30,000 of those occurring at specialized burn centers. In that same year, there were 3,400 fire and burn deaths. This included 2,550 deaths from house fires, 300 from vehicle crash fires, and 550 from other sources including electrical fires and hot liquids or objects. The survival rate for a burn injury is 96%. Because the majority of patients with burn injuries are treated as outpatients, it is important for clinicians to possess the knowledge and skills to treat burns. If a patient with a major burn is brought to an outpatient setting, it may be necessary to assess and stabilize the patient so that he or she can be safely transported by EMS to a hospital ED or burn center. Therefore, all practitioners should know how to perform a primary and secondary survey in the initial treatment of a burn victim.

Although thermal injury is the most common etiology of burn wounds, several other etiologies of burns exist. Various agents that can cause burn injuries are listed in Table 19.3.

Box 19.2 Discharge Instructions: Wounds and Lacerations

- Keep the injured extremity elevated above the level of the heart if possible.
- Cleanse the wound daily with warm, soapy water. Gently remove debris and any scab that is present.
- Lacerations over joints should be immobilized until the sutures are removed to prevent further injury from mechanical irritation.
- For lower extremities, the patient should be advised to do isometric exercises to prevent a deep vein thrombosis while wearing a splint.
- Watch for signs of infection: redness, increased pain, swelling, fever, red streaks progressing up the extremity, any purulent discharge (pus) from the wound.
- Check wound as needed for any signs of infection. For high-risk wounds, routine checks every 24 hours are recommended.

Table 19.3 Burn Injuries

Type of Injuries	Characteristics
Chemical	• *Damage:* Destruction of tissues from coagulation or desiccation of tissue protein; action continues until agent is removed; skin penetration by many chemicals leads to systemic toxicity • *Effects:* Injury is generally deeper than it appears; small percentage of admissions to burn units
Cold Liquids/Gases	• *Damage:* Frostbite (freezing of tissues) results in ice crystal formation, which draws water out of the cells into the extracellular space; crystals expand, causing mechanical destruction of cell membranes and organelles • *Effects:* Cell destruction, electrolyte imbalances
Electrical	• *Damage:* Destruction of tissues from heat generated by electric current passing through tissues; arc burn or thermal injury • *Effects:* Injury is usually more extensive than it appears; cardiac conduction system may be affected, leading to sudden death or arrhythmias; severe muscle contraction can produce long-bone or vertebral fractures; severe muscle destruction leads to release of myoglobin, which can affect kidney function
Radiation	• *Damage:* Occurs primarily by gamma/x-ray particles; affects the reproductive mechanisms of tissue cells, leading to cellular death • *Effects:* Proportional to extent of injury and depth
Thermal	• *Damage:* Destruction of tissues from flames, scalding liquids, or steam • *Effects:* Proportional to extent of injury and depth. Thermal burns account for highest percentage of admissions to burn units.

Chemical burns occur in industrial, military, home, agricultural, school, and research laboratory settings. For clinicians working in these settings, especially in a student health-care setting where there is a chemistry laboratory, it is important to have knowledge of the initial care of chemical burn injuries.

People living in the United States spend increasing amounts of time outdoors, working, playing, and exercising, often in clothing that exposes a large area of skin to the sun. Few people know the degree of risk posed by overexposure to the sun and that the risks go beyond skin cancer. Overexposure to ultraviolet (UV) radiation not only results in painful sunburn but also causes malignant melanoma, basal cell carcinomas, squamous cell carcinomas, actinic keratoses, premature aging of the skin, cataracts, immune-system suppression, sun poisoning (phototoxicity), and contact photodermatitis. *Sun poisoning* (*phototoxicity*), also called *sun sensitivity,* is considered a systemic or allergic reaction to overexposure to the sun, usually in conjunction with sunburn. *Contact photodermatitis* is an acute or chronic inflammatory skin reaction resulting from the combined effects of a photosensitizing substance (drugs or another chemical) plus UV light (immunological/delayed hypersensitivity).

Epidemiology and Causes

The risk of all types of burns is highest in people 18 to 35 years of age. The male-to-female ratio is 2:1 for both injury and death. Burns are the second most common cause of accidental death in the United States. The death rate in patients older than age 65 is three times greater than that of the overall burn population. According to the 2012 Fact Sheet of the American Burn Association, the ethnicity of burn victims on average for a year was as follows: 59% Caucasian, 19% African American, 15% Hispanic, and 7% other. For burn patients admitted to hospitals, 44% received burns from fire/flame, 33% from scalding (hot liquids), 9% from contact with hot items, 4% from electrical sources, 3% from chemical sources, and 7% from other sources. Mortality rates from burns have significantly decreased over the last four decades. In the 1950s, a 50% total body surface area (TBSA) burn was associated with a 50% mortality rate. Now, a young, previously healthy person can survive almost any size burn. This improvement in mortality rates is the result of a better understanding of early resuscitation, metabolic support after the injury, early wound excision and closure, and control of infection.

More than 25,000 products are capable of producing chemical burns. About 40% of all reported occupationally related injuries concern the skin, and about 25% of these are caused by chemical burns. Common household chemical burns are caused by lye (drain cleaners, paint removers), sodium hypochlorite (disinfectants, bleaches), sulfuric acid (toilet-bowl cleaners), and phenols (deodorizers, sanitizers). The body sites most often burned by chemicals are the face, eyes, and extremities.

Health problems resulting from overexposure to sunlight are caused by UV radiation, which is commonly split into three bands: UVA, UVB, and UVC. UVA

radiation is not absorbed by the Earth's ozone layer, which is in the atmosphere. The ozone layer protects the Earth by absorbing most UVB rays coming from the sun. UVB is particularly effective at damaging DNA. This damage is a cause of melanoma and other types of skin cancer. UVC radiation is extremely dangerous but is completely absorbed by ozone and normal oxygen. Researchers have estimated that individuals get 80% of their lifetime sun exposure by age 18. Malignant melanoma is one of the fastest-growing forms of cancer in the United States. New cases of melanoma have more than doubled over the past two decades. There may be a link between childhood sunburns and malignant melanoma later in life.

Sunburn can alter the distribution and function of WBCs up to 24 hours after exposure to the sun. Repeated exposure to UV radiation may cause more long-lasting damage to the body's immune system. No matter what a person's skin type or susceptibility to burns may be, sun exposure makes the body more vulnerable to infections and cancers. This is why diseases such as chickenpox, systemic lupus erythematosus, and herpes simplex become worse with sun exposure. Ultraviolet light therapy is used to treat psoriasis, however, because UV radiation decreases epidermal proliferation.

Overexposure to the sun can also change the texture of skin, giving it a tough, leathery appearance. The sun also causes discoloration in skin tone, including brown, red, yellow, or gray spots. Excess exposure to UV radiation can cause a painful burn of the cornea. Chronic eye exposure to UV radiation may increase the incidence of cataracts, pterygium (in which a fleshy membrane covers the eye), and possibly macular degeneration.

Risk for sun poisoning is increased in persons who take medications that cause photosensitivity, such as oral contraceptives, tetracycline antibiotics, amoxicillin, sulfa drugs, and thiazide diuretics. Risk of sun poisoning also increases with metabolic disorders such as diabetes mellitus or thyroid disease and underlying infection. Patients who have had previous episodes of sun poisoning or who use immunosuppressive drugs are also at increased risk. Other contributing factors include medical disorders such as discoid lupus erythematosus, systemic lupus erythematosus, or porphyria. Exposure to industrial light sources, such as welding arcs, places people at greater risk for phototoxicity.

Agents that may photosensitize the skin include oral antidiabetic agents, NSAIDs, antibiotics, phenothiazines, sulfones/sulfonamides, chlorothiazides, and griseofulvin. The PABA (*p*-aminobenzoic acid) in sunscreen lotion may also cause photosensitivity dermatitis.

Pathophysiology

Local Response

Cellular injury by heat results in the release of cellular enzymes and vasoactive substances, such as histamine, kinins, serotonin, prostaglandins, leukotrienes, and interleukin-1. The activation of complement also occurs. As a result, vascular permeability is altered; and significant hemodynamic, metabolic, and immunological effects occur locally and systemically. The magnitude of the response is proportionate to the extent of injury. At the capillary level, there is a significant shift of protein molecules, fluid, and electrolytes from the intravascular space to the extravascular space. Lymph flow increases initially but subsequently decreases or ceases because the lymphatic vessels become blocked by the serum proteins leaking through the walls of the damaged capillaries. In extensive burn injury (involving more than 25% TBSA), edema forms in both burned and unburned areas because of a generalized increase in capillary permeability and hypoproteinemia. The edema may also be caused by the volume and oncotic pressure effects of the large fluid resuscitation volumes. Maximum edema is seen 18 to 24 hours after burn injury. A decrease in cell transmembrane potential also occurs in extensive burns, causing a shift of extracellular sodium and water into the cell, which results in cellular swelling. With adequate resuscitation, the membrane potential is restored within 24 to 36 hours.

Systemic Response

The response of all organ systems to burn injury occurs in a biphasic pattern of hypofunction followed by hyperfunction. The degree of physiological change is proportionate to the extent of burn; it appears to reach a maximum response in the patient with burns over 50% of the TBSA. As the burn wound heals or is closed, organ function returns to normal.

The metabolic response is one of the most significant alterations after burn injury. Hypermetabolism begins as resuscitation is completed and is probably mediated by the secretion of catecholamines. The extensive healing process requires a rapid metabolic rate to support tissue anabolism and reaches its peak between the sixth and tenth days after burn injury. When the wound is closed, oxygen consumption slowly returns to normal. Protein wasting and weight loss are other elements of the metabolic response to a severe burn.

Wound Healing

When a burn injury disrupts the integumentary system, the body automatically responds with a series of overlapping physiological changes to repair and restore epithelial continuity. The *inflammatory response* begins at the moment of injury and lasts from 3 to 4 days after injury. Localized edema, erythema, heat, and tenderness are characteristic signs of the inflammatory response. During the *fibroblastic phase,* which occurs approximately 4 to 20 days after the injury, cells needed for tissue repair and reconstruction proliferate. Fibroblasts at the wound site migrate over the new capillary network, laying down a bed of granulation tissue (collagen) to fill

the wound space. During *wound contraction,* which occurs as granulation tissue forms, myofibroblasts cause the wound edges to pull toward the center. Epithelial cells from the burn margins then migrate across the wound and eventually reproduce to form a protective barrier. This process is called *epithelialization.* Epithelial cells also migrate from the hair follicles and sweat glands, forming small islands of cells known as *epithelial buds.* Newly forming epithelial cells are easily damaged by mechanical trauma and desiccation. If allowed to dry, the wound will form *neo-eschar,* retarding the healing process. The epithelial cells must secrete enzymes to dissolve the eschar in their path. The *maturation phase* occurs when immature granulation tissue is highly organized and serves to restore tissue strength. This phase begins approximately 20 days after burn injury and continues beyond 1 year. Contractures can occur if a burn wound heals with extensive scar tissue formation over a joint. A *contracture* is the fixation of a joint or area of skin into a flexed or fixed position. This is caused by atrophy and shortening of muscle fibers or by scar formation and the loss of the normal skin elasticity.

Under optimum conditions, a partial-thickness burn heals in 2 to 6 weeks. The persistence of eschar on a full-thickness burn may delay healing; if the area involved is large, this will cause the patient to remain hypermetabolic. As bacteria proliferate beneath the eschar, there is a possibility of infection. Approximately 2 weeks after burn injury, the eschar begins to separate from underlying tissue as a result of microbial and leukocytic action on subeschar collagen fibers. Separation generally occurs from the wound margins inward but may occur in patches. Eschar may also be removed earlier by surgical excision.

Clinical Presentation

Sun poisoning may present with urticaria, a red rash accompanied by edema, fever, fatigue, dizziness, gastrointestinal symptoms, or malaise. Hematuria, casts, and proteinuria may occur. Contact photodermatitis results in pruritic papules with erythema and occasionally vesicles 24 hours or more after sun exposure. The skin rash will occur in the area where the chemical was applied and sun exposure occurred.

Burn injuries have been classified traditionally from first through third degree. Currently second- and third-degree burns are classified as either partial-thickness or full-thickness. Partial-thickness injuries can be further categorized as superficial or deep. The signs and symptoms of the various depths of burn are as follows:

- *Superficial (first-degree) burns.* These burns involve the epidermal layer only. The patient presents with pain, hyperemia, and erythema. The surface is dry, with no vesicles or blisters, and blanches with pressure. The wound heals in approximately 5 days, without scarring. The prototype of a first-degree burn is a mild sunburn. If it occurs over a large surface area, it can result in fever, weakness, chills, and vomiting.
- *Superficial partial-thickness (second-degree) burns.* These burns involve the epidermis along with the upper layer of dermis. Signs and symptoms include erythema, hyperemia, pain, moist skin, and hypersensitivity to touch. Vesicles and blisters appear several hours after injury. The healing time is within 21 days, with minimal scarring.
- *Deep partial-thickness (second-degree) burns.* These burns produce destruction of epidermis with most of the dermis. Epidermal cells lining hair follicles and sweat glands remain intact. This level of burn may convert to full-thickness injury. The burn wound may be pale, mottled, pearly white, mostly dry, often insensate, and difficult to differentiate from a full-thickness burn. The burn will heal by wound contraction and reepithelialization within 3 to 6 weeks. Often excision and grafting are done to provide a better functional cosmetic result and to decrease length of healing time.
- *Full-thickness (third-degree) burns.* These burns result in destruction of all layers of skin down to or past the subcutaneous fat, sometimes involving fascia, muscle, and bone. The nerves are also destroyed. Hair pulls easily out of the follicles, and the patient does not feel pain when this is done. The clinical picture is of thick, dry, leathery eschar; white, cherry red or brown/black in color; the tissue is insensate, with blood vessels thrombosed. The wound will require skin grafting.

Diagnostic Reasoning

Diagnostic Tests

Initial laboratory studies for a patient with a major burn should include a CBC, electrolytes, BUN, creatinine, and glucose. Pulse oximetry and arterial blood gas determinations should be done, including a COHb level to determine the percentage of hemoglobin bound to carbon monoxide.

The COHb levels listed below correlate with the following clinical symptoms:

- Less than 10% COHb: No symptoms
- 20% COHb: Headache, nausea, vomiting, loss of dexterity
- 30% COHb: Confusion, lethargy, ST-segment depression on ECG
- 40% to 60% COHb: Coma
- More than 60% COHb: Death

If the COHb level is less than 40%, treatment should consist of 100% oxygen administered by high-humidity flow mask. A patient who has a COHb level of 40% or higher should be considered for transfer to a hyperbaric chamber.

Differential Diagnosis

Photodermatitis must be differentiated from contact dermatitis that may develop from one of the many substances in suntan lotions and oils. Sensitivity to the sun's rays may also be part of a more serious condition such as erythropoietic protoporphyria, systemic lupus erythematosus, pellagra, or porphyria cutanea tarda.

Management

Emergency Management: Major Burns

A patient with a major burn should be taken immediately to a burn center. A *major burn* is defined as follows:

- Partial-thickness burn greater than 25% TBSA in a person 10 to 50 years of age, or greater than 20% TBSA in a child younger than 10 years of age or in an adult older than age 50
- Full-thickness burn greater than 10% TBSA in any individual
- Serious burn involving the hand, face, foot, or perineum
- A burn complicated by inhalation injury
- An electrical burn
- A burn in an infant, an immunocompromised patient, or an elderly patient

Primary Survey Initial management of the patient with a major burn injury should include maintaining the patient's airway, breathing, and circulation. For airway management, the clinician should assess the patency of the patient's airway while maintaining the head and neck in a neutral position. If a spinal cord injury is probable, the APRN should apply a cervical collar, sandbags, and backboard as appropriate.

For breathing management, while the clinician is maintaining the patient's breathing, the clinician should simultaneously observe the patient's skin color, monitor the oxygen saturation via pulse oximetry (SpO_2), and auscultate the lungs to ensure bilateral effective ventilation. The clinician should be alert for signs of smoke inhalation and thermal airway injury if the patient has a history of being in a fire in an enclosed space. Signs and symptoms include facial burns; presence of soot around mouth and nose and in sputum; singed nasal hairs; coughing of carbonaceous black sputum; difficulty swallowing; signs of hypoxemia, such as tachycardia, dysrhythmias, anxiety, or lethargy; increased or decreased respiratory rate; increased use of accessory muscles for breathing; intercostal or sternal retractions; inspiratory stridor; hoarseness; and expiratory stridor. Once an airway injury has occurred, no measures can be taken to limit its progress, and complete airway obstruction can occur. If signs of airway injury are present, the patient will need to be intubated. After extensive swelling has occurred, intubation will be very difficult. Humidified oxygen at 5 to 10 L/min should be administered by face mask along with a bronchodilator (albuterol 5 mg unit dose nebulized or 50 mcg/puff, four to eight puffs by metered-dose inhaler with a spacer, every 15–20 minutes as needed). If the patient has signs of carbon monoxide poisoning (headache, nausea, vomiting, dizziness, loss of manual dexterity, confusion, lethargy, unconsciousness, and cherry-red skin color), 100% oxygen should be administered via a nonrebreathing mask.

For circulation management, if the patient presents in the outpatient setting with thermal injuries that involve more than 20% TBSA, the patient will need to be transported to a hospital emergency department or burn center. If there is evidence of burn shock, the clinician should provide for oral rehydration using balanced salt solutions. The patient should be encouraged to drink enough fluid to keep the urine clear and copious. If this is not possible, a large-bore (16- or 18-gauge) IV catheter should be inserted in an upper extremity vein, preferably through unburned skin. The clinician should infuse lactated Ringer's solution at an initial rate of 500 mL/hr. The specific hourly rate can be calculated later during the secondary assessment. Because the cell membranes leak even large molecules for the first 24 hours after a burn, the initial fluid of choice remains Ringer's lactate rather than protein solutions. If an indwelling urinary catheter is available, the clinician should insert a 16-French indwelling urethral catheter and measure the patient's urinary output. A urine output of 1 mL/kg per hour or 30 to 50 mL/hr should be maintained. A patient with an extensive burn injury can be expected to develop an ileus, so, if an 18-French nasogastric tube is available, it should be inserted and connected to low, continuous suction to prevent aspiration.

Secondary Survey The clinician should obtain a complete set of vital signs, including a rectal temperature. The airway and breathing should be continually reassessed, and the oxygen administration adjusted as indicated. Signs of pulmonary injury can be delayed for 12 to 24 hours after the initial exposure to noxious gases. After the patient's airway, breathing, and circulation are under control, management should include a secondary survey. If there is time for a secondary survey before transportation to the hospital or burn center, the patient's clothing should be removed. Jewelry should also be removed and secured in a safe place. The patient should be placed on and covered with a clean, warm sheet and clean blankets with overhead warmers if available. No other wound care is required until the patient reaches the hospital or burn center.

At this point a head-to-toe systematic survey can be performed, checking for neurological injuries and any fractures that need to be stabilized. The depth and extent of burn can now be estimated, using the "rule of nines," as shown in Figure 19.1. When the burns are scattered, a rule of thumb is that the size of the patient's palm is equal to approximately 1% TBSA.

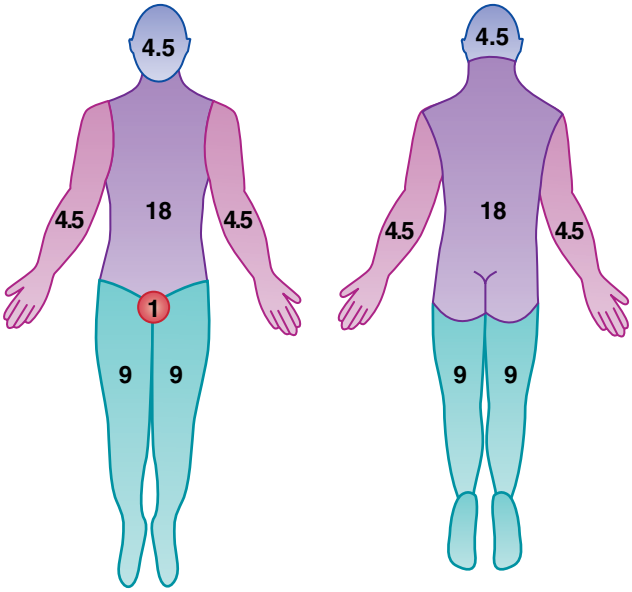

Figure 19.1 The rule of nines. *(Source: Richard, RL, and Staley, MJ.* Burn care and rehabilitation: Principles and practice. *FA Davis, Philadelphia, 1994, p 109.)*

The weight of the patient should be obtained, either from a scale or from the patient or family, and recorded in kilograms. At this point, the volume of fluids required for resuscitation can be calculated. The clinician should administer 4 mL/kg of body weight per percent TBSA over a 24-hour period. One-half of the calculated amount should be administered during the first 8 hours after the burn injury occurred—not after the time the IV line was first established. The remaining half of the fluid should be administered over the next 16 hours. Patients transferred to burn centers from outpatient settings often arrive overloaded with fluids. Pulmonary edema and hypoxia are exacerbated by overly vigorous fluid administration. Care must be taken to calculate the appropriate volume of fluids correctly and to monitor the patient's response to fluid resuscitation carefully.

During the secondary survey, the peripheral pulses should be evaluated every 15 minutes whenever patients have a burn injury over a large percentage TBSA. The clinician should observe the patient for edema formation as fluids are administered. There is the potential for the pressure of the edema fluid to obliterate arterial blood flow. This is especially true in extremities with circumferential full-thickness burns. The patient may need surgical removal or debridement of eschar to relieve the pressure. Blood pressure measurements should be taken every 15 minutes although they are often somewhat misleading in this phase.

Pain medication should be administered. Prostaglandin inhibitors, such as ibuprofen, can be used to suppress or reduce the systemic inflammatory response that occurs with burns of all severity. A short-acting narcotic, such as IV morphine or dilaudid, can also be administered if not contraindicated. The patient will need a tetanus immunization during the secondary survey, but administration of this medication and laboratory evaluations can be done once the patient reaches the hospital or burn center.

General Management: Minor Burns

A patient with minor burn injuries can usually be treated in an outpatient setting. Minor burn injuries include a burn of less than 15% TBSA in patients 10 to 50 years of age, or less than 10% in a child younger than age 10 years or an adult older than age 50 years.

Superficial (First-Degree) Burns These burns should be cooled with wet compresses. Ice should not be placed directly on the skin. Aloe vera gel can be applied topically to the burn. Remedies (anesthetic sprays) with benzocaine or lidocaine may provide relief from pain, but these medications produce sensitivity reactions in some people. The patient can be given ibuprofen (Motrin), 800 mg every 8 hours or aspirin or another NSAID. NSAIDs work by blocking the production of prostaglandins, which are thought to be important mediators of pain in sunburned skin. If sunburn is severe, the clinician should administer oral prednisone in a rapid taper: day 1, 80 mg; day 2, 60 mg; day 3, 40 mg; day 4, 20 mg; day 5, 10 mg. There are no benefits to prescribing topical corticosteroid ointments or creams.

Superficial Partial-Thickness and Deep Partial-Thickness (Second-Degree) Burns These burns should be irrigated gently with cool water or saline solution to remove all loose dirt and skin. If the burn is chemical, the caustic agent should be washed off with large amounts of water. Any necrotic skin should be peeled off or trimmed. Small, thick blisters should be left intact. Thin, fluid-filled blisters, greater than 1 inch in diameter, should be drained and the dead skin trimmed off using aseptic technique.

There are at least three different methods for the outpatient management of superficial partial-thickness burns. The first method is to apply a topical antimicrobial to the wound. Agents commonly used are presented in Drugs Commonly Prescribed 19.1. Silver sulfadiazine (Silvadene) is the most frequently used topical agent although it cannot be used in patients with sulfa allergies or on the face because of silver staining. Alternative topical agents for burns on the face are ophthalmic gentamicin ointment, neosporin, or bacitracin. When these ointments are applied to the face, no overlying dressing should be used. If antibiotic creams are unavailable, such as in an outdoor setting or in the home, aloe vera gel can be applied to the burn.

Burn wounds on areas other than the face should be covered with a dressing, which should be removed twice a day at home. The burn should be washed with mild antiseptic soap and water, then more antibiotic ointment and a clean dressing should be applied. This regimen

Drugs Commonly Prescribed 19.1 Burns

Topical	Indications	Dosage and Comments
Antimicrobial Agents		
Bacitracin ointment	Antimicrobial, especially for sensitive areas (e.g., lips, eyelids)	Apply to cleansed area 2–3 times daily. Does not penetrate eschar.
clotrimazole cream (Lotrimin)	Fungal infections of burn wounds	Apply thin coat to wound; wait 20 minutes before applying dressing. Not for ophthalmic use. May cause skin irritation and blistering.
mafenide acetate (Sulfamylon)	Active against most gram-positive and gram-negative organisms Drug of choice for electrical and ear burns	Apply 1–2 times daily using sterile gloves; do not use dressings (may reduce effectiveness and cause maceration). Monitor for signs of acidosis; intake and output; and for signs of allergic skin reaction. Penetrates eschar better than other agents. Pain occurs on application to partial-thickness burns and for 30 minutes thereafter. Allergic maculopapular skin rash may occur. Use with caution in patients with impaired renal or pulmonary function. Hyperchloremic metabolic acidosis may occur. Superinfection with fungi possible.
silver nitrate	Active against wide spectrum of bacterial pathogens and fungal infections Used for patients with sulfa allergy or diseases such as toxic epidermal necrolysis syndrome	Apply 0.5% solution wet dressings 2–3 times a day; ensure dressings stay moist. Preserve solution in a light-resistant container. Protect area with plastic to prevent staining from solution spills and splashes; stains everything black (including unburned skin). Poor penetration of eschar. Electrolyte imbalances may occur; methemoglobinemia may occur.
silver sulfadiazine (Silvadene)	Active against wide spectrum of microbial pathogens Most frequently used agent for partial- and full-thickness thermal injuries	Apply once or twice a day using sterile gloves; leave wounds exposed or apply gauze dressing over wound. Do not use if cream is dark in color. Transient neutropenia may occur after 2–3 days. Only moderate penetration of eschar. Bone marrow depression may occur. Use with caution in patients with impaired hepatic or renal function.

should continue for 7 to 10 days until the burn is healed. This particular method of therapy has some disadvantages in the outpatient setting. Some antimicrobial agents (such as Sulfamylon) encourage wound maceration and therefore cannot be used under a dressing. Also, most topical agents lose their potency in 6 to 24 hours after application, making frequent dressing changes necessary.

An alternative dressing for the superficial partial-thickness burn is to cover the burn with a fine-mesh gauze, such as Xeroform gauze, without a topical antibiotic. This gauze is covered with gauze pads, then a bulky absorbent dressing such as Kerlix is wrapped around the wound to provide some protective bulk. The clinician should inspect the wounds and change the dressings the following day because the maximum amount of wound seepage occurs within the first 24 hours; the burn wound should also be assessed for infection, which should be aggressively treated. The same type of dressing is reapplied. The burn is reevaluated after 4 days, and the bulky dressing removed. If a fluid collection has occurred beneath

the Xeroform gauze, the dressing will need to be removed, the wound cleansed, and a new Xeroform gauze applied. If the Xeroform gauze is still in place without any fluid collection, it should be left in place, and the burn rewrapped. Another follow-up visit should be scheduled for a reexamination in 5 days. At that time, the Xeroform gauze, impregnated with the crust from the burn, should separate from the epithelium, revealing healed epithelium. Once the wound is left open, it must be kept clean and protected from extremes of temperature. The wound should epithelialize in approximately 3 weeks. Epithelialization, however, may not occur for 2 to 3 months if the wound is a deep partial-thickness burn in which the only skin remnants are the hair follicles or sweat glands.

A third method for outpatient burn-wound management is to place a semisynthetic occlusive dressing such as Biobrane, xenografts, Op-site, or DuoDerm over the wound. These dressings are less readily available and are expensive. They are most useful for the immunocompromised patient because they minimize the risk of infection. They can be used on flat-surface superficial partial-thickness burns of the extremities and trunk. The goal is for the dressing to adhere to the wound surface and for there to be no exudate or fluid between the dressing and the burn. The dressing is usually removed after 7 to 10 days because the wound is typically healed by then. If there is leaking or nonadherence at any time, the dressing must be changed. Superficial partial-thickness burn wounds heal faster using this method, and patients find this method easier and more comfortable.

Hydrocolloid dressings have been found to significantly decrease the number of required dressing changes compared with chlorhexidine paraffin gauze dressing (Level I; Wasiak & Cleland, 2009).

The clinician should administer oral antibiotics only if the burn becomes infected. The current evidence does not support prophylactic antibiotic therapy in acute burns (Level I; Lee et al, 2009). Any partial-thickness burn will convert to a full-thickness burn if it becomes infected, especially with *Streptococcus* organisms; if infection occurs, the patient may have to be admitted for IV antibiotics. Signs of infection include pus, foul odor, cloudy blisters, increased swelling and redness in the normal skin around the burn, and fever greater than 101°F (38.3°C). Antibiotics prescribed for infections include oxacillin, mezlocillin, and gentamicin. All patients with infected burns should receive tetanus prophylaxis.

Chemical Burns

Consultation from physicians at a burn center should be obtained for treatment of chemical injuries. When a patient with a chemical burn is assessed, the clinician should don protective clothing and gloves. The first priority is to stop the burning process. Any of the patient's garments that have become saturated with the chemical should be rapidly removed, and the patient should be transported rapidly to a shower irrigation area. All other garments should be removed from the patient before the irrigation is complete. If the agent is a powder-like material, such as lime, the clinician should brush off as much as possible before irrigating the burned area. The hair and the areas under the nails and between the toes should be checked for collections of the chemical. The patient may be more comfortable on a chair in a running shower, but any patient who is unstable should be kept horizontal during the irrigation. A chemical burn should be irrigated with water for no less than 30 minutes and preferably for 60 minutes. Irrigation may need to be continued for hours in the case of alkali burns. Irrigation decreases the concentration of the chemical agent and physically removes it from the wound; the rate and amount of reaction between the chemical and the tissue will thus be decreased. Following irrigation in the outpatient setting, the clinician should place wet towels over the patient and arrange for transportation to the hospital. Although wet towels help to relieve pain and continue to dilute the chemical, caution is needed to prevent hypothermia if the burn (TBSA) is extensive. If possible, the clinician should take samples of the chemical agent with a product label to the ED. Use of pH litmus paper may help determine continued presence of alkali or acid in burn wounds. After irrigation and debridement of remaining particles and devitalized tissue, antimicrobial agents should be used and tetanus immunization updated as needed.

For moderate to large burns caused by hot tar or asphalt, the wound should be rapidly cooled with large volumes of water. The tar can then be removed using a petrolatum-based product such as Neosporin ointment. When a large body surface area is involved, an unopened jar of mayonnaise will suffice. The wound can be dressed with a petrolatum-based dressing such as Xeroform gauze. The dressings can be changed, and the wound should be washed with water every 6 to 8 hours until the tar dissolves. Tar can be removed from the cornea or conjunctiva with polysorbate-containing neomycin sulfate; consultation with an ophthalmologist is recommended.

If a patient presents with fingers that are adhered together with a fast-setting epoxy glue, the glue can be removed with acetone. If the glue is on the mucous membranes, the area can be swabbed with vegetable oil until the glue is removed. For glue in the eyes, the clinician should use an ophthalmic antibiotic ointment. Care must be taken or else the drying glue can cause corneal abrasion. Once the glue is removed, the eye should be examined with fluorescein and a Woods lamp with a black light to discern corneal abrasion.

If exposure to hydrofluoric acid (used in glass etching) or oxalic acid has caused a chemical burn, the affected area should be irrigated with water and then neutralized with subcutaneous injections of 10% calcium gluconate. This should be done only after consultation with physicians at a burn center.

If phenol (an acidic alcohol used in sanitizers and disinfectants) is the causative agent, the area should be irrigated with water only if a high-density shower is available. Phenol is more soluble in polyethylene glycol; therefore, a 50% solution of this agent should be used to irrigate the skin as soon as possible.

Follow-up and Referral

Although dressing changes may not have been recommended until 5 to 7 days after injury, all patients with a burn injury must still be reassessed in 24 hours to reevaluate the depth and extent of the burn.

Patient Education

Patients should be advised to elevate the burned area, especially if it is an extremity, and to return to the clinician's office or the ED if signs of an infection appear. Patients should also be given a prescription for analgesic medication.

Patients with sunburns should be informed that sunscreens with PABA may cause photosensitivity dermatitis. Photoplex broad-spectrum sunscreen lotion not only provides protection from UVB radiation but also offers absorbent protection from UVA rays and may be beneficial for patients who experience photosensitivity activated by UVA. Other useful substitutes are sunshades that contain titanium dioxide, zinc oxide, or talc. The patient should notify the health-care provider if pain and fever persist for more than 48 hours. Patients should be informed about the sunscreen protective factor index (SPF), a system of evaluating the effectiveness of various formulations for protecting the skin from the sun. Protective agents are rated 1 to 50 by the Food and Drug Administration (FDA). A sun-protective factor (SPF) of 15 means that the sunscreen provides 15 times the protection of unprotected skin.

The patient should also be informed about the Ultraviolet (UV) Index, which was developed by the National Weather Service and the Environmental Protection Agency. The UV Index provides a forecast of the expected risk of overexposure to the sun and indicates the degree of caution individuals should take when playing, working, or exercising outdoors. The UV Index predicts exposure levels on a 0 to 10+ scale, where 0 indicates a low risk of overexposure and 10+ means a very high risk of overexposure. A patient information sheet on sun safety tips should be given to patients, especially those who have sustained a sunburn severe enough to require treatment. See Table 19.4 for patient information for patients with sunburns.

Table 19.4 Patient Information: Sunburn

- Always wear sunscreen when outside on a sunny day. A sunscreen with a sun-protection factor (SPF) of at least 15 will block most harmful UV radiation. For the average adult, the recommended dose is 1 ounce, or one-quarter of a 4-ounce bottle, per application. Reapply every 2 hours, after being in the water, or after exercising and sweating.
- Use broad-spectrum sunscreens—those that contain active ingredients that absorb at least 85% of the UVA and UVB rays of the sun.
- Protect sensitive areas such as the nose and rims of the ears. Use a lip balm containing a sunscreen. This can help keep some people from getting cold sores.
- Minimize exposure to the sun during the hours when the sun is directly overhead, when exposure is most damaging, from 8 a.m. to 4 p.m. Sun (UV) exposure before 8 a.m. or after 4 p.m., when the sun is lower on the horizon, is typically only one-third that at midday. If your shadow is shorter than you are (around midday), you are being exposed to high levels of UV radiation.
- Wear sunglasses that block 99%–100% of UV radiation. Babies and children should also be protected with sunglasses in order to prevent cataracts that may develop later in life.
- Wear a hat with a wide brim to provide protection to your eyes, ears, face, and the back of your neck.
- Wear tightly woven, loose-fitting clothes during prolonged periods in the sun.
- Avoid sunlamps and tanning parlors.
- Watch for the UV Index:
  - UV Index 0–2 (minimal): Precautions include wearing a hat.
  - UV Index 3–4 (low): Precautions include wearing a hat and using a sunscreen with an SPF of at least 15.
  - UV Index 5–6 (moderate): Precautions include wearing a hat, using a sunscreen with an SPF of at least 15, and staying in shady areas when outside.
  - UV Index 7–9 (high): Precautions include wearing a hat, using a sunscreen with an SPF of at least 15, staying in shady areas when outside, and staying indoors between the hours of 10 a.m. and 4 p.m.
  - UV Index 10+ (very high): Precautions include staying indoors as much as possible and taking other precautions when outdoors.
- Be aware that UV radiation increases 5% for every 1,000 feet of altitude. In North America, the sun is closest to the Earth on June 21, so spring skiing in the Rocky Mountains without protection is very dangerous. Snow and water can also reflect the sun's rays, making sun exposure more intense.

ANIMAL AND HUMAN BITES

An animal bite is a bite wound to humans from dogs, cats, or other animals, including other humans. In most cases, bites result in puncture wounds, possible lacerations, and, in some cases, crush injuries. All bites, regardless of the source, are considered to be contaminated wounds and have a substantial risk for infection.

Dogs inflict 60% to 90% of mammalian bites, with an overall infection rate of 15% to 20%. Risks of infection from dog bites are greatest for puncture wounds, crush injuries, and bites to the hand. Dog bites in general have a 5% infection rate, but a dog bite to the hand has a 40% infection rate. The most common infectious agents isolated from dog bites are *Staphylococcus aureus, Pasteurella multocida, Corynebacterium* species, and alpha-hemolytic streptococci.

Cats inflict 5% to 20% of mammalian bites. The needle-like teeth of the cat result in puncture wounds with a high incidence of infection—around 50%. In more than 50% of these wounds, *Pasteurella multocida* is isolated; this bacterium causes wound infections that develop within 24 hours of the bite, resulting in an intense inflammatory response. Serious bone and joint infections may be caused by *P multocida.*

The third most common cause of mammalian bites is from human beings: These bites account for 2% to 3% of bites reported. Common infectious agents isolated from human bite wounds include *S aureus,* streptococci, *Corynebacterium* species, *Bacteroides* species, and *Eikenella corrodens.* Two percent of reported bites are from rodents.

Epidemiology and Causes

Two to five million animal bites occur annually in the United States. Of these bites, 80% result in only minor injury. Researchers have reported that 1% of all patient visits to the ED are the result of bite wounds, and 1% to 2% of these wounds result in hospitalization. About 900 victims of dog bite injuries are treated in the ED every day. Bite wounds occur in all age-groups but are most common in children. Half of dog-bite victims are children younger than age 15. The majority of bite wounds are from a domestic pet known to the victim, with large dogs being the most common source of injury. Cat bites are more common in women, although, in general, men receive more bite injuries than women do. Human-bite injuries from fistfights are common in teenagers and in alcohol-intoxicated men aged 30 to 35 years. Accidental human bites occur most commonly in children, usually as a result of poorly supervised interactions. Approximately 10% of bite wounds in the ED require suturing and follow-up care. Animal bites cause 10 to 20 deaths annually in the United States and involve mostly infants and small children.

Some of the causes of animal bites include separating fighting animals; chasing wild animals; fist-fighting; disturbing a sleeping, feeding, unfamiliar, or injured animal; and kissing, teasing, or playing recklessly with an animal. Individuals who are more likely to be bitten by animals include those who work in animal control, mail delivery, farming, hunting, police work, and veterinary medicine. Some sick or injured wild animals—such as squirrels, skunks, or bats—will attack humans without provocation and may carry rabies. The clinician should be familiar with state laws and regulations regarding bite wounds from mammals and rabies prophylaxis, especially in areas where rabies is endemic. If the animal can be captured, it should be observed for 10 days for signs of rabies. Unfortunately, if the animal is killed and not reported or if it escapes, the incidence of potential rabies goes undocumented and may continue to pose a threat to the community.

Pathophysiology

The risk of bite-wound infection depends on the wound location, tissue damage, patient characteristics, time elapsed before treatment, and the type of animal that inflicted the bite. Wounds should be classified as low risk or high risk to facilitate decision making regarding antibiotic therapy and wound suturing. *Low-risk wounds* include lacerations involving the extremities, face, and body. Wounds at low risk for infection include bites on the face, ears, scalp, and mouth. Large, clean lacerations and bites by rodents are at low risk for infection. *High-risk wounds* include those in the distal extremities (hand, wrist, or foot), the scalp of an infant, a wound over a joint, or a penetrating wound of the cheek. Puncture wounds and nondebridable crush injuries are of high risk. Patients at high risk for infection are those older than age 50 years and individuals with prosthetic joints or valves, asplenia, chronic alcoholism, diabetes mellitus, altered immune status, or peripheral vascular disease, or patients who are on chronic corticosteroid therapy. Bites from domestic cats, large cats, primates, pigs, or humans (especially hand wounds) present the highest risk of infection.

Human bites in locations other than the hand, if treated promptly, have no greater risk of infection than a dog bite. Most human bites are sustained in fights, but 15% to 20% of bites reported in one study were secondary to "love nips" (related to sexual activity). A closed-fist injury ("fight bite") occurs from a laceration over the metacarpophalangeal (MCP) joint caused by striking an opponent's tooth. When this occurs, infectious organisms from the mouth are inoculated directly into the bone or joint, which can lead to septic arthritis or osteomyelitis. Also, when the fingers of the closed fist are extended, the injured extensor tendons retract proximally, sealing off the tissues. This sets the stage for a rapidly progressive infection of the tendon and adjacent tissue layers.

Clinical Presentation

Subjective

The circumstances of the bite injury should be determined. These include the area(s) of the body injured,

time elapsed since the injury, type of animal (including breed), current location of the animal, relationship of the animal to the victim, vaccination and health status of the animal, and whether the attack was provoked or unprovoked. The patient should be asked about his or her occupation, medication allergies, tetanus immunization status, any history of immunological compromise, and any specific musculoskeletal, neurological, or vascular complaints resulting from the bite. If the bite is on the patient's hand, the clinician should ask the patient which hand is the patient's dominant hand. Any comorbid conditions should also be determined.

Objective

Seventy-five percent of the bite wounds seen in the ED or practitioner's office will be located on the extremities where the victim handled or attempted to avoid the animal or another person. Injuries to the head and neck are the next most common bite wounds. The clinician should inspect the skin and soft tissues, noting the presence or absence of lacerations, punctures, scratches, abrasions, swelling, crush injuries, and/or devitalized tissue. All puncture wounds should be examined carefully, and the likelihood of injury to structures beneath the skin must be considered. A vascular examination should be performed, noting skin temperature, capillary refill time, and relevant pulses.

The range of motion of all affected areas should be assessed, evaluating the functional status of potentially involved tendons. Motor and sensory nerve function should also be evaluated. To assess sensory function of the hand, the clinician must note sensation to light touch and two-point discrimination on the volar pads of the fingertips. The patient should be able to detect stimuli less than 5 mm apart in the axis of the digit; the response should be compared with the uninjured side. The patient should be evaluated for a skeletal injury and carefully assessed for neurovascular, joint, tendon, and osseous injury.

If the patient does not present with the bite wound until several hours to several days following the injury, the clinician should perform a careful search for evidence of local or systemic infection and regional adenopathy. Infection will be evidenced by increased pain, swelling, erythema, warmth, decreased range of motion at joints, or drainage from a puncture-wound site. A high index of suspicion should always be maintained for the possibility of a retained foreign body in the wound, especially when an infection develops at a puncture-wound site.

Diagnostic Reasoning

Diagnostic Tests

A radiograph of the affected area should be obtained if a fracture is suspected; if a foreign body is present (e.g., tooth fragment, with a higher risk of tooth fragments in bites from older animals); if a bone, joint, or tendon has been penetrated; or if a puncture wound has become infected. In general, two-view x-ray films should be taken. A culture and Gram stain are not useful before the onset of clinically apparent infection. The examination of purulent material may show a predominant organism in an established infection, but culture is not warranted unless the results will change the treatment. If the patient presents with a localized wound infection several hours or days after the bite, the clinician should obtain a site Gram stain and both aerobic and anaerobic cultures after superficial decontamination of the wound but before debridement of devitalized tissues. Cultures of wounds are also indicated in cases in which an immunocompromised patient is infected, where there is sepsis, or when antibiotic therapy has failed. To obtain optimal cultures, the clinician should perform percutaneous or deep wound aspiration. If significant blood loss has occurred, it is important to obtain a CBC.

If the patient is seriously ill with a bite-wound infection, diagnostic tests should include a thorough laboratory evaluation (including CBC with platelets, electrolyte panel, glucose level, BUN and creatinine levels, and PT/PTT), at least two blood cultures, wound-site Gram stain and cultures, and appropriate x-ray studies.

Differential Diagnosis

The diagnosis is typically straightforward by history; no differential diagnoses are indicated. However, to properly direct management, it is critical that the type (source) and extent of the bite wound be characterized as much as possible.

Management

Emergency Management

The clinician may treat bite wounds in the office using the following protocol.

General Management

Analgesia Pain management is commonly provided with analgesic agents such as NSAIDs and acetaminophen (Tylenol). If nonnarcotic oral agents are not effective and the patient is in severe pain, ketorolac (Toradol) 30 to 60 mg IM or meperidine (Demerol) 1 mg/kg IM with hydroxyzine (Atarax) 25 to 50 mg IM may be tried.

Wound Cleansing Bites and scratches should be cleansed with mild soap and water or 1% povidone-iodine (Betadine) solution, removing the animal's saliva from the wound. Rid the wound of any particulate matter. If the bite was caused by a potentially rabid wild or domestic animal (e.g., skunk, raccoon), the clinician, wearing protective gloves, should thoroughly irrigate the wound with 1% benzalkonium chloride, which has been demonstrated to be capable of inactivating the rabies virus.

Local Anesthesia Using a 25-gauge or smaller needle, the clinician should infiltrate the wound edges with 1% lidocaine (without epinephrine). The maximum dose of

lidocaine for local infiltration is 4 mg/kg (0.4 mL/kg of a 1% solution).

Wound Irrigation The wound should be irrigated with 500 to 2,000 mL of normal saline. For wounds considered to be at high risk for infection, the clinician can use a 1% povidone-iodine (Betadine) solution. For irrigation, a 30-mL syringe with an 18- to 20-gauge plastic catheter should be used to achieve an irrigation pressure of 5 to 8 psi. This method of irrigation has been shown to reduce wound infection.

Wound Debridement The clinician should remove foreign material, devitalized tissue, and eschar. Margins of puncture wounds should be debrided to an approximately 1- to 2-mm rim to allow for better drainage and improved cleansing.

Wound Closure Fresh facial bites without signs of inflammation should be closed with sutures after thorough wound cleansing and preparation. Bite wounds of the hand should not be sutured. For bites to other areas in need of closure or bites greater than 24 hours old, one may consider using delayed primary closure. A layer of fine-mesh gauze can be applied to the wound, which should be packed open, dressed, and followed closely. If there is no purulence or wound-margin erythema at 3- to 5-day follow-up, wound closure may be performed.

Tetanus Immunization Bite wounds are tetanus-prone injuries. If the patient has received a primary immunization series but not a booster within the past 5 years, a tetanus booster should be administered. For patients with absent or incomplete primary immunization, 250 units of tetanus immune globulin should be given in addition.

Antimicrobial Therapy Patients should receive antibiotic prophylaxis for 3 to 5 days if the wound is a fresh bite wound; if they were bitten by a cat; have a hand bite; have moderate to severe tissue damage; have a wound that may involve a tendon, bone, or joint; have one or more puncture wounds; or have a suppressed immune system. Patients with infected wounds should be given antibiotic therapy based on the results of aerobic and anaerobic culture. The most common causative organisms isolated in wound infections after animal attacks are *Staphylococcus* and *Streptococcus.* Antibiotics prescribed should also cover the less common pathogens such as *Pasteurella* and *Eikenella.* Antimicrobial prophylaxis for cat bites, high-risk dog bites (to the hand, or bites with considerable tissue damage), and human bites can be provided with amoxicillin and clavulanate for 3 to 5 days. An alternative that has fewer GI side effects is cefuroxime, also for 3 to 5 days. Hospital admission and parenteral antibiotic therapy will be necessary for all significant human bites to the hand, especially closed-fist injuries and bites involving penetration of the bone or joint. Cefuroxime IV or ampicillin-sulbactam IV, or ticarcillin-clavulanate IV, should be used for these high-risk bites.

Positioning The injured area should be elevated for several days after injury. For bites located over joints, the joint should be immobilized for 3 to 5 days in proper position depending on the bite location: 20 degrees wrist extension, 70 to 90 degrees flexion for metacarpophalangeal joints, and 10 degrees flexion for proximal interphalangeal and distal interphalangeal joints.

Rabies Prophylaxis Rabies is caused by a rhabdovirus that can be found in the saliva of many mammals. The rabies virus is highly neurotoxic and can be fatal. The clinician should refer questions about postexposure prophylaxis to the local health department or an infectious disease specialist. If a dog or cat is healthy and available for 10 days of observation, showing no development of rabies, no treatment of the exposed person is necessary. At the first sign of rabies in the dog or cat that inflicted the bite, begin treatment. About 85% of all cases of animal rabies in the United States now occur in wildlife. Skunks, foxes, bats, raccoons, coyotes, bobcats, and other carnivores should be considered rabid unless proven negative by laboratory test. The risk of rabies in lagomorphs (rabbits) and rodents (e.g., mice, rats, chipmunks, and squirrels) is minute.

If postexposure rabies is indicated, both rabies immune globulin (RIG) and human diploid-cell rabies vaccine (HDCV) or rabies vaccine, adsorbed (RVA) should be given as soon as possible. The clinician should discontinue the vaccine if fluorescent-antibody tests for rabies of the sacrificed animal's neural tissue are negative. Dosing is as follows:

- RIG: 20 IU/kg. If anatomically possible, one-half the dose should be infiltrated around the wound and the other half given IM (in the gluteal muscle).
- HDCV: 1 mL IM in deltoid region on days 0, 3, 7, 14, and 28 if the patient has not been previously vaccinated.
- RVA: 1 mL IM in deltoid region on days 0, 3, 7, 14, and 28 if the patient has not been previously vaccinated.

Individuals who have been previously vaccinated with either HDCV or RA should not receive RIG; they should, however, receive 1-mL "booster" doses IM of either HDCV or RVA on days 0 and 3.

The clinician should also evaluate the potential for transmission of hepatitis B or C virus (HBV or HCV) in human bites. If HBV or HCV prophylaxis is indicated, hepatitis B immune globulin (HBIG), 0.06 mL/kg IM, should be administered immediately and repeated in 30 days. Also, the practitioner must consider whether the human bite was by a known HIV carrier.

Postexposure HIV Prophylaxis Health-care workers working with combative HIV-positive patients may be victims of human bite wounds; these workers may also be exposed to a needle stick or mucous membrane exposure involving an HIV-positive patient and should

refer to the section on this topic in Chapter 17 that covers postexposure HIV prophylaxis, which is an emergency problem.

Follow-up and Referral

The patient should be discharged to home after thorough and meticulous wound management, with follow-up within 48 hours. Infection, cellulitis, abscess, osteomyelitis, septicemia, tenosynovitis, septic joint (suppurative arthritis), rabies, and the loss of an injured body part are all potential complications of bites. Other systemic diseases that can occur as complications are bubonic plague, cat-scratch disease, rat-bite fever, leptospirosis, tularemia, tetanus, and sporotrichosis.

Patients with severe cellulitis, systemic manifestations of infection, failure to respond to appropriate outpatient treatment within 48 hours, or bite-wound infections that involve a bone, joint, tendon, or nerve should be admitted to the hospital. The practitioner should obtain early consultation with an infectious disease specialist if needed. Septic arthritis, osteomyelitis, and closed-fist injuries ("fight bites") will require orthopedic consultation.

Patient Education

If the bite was inflicted by a wild animal or in an unprovoked attack by a domestic animal, the practitioner should ask the patient to have the animal that inflicted the bite checked for rabies. The patient or his or her family should contact the local health department and consult with the animal control officer about the patterns of rabies among the animals in the local area. Individuals should be taught the importance of not petting or feeding strange or wild animals.

Patients will need to be reminded to elevate injured extremities to prevent swelling and to return for follow-up if signs of fever, redness, or swelling occur. The clinician should instruct patients to watch for red streaks, increased warmth at the wound site, increasing pain, foul odor, or increased drainage.

ARTHROPOD BITES AND STINGS

Arthropods are members of Arthropoda, a large phylum of animal life characterized by an external body support structure known as an exoskeleton, which includes lobsters and crabs, as well as mites, ticks, spiders, and insects. Arthropod bites and stings involve penetration of the skin by some part of the animal accompanied by release of venoms that can cause local or systemic symptoms. Some arthropods, such as ticks, also transmit disease. The majority of disorders caused by bites and stings of arthropods are from spider bites; bee, wasp, and ant stings; caterpillar spine irritation; interactions with sucking bugs, beetles, flies, and other winged insects; bites from lice, fleas, mites, and ticks; and stings from scorpions.

The venoms produced by venomous insects and other arthropods can be classified according to their effects:

- Vesicating toxins (e.g., from blister beetles, certain stinging caterpillars, and millipedes) produce blisters.
- Neurotoxins (e.g., from black widow spiders, bark scorpions, certain ticks, wheel bugs, and Hymenoptera [honey bees, bumblebees, wasps, hornets, yellow jackets, and fire ants]) attack the CNS.
- Cytotoxic and hemolytic toxins (e.g., from Hymenoptera, ground scorpions, mites, chiggers, wheel bugs, and the brown recluse spider) destroy tissue.
- Hemorrhagic toxins (e.g., from lice, fleas, ticks, mites, true bugs, and biting flies) prevent blood from clotting.

Of the Hymenoptera, the yellow jacket is the major cause of insect-sting reactions. The yellow jacket, hornet, and other wasps feed on sugary sources and are attracted to foods commonly found in garbage cans and at picnics. Yellow jackets, wasps, and hornets nest under logs, in the ground, or in walls; care should be taken to avoid disturbing them during gardening and lawn mowing. When a wasp stings, it injects a venomous fluid under the skin.

The imported fire ant is a small, light reddish brown to dark brown, nonwinged stinging insect that is responsible for increasing numbers of acute allergic reactions. This insect attaches itself to its victim by biting with its jaws; then it pivots around its head, stinging in multiple sites in a circular pattern with its stinger, which is located on its abdomen. The two species of imported fire ants (originally from Brazil) are found predominantly in nine southern states, particularly along the Gulf Coast, and are gradually spreading westward and northward. Fire ants inhabit loose dirt and make nests that produce up to 200,000 ants during a 3-year period. Fire ants swarm if provoked and may attack in great numbers. The fire ant's venom causes hemolysis, the depolarization of cellular membranes, activation of the alternate complement pathway, and general tissue destruction.

The brown recluse spider's *(Loxosceles reclusa)* natural habitat is along the Mississippi River Valley, especially in northwestern Arkansas and southern Missouri. Because this spider can live in old boxes and furniture, it is easily transported to other states. The brown recluse spider prefers warm, dry locations such as woodpiles, cellars, and abandoned buildings; it is generally nocturnal in activity. The "fiddleback" spider has a characteristic violin-shaped marking on the dorsum of its cephalothorax (head and body section). The spider's venom contains sphingomyelinase D; it is chiefly cytotoxic, causing local tissue destruction. The necrosis is caused by an aggregation of leukocytes and platelets that forms a hemostatic plug in venules and arterioles.

Black widow spiders *(Lactrodectus mactans)* are relatively aggressive. They are found throughout the United States, predominantly in the South. Around houses, the black widow spider is found in protected places such as garages, storage sheds, crawl spaces under buildings, and rainspouts. Female spiders of the genus *Lactrodectus* carry the characteristic orange-red hourglass-shaped marking on the ventral abdomen. Black widow spiders are the most feared of all spiders because they injure their victims by injecting one of the most potent venoms secreted by any animal. The *Lactrodectus* venom is a neurotoxin that acts on the myoneural junction and exerts its damage by releasing acetylcholine and norepinephrine.

Scorpions are found throughout the world. They are nocturnal and spend the day under rocks, logs, and floors. The only species that is particularly dangerous, *Centruroides exilicauda* (the bark scorpion), is found mostly in the southwestern United States. This small Mexican scorpion is usually less than 2 inches long, yellow to brown, and possibly striped. The last segment of the scorpion's tail-like structure contains the venom glands and stingers. Most scorpions are relatively harmless, producing only local reactions, but the venom of *Centruroides exilicauda* has effects similar to those of black widow spider venom, producing severe systemic toxicity. The venom is predominantly a neurotoxin that causes repetitive firing of axons by activation of sodium channels.

Some of the more common ticks in the United States are the brown dog tick and the American dog tick. Ticks are frequently encountered by hikers and people who work outdoors. When feeding, ticks make a small hole in the skin, attach themselves with a modification of one of the mouthparts (which has teeth that curve backward), and insert barbed, piercing mouthparts to remove blood. The American dog tick *(Dermacentor variabilis)* may transmit Rocky Mountain spotted fever (caused by the intracellular bacteria *Rickettsia rickettsii*), tularemia (caused by the coccobacillus *Francisella tularensis*), and other diseases from animals to people. This tick has also been reported to cause paralysis if it attaches at the base of the skull or along the spinal column. Paralysis is caused by a toxic secretion produced by the feeding tick. Lyme disease (caused by the spirochete bacterium *Borrelia burgdorferi*) is also transmitted by ticks. Most disease transmission occurs in the New England states, where the primary vector is the deer tick/black-legged tick *(Ixodes scapularis).* Species that are close relatives to the deer tick, such as the western black-legged tick *(Ixodes pacificus),* are also capable of transmitting the disease.

Fleas are wingless, blood-sucking insects, some species of which transmit arboviruses to humans by acting as host or vector for the organism. Certain species of fleas transmit plague, murine typhus, and tularemia. If a house has been previously occupied by pets that were infested with fleas, the abandoned hungry fleas may form a welcoming party for the newly arrived "human guests."

Chiggers, or "red bugs," are the larvae of harvest mites. Infestations due to chiggers are caused by mite larvae that feed on the host skin cells. In other parts of the world such as India, Central and Southeast Asia, and Australia, chiggers may transmit scrub typhus (caused by the rickettsial bacteria *Orientia tsutsugamushi*). Chiggers become active in the spring, although in southern states, such as Florida, they may be active all year. Chiggers attach themselves to the skin of humans or frequently to hair follicles or pores by inserting their piecing mouthparts. They prefer to attach themselves to parts of the host's body where clothing fits tightly or where the flesh is thin, tender, or wrinkled. During feeding chiggers inject digestive enzymes into the skin, which dissolves tissue. Chiggers feed by sucking up the liquefied tissues; they do not burrow in the skin. After 3 days, when the larva is engorged, it drops off. Chiggers are most often found in low, damp areas where vegetation is heavy, although some species prefer dry areas. They are most abundant in areas covered with shrubs and small trees, where rodents are numerous.

Mosquitoes are blood-sucking arthropods attracted to hosts by moisture, carbon dioxide, estrogens, sweat, or warmth. They are vectors of many infectious diseases.

The species of blood-sucking flies that can produce allergic reactions are deerflies, blackflies, horseflies, and sandflies. Fly bites can also result in cutaneous myiasis in which parasitism by fly larvae occurs. When a fly, such as the human botfly, deposits an egg on human skin, the egg hatches immediately, and the larva enters the skin through the bite or through another small break in the skin. The larvae grow to 15 to 20 mm under the skin, as a growing red, pruritic papule develops into a tender furuncle, with eventual emergence of the fly larvae.

Some of the stinging caterpillars are the puss caterpillar, saddleback caterpillar, and the hag moth caterpillar. These caterpillars are found primarily in the southeastern states, especially in Texas and Florida. These caterpillars have spines that are hollow hairs containing poison sacs. When the spines break off, a toxin flows from the spines onto the victim's skin, causing a burning sensation.

Epidemiology and Causes

Millions of people in the United States are injured by venoms produced by insects and other arthropods each year, with a notable number of deaths. In one 10-year period, 65 deaths were reported to be caused by spiders in the United States. Of these, 63 deaths were from black widow spider bites. Bee and wasp stings cause more deaths than any other venomous animal. There are 40 to 50 fatalities each year from Hymenoptera stings. These insect stings result in a rapid progression

of toxic effects: 80% of the deaths result from anaphylactic shock less than 1 hour after the sting. Spider bites, however, have a longer time interval between bites and time of death, with 89% of victims dying more than 12 hours after being bitten. Ninety-five percent of all venomous animal fatalities occur from April to October, when animals and potential victims are most active. The risk of insect bites increases with lack of protective measures and in areas with heavy insect infestations. Previous exposure to venom can predispose the victim to anaphylaxis.

Pathophysiology

The normal or usual reaction following an insect sting is local erythema, pain, pruritus, and swelling. Insect stings always cause pain. This normal reaction should subside in 1 to 2 hours. The more significant reactions to insect bites can be categorized as large local reactions, toxic reactions, systemic or anaphylactic reactions, delayed reactions, and unusual reactions.

A *large local reaction* could spread more than 6 inches beyond the sting, consisting of prolonged and marked edema at the site of the sting injury, peaking at 48 hours and lasting as long as 1 week. This reaction may be accompanied by nausea, vomiting, and fatigue. A large local reaction can involve one or more neighboring joints and may even produce airway obstruction if the sting was in the mouth or throat. The history of a large local reaction is typically not associated with the risk of anaphylaxis upon future stings.

A *toxic reaction* occurs when there is a history of multiple stings, often more than 10. Toxic reactions are caused by nonantigenic properties of Hymenoptera venom. They resemble systemic reactions but have a greater frequency of gastrointestinal disturbances. Diarrhea, nausea, vomiting, light-headedness, and syncope are common signs. The patient may also have headache, drowsiness, fever, involuntary muscle spasms, edema without urticaria, and occasionally seizures. Urticaria and bronchospasm are not present, and the symptoms usually subside within 48 hours.

Systemic or anaphylactic reactions may range from mild to fatal. The majority of such reactions occur within the first 15 minutes, and nearly all will occur within 6 hours after the insect sting, but some may not occur until 24 to 36 hours later. The shorter the interval between the sting and the onset of symptoms, the more severe the reaction. Fatalities that occur usually result from either hypotension or airway obstruction. The patient will present initially with generalized urticaria, itching eyes, dry cough, and facial flushing. These symptoms may progress rapidly to chest or throat constriction, dyspnea, wheezing, laryngeal stridor, frothy sputum, cyanosis, diarrhea, abdominal cramps, nausea, vomiting, chills and fever, vertigo, shock, loss of consciousness (LOC), and involuntary loss of bowel and bladder function.

When an individual predisposed to Hymenoptera allergy is initially stung, there is an increase in the production of antigen-specific IgE antibodies. The antibodies become attached to mast cells and basophils, and the individual becomes sensitized to undergo an anaphylactic reaction after a subsequent sting. Anaphylaxis is a type I immediate hypersensitivity immune response to a triggering antigen/allergen found in insect venom. In this type of reaction, once introduced into the body, the circulating venom antigen binds to antigen-specific IgE molecules that are bound to mast cells and basophils. Binding of two or more cell membrane–bound IgE molecules to the same antigen (a process known as antibody cross-linking) leads to the degranulation of mast cell and basophil cytoplasmic contents and the release of preformed vasoactive mediators including histamine and tryptase. These substances are potent systemic vasodilators, accounting for the immediate flushing and life-threatening symptoms of hypotension, angioedema, and mucosal swelling with potential airway compromise.

Infusion of histamine into normal subjects causes the following effects and can be diminished by antagonists of specific histamine receptors: flushing (H_1 plus H_2), hypotension (H_1 plus H_2), tachycardia (H_1), headache (H_1 plus H_2), pruritus (H_1), rhinorrhea (H_1), and bronchospasm (H_1). Honeybee venom contains histamine. Wasp venom contains histamine and serotonin. Hornet venom contains histamine, serotonin, and acetylcholine. The fact that histamine acts through both H_1 and H_2 receptors emphasizes the importance of administering both H_1 and H_2 antihistamines during allergic reactions. However, the only reliable method of countering the life-threatening hypotension and mucosal edema associated with anaphylactic histamine release is with immediate administration of epinephrine, a potent vasoconstrictor.

Following this immediate response, through complex lymphocyte (e.g., T cell) and granulocyte interactions, other inflammatory vasoactive cytokines, including prostaglandins, leukotrienes, and bradykinin, begin to form several hours after exposure. These substances contribute to a second, later phase of anaphylaxis that typically occurs 6 to 12 hours after acute exposure to the triggering antigen. Leukotrienes and prostaglandins are responsible in part for vascular permeability, vasodilation, smooth-muscle contraction, and mucus secretion. Downregulation of the inflammatory response by these de novo–formed mediators is the goal of steroid treatment in anaphylaxis because steroids such as hydrocortisone and methylprednisolone exert their peak effects 4 to 8 hours after administration and are ineffective against the immediate life-threatening anaphylactic response. In turn, steroids are more helpful for severe, prolonged allergic reactions and to manage delayed, late-phase responses. Of note, late-phase anaphylactic reactions may be as severe as early-phase reactions. Thus, corticosteroids are a cornerstone of extended

management for 24 to 48 hours after the onset of the initial acute reaction.

Another type of *delayed reaction* to insect venom can appear 10 to 14 days after an insect bite or sting; this reaction is also antibody mediated, but by IgG or IgM, rather than by IgE. This type of reaction presents as a serum sickness–like illness, which is a type III antigen–antibody response in which immune complexes are deposited in the various tissues of the body. The patient's signs and symptoms include malaise, headache, fever, urticaria, lymphadenopathy, and polyarthritis. Additional unusual reactions may be neurological or vascular in nature. They include nephrosis, vasculitis, serum sickness, encephalitis, and neuritis. Their etiology varies but may be due to an immunological pathogenesis.

Clinical Presentation

Subjective

The clinician should determine the history of the sting or bite, including the exact time of injury, and an exact description of the arthropod or species of insect, if possible. As the skin is inspected for signs of the insect or spider bite, the patient should first be evaluated for any anaphylactic symptoms or signs of a systemic reaction. The clinician should also determine if the patient has had previous allergies to insect bites, a history of allergies or asthma, or any known allergies to horses or horse serum. A family history of anaphylaxis to bites or stings should also be elicited.

With stinging insects, the patient will usually remember the insult because the sting induces immediate pain. For biting insects, there may be some delay between the actual bite and the itching that follows. The patient's history should be carefully pursued to identify the probable source of exposure. For indoor exposure, fleas are common offenders although spider bites are also responsible for indoor bites. The clinician should inquire about whether pets have recently occupied the dwelling or if the patient has been to a home with pets.

Objective

Hymenoptera (bee and wasp) stings produce immediate pain and a red papule surrounded by a pale zone of edema, with varying amounts of local swelling. Large local reactions are common, spreading more than 6 inches (15.2 cm) beyond the sting, peaking at 48 hours, and lasting as long as 1 week. A mildly sensitive person will experience hives, malaise, wheezing, conjunctivitis, rhinitis, fever, and nausea. A severely sensitive person will suffer diffuse urticaria, facial swelling, laryngeal edema, bronchospasm, vomiting, cyanosis, abdominal pain, arrhythmias, and hypotension. Most fatalities occur within 1 hour of the sting.

Fire ant stings produce vesicles that become sterile pustules; these pustules subsequently become necrotic within several hours and may take up to 10 days to heal. If broken, the pustules may become infected. Systemic symptoms include nausea, vomiting, faintness, headache, fever, numbness, and muscle spasms.

Brown recluse spider bites are unusual in that persons bitten usually do not feel pain for 2 to 3 hours. A single necrotic lesion occurs, usually measuring 0.5 to 2 cm in size, self-limited in spread, and lacking adenopathy or sustained general toxicity. The typical bull's-eye lesion is created when the red blister is encircled by a pale, irregularly shaped and ischemic halo, which in turn is surrounded by extravasated blood. The pustule may gradually grow to form a crater-like lesion over 3 to 4 days, with associated lymphadenopathy and low-grade fever. Rarely, there is a generalized systemic reaction 24 to 48 hours after the bite, with fever, malaise, arthralgias, rash, and hemolysis.

Black widow spider bites create an initial puncture wound that disappears rapidly, leaving a local swelling where tiny red spots appear. Symptoms of envenomation occur within 10 to 60 minutes, including severe pain in the bitten extremity and muscle spasms of the abdomen and trunk. Diffuse paresthesias, ptosis, and hyperactive deep tendon reflexes may be noted. Victims are in agonizing pain and may develop hypertension, headache, muscular rigidity and spasm, hyperreflexia, vomiting, abdominal pain, agitation, or psychosis. Symptoms peak at 2 to 3 hours after the bite and may last up to 24 hours.

Scorpion stings are immediately intensely painful, with little or no erythema or swelling. Generalized reactions may occur within 1 hour and progress to maximum severity in 5 hours. The reactions can be graded as follows:

- Grade I: Local pain and paresthesias at the site of envenomation
- Grade II: Pain and paresthesias remote from the sting bite, along with local findings
- Grade III: Either somatic skeletal or cranial nerve neuromuscular dysfunction, including blurred vision, wandering eye movements, hypersalivation, difficulty swallowing, upper airway obstruction, slurred speech, jerking of the upper extremities, restlessness, arching of the back, severe involuntary shaking and jerking
- Grade IV: Both cranial nerve and somatic skeletal neuromuscular dysfunction

Hypertension, nausea, vomiting, hyperthermia, tachycardia, and respiratory distress may also occur. Children younger than 10 years of age are more likely to have severe or prolonged reactions to scorpion stings. Older children and adults usually recover within 10 to 12 hours.

Tick bites can produce lesions that vary from small pruritic nodules to extensive ulceration, induration, and erythema. The lesions may be accompanied by malaise, fever, and chills. Tick-induced paralysis occurs more frequently during the spring and summer, when ticks are

feeding. Symptoms occur 5 to 6 days after the adult female tick attaches and include irritability, restlessness, and paresthesias in the hands and feet. Over the next 24 to 48 hours, ascending, symmetric, and flaccid paralysis, with loss of deep tendon reflexes, occurs. Within 1 to 2 days, severe generalized weakness is possible, accompanied by respiratory paralysis.

Flea bites produce lesions that are so similar to those of lice and scabies that diagnosis is often difficult. Flea bites produce itching papules, found in zigzag lines, especially on the legs and in the waist area. The lesions present as central hemorrhagic puncta surrounded by erythematous and urticarial patches. Pruritus is intense. Once the lesions clear, dull red spots may persist. Impetigo may develop as a complication. If the fleas remain in the environment, new lesions continue to appear.

Itching from *chigger bites* is usually noticed 4 to 8 hours after chiggers have attached or have been accidentally removed. Initially, a papule develops and ultimately enlarges over 24 to 48 hours to form a nodule. Pruritus peaks on the second day. The fluid injection causes nodules to appear, which may last for 2 weeks. Patients who exhibit an allergic reaction to the fluid injected (saliva) will develop severe soft tissue edema, itching, and fever. Chigger bites usually occur around the ankles, waistline, knees, or in the armpits. Mite infestations may be associated with an erythema multiforme–like rash and fever.

An immediate skin reaction to *mosquito bites* includes erythema, wheal, and itching. A delayed reaction 12 to 24 hours later consists of redness, edema, and a burning pruritus. Blistering and necrosis can also occur. The immediate reaction is of short duration, whereas a delayed reaction may persist for hours, days, and even weeks. Some individuals have a history of allergy to mosquito saliva, consistent with an increasing reaction to seasonal exposures accompanied by progressively more pronounced edema and pruritus. The allergic response can be accompanied by fever, generalized malaise, nausea, vomiting, and necrosis, with resulting scarring.

Blood-sucking flies can cause pain and subsequent pruritus when they pierce the skin. Allergic reactions can occur; if flies inject their eggs under the skin, the patient can also develop myiasis. As the fly larvae hatch and grow under the skin, the initial pruritic papule becomes a furuncle with a central opening that exudes serosanguineous fluid. The tip of the fly larva may even protrude from the central opening, or bubbles produced by its respiration may be seen.

The *puss caterpillar's sting* causes intense, immediate pain, often in spasms. This is followed by local edema, pruritus, and a rash of red blotches and ridges. The lesions consist of red or white papules and vesicles, often forming a perfect grid like mark where the caterpillar made contact. Ordinarily no systemic manifestations occur; the localized symptoms typically subside within 24 hours. In some patients, however, the intense pain may cause nausea and vomiting, as well as headache, fever, and lymphadenopathy. The papular or urticarial rash usually subsides within a few hours to 1 to 2 days after contact, but it may persist for up to 1 week.

Diagnostic Reasoning

Diagnostic Tests

In an arthropod bite or sting that results in systemic involvement, the APRN should order blood type and crossmatch, coagulation studies, CBC, electrolytes, BUN, creatinine, and urinalysis. ABGs and pulse oximetry may also be necessary. For suspected tick-borne diseases such as Rocky Mountain spotted fever and Lyme disease, further laboratory studies are in order. For example, spirochetes can be seen in the blood smear in 70% of cases of tick-borne relapsing fever. Lyme disease, Rocky Mountain spotted fever, and tularemia, which also occur from tick bites, are diagnosed by antibody titer. However, results from these antibody titer assays are often not available for days to weeks, with empiric treatment often initiated before this. Thus, these tests are usually sent for confirmation only when a strong suspicion already exists and should not be sent indiscriminately.

Differential Diagnosis

Consultation with a regional poison control center may be indicated to correctly identify, diagnose, and/or treat arthropod bites and stings. It is very helpful to know which arthropods are indigenous to the local area, especially which ones have been causing recent infestations and injuries.

Bites of fleas, lice, and scabies mites produce lesions that are so similar that diagnosis is often difficult. Cercaria or nonhuman schistosomes cause similar lesions, which appear after the patient has been in infected water. Scabies has a more gradual onset but should also be considered in the differential diagnosis. The diagnosis of chigger infestation can usually be made on the basis of probable outdoor exposure and typical skin lesions. Patients who present with a "bull's-eye" rash following a suspected deer tick bite should be tested for Lyme disease.

When examining an urticarial reaction to an insect bite, other causes of urticaria should be considered; but if the hive (wheal) has a central punctum, its cause is likely an insect bite. Other foreign bodies can produce pruritic papules in the skin. Dermatitis herpetiformis should be included in the differential diagnosis, particularly when only excoriations are found. Eruptions associated with other viruses or with atopic dermatitis, allergic or irritant contact dermatitis, and drug sensitivity must also be considered. An uncommon idiopathic disorder, Mucha-Habermann disease, also presents with scattered necrotic papules and vesicles, but this type of rash is usually more generalized and symmetric. Some

of the other skin conditions that may be confused with local or systemic reactions to arthropod stings and bites include streptococcal necrotizing fasciitis, focal cutaneous necrosis, various infections, local thromboses, punctures, trauma, drug reactions, vasculitis, purpura, Arthus (type III, serum sickness) reactions, emboli to the skin, other bites that leave small puncture wounds, and artifacts.

Anaphylaxis from an insect sting may be confused with a vasovagal reaction, which is a disorder of central vasoregulation caused by increased parasympathetic tone mediated by the vagus nerve (cranial nerve X). A vasovagal reaction typically produces pallor, nausea, bradycardia, extreme diaphoresis, and hypotension that may result in syncope, whereas flushing, hypotension, tachycardia, and mucosal edema with severe bronchoconstriction are seen in anaphylaxis. Severe reactions to scorpion stings may present with symptoms similar to those of insecticide poisoning, with direct CNS effects.

Confirmation of stinging insect allergy is made by the detection of venom-specific IgE. This can be performed through an immediate reaction skin prick test, which measures the cutaneous histaminic response to dilute doses of allergen after scratching the skin surface with an antigen-coated needle tip, allowing for binding to IgE on skin mast cells with subsequent degranulation. Yellow jacket, honeybee, yellow hornet, bald-faced hornet, and wasp extracts are available for diagnosis and treatment of stinging insect allergies. A patient is considered sensitive if a skin reaction of 1+ or greater occurs at a venom concentration of 1 mg/mL or less, provided that the 1+ reaction is greater than that of the diluent control. This is the most sensitive test for picking up allergic states and is commonly used as an allergy screening tool. However, it lacks specificity and may thus overestimate allergic states.

IgE antibodies reacting with venom also may be measured by serum assay known as the radioallergosorbent test (RAST). In this test, a patient's serum is applied to a culture plate surface coated with the specific allergen of interest, allowing for specific antibody-binding to the plate. After excess serum is rinsed away, a second fluorescent-labeled antibody specific for the constant region of IgE is applied to the plate to reveal any of the patient's antigen-specific IgE that bound to the plate during the first step of the assay. Thus, the greater the amount of fluorescence, the higher the concentration of antigen-specific IgE in the patient's serum. The RAST is not as sensitive as the skin test although it is more specific and is thus more effective in ruling out, rather than ruling in an allergic state.

Management

Emergency Management

Anaphylactic shock and respiratory distress are true emergencies; the clinician should focus on stabilizing the patient while arranging for immediate transport to the ED.

Systemic or Anaphylactic Reactions It should be stressed that anaphylaxis may be triggered by etiologies other than bites and stings. Anaphylactic reactions are extreme emergencies and may be a reaction iatrogenically caused by medications, environmental exposures, and especially food allergies, which are quite common. The treatment for anaphylaxis is standard and is included here.

The clinician should place a conscious patient in a comfortable position, ensuring unimpeded ventilation. Hypotensive patients should be placed supine or in a modified Trendelenburg position if respiratory status allows.

The clinician must maintain an adequate upper airway and give supplemental oxygen by mask or nebulizer with inhaled racemic epinephrine (0.5 mL of 2.25% epinephrine in 2 mL of normal saline), not to exceed three treatments in 60 minutes. However, racemic epinephrine should not be considered an adequate substitute for systemic epinephrine in the case of a life-threatening attack. Thus, in the case of impending upper airway compromise, inadequate oxygenation, or profound shock, the clinician must prepare for immediate administration of systemic epinephrine (as described below) and endotracheal intubation if necessary to maintain an open airway. Cricothyrotomy is to be performed if severe angioedema precludes intubation via the oral route.

In the case of airway edema, bronchospasm, and/or cardiovascular instability (with or without cutaneous manifestations of urticaria or angioedema), the clinician should immediately administer aqueous epinephrine 1:1,000 IM into the upper outer thigh region, which provides the most rapid entry into the systemic circulation. The dose is 0.3 to 0.5 mg every 10 to 20 minutes as indicated. One can inject 0.1 to 0.2 mg of the epinephrine dose directly into the sting bite, causing vasoconstriction and reduction of swelling. If the reaction is limited to urticaria and pruritus, there is no wheezing or facial swelling, and the victim is more than 45 years old, one should reserve epinephrine for a worsened condition. Epinephrine maintains the blood pressure, causes bronchial dilation, and antagonizes adverse actions of the mediators of anaphylaxis. It also reduces the subsequent release of mediators through its action on mast cells and basophils.

In the setting of vasodilatory anaphylactic responses with hypotension, laryngeal edema, or severe bronchospasm, when there is no response to IM epinephrine, IV administration is a more appropriate route. Epinephrine is the single most life-saving treatment in the reversal of hypotension, airway edema, and bronchoconstriction associated with anaphylaxis. The clinician should place 0.1 mg (1 mL of 1:10,000 solution epinephrine) in 10 mL of normal saline (NS) and administer as a slow IV push over 10 minutes. This dose is to be repeated once

or twice every 10 minutes as required. Alternatively, a continuous infusion of IV epinephrine at 1 to 5 mg/min can be started. This is constituted by adding 1 mg of 1:1,000 aqueous epinephrine (1 mL) to 250 mL NS, creating a concentration of 4 mg/mL.

Excessive infusion rates may be associated with cardiac ischemia and arrhythmias. One-half of the above recommended doses should be used initially in elderly patients or those with cardiovascular disease, diabetes mellitus, thyroid disease, cerebral arteriosclerosis, or Parkinson's disease. Patients who are taking beta-adrenergic blocking agents may be refractory to treatment with epinephrine. Glucagon (5–15 mg/min IV) may be a useful agent in the treatment of anaphylaxis in the presence of beta blockade.

Antihistamines are included in the treatment regimen. With H_1-blocking antihistamines, the clinician may administer diphenhydramine IV or PO as needed (in severe anaphylaxis, administer 100 mg IV initially); or hydroxyzine IM as needed. The newer generation H_1 blockers such as cetirizine, fexofenadine, and desloratadine are less sedating and may be just as effective if the patient may be treated with oral medications. For H_2-blocking antihistamines, the clinician may administer cimetidine IV or ranitidine IV. If available, cimetidine is the preferred H_2 blocker because it has greater peripheral effects than does ranitidine, which is more specific for the gastrointestinal tract.

In addition to immediate epinephrine as described previously, albuterol may be used to treat bronchospasm, administered via nebulizer every 20 minutes as necessary. A loading dose of aminophylline 6 mg/kg IV (if the patient is not currently taking aminophylline or theophylline) may be administered over 20 to 30 minutes, followed by a continuous IV infusion (0.7 mg/kg per hour) in otherwise healthy nonsmoking adults.

Circulatory support should be provided as necessary. The clinician may infuse 0.5 to 1 L of either NS or lactated Ringer's solution every 20 to 30 minutes as needed to support the blood pressure at a level above 90 mm Hg systolic. The need for further fluid resuscitation should be determined by monitoring blood pressure, cardiac rhythm, and urine output. Usually, a total of 3 L can be given rapidly to an adult without ill effect. The clinician should be cautious with patients with congestive heart failure or the elderly, given the risk of pulmonary edema. Hypotension that is refractory to epinephrine and IV fluids may be treated with norepinephrine (Levophed) via IV infusion. Phenylephrine (Neo-Synephrine) as an IV bolus every 10 to 15 minutes as necessary or as a continuous IV infusion may also be used. The infusion should be decreased once blood pressure has stabilized. Glucagon is also useful in patients on beta-adrenergic blocking agents because it stimulates cardiac inotropic and chronotropic function independent of beta blockade. Patients taking beta blockers may also benefit from terbutaline SC.

If the allergic reaction is prolonged or severe or if the patient is regularly medicated with corticosteroids, the clinician should administer hydrocortisone, methylprednisolone, or dexamethasone IV, with a 10-day oral taper to follow. If the therapy is initiated orally, the clinician should administer prednisone 60 to 100 mg daily. Even in the case of reactions that do not appear to be prolonged, systemic corticosteroid therapy should be administered for 24 to 48 hours after the onset of the initial reaction to minimize the chance of late-phase anaphylactic reactions, which may manifest up to 24 hours after the initial reaction and may be as severe as early-phase reactions.

General Management

Normal Reactions Normal reactions to arthropod bites and stings do not require treatment other than local applications of cold compresses (ice) and analgesics. NSAIDs such as ibuprofen PO are effective if given immediately because they block prostaglandins. Secondary infections are common; therefore, a topical antimicrobial ointment such as mupirocin 2% (Bactroban) ointment should be applied to the area.

Large Local Reactions Large local reactions to arthropod bites or stings are treated with antihistamines, such as diphenhydramine IV or PO and cimetidine IV or PO. Intramuscular administration of diphenhydramine is not usually done because of the pain involved and the fact that the drug is absorbed very rapidly PO. A corticosteroid such as methylprednisolone PO the first day, then tapered over 5 days, will hasten resolution of a large local reaction to a bee or wasp sting. Tapering slowly prevents a rebound flare-up of symptoms. Some clinicians also administer IV calcium gluconate. Importantly, large local reactions are not associated with the risk of anaphylaxis on future stings by the same type of insect.

Delayed Serum Sickness-Type Reactions Delayed serum sickness-type reactions in response to multiple bee, wasp, or fire ant stings can be managed with a corticosteroid such as prednisone (Deltasone) 60 to 100 mg, tapered over 2 weeks. The pruritus caused by insect bites can be controlled by a variety of oral antihistamines. Hydroxyzine is commonly prescribed because its dosage is very flexible, and it produces few anticholinergic adverse effects. If patients are driving and working during the day, they should reserve the hydroxyzine for nighttime use to help with sleep. Treatment of urticaria may also require an antihistamine that is an H_2 blocker, such as cimetidine.

For arthropod bites, when topical steroids are needed, class I (e.g., betamethasone dipropionate) or class II (e.g., fluocinonide) topical steroids may be administered 2 times daily. Lesions may take weeks to resolve. Topical antipruritics include lotions with 0.25% menthol, 1% phenol, or both (Sarna lotion) and topical anesthetics such as pramoxine (Pramosone).

Topical antihistamines and benzocaine are not recommended because of their potential for allergic sensitization. Topical doxepin (Zonalon) is now available and is effective. Infected insect bites can be treated with topical 2% mupirocin or neomycin. Extensive impetigo will need treatment with oral antibiotics, dicloxacillin, or erythromycin.

Hymenoptera Stings When a patient is stung by a honey bee, the stinger should be removed by scraping it with a dull object. The stinger should not be grasped and pulled because this contracts the venom sac, thus releasing more toxins. Wasps and other bees do not leave a stinger and are capable of stinging many times. One should cleanse the site and apply antiseptic. Blisters from fire ant stings should not be broken. Ice should be applied with a pack, with or without a paste of papain (unseasoned meat tenderizer), and the body part should be elevated.

There is no specific antivenin for Hymenoptera stings. If the reaction is extensive or if there is envenomation from multiple stings, more aggressive therapy may be indicated. This includes administering IV calcium gluconate with an antihistamine such as diphenhydramine, IV or orally. Oral prednisone, 40 mg daily for 2 to 3 days, can be very helpful in reducing the local swelling. Appropriate tetanus prophylaxis should be completed. In severe envenomations, an IV corticosteroid such as hydrocortisone, 2 mg/kg should be administered at the earliest opportunity (see also the section on systemic or anaphylactic reactions).

Brown Recluse Spider Bite The patient should apply cold compresses intermittently for the first 4 days after the bite, over a sterile dressing. Administer an oral antibiotic, such as dicloxacillin, cephalexin, or erythromycin for 10 days. Elevation of the affected part may be beneficial. Drug treatment is controversial; many brown recluse spider bites are minor and heal without specific treatment other than tetanus prophylaxis. One current treatment for a severe wound is to obtain a glucose-6-phosphate dehydrogenase (G6PD) screen and if negative, immediately give dapsone (Avlosulfon) 50 mg (adult dose) orally 2 times daily for 10 days. If G6PD enzyme deficiency is documented, the patient should discontinue dapsone to avoid hemolysis.

Black Widow Spider Bite The natural course of the envenomation is to resolve completely after a few days, with pain persisting for a week or more. Ice should be applied judiciously to the bite wound. The clinician should administer a narcotic analgesic, such as morphine. All opioids may have a histaminic agonist effect, so these medications should be avoided in cases with significant histaminic responses. Muscle relaxants such as diazepam (Valium) may also be given. The patient should be monitored for hypertension and administered a centrally acting or vasodilating antihypertensive if necessary. An alternative, more controversial treatment for black widow spider bites would be to add calcium gluconate 0.1 to 0.2 mL/kg IV given slowly to alleviate muscle spasm. Reserve antivenin for seriously ill infants and older patients and proceed with horse serum sensitivity testing. One vial of antivenin is sufficient for most patients.

Scorpion (Centroides exilicauda) Bite The patient should apply ice for 30 minutes each hour to relieve local pain. Intense cooling should be avoided, and the affected part should be immobilized. Do not apply a tourniquet. Opiate analgesics should be avoided because they potentiate the toxicity of the venom and may lead to apnea. The clinician should administer diazepam or phenobarbital to control seizures, along with sympathetic antihypertensive agents to control hypertension. Hyperthermia from uncontrolled muscular activity can be managed with cooling. The administration of antivenom (antivenin) is controversial because it is derived from horse serum and thus carries a risk of anaphylaxis. Horse serum sensitivity testing is done to screen against anaphylaxis, which is a risk with many of the antivenin medications. Antivenin should be administered only in a hospital critical care setting.

Tick Bite The clinician should always remove ticks. The tick can be covered with alcohol, machine oil, mineral oil, salad oil, or gasoline on a tissue or gauze pad. This blocks the tick's breathing pores and causes it to withdraw from the skin. It may take 30 minutes for the tick to disengage its mouthparts. Ticks should not be removed manually because squeezing the tick's body may inject more viral or bacterial pathogens into the victim. The clinician should observe for a local reaction or infection at the site. Most victims of tick paralysis will show improvement within hours of tick removal and return to normal in several days. Patients with Rocky Mountain spotted fever or Lyme disease will require further treatment, including antibiotics and follow-up monitoring for chronic health problems.

Flea Bites The patient should clean the lesions well with soap and water and apply a topical antiseptic ointment. To relieve pruritus and discomfort, calamine lotion with phenol can be applied. A systemic antihistamine, such as hydroxyzine (Atarax), can be administered to control itching.

Chigger Bites Chiggers are easily removed from the skin by taking a hot bath or shower and lathering with soap several times. The bath will kill attached chiggers. For moderate to severe cases, topical steroid creams and oral antihistamines may provide some relief. Systemic steroids will also provide relief for severe pruritus. Topical antibiotic therapy is indicated for secondary infection.

Mosquito Bites Immediately after the person is bitten, he or she should apply a cold (ice) pack. A topical steroid ointment can be applied to the site. Oral steroids such as prednisone should be used only when the reaction is prolonged and severe, given their potential adverse effects.

Fly Bites Fly bites are treated the same as mosquito bites. In addition, if the patient presents with cutaneous myiasis, the clinician should exert pressure to extrude the organism (fly larva). The larva may emerge if its breathing hole in the skin is occluded with heavy oil, nail polish, or bacon fat. Alternatively, the clinician can inject 2 mL of local anesthetic into the base of the lesion, thus extruding the larva by fluid pressure. Take care not to rupture the larva because an inflammatory reaction may result.

Caterpillar Spine Irritation Broken-off spines can be removed by applying adhesive tape, a commercial facial peel, or a thin layer of rubber cement. Then an oral antihistamine and/or NSAID can be administered. If the dermatitis is persistent and severe, the clinician should prescribe oral prednisone 60 to 100 mg for adults, to be tapered over 10 days.

Follow-up and Referral

After a severe allergic reaction, further delayed reactions and recurrence of symptoms are possible, particularly as the effects of the medication decrease. Patients may benefit from repeated doses of antihistamines and glucocorticoids over the next several days. All patients with severe allergic reactions who are discharged home should have follow-up in 24 to 48 hours. All such patients should be referred to an allergy specialist.

Individuals who have experienced a serious anaphylactic reaction should be prescribed three kits for the self-administration of epinephrine by injection or nebulization (EpiPen or Ana-Kit) and instructed on its use. These patients should also keep in each kit oral diphenhydramine and cimetidine. One kit should be kept in a bag or purse that is carried with the individual at all times, a second in the school or work setting, and a third kit should be kept in the home. Many individuals also keep a kit in the glove compartment of a personal vehicle. However, it is important to explain to the patient that extremes of heat and cold can affect the stability of many medicines, including life-saving epinephrine. Thus, storing a kit in the glove compartment is not recommended.

Individuals with a history of an acute allergic reaction (including systemic cutaneous reactions) with positive venom skin tests or a serum sickness-type reaction after an insect sting are considered at risk for subsequent sting reactions. Venom immunotherapy to prevent IgE-mediated allergic reactions may be recommended, and referral to an allergist is required for specialized assessment, including allergy testing (venom skin testing and venom-specific serum IgE–RAST testing). Of note, venom immunotherapy will not prevent future type III immune complex-mediated serum sickness reactions, which do not involve the IgE allergic antibody. In addition, patients with large local reactions are not considered candidates for venom immunotherapy and do not require venom skin tests, because these reactions are not associated with the risk of anaphylaxis on future stings. Patients who have been treated for anaphylaxis and who use beta-adrenergic blocking agents should be switched to alternative medications.

Patient Education

Patient education information regarding arthropod bites and stings is provided in Table 19.5.

HEAD TRAUMA

Head traumas that may be encountered by the clinician in a primary-care setting include cerebral contusions, concussions, skull fracture, and epidural or subdural hematomas. In contrast, subarachnoid hemorrhage typically results from the spontaneous rupture of intracranial aneurysms (greater than 80% of cases), rather than a traumatic etiology.

Epidemiology and Causes

Head trauma is a leading cause of morbidity and mortality in the United States. It affects approximately 2 million persons per year, with about one head injury occurring every 15 seconds. About 30% of all visits to the ED are for treatment of head-related injuries. The vast majority of head traumas result from motor vehicle crashes in young adults aged 15 to 24 years. The next most common causes are football and wrestling in men and soccer and basketball in women. Although it is estimated that approximately 3.8 million concussions occur in the United States annually during competitive sports and recreational activities, half of those go unreported. In people older than age 65 years, falls account for the majority of head injury deaths. Falls are the most common reason for an injury-related visit to an emergency department. Traumatic brain injury (TBI) may also be the result of drugs and alcohol, violence, and sports-related injuries.

Pathophysiology

Mild head trauma is usually the result of a sudden deceleration injury or rotation force that causes shearing forces within the brain. These forces cause axonal and blood vessel disruptions. Injury to small blood vessels can manifest themselves as petechial hemorrhages; or, if the bridging veins connecting the cortex to the venous sinuses are involved, acute subdural hematomas may occur, which are potentially fatal. In contrast, subarachnoid hemorrhages, with their resultant meningeal findings including extreme headache and neck stiffness, result far more commonly from ruptured intracranial saccular aneurysms, also called berry aneurysms (greater than 80% of cases), rather than from trauma.

The area of cerebral injury becomes ischemic and edematous. As edema increases, the autoregulatory control of intracranial vessels is lost. The blood–brain barrier breaks down, resulting in increased loss of fluid into the brain parenchyma, which in turn results in increased

Table 19.5 Patient Education: Arthropod Bites and Stings

- Avoid mowing lawns or working with flowering ornamentals when bees and wasps are collecting nectar.
- Stand still if a stinging insect is near you. If it attacks, brush it off (do not slap at it) to prevent a sting.
- Do not walk in the yard in bare feet.
- Wear gloves when gardening.
- Keep garbage cans covered outdoors. Sweet items like soft drinks, ripened fruits, and watermelons attract bees and wasps.
- Avoid perfumes, hair sprays, and colognes.
- Pick fruit as it ripens and dispose of rotten fruits.
- If you are attacked by a swarm of bees, wasps, yellow jackets, or hornets, leave the area immediately, using your arms to protect your face.
- Control wasps by applying insecticides to the nest.
- Avoid areas where insect exposure is likely to occur and always wear shoes when outdoors.
- Avoid wearing perfumes, after-shave lotions, and brightly colored clothing outdoors because these attract insects.
- If you are severely allergic to bee or wasp stings or to any medication, wear medical identification jewelry indicating the anaphylaxis-causing substance or event.
- Check bathrobes and bed sheets for spiders if you are about to use them after a long absence.
- When you enter an attic or storeroom to open cardboard boxes, give the brown recluse spiders a chance to vacate, because they will avoid you if they can.
- Have someone try to capture the spider for identification. Immediately seek health care, and contact the local poison control center.
- Treat pets for ticks by using dusts, dips, or sprays.
- When you enter tick-infested areas, keep clothing buttoned, shirts tucked inside trousers, and trousers inside boots.
- Wear light-colored clothing because this makes it easier to spot ticks; lighter clothing is also less attractive to biting flies.
- Do not sit on the ground or on logs in brushy areas.
- Keep brush cleared or pruned along frequently traveled areas. Use repellents to protect exposed skin; however, ticks will crawl over treated skin to untreated parts of the body.
- For treatment of flea infestations, treat not only the pet, but also professionally fumigate the house.
- If you are going into areas suspected of being infested with chiggers, wear protective clothing and use repellents.
- Apply a repellent containing *N,N*-diethyl-3-methylbenzamide (commonly known as DEET) and wear permethrin-impregnated fabric.
- Apply repellents to legs, ankles, cuffs, waist, and sleeves, either to clothing or directly to the body as directed by the repellant's label.
- Avoid unnecessary use of lights at campsites, and camp in a site that is high, dry, open, and uncluttered.

intracranial pressure (ICP). As ICP increases, cerebral blood flow decreases, leading to tissue hypoxia, a decrease in the serum pH level, and an increase in the carbon dioxide level. This process leads to cerebral vasodilation and edema, which further increases the ICP (a vicious cycle). The increased ICP causes compromise in cerebral perfusion that, if not treated and reversed, leads to increasing hypoxia and secondary brain injury. If the condition remains untreated, the brain herniates downward toward the brainstem, causing irreversible brain damage. A summary of the clinical features of ICP and management guidelines is provided in Table 19.6.

Cerebral Contusion

A *cerebral contusion* is a focal brain injury involving cortical bruising, and, at times, vessel lacerations. This is one of the most common cerebral injuries; it is associated with hemorrhage, edema, and brain swelling. Contusions are classified as *coup* (injury directly beneath the point of impact) or *contrecoup* (injury directly opposite the point of impact). Temporal and frontal lobes are the most common sites affected. Contusions are graded as mild or severe and superficial or deep. Superficial contusions usually involve the cortical and subcortical tissue, whereas deep contusions penetrate the white matter.

Concussion

A *concussion* involves diffuse brain injury. It is associated with a transient loss of consciousness that occurs immediately following nonpenetrating blunt head trauma. Most patients with only a brief loss of consciousness (less than 5 minutes) are not admitted to the hospital if their subsequent neurological exam remains within normal limits. However, close observation by a responsible adult educated in the warning signs of neurological deterioration is critical for at least the next 24 hours.

A mild concussion is associated with a slightly longer loss of consciousness. It classically presents with confusion,

Table 19.6 Clinical Features and Management of Increased Intracranial Pressure (ICP)

0–15 mm Hg: normal
>15 mm Hg: increased

Clinical Features	Management to Reduce ICP
Decrease in level of consciousness	Elevation of head
Headache	Restriction of fluids
Nausea	Acetazolamide (Diamox) 250 mg 4 times daily
Vomiting	Induced hyperventilation
Amnesia	IV mannitol (Osmitrol) infusion
Agitation, restlessness	IV furosemide (Lasix)
Increased BP with a widening pulse pressure	Possible surgical evacuation of hematoma
Decreased pulse rate	
Changes in respiratory rate and pattern	
Papilledema, one or both eyes	

Pupil Assessment
PERL—pupils equal and react to light
PERRL—pupils equal, round, and react to light
PERRLA—pupils equal, round, react to light and accommodation

disorientation, and, at times, retrograde amnesia (inability to recall events surrounding the injury) or post-traumatic amnesia. The confusion and disorientation usually last only minutes, but recurrent dizziness, headache, and difficulty concentrating may last for months.

A classic concussion, resulting from a loss of consciousness of less than 6 minutes, typically produces retrograde and post-traumatic amnesia and mild neurological impairment. The duration of amnesia can be a predictor of severity: The longer the amnesia, the more severe the concussion. Severe concussions usually have a normal head computed tomography (CT) scan and neurological exam; however, these patients are typically admitted to the hospital for close observation.

Postconcussion syndrome is usually associated with mild head trauma. The syndrome consists of the following signs and symptoms, which can start as early as 1 day post-trauma and persist up to 6 months after injury: headaches, dizziness, fatigue, irritability, insomnia, anxiety, impaired concentration, and loss of memory. Loss of consciousness does not have to occur for postconcussion syndrome to develop, and it is estimated that up to 50% of patients who suffer mild head trauma will develop this syndrome.

Skull Fracture

Skull fracture may occur with a severe blow to the head. Skull fracture increases the risk of underlying epidural or subdural hematoma. Basilar skull fractures (fracture of the base of the skull) can occur as an extension of fracture in another area of the skull. Basilar skull fractures can cause leakage of cerebrospinal fluid (CSF), an entry point for bacteria leading to meningitis, or pneumocephalus (air entry into the CSF-filled spaces within the head). Key clinical manifestations associated with basilar skull fracture are hemotympanum (blood behind the tympanic membrane), ecchymosis over the mastoid process ("Battle's sign"), or periorbital ecchymosis ("raccoon sign"). Routine x-ray films may not reveal skull fracture; therefore, radiographs are usually nondiagnostic and can cost precious minutes of critical-care time. The clinician should be aware that basilar skull fracture is a clinical diagnosis and proceed immediately with a head CT. CSF may leak through the cribriform plate region of the skull causing nasal CSF rhinorrhea. Patients with suspected skull fracture require careful examination of the cranial nerves. Cranial nerves (CNs) that are likely to be injured include the olfactory nerve (CN I), optic nerve (CN II), oculomotor nerve (CN III), trochlear nerve (CN IV), trigeminal nerve (CN V), abducens nerve (CN VI), facial nerve (CN VII), and acoustic nerve (CN VIII).

Epidural Hematoma

Severe head trauma can cause intracranial bleeding that can put pressure on the brain tissue. The brain is surrounded by the *meninges,* three layers of protective membranes. The layers from the cranial bone going interiorly consist of the dura mater, arachnoid membrane, and pia mater (see Fig. 19.2). Between each membrane is a compartment or space where blood from ruptured vessels can collect. Between the cranial bone and dura mater is the epidural space. The middle meningeal artery courses through this space and can rupture when the cranium (skull) is fractured. The middle meningeal artery runs tightly along the wall of the cranial bone, forming grooves in the bone. With a skull fracture, this artery is easily ruptured and bleeds rapidly within the epidural space, resulting in an *epidural hematoma.* The volume of

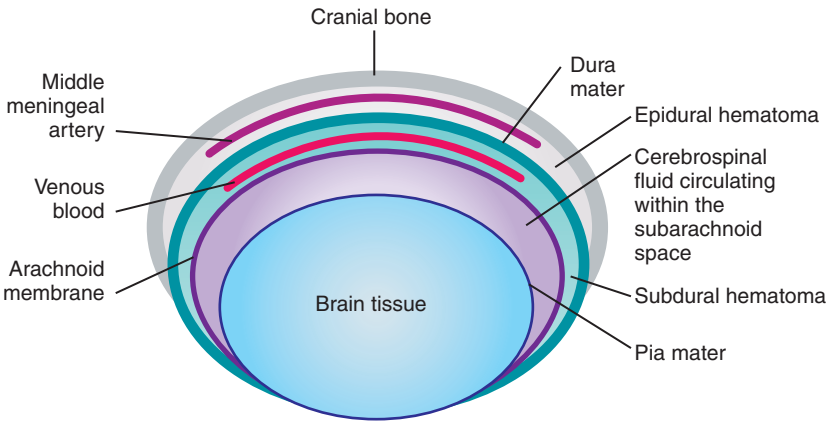

Figure 19.2 The layers of the meninges, cranial circulation, and location of hematomas. *(Courtesy of Teri Capriotti, DO, MSN, CRNP.)*

blood may be large enough to displace the brain, causing neurological deficits and coma within hours after skull injury. Skull x-ray films reveal a fracture line that passes through a groove on the cranium. A head CT scan can visualize the region of the bleed, and brain dysfunction is due primarily to parenchymal compression, which can be relieved with evacuation of blood from the epidural space. A head CT should be considered by the clinician in any head injured patient who meets any of the following criteria:

- Is on anticoagulants, or those with a history of bleeding dyscrasias
- Has sustained loss of consciousness
- Has an altered mental status
- Is suspected of alcohol or drug ingestion
- Has vomited repeatedly
- Has a Glasgow coma scale below 15
- Is older than age 60
- Has a Battle's or raccoon sign
- Is an infant with suspected shaken baby syndrome

Subdural Hematoma

Head trauma can also cause a *subdural hematoma,* which is a venous bleed. Venous bleeding occurs within the subdural space—the compartment between the dura mater and arachnoid membrane (see Fig. 19.2). A venous bleed is slow and will clot off in a short amount of time. Thus, a subdural hematoma may develop slowly over days to weeks and can be due to relatively mild head trauma. Thus, subdural hematomas may be acute (less than 72 hours old), subacute (between 3 and 20 days old), or chronic (greater than 20 days old). Acute subdural hematomas most commonly result from traumatic rupture of the bridging veins, which span the cortex and the dural venous sinuses. If such acute bleeds require surgical intervention and are not rapidly treated within several hours after injury, mortality rates are strikingly high (up to 90%).

In contrast, chronic subdural hematomas pose less of a mortality threat. The majority originate from subdural hygromas, which are potential spaces formed between the dura mater and the brain surface following separation of the dura–arachnoid interface due to ischemic or traumatic brain injury or atrophy resulting in a loss of brain parenchyma. These spaces become filled with CSF. A neomembrane eventually forms that lines the space, becoming a site of neovascularization by fragile intracranial vessels prone to rupture and formation of the chronic subdural hematoma.

Neurological deficits may not be noted until a large volume of blood is present. Brain dysfunction is due primarily to parenchymal compression, which can be relieved with evacuation of blood from the subdural space. CT scans and x-ray studies may not clearly reveal a subdural hematoma, making it difficult to diagnose. Magnetic resonance imaging (MRI) can show displaced brain tissue away from the skull, which is a key finding of subdural hematoma. Patients on anticoagulants, with coagulation deficiencies, or with liver impairment are particularly susceptible to subdural hematomas. Alcohol abusers are also susceptible to subdural hematomas, which may be a subacute as well as an acute condition. It can be a slowly evolving source of increased intracranial pressure.

Clinical Presentation

Subjective

A full history of the event causing the head injury is needed. This should include the mechanism of injury, an approximation of the amount of force involved with the trauma (if the event was witnessed), and whether the patient experienced loss of consciousness (LOC). Epidural hematomas are especially characterized by the patient losing consciousness briefly, then a brief "lucid" moment when the patient may be awake and talking, followed by a momentary unconsciousness occurring minutes after the injury, then becoming increasingly symptomatic, possibly progressing to coma. If a family member or friend is with the patient, the clinician should ask that person if the patient appears normal; a person close to the patient can identify subtle changes that the clinician may not recognize. Patients may

complain of headaches and confusion. When a patient complains of "the worst headache of my life," the clinician should suspect a subarachnoid bleed or subarachnoid hemorrhage.

Clinical presentation depends on the structures involved. General symptoms include behavior, motor, and speech deficits. Intoxicated patients present clinical challenges. Signs and symptoms of cerebral injury can be masked by alcohol intoxication. These patients require a head CT scan, close monitoring, and serial neurological exams until they are sober because their history and initial physical exam will be unreliable.

Objective

A patient presenting with a head injury should receive a rapid neurological exam to rule out significant cerebral injury. This exam should include checking mental status, cranial nerves, extremity strength, deep tendon reflexes, and cerebellar function. Hypoactive reflexes may result from damage to the spinal cord.

The Glasgow Coma Scale (GCS) may also be used to rapidly evaluate the level of consciousness (see Advanced Assessment 19.2). The GCS establishes baseline data in each of three areas; eye opening, motor response, and verbal response. A numerical score is assigned according to the chart. A score of 15 represents normal neurological function; a score of 7 usually indicates an unconscious patient, and a score of 3 represents a deep coma state. With any head trauma, the GCS should be done at least every 2 hours to assess for any changes.

The clinician may note bradycardia, hypotension, somnolence, seizures, and focal deficits. With a cerebral hemorrhage, these clinical features generally develop immediately after the trauma. These symptoms develop several hours after the injury with an acute epidural hemorrhage. An acute subdural hemorrhage may occur in a day or months after the head trauma.

All patients should be monitored for signs of increased ICP (see Table 19.6). The early signs of increased ICP are headache, nausea and vomiting, amnesia, altered

Advanced Assessment 19.2 Rapid Neurological Exam

Level of Consciousness		
Glasgow Coma Scale		
Motor response	6	Follows commands
	5	Localizes pain on stimulus
	4	Withdraws from painful stimulus
	3	Shows abnormal flexion in response to pain
	2	Shows abnormal extension in response to pain
	1	No response
Verbal response	5	Oriented
	4	Confused
	3	Inappropriate words
	2	Unintelligible sounds
	1	No responses
Eye-opening	4	Spontaneous
	3	Opens eyes on verbal command
	2	Opens eyes on painful stimulus
	1	No response
Score: 15 = normal; <7 = coma.

Advanced Assessment 19.2 Rapid Neurological Exam—cont'd

Cranial Nerves		
CN I	Olfactory	Smell (not usually assessed during acute exam)
CN II	Optic	Visual acuity, gross visual fields, funduscopic exam
CN III	Oculomotor	Pupillary response, eye movement (upward and medial gaze)
CN IV	Trochlear	Eye movement (downward and medial gaze)
CN V	Trigeminal	Teeth clenching, corneal reflex
CN VI	Abducens	Eye movement (lateral)
CN VII	Facial	Frown, smile, and puff cheeks; assess symmetry
CN VIII	Acoustic	Hearing
CN IX	Glossopharyngeal	Gag reflex
CN X	Vagus	Swallowing, gag reflex
CN XI	Spinal accessory	Shrug shoulders and turn head; assess strength and symmetry
CN XII	Hypoglossal	Articulation and tongue movement
Gross Motor Strength and Symmetry		
Upper and lower extremities		Look for symmetry and strength.
Cerebellar Function		
Romberg's test		Look for stability and pronator drift.
Coordination		Finger to nose and heel to shin
Reflexes		Biceps, triceps, patellar, Achilles, Babinski

level of consciousness, changes in speech, drowsiness, agitation, restlessness, and/or loss of judgment. Any of these signs should prompt the caretaker to take the patient to the ED immediately.

Late signs of increased ICP are dilated, nonreactive pupils (from pressure on the oculomotor nerve), unresponsiveness to verbal or painful stimuli, abnormal posturing patterns (e.g., flexion, extension, or flaccidity), increased systolic blood pressure resulting in a widening pulse pressure, decreased pulse rate, and changes in respiratory rate and pattern. The last three are known as the *Cushing response or reflex.* The late signs are usually observed in patients who are hospitalized and currently being monitored.

In addition, a patient with a basilar skull fracture should be assessed for the following:

Hemotympanum—blood behind the tympanic membrane
Battle's sign—ecchymosis over the mastoid process
Raccoon sign—periorbital ecchymosis
Rhinorrhea with CSF, or ear drainage with CSF
Alterations with cranial nerve function:

- CN I, olfactory nerve—anosmia, may experience loss of smell, or hyposmia
- CN II, optic nerve blindness, field cuts
- CN III, oculomotor nerve—assess for PERL problems indicative of increased ICP, loss of eye movements, diplopia, ptosis, dilated or unreactive pupil
- CN IV, trochlear nerve—impaired downward gaze, diplopia
- CN V, facial nerve—loss of sensation, absent blink/corneal reflex, muscle atrophy
- CN VI, abducens nerve—eye fails to abduct, diplopia
- CN VII, facial nerve—if lower motor neuron affected—ipsilateral (same side) weakness of entire side of face, loss of corneal reflex. If upper motor neuron affected—contralateral (opposite side)
- Weakness of lower half of face
- Lost, delayed, or metallic taste
- CN VIII, acoustic nerve—dizziness, hearing loss

Diagnostic Reasoning

Diagnostic Tests

For mild head injuries, if the patient did not have a loss of consciousness and did not exhibit focal neurological signs or have a history of significant mechanism of injury, close monitoring by a responsible adult is appropriate.

Patients with a history of LOC, significant mechanism of injury (which includes a fall that is equal to their height), a GCS score of 14 or less, impaired alertness or memory, a palpable depressed fracture, signs of increased ICP, positive findings on a rapid neurological exam, or a documented skull fracture should have a head CT scan. A plain CT scan is indicated; CT with contrast is not indicated for minor head trauma. If a cerebral hemorrhage is found, emergent surgery is indicated.

Electroencephalography (EEG) may be helpful when a post-traumatic seizure disorder is suspected. A lumbar puncture may be done for support in diagnosing subarachnoid hemorrhage as indicated by the presence of red blood cells, elevated proteins, and a moderate reduction in glucose. A lumbar puncture is contraindicated in an intracerebral hemorrhage because it may precipitate a herniation syndrome in patients with a large hematoma. MRI can show displaced brain tissue away from the skull, a key finding with a subdural hematoma.

Differential Diagnosis

Typically, a patient with a head trauma will present following an injury, making the diagnosis obvious. However, if a closed head injury occurred and the patient is comatose, other conditions that can result in coma must be ruled out, such as drug overdose, cerebrovascular accident, diabetic ketoacidosis, neuromuscular disorders, and so on.

Management

Emergency Management

A thorough history and physical exam are necessary for any patient who presents with a head injury. Immobilization should be maintained until the patient is fully awake and CT findings are negative. It cannot be stressed enough that a head CT needs to be ordered on any head-injured patient who is on anticoagulant medication such as warfarin or clopidigrel. (See Nursing Research–Based Practice 19.1 for a study related to CT orders.)

General Management

A patient with a minor head injury may be sent home with a competent caregiver who is able to follow the instructions listed under Patient Education. Management of patients with traumatic brain injuries is presented in Table 19.7.

Patients with temporal cerebral injury can be problematic because these structures are close to the tentorium and midbrain. Progressive edema can lead to elevated ICP and herniation. It is important that the clinician repeat neurological assessments often to look for subtle changes that represent early signs of increased ICP. The earlier these signs are identified and treatment is begun, the better the prognosis for the patient.

An abstract of an article on using healing touch as a complementary therapy for traumatic injuries in general is provided in Nursing Research–Based Practice 19.2.

Follow-up and Referral

A patient with a mild head injury who is sent home with a competent caregiver may not need any follow-up unless problems develop. The patient and caregiver must be alert to signs and symptoms of increased ICP. Very small bleeds may not be revealed on the initial head CT and can bleed insidiously. Patients and family members should verbalize understanding of discharge instructions and return accordingly. (See Patient Education.)

The patient with a severe head injury will be followed by a neurosurgeon. The patient may be discharged from the hospital directly to a rehabilitation facility and will be followed by their staff.

Research has shown that the prevalence of any psychiatric illness in the first year after moderate to severe TBI approached 49%, and it approached 34% after mild TBI. Persons with a mild TBI with prior psychiatric illness had evidence of persisting psychiatric illness. Patients with any TBI should be followed closely and monitored for any affective disorders to determine the need for early postinjury psychiatric intervention.

Patient Education

The patient with a mild head injury should be with a responsible adult for the first 24 hours after injury. Decreased activity and light diet are recommended for the first 24 hours. The patient should be awakened every 2 to 4 hours during the first 24 hours. The patient should report back if he or she develops vomiting, an inability

Nursing Research–Based Practice 19.1

Brown, R, and Furyk, J. Racial disparities in health care—emergency department management of minor head injury. *Int J Emerg Med* 2(3):161–166, 2009.

International research has demonstrated disparities in the emergency department (ED) care of patients of certain racial or ethnic backgrounds. The management of minor head injuries requires a careful clinical assessment to determine the requirement of a CT scan of the head. This study used a retrospective, structured, medical record review of 270 patients presenting to an ED with minor head injury. The findings showed no statistically significant disparity based on race in the management of minor head injuries with regard to decision to perform a CT head scan. There is some evidence that indigenous patients waited longer to be seen.

Table 19.7 Traumatic Brain Injuries (TBIs)

Injury	Clinical Features	Diagnosis	Management
Concussion	Brief loss of consciousness (<5 minutes) Mild concussion—slightly longer loss of consciousness, confusion, disorientation, retrograde amnesia, recurrent dizziness, headache, dizziness, vertigo, difficulty concentrating, bradycardia, hypotension, transient neurological deficits, visual disturbances	History MRI Positron emission tomography	Close observation for 24 hours Nonnarcotic pain medications
Cerebral Contusion	Longer loss of consciousness Changes in personality, behavior, and speech deficits Intracranial pressure (ICP) elevation	History	Monitor Glasgow Coma Scale (GCS) Neurological consultant
Basilar Skull Fracture	Hemotympanism—blood behind tympanic membrane Battle's sign—ecchymosis over mastoid process Raccoon sign—periorbital ecchymosis CSF rhinorrhea Alterations in cranial nerve functioning CSF otorrhea	Cranial nerve examination Skull x-ray films CT	Monitor GCS Neurological consultant Antibiotics if infection present Rare—intracranial surgical repair Monitor intracranial pressure
Epidural Hematoma	Brief loss of consciousness → lucid moment → longer period of loss of consciousness Headache, confusion, somnolence, seizures, focal deficits, pupil abnormalities (unilateral and eventual bilateral pupil dilation and decreased reactivity to light) Hemiparesis or hemiplegia, flexion or extension posturing	CT scan	Monitor GCS Neurological consultant With a significant mass effect—immediate surgical evacuation and ligation of bleeding vessels; if not possible, burr holes to evacuate hematoma
Subdural Hematoma (SDH)	Extreme headache, neck stiffness Progressive decrease in level of consciousness, ataxia, seizures, incontinence, and eventual pupil and motor function alterations With severe SDH, GCS usually <8	MRI	Neurological consultant Monitor ICP Monitor GCS Surgical intervention

Nursing Research–Based Practice 19.2

Burr, JP. Jayne's story: Healing touch as a complementary treatment for trauma recovery. *Holistic Nurs Pract* 19(2): 211–216, 2005.

Trauma recovery is a complex process. Present research acknowledges the difficulties of trauma recovery and limited conventional treatment options. Human biofield therapies are used successfully in a variety of settings for various patient complaints. The practices of human biofield manipulation; healing touch; and its predecessor, therapeutic touch, are effective holistic therapies that treat body, mind, and spirit to improve physiological and psychological complaints, health perception, and well-being. Jayne's story illustrates the beneficial integration of healing touch as a complementary therapeutic option in recovery from motor vehicle collision trauma. Support for incorporating healing touch therapy in the recovery regimen of individuals recuperating from trauma is suggested.

to move his or her arms or legs equally well, a temperature of 100°F (37.7°C), a stiff neck, pupils of unequal size or shape, convulsions, severe headache that does not go away with acetaminophen or ibuprofen, confusion, disorientation, or a change in personality or behavior. These signs and symptoms are indicative of increased ICP and demand immediate attention in the ED.

MUSCULOSKELETAL TRAUMA

Musculoskeletal trauma refers to injuries involving the musculoskeletal system. These injuries may present as minor innocuous wounds or with obvious deformities. The clinician needs to resist the urge to treat the obvious deformity or fracture and neglect looking for the occult injury. Musculoskeletal sequelae can be associated with or caused by problems in other systems—neurological, endocrine, nutritional, or psychological. A thorough history and physical examination are required to rule out other bodily system involvement. This section discusses the musculoskeletal trauma of sprains, strains, and fractures.

Epidemiology and Causes

Musculoskeletal injuries are one of the most common injuries seen in the office and emergency/urgent care setting. Patients of all ages are susceptible to injury. The annual cost of caring for people with musculoskeletal system injuries is in the billions of dollars. The loss of productivity to industry is staggering. Musculoskeletal disorders as a frequent cause of work disability account for productivity losses equivalent to 1.3% of the gross national product. There is an increase in the incidence of injuries among the younger population that can be attributed to a higher participation in sports and riskier recreational activities such as in-line skating (rollerblading) and skiing.

Fitness classes and field sports are the most common culprits associated with musculoskeletal injuries in the younger population. Racket sports, walking, and low-intensity sports are associated with injuries in older adults. Usually the lower extremities are involved, especially the knees and ankles. Older patients tend to have more overuse injuries, such as metatarsalgia, plantar fasciitis, and meniscal knee injuries. Younger patients tend to have more patellofemoral syndromes and stress fractures.

Knees and ankles are the most common sites injured in high school athletes. Sprains and strains are by far the most common type of injuries.

Occupational strains occur more often in the morning hours and in the first 4 hours of the work shift. Days earlier in the week, especially Monday, have a higher incidence of injury. Married workers aged 30 to 50 years are injured more frequently than other individuals. The occupations associated with a higher than average risk include nurses and truck drivers.

Americans have a fracture rate of approximately 21.1/1,000 per year (23.5 per year per 1,000 males and 18.8 per year per 1,000 females), which is very similar to the rate in other industrialized countries. Males aged 15 to 49 years are almost three times more likely to sustain a fracture than females of the same age. There are three main peaks of fractures distribution—first among young adult males, second among older adults (affecting elderly men and women equally), and last, an increase in fractures, especially of the wrist, in women older than age 40 years.

Pathophysiology

Sprains and Strains

A *strain* involves microscopic and macroscopic tears or stretching of muscle fibers. These injuries require more than just muscle contraction to occur; excessive stretching or stretching while the muscle is being activated is required. The injury usually occurs within the muscle's normal range of motion. The portion of the muscle that is typically injured is at the muscle–tendon junction. Research has shown that muscles that cross multiple joints or have a complex architecture are more susceptible to strains. Muscles most frequently injured include the hamstring, rectus femoris, gastrocnemius, and adductor longus muscles. A severe strain to the rectus femoris, hamstring, or abdominal wall muscles has been shown to have a poor prognosis for rehabilitation and may benefit from surgical repair.

A *sprain* is caused by stretching or twisting beyond the normal range of motion of a joint or musculo–ligamentous unit. A sprain can be impossible to differentiate from a strain during the physical exam. Injuries involving joints are usually sprains because ligaments are more prominent around joint capsules. A history of overuse and/or excessive force, as opposed to a fall, hyperextension, or twisting of a joint, is more likely related to a strain. If bony tenderness at the injury site is found during the physical exam, x-ray films are required to rule out fractures. A high suspicion of fracture is required, especially in the young and in older adults. The young are not able to provide an accurate history and full cooperation during the physical exam. Many minor fractures (such as a torus fracture) are missed because the child does not complain and the parents or guardians are not aware of an injury. Older adults can have blunted pain sensation, especially to the extremities, related to neuropathies. The clinician should be aware of this and should be very astute when considering x-ray studies on these populations.

Fractures

A *fracture* is a break in the continuity of a bone; a fracture is usually associated with a blunt force. Fractures are classified as *open* or *closed,* depending on whether they communicate with the atmosphere. Open fractures have an increased incidence of infection and must be aggressively treated. Many need to be surgically irrigated.

Fractures can also be partial or complete. A *partial fracture* involves disruption of only a portion of the cortex, whereas a *complete fracture* involves circumferential disruption in the cortex. Complete fractures are unstable; inappropriate initial stabilization can lead to additional injuries to the muscles or neurovascular structures.

When assessing the patient, the clinician should ask about the mechanism of injury. Fractures can occur at locations other than the obvious site of injury. The force can be transmitted to other areas of the body, causing fractures. A person who fell off a roof and landed on his or her feet may have an obvious calcaneus (heel bone) fracture, but fractures of the hips, pelvis, and back must also be ruled out.

The goal of fracture management is to align the bones in a near-normal plane in order to allow the fragmented ends to heal together and return to normal function. The initial phase of healing starts with hematoma formation. This bridges the fractured fragments. The inflammatory phase follows, and granulation tissue is formed on the fracture surfaces. During this process, the hematoma is reabsorbed, which provides the first continuity between the fragments. This takes place approximately 10 to 14 days after injury. During this time, the bone surrounding the fracture line becomes less dense. This makes the fracture line easier to identify. Callus is then formed on both the periosteal and endosteal surfaces of the bone; the callus acts as a biological splint. The calcification of the bone then begins: First, calcium phosphate is deposited, and then the bone undergoes osseous metaplasia. It takes approximately 2 to 3 weeks for the callus to be visible on x-ray film. The callus is then slowly reabsorbed, and the fracture surfaces develop a firm bony union. During this phase, the calcified region undergoes organization, and the peripheral margins begin to smoothen. The process ends with remodeling, then consolidation.

In a healthy adult, the whole process takes approximately 2 months for smaller long bones (such as the humerus) and up to 4 months for large bones (such as the femur). Oblique fractures typically heal more quickly than transverse ones. Children tend to heal more quickly, and older patients more slowly.

Radiologic (x-ray) evidence of abundant callus formation at the fracture site that is organized, and bone ends that have remained stable on serial films, means the fracture should be stable enough to remove the cast. Limited activity is recommended until full strength is returned.

Clinical Presentation

Subjective

The signs of any musculoskeletal injury involve one or more of the following: pain, swelling, deformity, disability, abnormal motion, and tenderness. The history and mechanism of injury will help guide the physical exam. It will help to focus on obvious and occult areas of injury. Documentation of the mechanism in the history is important. It is imperative that occult injuries are identified.

Objective

The importance of performing a thorough and complete physical exam cannot be emphasized enough. Life-threatening injuries must be identified quickly. This is facilitated by completing a quick primary survey, which can be accomplished in 90 seconds by an experienced practitioner. Following the primary survey, the more complete and thorough secondary survey can be performed. This is when fractures should be identified.

Diagnostic Reasoning

Diagnostic Tests

It is imperative that suspected sites of musculoskeletal trauma be radiographed to rule out fractures. Radiographic (x-ray) studies are the mainstay of orthopedic care. It is important that the clinician order the correct x-ray exam for the injury suspected. There are evidence-based guidelines to help clinicians choose the most appropriate imaging exam for patients' clinical conditions. The latest version of the American College of Radiology (ACR) Appropriateness Criteria is located at www.acr.org/Quality-Safety/Appropriateness-Criteria. Many x-ray studies will include views of several joints and bones. The clinician must resist ruling out fractures in regions other than the area the specific x-ray exam ordered is intended to reveal. Each x-ray study has a specific technique that ensures that the correct angles, bony structures, and other information are included to allow the practitioner to rule out pathology to that specific region. If a patient has pain in the foot and the ankle, an ankle x-ray film will miss foot pathology, and a foot x-ray film will miss ankle pathology. Advanced Assessment 19.3 presents tips on reading an extremity x-ray film.

Many providers will order routine comparison views of the uninjured extremity, especially in children with open growth plates. This may be helpful on rare occasions. Unfortunately, many x-ray technicians have this as "standing orders" from their facility. This practice should not be condoned, because it exposes a growing child to unnecessary radiation when a thorough exam usually pinpoints the location of the injury. When examining an infant or a child who will not move or bear weight on an extremity, the clinician should palpate the entire extremity while observing the patient's facial expressions. Once the injury is palpated, the patient's face will reveal discomfort, which will assist the clinician in localizing the injured site.

Differential Diagnosis

The goal of differential diagnosis in musculoskeletal trauma is to distinguish more serious bony fractures from strains and sprains, because these injuries are

Advanced Assessment 19.3 Reading an Extremity X-Ray Film

- Conduct a thorough history and determine the mechanism of injury. This will help to determine the location and type of injury to expect. The area of injury should be examined. These procedures will focus your attention to the area of suspicion on the film. Always review the x-ray film after the exam, even if you viewed it before examining the patient.
- Using a well-lighted viewing box, follow the cortex of the injured area, looking for any defects. The cortex should be smooth and crisp; any area of haziness or any defect needs to be scrutinized using a bright (hot) light.
- Look at the soft tissue surrounding the area of concern. Injuries will cause soft tissue swelling. This may help focus your attention on the injured area. Scrutinize this region with a bright (hot) light.
- Several regions of the body, especially joints, have certain signs to look for that may reflect an occult injury. Confer with the collaborating physician or refer the patient to an orthopedic physician.

treated differently. As joint swelling and tenderness is a common presentation of such injuries, it is also critical to consider a variety of rheumatological and infectious disorders, such as a septic joint, rheumatoid arthritis, or osteoarthritis. An appropriate history that seeks to characterize any preceding musculoskeletal trauma typically readily differentiates these conditions. However, if suspected, basic laboratory tests such as a CBC may also be helpful.

The differential diagnosis for fractures also includes *reflex sympathetic dystrophy.* Also known as Sudeck atrophy and causalgia, this is a post-traumatic syndrome with three clinical stages—*early, dystrophic,* and *atrophic.* Early in the condition, a constant aching or burning occurs in the affected limb. Motion or external stimulation increases the symptoms, usually out of proportion to the original injury. The dystrophic stage follows in which the skin of the affected extremity becomes glossy and cold and range of motion is limited. Finally, the atrophic stage is marked by skin atrophy and contracture. No correlation exists between incidence or symptom severity and the extent or type of the original musculoskeletal injury. Thus, early diagnosis of this syndrome is difficult, especially after an apparently trivial injury. Early diagnosis is extremely important, however, because the earlier treatment is initiated, the better the response. Treatment is aimed toward restoration of function through physical therapy. Antidepressant therapy may be beneficial, as may prednisone.

Management

Emergency Management

Emergency management of the patient with musculoskeletal trauma initially consists of RICE therapy discussed below. If the patient can be seen immediately in the primary-care office with radiographic capabilities, the patient may choose to see the clinician. If not, the patient should go directly to the ED.

General Management: Sprains and Strains

After appropriate stabilization and 2 to 3 days of rest and elevation, the injury site can be examined more easily. The pain and swelling typically will be reduced, which will facilitate a better physical exam. Injuries that had negative x-ray studies initially but were extremely painful or were suspicious for fracture can be reradiographed in 10 to 12 days. Because of the healing process, the fracture line can be more easily visualized at that time.

RICE Therapy Rest, ice, compression, and elevation (RICE) are the mainstay of all musculoskeletal injury treatment. The amount of rest needed depends on the severity of the injury.

Rest means no use of the affected limb or joint, for minor injuries or sprains for 1 to 2 days, then slow progression as tolerated by the patient. If the activity being performed causes pain to the injury site, the level of activity needs to be reduced to levels that do not cause pain. Mild discomfort after activity is considered normal during the rehabilitation phase.

Ice, a potent anti-inflammatory, should be applied 30 minutes on and 30 minutes off, three to five times per day, to the injury site. Ice is also recommended during the rehabilitation phase if mild pain after activity is experienced. Ice therapy for 24 to 48 hours after the injury is recommended. After that period, warm, moist heat to the region is advocated to increase the circulation to the area, which promotes reabsorption of blood and edema that has collected at the injury site.

Compression by elastic wrap or other splinting material is used to provide counterpressure at the site of injury to help tamponade bleeding to the region. This will help decrease the amount of swelling and blood at the injury site. The influx of blood causes localized inflammation, which leads to leaking of plasma and other substances into the area. Instruct the person applying the compression wrap to always include the distal extremity—the foot or hand—to prevent a tourniquet effect.

Elevating the affected limb above the level of the heart will decrease bleeding into the tissue surrounding the injury and help to reduce the pain. After the first 48 hours, when bleeding into the area has stopped, elevation will facilitate reabsorption of blood and fluids at the injury site.

Pain Management The use of an NSAID for pain management is also recommended in conjunction with RICE therapy. Muscle relaxants such as cyclobenzaprine

(Flexeril) may be indicated for the management of acute painful musculoskeletal conditions associated with muscle spasm. They reduce tonic somatic muscle activity at the level of the brainstem.

General Management: Fractures

Initial fracture care involves stabilization of the bone ends to avoid further injury or damage to neurovascular structures. During the secondary survey, when possible fractures are identified, immediate temporary splinting should be instituted. Severely angulated long bone fractures should be straightened before they are splinted. Splints should be applied in such a way as to immobilize the joints above and below the fracture site to avoid motion of the bone ends involved. Commercially available metal and plastic splints are used for this purpose.

After the radiograph and confirmation of a fracture, a more permanent splint should be applied. During immobilization, the clinician must consider the fact that fracture sites will continue to swell in the first 24 to 48 hours. Placing a rigid circumferential cast on the patient in the first 24 to 48 hours can lead to vascular compromise and compartment syndrome. To avoid this, the patient should be placed in a plaster splint. A plaster splint is placed on only half of the splinted limb and can be adjusted or molded to allow optimal stabilization of certain fractures. The skin should be padded to avoid local necrosis, and the splint should be secured by an elastic bandage. This type of splint allows the extremity to swell without affecting distal circulation.

Even with good technique, some fractures are not visible initially and will not appear until 7 to 10 days after the injury. At that time, the margins of the fracture absorb and will widen the radiolucent line at the fracture site. New bone will also be produced beneath the periosteum at the margins of the fracture, which will accentuate the fracture line. This will allow fractures that were not identified initially to be visualized. If a fracture is suspected but not visible at the initial visit, the injury should be treated as a fracture and reexamined clinically and radiographically in 7 to 10 days. The patient should be informed of the rationale for this treatment. Always add this to the discharge instructions in writing and have the patient sign his or her understanding.

Follow-up and Referral

The patient should be reexamined by an orthopedic surgeon in 3 to 4 days after application of a cast or splint to evaluate his or her neuromuscular status. In addition, the patient should be instructed to report any of the following signs and symptoms, which may reflect compartment syndrome—intense pain, hypoesthesia (a dulled sensitivity to touch), paresthesia (numbness, prickling, or tickling), muscular weakness, or paralysis. The patient with these signs should be referred to an orthopedic surgeon immediately. In 6 weeks to 2 months, a follow-up with the orthopedic surgeon and an x-ray film will determine whether bone consolidation has occurred and if the cast can be removed.

Patient Education

Any site of a previous bony fracture will be weakened no matter how long after healing, and this site will always be more prone to a second fracture. Patients should always take this into account when deciding on what type of exercise or musculoskeletal activity to engage in.

In the future, it may be possible to predict which patients are at higher risk for fractures. Single bone mineral density measurement may be able to predict the risk of fragility fractures (distal radius, proximal humerus, hip, and vertebra) in women. This would help identify populations who would benefit from teaching and prevention strategies.

To avoid musculoskeletal injury, good physical conditioning is important. Consistent activity and exercise will strengthen muscles and reduce the chance of injury. See Chapter 15 for patient education about ways to prevent musculoskeletal injuries.

LOWER BACK PAIN

Up to 80% of the population experiences lower back pain at some time in their lives. A common problem in the workplace due to muscular or ligamentous strain, lower back pain accounts for one of the most frequent causes of days lost from work. Only about 15% of patients have a specific injury.

Pathophysiology

Lumbar spinal nerve impingement is a common cause of lower back pain. Disk herniation produces the deficits predictable for the site involved as listed in Table 19.8.

Clinical Presentation

Subjective

If no accident or trauma is involved, the patient will usually complain of a time-sequence history of symptoms which may be gradual or sudden and may be localized in the lumbosacral area or radiating. If a disc syndrome is present, the patient may complain of radiation into the leg, sensory changes, motor weakness, or difficulties with bowel or bladder function.

Objective

The clinician should perform a neurological examination of the lower extremities that will detect the small deficits produced by disc disease and the large deficits produced by such problems as cauda equina tumors. Performing a straight-leg-raising test may indicate nerve root irritation if radicular pain is produced when the leg is raised 60 degrees or less.

The disc herniation and radiculopathy of lumbar spinal nerves L4 to L5 and L5 to S1 are particularly

Table 19.8 Lumbar Spinal Nerve Impingement/Herniated Disc Signs

Spinal Nerve Affected	Dermatome; Sensory Deficit	Myotome; Weakness Shown	Reflex Affected
L4	Anterior thigh, medial shin	Quadriceps; knee extension weak	Patellar
L5	Great toe, dorsum of foot	Anterior tibial and extensor hallucis; dorsiflexion of great toe (walking on heels)	
S1	Lateral border of foot, small toe	Gastrocnemius; plantar flexion of foot (walking on toes)	Achilles

Any L4–S1 root irritation can cause "sciatica": pain from buttock down lateral leg; + straight leg raising sign; if patient develops acute bladder, bowel problems, bilateral leg involvement = medical emergency.

Source: Teri Capriotti, DO, MSN, CRNP.

common sources of acute back pain often due to trauma. L4 to L5 and L5 to S1 radiculopathy ("sciatica") may be objectively assessed in terms of dermatome sensory deficit, myotome muscle weakness, and deep tendon reflex deficits as depicted in Table 19.8. The clinician should assess for the inability to walk on toes, inability to walk on heels, and the inability to dorsiflex the great toe, which may relate to specific lumbar spinal nerve involvement.

Classic lower back pain that is less serious involves pain in the lower back with or without pain radiating down one leg.

Diagnostic Reasoning

Diagnostic Tests

In the majority of cases, a precise diagnosis cannot be made. Usually the initial history and physical examination will lead to the diagnosis. The challenge is to identify patients who require more extensive or urgent evaluation. Diagnosis is usually not confirmed by palpation of the spine. Lumbar x-ray films are usually not indicated for patients with acute low back pain unless there is evidence of a possible fracture or a possible tumor or infection. Magnetic resonance imaging (MRI) is reserved for patients who are surgical candidates or who have evidence of systemic disease.

Differential Diagnosis

The differential diagnoses for lower back pain include muscular strain; primary spine disease such as disc herniation or degenerative arthritis; systemic disease, such as metastatic cancer; and regional diseases, such as aortic aneurysm. Patients with systemic disease such as vertebral osteomyelitis typically have a history of smoking, weight loss, age older than 50 years, diabetes mellitus, a history of recurrent urinary tract infections, and cancer. The clinician should be aware of a potential spinal abscess, which is very rare; however, any patient presenting with low back pain, radiculopathy, and fever should have an MRI immediately, because pressure on the spinal cord may be causing irreversible damage. Low back pain at night, unrelieved by rest of lying supine, may suggest a malignancy, either vertebral body metastasis, multiple myeloma, or a cauda equina syndrome, which is a serious complication of herniated disk and needs emergency medical treatment. Cauda equina syndrome, multiple lumbar nerve root compressions, is a medical emergency; the patient would present with leg weakness or saddle area anesthesia, bowel or bladder incontinence, or impotence.

Low back pain that worsens with rest and seems to improve with activity is usually caused by ankylosing spondylitis or other seronegative spondyloarthropathies, especially with an insidious onset after age 40.

Patients with penetrating peptic ulcer disease may present with back pain, and this should be ruled out as a diagnosis. Patients with endocarditis may present with a cardiac murmur in addition to back pain, and this should be further evaluated. In addition, referred back pain may be a result of renal stones.

Management

The majority of patients with lower back pain will improve in 1 to 4 weeks. Conservative therapy is indicated if all the differential diagnoses are ruled out. Treatment consists of NSAIDs, unless severe pain requires opioids or muscle relaxants, for 1 to 2 weeks. NSAIDs have proven to be as effective as opioids and muscle relaxants, and the latter should be avoided if at all possible. The adage of "let pain be your guide" refers to keeping the patient mobile and ideally staying at work. Patients should not stay in bed for longer than 2 days, unless the pain is due to sciatica, which may require a week in bed. A program of exercise should be developed that allows the patient to return to a normal regimen as soon as possible.

Some patients benefit from heat therapy and some from ice therapy. It is individualistic. When heat is preferred, moist heat for 20 to 30 minutes at least four times per day may be effective. When cold therapy is preferred, ice over the affected area for 10 to 15 minutes every 1 to

2 hours may be effective. Some patients prefer heat alternated with ice.

Intensive rehabilitation for chronic back pain is more cost-effective and results in a reduction of disability and fewer complications than surgery, although research shows that it is slightly less effective than spinal fusion surgery.

Follow-up and Referral

If patients cannot be managed by a general clinician, a specialist may be needed depending on the radiographic or MRI results. Physical therapy may be ordered by the general clinician or by a specialist. Patients should be followed up in 1 week to verify that the injury was in fact lower back pain and not more serious.

Patient Education

All patients should be taught good body mechanics. These include the following:

- Ask for help if the weight is too great to lift by oneself.
- Keep the back straight; lift with the legs.
- Push rather than pull objects.
- Do not twist sideways; face the object to be lifted.
- Use a footstool to lessen back strain.
- Do not sit or stand for prolonged periods of time; move or stretch at least every 30 minutes.
- Sleep on a firm mattress, and sit in a supportive chair.
- Maintain good posture.
- Wear flat, supportive shoes.

An exercise program should be developed to strengthen the back, relieve pressure on compressed nerves, and help protect the patient's back from reinjury. Although most exercises should not be attempted until the episode of acute back pain is resolved, therapeutic exercises may relieve pain.

FOREIGN BODY OBSTRUCTIONS

This section discusses ear, nose, throat, vaginal, and rectal foreign body obstructions. Common foreign body obstructions and their treatment are discussed in Table 19.9.

Epidemiology and Causes

Foreign body obstructions are common problems seen in the primary-care setting. Most of these problems involve children. Foreign body obstructions most commonly result from the patient inserting a foreign body into a body orifice.

Pathophysiology

The pathophysiology of a foreign body obstruction depends on which orifice is obstructed. Otic (ear canal) occlusion may contribute to otitis externa or otitis media, especially if the tympanic membrane is ruptured. Nasal occlusion may predispose to rhinitis, sinusitis, or epistaxis (nosebleed). Moreover, nasal, pharyngeal, tracheal, or even esophageal occlusion may all result in varying degrees of respiratory compromise if the respiratory tract is at all obstructed either internally or via external compression on the airway.

Table 19.9 Common Foreign Body Obstructions

Ears

Foreign bodies in the auditory canal are common problems, especially in children. Foreign bodies can be vegetative, inanimate, or animate objects. Foreign bodies in the ear are usually asymptomatic unless they are left in the ear for a prolonged period of time and an infection develops. The clinician should obtain a complete history to elicit whether there is a possibility of multiple foreign bodies. The practitioner should assess both ears to obtain a comparison view. It is important to try to ensure that there is no perforation of the tympanic membrane before trying to remove the foreign body.

Children can have a foreign body in the ear for such a long period that cerumen will eventually mask the foreign body. The clinician will need to have clear views of the tympanic membrane in any child with repeat otitis media symptoms to rule out foreign body.

A live insect trapped in the ear canal usually causes great distress. The patient will present with agitation, nausea, and tearing. The initial therapy is to immobilize the insect. This can be done by placing 2% lidocaine in the external ear canal, which will terminate the movement of the insect. The insect can then be removed.

Removal of inanimate objects is not always straightforward. If the patient is uncooperative or the foreign body is difficult to grasp, ear, nose, and throat (ENT) consultation is suggested. If the object becomes lodged too deeply, it will be difficult to remove, and the patient may need general anesthesia for successful removal. If the object is small, irrigation is an option.

If the object is appropriately shaped and accessible, alligator or bayonet forceps may be used to grasp and remove it. Suctioning may also assist in the removal of an object. A Yankauer suction catheter has a small orifice and a firm catheter tip that may facilitate foreign body removal.

After successful removal of the object, the ear canal needs to be checked for infections, superficial scratches, and tympanic-membrane perforation. If there is no evidence of infection, the patient may be discharged home. If an infection is present, it should be treated as an otitis.

Continued

Table 19.9 Common Foreign Body Obstructions—cont'd

Nose

Nasal foreign bodies are most commonly seen in children. They are usually discovered after purulent discharge is noticed. The history is important, but children are usually reluctant to admit to what or how much they have placed in their nose.

The diagnosis is made by direct visualization. If the patient or child is uncooperative, a restraining device or sedation may be needed. If the patient is cooperative, the following steps may be used to remove the foreign body:

- Help the patient to blow his or her nose to see if the foreign object will come out.
- If the mucosa appear swollen, soak a pledget in Neo-Synephrine and insert it into the nare; care should be taken not to push the foreign body further into the nose.
- Using a nasal speculum and alligator or bayonet forceps, visualize the foreign body and gently remove it. Other methods include using an ear curette, single skin hook, or right-angle ear hook. Another method that has been used is to pass a small urinary catheter superior to (beyond) the object, inflate the balloon, and pull the object out.

All of these methods can be successful if the patient is cooperative. Care must be taken not to push the foreign body down the back of the patient's throat, where it may be aspirated into the trachea.

After successfully removing the object, the clinician should inspect the nares for other foreign bodies. No further treatment is necessary.

If removal is unsuccessful, referral to an ENT specialist may be necessary.

Throat

Swallowed objects are commonly seen by the primary-care provider. Usually, they are not life-threatening, but any object that becomes lodged in a position where it can obstruct the airway is a true emergency. Although most swallowed objects will pass spontaneously, up to 10%–20% require some type of intervention. There are several physiological narrow spaces in the esophageal-gastrointestinal tract that may restrict movement of objects. In the pediatric population, the cricopharyngeal area is the most common site for obstruction, followed by (in order of frequency) the thoracic inlet, aortic arch, tracheal bifurcation, and hiatal narrowing. The majority of obstructions in adults occur at the distal end of the esophagus. Usually once the object has passed through the pylorus, it will pass through the rest of the GI tract without problems. If the object has sharp edges, however, it can injure the intestines and/or become lodged anywhere in the GI tract. Ingested foreign bodies can also cause airway obstruction or perforation.

If the object becomes lodged in the esophagus, the adult patient may present with the feeling of something in the throat, pain, and the inability to swallow secretions. Pediatric patients may present with vomiting, gagging, choking, stridor, inability to swallow, increased salivation, and a sensation of a foreign body in the chest.

If there is a possible foreign body ingestion, a chest x-ray study should be ordered to see if the object is lodged in the esophagus. Foreign bodies will show up only if they are radiopaque. If the object is in the stomach, the patient should be monitored for passage of the object through the GI tract. The stool will need to be examined. If the object is not found, an abdominal flat-plate x-ray film can be used to determine the location of the object. Objects that fail to be expelled may have to be removed by invasive procedures such as colonoscopy or surgery.

A food bolus is usually the cause of ingested foreign bodies in the adult population. Typically, inadequately chewed meat is the main culprit. If the patient is unable to swallow saliva secretions, a chest x-ray film should be obtained. Glucagon, a smooth-muscle relaxant, may be administered intravenously to relax the esophagus. A 1-mg dose is given IV; the dose may be repeated after 20 minutes if the object has not passed. The patient will usually vomit, which causes the foreign body to be expelled; it is important to ensure that the patient does not aspirate the vomitus. If glucagon has not produced a successful effect, a GI consultation should be obtained. Some references recommend a barium swallow to visualize where the obstruction is located; however, most GI specialists prefer that no barium be given because it can obstruct their view of the bolus during endoscopy.

If a coin becomes lodged in the esophagus, it should be removed by endoscopy. Two other methods that may be tried include passing an indwelling urinary catheter behind the object, inflating it, and pulling the object out. Objects that become lodged in the esophagus can be safely pushed into the stomach by a small urinary catheter.

Ingestion of button batteries is a true emergency situation. The batteries can cause burns to the GI mucosa and must be removed quickly.

The treatment for ingestion of a sharp object is controversial. Most practitioners recommend that sharp objects be removed so that they do not cause a perforation before they pass into the intestine.

Vagina

Vaginal foreign bodies can be the result of children exploring their sexuality or an incident of child abuse; in adults, the foreign body may be a forgotten tampon or diaphragm. The only treatment necessary is removal of the foreign body. Most of the discharge and odor will disappear after the foreign body is removed. If the foreign body is lodged in the side

Table 19.9 Common Foreign Body Obstructions—cont'd

wall of the vagina, the clinician should irrigate the area with normal saline to gently remove the object from the wall. If a foreign body is suspected in a small child, general anesthesia for exploration should be considered if the object is not visible and cannot be removed by gently pulling on the labia. Emotional support and reassurance is important to patients. Privacy must be maintained to avoid undue embarrassment.

Rectum

A variety of objects have been inserted into the rectum. They are usually found in the rectal ampulla and are usually palpable with digital examination. All patients presenting with the chief complaint of foreign body in the rectum need x-ray exams of the abdomen to show the position, shape, and number of foreign bodies in the rectum. The x-ray film will also show if free air is present in the abdomen. This is indicative of a perforation of the bowel, which is the most serious potential complication.

Removal of the foreign body from the rectum requires that the rectal sphincter be relaxed. If a brief attempt at removing the foreign body is unsuccessful, the practitioner should consider conscious sedation to relax the sphincter muscle. Conscious sedation requires close monitoring and is best carried out in an inpatient or emergency setting. If there is any possibility of perforation, an emergency GI consultation is needed.

A vaginal occlusion, if unattended, can lead to toxic shock syndrome (mediated by infection with *Staphylococcus aureus* or *Streptococcus pyogenes*) or pelvic inflammatory disease. A bowel obstruction may result from a foreign body occluding the rectum if the object inserted is high enough. Obviously, early diagnosis and intervention will best protect against adverse effects from prolonged obstruction.

Clinical Presentation

Subjective

The patient will present with a complaint of a foreign body, with signs and symptoms specific to the bodily orifice involved. However, if the individual is unaware of the presence of a foreign body, such as in the case of a forgotten tampon left in place, the patient may complain of a foul-smelling vaginal discharge. Alternatively, a nasal or otic occlusion may lead to a feeling of head fullness or headache. Of note, many of these affected patients are children who may or may not be able to fully express their discomfort or pain verbally.

Objective

Based on the patient's complaint and the orifice involved, the signs will vary. A rectal occlusion may cause abdominal cramping, an increase in bowel sounds, and abdominal distention. A vaginal occlusion may result in a foul-smelling vaginal discharge. An insect or piece of cotton caught in the ear may cause equilibrium problems, dizziness, tinnitus, and diminished hearing on the affected side. A foreign body in the nose of an adult is rare.

Diagnostic Reasoning

Diagnostic Tests

Diagnostic tests are usually not indicated, but radiological studies may be appropriate if physical examination is insufficient to fully characterize the obstructing organism. However, because the majority of foreign bodies are not radiopaque, x-ray findings may be quite subtle, requiring formal interpretation by a radiologist. In some cases, direct endoscopy of the nasopharyngeal, respiratory, or gastrointestinal tracts may be required to identify the obstructing object.

Differential Diagnosis

The diagnosis is usually obvious because of the patient's complaint.

Management

Emergency Management

The clinician may attempt to remove the foreign body in the office. If the attempt is unsuccessful, the patient should be sent to the ED.

General Management

See Table 19.9 for general management of ear, nose, throat, vaginal, and rectal foreign body obstructions.

Follow-up and Referral

Follow-up is usually not indicated once the foreign body is removed. The patient should be alerted to signs and symptoms of an infection should one occur after discharge. If a rectal perforation has occurred as a result of a foreign body, an emergency gastroenterology referral is indicated.

Patient Education

Because children are usually involved in foreign body incidents, prevention is essential. Parents should be encouraged to buy age-appropriate toys and to keep small objects out of the reach of children. Also, children should be taught not to put objects in the various orifices of their bodies.

DISASTER PLANNING AND THE JOINT COMMISSION'S STANDARDS

Disaster preparedness has always been a foremost concern for the medical community; however, recent events including natural disasters and acts of terrorism have triggered increased concern. Whether in cities or rural settings, communities rely on the local hospital to be organized and equipped to meet their needs. Unfortunately, some community hospitals are insufficiently staffed in times of need (Level I; The Joint Commission, 2006).

Communications between the ED and other agencies, for example, can be a formidable challenge to effective disaster management. Coordination between departments, agencies, and organizations should focus on exchanging current information, working together for a common cause, and maintaining a clear flow of information. In addition, relief assistance may not arrive for several days, employees may not be willing or able to get to the hospital, and communication disruptions with outside agencies are possible. Recent catastrophes have put hospitals on notice to develop standards; disaster research must be retrospective and applied to reduce future disaster-related morbidity and mortality.

The Joint Commission has required disaster planning for more than 30 years. According to The Joint Commission, disaster planning for hospitals must include critical standards for effectiveness, standards based on lessons learned, and realistic strategies. Each hospital should have these guidelines in the ED, as well as a current reference text on disaster preparedness and management. An emergency planning guide is available online from The Joint Commission (2006), and the World Health Organization also has a Hospital Emergency Response checklist.

Caring-Based Nursing: The Practice

All segments of our profession need to work together toward a common goal, a future in which legal and professional regulation and education of nurses at the graduate level are aligned so that one educational product, the advanced practice nurse, is prepared to fill a variety of roles in the health care system. —Linda R. Cronenwett: Molding the future of advanced practice nursing. Nursing Outlook *43:112–118, 1995.*

Palliative Care

Chapter 20

DEATH AND DYING IN AMERICA

At present, in the United States, the total number of deaths from all causes is more than 2.5 million per year. The leading causes of death in the United States continue to be heart disease and cancer, accounting for nearly 50% of overall deaths, followed by stroke and respiratory disease (Centers for Disease Control and Prevention, 2010).

In 1900, the average life expectancy in the United States was about 50 years; by 2011, this had increased to approximately 78.7 years according to the Organization for Economic Cooperation and Development (OECD), slightly lower than the OECD worldwide average of 80.1. Use of antimicrobials, improved sanitation, and technological advances have all significantly increased life expectancy for the average American. Cancer has long been known to be a disease of aging. Changes in demographics occurring in the United States will increase the number of cancer cases and cancer deaths for the population aged 65 and older. Currently, 60% of all cancers and 70% of deaths from malignant tumors occur in this age-group. Thus, there will be a substantial increase in the numbers and proportions of Americans in this age-group, who are at highest risk and most vulnerable to cancer.

Significantly, however, although cancer accounted for the largest number of hospice admissions when hospice care in the United States was first established in the 1970s, today, cancer diagnoses account for less than half of all hospice admissions (36.9%). Along with an increased lifespan has come oftentimes many years of slow death from chronic, progressive diseases. According to the National Hospice and Palliative Care Organization (NHPCO, 2013), the top four noncancer primary diagnoses for patients admitted to hospice in 2012 were debility unspecified (14.2%), dementia (12.8%), heart disease (11.2%), and lung disease (8.2%).

Where Death and Dying Occur

Discussions of where people die shed little light on how they die, how physical symptoms are managed, how psychological and spiritual issues are addressed, the level of training and education the staff has in end-of-life care management, and how suffering is relieved. The site where death occurs is influenced by many factors including age, marital status, family support, finances, reimbursement issues, cultural beliefs, and cause of death.

Until the 20th century, most people died at home, cared for by family and close friends. Over the past century, death has become institutionalized, with a shift from the home to the hospital or health-care institution. Statistics for 2011 regarding deaths in the United States reveal that about 25% of deaths occurred at home, about 25% in a nursing facility, and about 50% in a hospital—15% in the emergency department and 35% in acute care. The National Hospice and Palliative Care Organization (NHPCO, 2013) estimated that more than 44.6% of all deaths in the United States involved patients who are receiving hospice care, a distinct increase. However, often these patients are receiving hospice care for just a few days before they die. Additionally, people continue to be hospitalized more frequently in the last 3 months of life and often spend time in an intensive care unit, subject to technological and life-saving measures, and spend a disproportionate amount of healthcare dollars (Institute of Medicine [IOM], 2014).

Hospice Care

Barriers to utilization of hospice care include the following:

- Difficulties in estimating prognosis
- Criterion that the patient have a life expectancy of 6 months or less
- Primary management at home with intermittent respite of care available for symptom control
- Need for a caregiver in the home
- Patient and family fear
- Communication problems
- Lack of knowledge and access to services
- Problems with funding mechanisms of insurers

Prognosticating a life expectancy of 6 months or less in non–cancer-related diseases has been especially difficult.

Medicare hospice eligibility criteria are that (1) the patient be eligible for Medicare Part A (Hospital Insurance); (2) the patient's doctor and the hospice medical director certify that the patient is terminally ill and has 6 months or less to live if the illness runs its normal course, (3) the patient must give informed consent to the hospice care; and (4) the patient receive care from a

Medicare-approved hospice program (U.S. Department of Health and Human Services, 2008).

A new program from the Centers for Medicare and Medicaid Services may change this. Until now, to receive hospice care, patients had to agree to forego any further attempts at curative treatment. The new Medicare Choices Model will soon offer an option for Medicare beneficiaries to receive hospice care services while still receiving treatment for curative care.

A PARADIGM SHIFT TO PALLIATIVE CARE

Hospice and *palliative care* are terms that are often used interchangeably. Both provide supportive medical, social, emotional, and spiritual services to patients and their caregivers. Both services rely on the combined knowledge and skill of interdisciplinary teams of professionals. Hospice care provides care to patients at the end of life. Palliative care provides comfort care and a support system to both the family and patient, integrating the psychological and spiritual aspects of patient care, throughout the trajectory of illness, from the time of diagnosis until death, and encompasses end-of-life care. This includes offering help to bereaved family members after the death of a loved one. The hospice movement in the United States has been greatly influenced by the work of Dr. Elisabeth Kübler-Ross, who researched the dying process and advocated changes in the way society views death. In the United States, the first hospice opened in 1974 in New Haven, Connecticut. It was based on St. Christopher's Hospice, founded in Great Britain in 1967. Since that time, hospital-based hospice programs have been primarily replaced by home-based and nursing home–based hospice programs.

Primary practitioners who provide care to chronically ill patients with terminal conditions are expected to incorporate the basic elements of palliative care into their practice, regardless of setting. These elements are defined by the eight domains of palliative care as outlined in the *Clinical Practice Guidelines for Quality Palliative Care, Second Edition* (2009) (National Consensus Project for Quality Palliative Care [NCP], 2009) (Table 20.1).

Five national palliative care organizations formed a consortium to oversee the National Consensus Project for Quality Palliative Care (NCP). These include the American Academy of Hospice and Palliative Medicine, Center to Advance Palliative Care, Hospice and Palliative Care Nurses Association, Last Acts Partnership, and National Hospice and Palliative Care Organization. Together, these five organizations, came to consensus, issuing the following statement: "The goal of palliative care is to prevent and relieve suffering and to support the best possible quality of life for patients and their families, regardless of the stage of the disease or the need for other therapies. It can be delivered concurrently with life-prolonging therapies

or as the main focus of care. Leadership, collaboration, coordination, and communication are key elements for effective integration of these disciplines and services" (NCP, 2009). Other definitions include patient- and family-centered care that optimizes quality of life by anticipating, preventing, and treating suffering. Palliative care throughout the trajectory of illness involves addressing physical, emotional, psychosocial, religious, and spiritual needs of patients and their families.

Suffering and Spirituality

Receiving a diagnosis of an incurable disease can be one of the most frightening experiences for any human being. Fear of potential suffering and pain as well as fear of loss of control, of relationships, and of existence itself are some of the issues that confront the patient. Psychosocial distress may significantly influence treatment decisions, quality of life, and disease progression. All care providers and clinicians on the front lines of cancer care can improve the recognition and management of cancer-related distress. Up to 43% of patients with cancer report measurable levels of psychosocial distress, and this is most likely a gross underrepresentation.

The diagnosis of suffering is often missed by healthcare providers, perhaps because suffering is an experience of the whole person and is highly personal and subjective. Cassell (1999) suggests that suffering is the state of distress caused by the threat of the loss of intactness or the disintegration of a person from whatever the cause. In serious illness, all aspects of the individual are affected: physical, mental, spiritual, emotional, and social. Suffering involves an eroding of the normal defenses that help us to keep intact, to relate to others, and to have purpose in life. Human suffering is a complex, multidimensional experience that often goes beyond physical pain. To this point, the National Comprehensive Cancer Network (NCCN) 2014 guidelines include 72 pages of clinical guidelines on "Distress Management" (NCCN, 2014).

When a life-threatening disease is first diagnosed, the individual may be terrified but must often quickly make

decisions regarding his or her treatment. During this phase, the patient often seeks counsel, support, and advice from others including friends, relatives, and health-care professionals. Characteristic of this phase is an information-gathering period, in which the patient becomes knowledgeable about the disease, treatment, and adverse effects. The patient's exploration may extend to religious and/or spiritual aspects of being. After treatment, the patient may experience ongoing anxiety and depression related to fear of disease relapse. With disease relapse and progressive illness and disability, the patient may become more depressed and verbalize feelings of hopelessness. In one study (Flaming, 1995) that evaluated nurses' perspectives of patient suffering, four domains of suffering were identified: to bear it, to stay in control, to protect themselves, and to strengthen.

Ferrell and Coyle (2008) describe nurse suffering that occurs when nurses witness the suffering of their patients. The relationship among the nurse, the patient, and the patient's family can be close and intense; and each party is vulnerable to each other. Nurses who care for cancer patients and palliative care staff who deal with cancer patients are at great risk for suffering given the percentage of patients who die or who are close to death.

Spirituality is concerned with the transcendental, the inspirational, and existential way we live our lives. From his experience in Auschwitz, Victor Frankl (1959) came to believe that suffering can be helpful if a meaning to suffering is identified. He used the terms *existential frustration* to define the confusion felt from a lack of meaning in one's situation and *existential vacuum* as the absence of meaning in one's life. When one is faced with unavoidable suffering, according to Frankl, the individual is free to choose how to respond and may either be master or victim. Finding meaning in suffering, says Frankl, comes from transcendence, or rising above the self, and finding meaning. Meaning encompasses three domains: creativity, experience, and attitude. Meaning can be found in creating something or accomplishing a task; experiential meaning involves finding pleasure or nourishment of the soul in ordinary things; and attitudinal meaning involves finding courage or experiencing joy despite a terrible, unalterable situation.

Providing care to people who are suffering is an awesome task that often challenges religious or spiritual beliefs. It calls for the highest level of knowledge, sensitivity, and empathy. Patients who are ill or dying report that they want nurses and doctors who are caring. We often hear stories from patients about "uncaring" health professionals who seem cold and indifferent to the suffering of their patients, and we all too frequently see some of these individuals in our daily practice. Palliative care encompasses the basic tenets of caring, including respect for the individual, empathy, and compassion. It calls for a *Circle of Caring* (see Chapter 1).

Medical and Nursing Education in Palliative Care: A Recent History

Education of health-care professionals in palliative and end-of-life care was not routinely a part of medical and nursing curriculums. In many clinical settings, including both inpatient and ambulatory care, there were no established guidelines for pain and symptom management for patients with cancer, including terminal or end-of-life care. Even in settings in which guidelines existed, there was variable support for or assurance that these guidelines were adhered to in practice.

A growing recognition of the need to provide better care for dying patients, many of whom were in pain and suffering, led the Robert Woods Johnson Foundation to fund a landmark study. Funded with $28 million dollars, the study was conducted over a 4-year period and included 9,000 participants suffering from life-threatening illnesses in five U.S. teaching hospitals across the country. In 1995, the reports of this study were published in the *Journal of the American Medical Association.* Named the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment, it became known by the acronym SUPPORT.

Some disturbing findings in the study were as follows:

- Forty-six percent of patients with do-not-resuscitate (DNR) orders had the order written 2 days before death.
- Fewer than 50% of physicians understood their patients' preferences.
- Fifty percent of patients who could communicate had moderate to severe pain during the last 3 days of life.

A 1997 study by an Institute of Medicine (IOM) panel concluded that physicians and other caregivers in the United States fail to provide competent palliative and supportive care to dying patients. It also concluded that a significant number of terminally ill patients experience serious pain and other discomforting symptoms such as dyspnea. These findings were dismally reconfirmed in a recently published IOM report (September 2014) on care of the dying. This report, prepared by an appointed committee of 21 experts and released on September 17, 2014, concluded that the United States needs to overhaul its "broken" end-of-life care system to improve patient's quality of life in their final days and to cut rising health care costs. The 507-page report, titled *Dying in America,* was funded by a $1.5 million anonymous donation (Belluck, 2014). The conclusions of this study were that physicians and other caregivers in the United States *still* fail to provide competent palliative and supportive care to dying patients.

Multiple studies document deficiencies in knowledge about pain and palliation of symptoms associated with progressive disease. In a 1997 survey of medical residents

in a university-based surgical program, a significant number of deficits existed in the knowledge of how to provide care for common symptoms of advanced cancer, including management of opioid-related nausea, vomiting, and terminal dyspnea (Oneschuk et al, 1997). Other surveys have documented deficiencies in physicians during their residencies in the areas of opioid selection, conversion, and management of opioid toxicities and addiction. In a 2003 survey of approaches of medical oncologists toward palliative care for patients with advanced cancer, only a minority of physicians collaborated with a palliative care specialist, a palliative home service, an inpatient hospice, or a psychologist. Overall, 88.4% of respondents supported the belief that medical oncologists should coordinate the end-of-life care, but a substantial minority, 42%, felt that they were inadequately trained for this task (Cherny & Catane, 2003).

Nurses' knowledge of and attitude toward pain and symptom management strongly parallel those of physicians, although there is some evidence that educational efforts have been beneficial. McCaffery and Ferrell (1997) compared the results from surveys in 1995 and 1998 of nurses' knowledge of pain assessment, opioid dosing, and likelihood of addiction. They found improvements in the nurses' assessment and titration upward of opioid dose as well as a decrease in concerns about addiction, although a clear association still existed between time on opioids and concerns about addiction. In another study of nurses' knowledge and attitudes of cancer-related pain, O'Brien et al (1996) found that experienced nurses who have cared for cancer patients are more knowledgeable and have more liberal attitudes toward pain management than nurses who have not cared for cancer patients.

Professional Educational Efforts to Improve the Practice of Pain Management and Palliative Care

Major educational efforts have been made by health-care professionals to improve professional knowledge deficits. A variety of approaches and specific programs have been identified to address these knowledge deficits. The Joint Commission standards on pain management have been helpful in making institutions accountable for assessment and management of pain across practice settings (Berry & Dahl, 2000). Efforts at the academic and clinical level provide a framework for care of patients with advanced disease and for patients who are dying. Curriculum changes for both nurses and physicians in many schools now include comprehensive palliative care. In many hospitals, services of palliative care experts or pain and symptom management specialists are being incorporated into the routine care of patients, and the number of training centers nationally is increasing. Many hospitals now provide programs for nurses offering education or clinical mentors. Quality assurance and improvement programs examining pain and symptom management now exist in many institutional settings.

Directives now exist from major professional organizations advocating pain and symptom management. These organizations include the American Nurses Association, American Pain Society, American Board of Internal Medicine, Oncology Nursing Society, American Geriatric Association, American Society of Pain Management Nurses, International Society of Nurses in Cancer Care, International Association for the Study of Pain, European Oncology Nursing Society, and the American Society of Clinical Oncologists. These clinical practice guidelines and directives, as well as major national professional educational efforts on end-of-life-care (End of Life Nursing Education Consortium [ELNEC] and Education for Physicians on End of Life Care [EPEC]), are addressing the problem of inadequate control of pain and knowledge deficits.

In addition, clinical practice guidelines have recently been established by the National Comprehensive Cancer Network (NCCN), which recommends (among other things) routine screening for cancer-related *distress* on diagnosis and admission and at pivotal times in the disease process. These guidelines (NCCN, 2014) also promulgate the use of approved distress assessment tools for screening and the use of clinical pathways based on assessment results. And the ELNEC core curriculum for undergraduate, graduate, and specialty tracks now includes adult, pediatric, geriatric, critical care, veteran, and public hospital foci.

The 2014 IOM report reiterated yet again that medical schools and groups that accredit and regulate health-care providers still need to *greatly* increase training in palliative care and set standards so the clinicians know how to compassionately and effectively treat patients who want to be comfortable but avoid extensive medical procedures.

PALLIATIVE CARE

Palliative care focuses on the management of disease in patients with active, progressive disease. The focus of care is on the quality of life. Palliative care furthers the World Health Organization's (WHO's) definition of health, affirming dying as a normal life process. Palliative care as defined by the WHO (2010) is an approach that improves the quality of life of patients and their families facing the problems associated with life-threatening illness through the prevention and relief of suffering by means of early identification and impeccable assessment and treatment of pain and other problems—physical, psychosocial, and spiritual. The goals of care are to alleviate symptoms in a compassionate way, to neither hasten nor postpone death, and to provide a support system to both the family and patient, integrating the psychological and spiritual aspects of patient care throughout the trajectory of illness.

Specifically, according to the WHO (2010), palliative care does all of the following:

- Provides relief from pain and other distressing symptoms

- Affirms life and regards dying as a normal process
- Intends to neither hasten nor postpone death
- Integrates the psychological and spiritual aspects of care
- Offers a support system to help patients live as actively as possible until death
- Offers a support system to help the family cope during the patient's illness and in their own bereavement
- Uses a team approach to address the needs of patients and their families, including bereavement counseling, if indicated
- Will enhance the quality of life and may also positively influence the course of illness
- Is applicable early in the course of illness, in conjunction with other therapies that are intended to prolong life, such as chemotherapy or radiation therapy, and include those investigations needed to better understand and manage distressing clinical complications

If we examine the characteristics of the most prevalent chronic illnesses, including coronary artery disease, chronic lung disease, cancer, cerebrovascular disease, and diabetes mellitus, similarities are apparent. For all chronic illnesses, there is the initial diagnostic period when symptoms become present. This may be over a period of days, weeks, or months and is generally a highly stressful period, with disruption in function and routine. Once a treatment plan is initiated, symptoms may resolve, and the patient may enter a period of remission or stability lasting months or years. What follows are periods of exacerbation, often with hospitalizations, and periods of remission. During this time the patient usually experiences signs and symptoms of disease; alterations in lifestyle, role, family, and job relationships; and often psychological and spiritual distress. As time progresses, if the patient is not cured of the disease or stability is not long lasting, there comes a time of downward progression of disease with a decline in function and worsening symptoms. It is during this time most patients are referred for palliative care. Americans struggling with chronic illnesses and their associated disabilities are often in greatest need of assistance during the last months to year of life. About 30% of Medicare expenditures arise in the patient's last year of life.

The goals of treatment for all chronically ill patients need to be clearly defined by the health-care provider, communicated to the patient and family at the time of diagnosis, and reinforced throughout the trajectory of illness. Broadly, these goals, which parallel the trajectory of disease, can be classified as curative, slowing progression of disease, and palliative control of symptoms or comfort care only. The terminal phase includes the management of symptoms at the end of life. Throughout all phases of illness, emphasis should be placed on palliative control of symptoms either from disease or treatment and maintaining optimum quality of life for the patient.

Expert opinion and qualitative research have characterized priority concerns for patients in late life. Important topics including pain management, family support, ensuring continuity, making informed decisions, providing for emotional and spiritual support, sustaining function, and increasing survival (Hanson et al, 1997; Singer et al, 1999; Steinhauser et al, 2008; Weinrich et al, 2003).

The Palliative Care Plan

The WHO (2010) has indicated the need for integration of palliative care services throughout the trajectory of illness and stages of cancer from diagnosis to death, and providing support and bereavement counseling for the family after the death of the patient. Devising a palliative plan of care should be part of the ongoing plan of care for the chronically ill patient. Appropriate care depends on several factors, including ongoing communication with the patient and family; assessment of the patient's and family's understanding of goals of care; religious, cultural, and spiritual beliefs; access to community agencies; psychological assessment and coping strategies; and preferences regarding advance directives. Dimensions of a palliative care plan for the health-care provider are outlined in Advanced Practice Nursing Interventions 20.1.

Palliative Cancer Care

In 2014, the American Cancer Society estimated that about 1,665,540 new cases of invasive cancer will be diagnosed in the United States in the next year (American Cancer Society, 2014). This does not include carcinoma in situ (noninvasive cancer) or certain types of skin cancers. Among women, the most commonly diagnosed cancers are those of the breast, lung and bronchus, and colon and rectum. Among men, the most common cancers are cancers of the prostate, lung and bronchus, and colon and rectum. Preliminary data suggest that overall cancer mortality has begun to decline; however, the number of deaths has continued to increase because of the aging population. Cancer is a disease of aging and a prominent cause of overall morbidity and death. From 2002 to 2006, the median age at diagnosis for cancer of all sites was 66 years of age (Horner et al, 2009); 585,720 people are expected to die of cancer this year (2014), which equates to almost 1,600 per day. Relative survival rates have increased for a variety of reasons. Between 2003 and 2008 the relative survival rate was 68%, as contrasted with a 49% relative survival rate from1975 to 1977 (American Cancer Society, 2014).

The Role of the Primary-Care Provider in Palliative Cancer Care

The health-care provider, as the primary-care provider of record, is critically important. There are a number of important points in the continuum of care for the patient with a chronic, irreversible disease process, most commonly a diagnosis of cancer, which call for a careful, comprehensive response. Often the primary-care provider is the first clinician to see the patient and because of this plays a crucial role. Although many patients are referred to specialists, the primary-care provider commonly provides a

Advanced Practice Nursing Interventions 20.1 Dimensions of a Palliative Care Plan

1. Assess the extent of disease documented by imaging studies, laboratory data.
2. Assess and provide interventions for physical signs and symptoms including pain, dyspnea, delirium.
3. Assess coping strategies and psychological symptoms including presence and absence of depression, suicidal ideology.
4. Determine level and quality of support provided by family and friends. Is additional assistance needed in the home and can it be put into place? Determine community resources and identify what kind of assistance is available.
5. Identify coping strategies and psychological symptoms in family members or caregivers.
6. Perform a religious and spiritual assessment including degree of comfort from beliefs.
7. Evaluate the impact of disease on functional status. What can the patient do, and what assistance is needed with bathing, dressing, ambulation, meal preparation?
8. Evaluate what advance care planning has been done. Have the patient's wishes and preferences for resuscitation, artificial feeding, and hydration been discussed? Has the patient identified a surrogate decision-maker who knows the patient's wishes? Is there documentation on advance directives in the medical record?
9. Evaluate overall quality of life and well-being. Does the patient feel secure that all that can be done is being done? Does the patient feel that physical and psychological symptoms are being satisfactorily addressed? Does the patient feel there is meaning to his or her life?
10. Identify the family burden of caring for the patient. Is attention being paid to support the caregiver so that burnout does not occur? What is the financial burden to the caregiver, and can he or she manage bill paying and reimbursement issues?
11. Determine the level of care needed in the home and provision for that care. What reimbursement issues affect obtaining the level of home care needed?
12. Is there a system in place for ongoing support and assistance to family members and caregivers after the death of the patient?
13. Has the patient identified his or her desire for their place of death? Has he or she communicated these wishes to the family, partner, caregiver?
14. Provide for bereavement counseling and support for the family beyond the life of the patient.

number of essential functions over many years of care, such as teaching about risk factors for many diseases (e.g., avoiding ultraviolet light exposure to prevent skin cancer), detecting occult disease in asymptomatic patients, or diagnosing disease in those with suspicious symptoms. In patients who have a strong family history of some malignancies, the primary-care provider has a responsibility to educate and make appropriate referrals to specialists for genetic testing and/or counseling. NCCN (2014) also provides comprehensive cancer guidelines on screening and prevention of disease. The Patient-Centered Medical Home as identified in the Affordable Care Act should increase the primacy of the role of primary-care provider. This should be a person that knows the patients *the best.*

Discussing the diagnosis and its associated options, as well as arranging for specialty care, is critical. This may be especially difficult in the diagnosis of cancer, which most patients and families still perceive as a death sentence. It may be helpful to set a special appointment time for this discussion and encourage the patient to bring along a family member or advocate. A good understanding of the diagnosis and the potential prognosis is essential to the discussion, as well as awareness of the potential treatment options. There is a whole body of literature on the art of sharing difficult news with patients and families. Again, this often falls to the primary-care provider, who may not be as used to these types of conversations. Nonetheless, they are important aspects of the primary-care provider's role. The 2014 IOM report, drafted by an interdisciplinary panel that included doctors, nurses, insurers, religious leaders, lawyers, and experts on aging, again emphasizes the need for insurers to create financial incentives for primary-care providers to support ongoing conversations with patients and families on advanced care planning. These, they say, should start as early as major teenage milestones, such as getting a driver's license and deciding if one wants to be an organ donor.

Because the therapeutic window for treatment of certain cancers is small, advice given during this first discussion may be crucial in determining the patient's and family's course of action. Utilizing caring processes and active listening skills during this time is important. It is essential to the subsequent care of the patient that as much information about the patient—biological, emotional, and spiritual—be provided to the specialty care provider.

The patient should be referred for ongoing emotional and/or spiritual support at the time of diagnosis. As a trusted care provider, the primary care provider is the ideal member of the team to recommend and implement this and provide for ongoing follow-up care. This involves being knowledgeable of the appropriate time intervals for certain follow-up tests and knowing what to look for

and when. The American Cancer Society is an excellent source for all health-care providers for state-of-the art information on cancer treatment.

The recognition and management of complications, either during or after treatment, is another responsibility of the primary-care provider. Some of these complications may represent metastatic spread of the original cancer, and a high index of suspicion must be vigilantly maintained. In some cases, complications may be life-threatening. Advanced Practice Nursing Interventions 20.2 summarizes the role of the APRN in palliative cancer care.

PRINCIPLES OF PALLIATIVE CARE

The health-care provider who delivers primary care is often the one who provides care at the end of life; therefore, having a baseline knowledge of symptom management is crucial. Seriously ill patients with chronic disease and multiple comorbid medical conditions often cross practice settings from emergency department to home and from home to hospital. Because the Medicare hospice benefit is limited to patients with a 6-month prognosis, many patients with long-standing chronic illnesses, including cancer, are ineligible for hospice care, which for many patients has led to unrelieved suffering.

Principles of palliative care useful for the primary-care provider include the following:

1. Careful evaluation of the patient's symptoms
2. A clear understanding of the pathophysiological mechanisms involved in each symptom
3. A judicious approach to diagnostic testing (with an aim of avoiding "overtesting" and testing that does not affect management). Diagnostic testing should always be consistent with a clear understanding of the goals of care for each patient.
4. Establishment of a treatment plan that is simple and subject to continual reevaluation
5. Determining what the patient's and caregiver's expectations are regarding the patient's care at this stage of illness
6. Determining if the patient has special wishes regarding end-of-life care, including place of death and if advance directives have been discussed and documented
7. Referral to a pain and palliative care specialist for aggressive management of these symptoms if routine interventions are inadequate

Pain control is paramount. Pain is the symptom most feared by dying patients. Although usually the manifestation of physical distress, pain may be exacerbated by anxiety, fear, loneliness, and depression. Patients differ vastly in the extent of clinical disease that yields pain, as well as in their ability to tolerate, accept, or cope with pain. Pain expected to be transient may be treated on an as-needed (prn) basis, but chronic pain needs to be treated via a scheduled regimen. The section of this chapter on pain discusses this in greater detail.

Clinical problems frequently seen in terminally ill patients include pain, dyspnea, fatigue, depression, anorexia, weight loss, constipation, and anxiety. Initial evaluation of symptoms must begin with determining the etiology of the symptom evaluated. This is usually done as part of the initial work-up. If the etiology of pain is secondary to the treatment, one should ask whether the treatment can be adjusted or whether it should be discontinued. Goals of care should be reviewed on a routine basis, especially at intervals when treatment decisions need to be made. Other challenges are the ethical dilemmas that may be faced by the health-care provider whose own beliefs may conflict with or be different from the patient's and the family members' or caregiver's. It

Advanced Practice Nursing Interventions 20.2 The Role of the Advanced Practice Nurse in Palliative Cancer Care

1. Teaching about risk factors for cancer and lifestyle change to decrease risk
2. Coordination of screening tests in asymptomatic patients (mammogram, colonoscopy)
3. Detecting cancer in asymptomatic patients or those with specific symptoms
4. Informing patient and family of diagnosis and prognosis; it is helpful if this is done in collaboration with the physician involved in the care of the patient
5. Arranging for follow-up care, including psychosocial and spiritual support
6. Being an active participant of the interdisciplinary team
7. Providing follow-up care for ongoing symptom detection and management
8. Identifying and managing complications of care
9. Providing follow-up care and early detection of possible recurrences
10. Providing palliative care
11. Providing referral to a palliative care specialist as indicated
12. Providing for assistance with advance care planning
13. Providing for bereavement counseling and support

is important for health-care providers to recognize that their beliefs are just that, and may frequently differ from those of the patient. For example, one of the most common and controversial clinical issues at the end of life is the need for hydration. Differences of opinion may exist not only between health-care providers and the patient or caregiver, but between family members. When there are concerns about nutrition and hydration at the end of life, the amount of food or fluid given to a dying person should be guided by the patient's desires and his or her ability to tolerate nourishment orally, rather than by calculated nutritional or fluid requirements. It is also important to understand that cultural differences often play a role and should be respected. At the end of life, small amounts of fluids, ice chips, or mouth swabs— classic nursing interventions—are often beneficial.

Another frequent challenge is determining the best way to deliver medication, especially in the home or hospice setting, when the patient is unable to swallow. Routes of administration to consider for the dying patient who cannot swallow include sublingual, intravenous, transcutaneous, subcutaneous, and spinal (e.g., intrathecal, epidural). Creativity is frequently called for, as well as the ability to work in concert with a team of providers, such as pharmacists, clergy, and home-care nurses.

PALLIATIVE CARE OF SYMPTOMS IN DYING PATIENTS

Numerous studies have evaluated symptoms during the last weeks of life and indicate that patients experience a high degree of symptom distress and suffering. Ingham and Portenoy (1996) suggested that symptom assessment should be multidimensional, involving determination of the incidence, duration, severity, amount of distress, and impact on function and quality of life. A variety of symptoms in the last year and weeks of life have been identified in the literature including pain, distress, weakness, fatigue, cognitive impairment, and dyspnea.

The Patient's Voice 20.1

Palliative Care

The Patient

"The pain was intolerable, every time I moved my back hurt. The morphine tablets made me sleepy and constipated. The pain of trying to have a bowel movement was almost as severe as the back pain. My doctor basically told me to bear it as these side effects were common."

The Son

My father was clearly dying and was confused at times. The nursing staff gave him injections for pain, but they did not seem to help. When I questioned the nurses, they told me they could not give him more because they did not want to slow his breathing. I thought, "He's dying. Make him comfortable."

Several studies have demonstrated that the most difficult end-of-life symptoms to manage are pain, respiratory distress, and confusional states. In a retrospective review of 100 patients in an inpatient palliative care unit, Fainsinger et al (1991) identified 16% of the patients required sedation to control pain and delirium. In another evaluation of patients during the last week of life, Conill and colleagues (1997) assessed patients at two intervals—their initial consultation and then during the last 7 days of life. Asthenia, anorexia, and dry mouth were the three most common symptoms in both periods, but the incidence of confusional states doubled during the last week of life (30.1% and 68.2%, respectively). Potter et al (2003) assessed 400 patients referred to palliative care services and found the most prevalent symptoms in the cancer population were pain (64%), anorexia (34%), constipation (32%), weakness (32%), and dyspnea (31%).

Needs of nursing home patients at the end of life have also been identified. In one study during the last month of life of nursing home and residential care/assisted living residents, the most common symptoms include pain, dyspnea, fatigue, problems with cleanliness, and symptoms affecting intake. Seventy-seven percent of those studied were cognitively impaired (Hanson et al, 2008). Identification and management of pain and distress in these patients can be especially difficult.

The suffering that patients experience at the end of life is not necessarily related to the severity of the symptom(s). Mild symptoms may cause severe distress, especially if the meaning of that symptom is frightening—if it signifies that death is near. Unrelieved symptoms at the end of life are extremely devastating; they can rob patients and their loved ones of valuable time and meaningful interaction. During this time nurses have a responsibility as patient and family advocates to ensure that symptoms are addressed and treated appropriately.

Palliative management of three of the most difficult symptoms—pain, dyspnea, and delirium—are discussed in the sections that follow. Accurate assessment and diagnosis of these symptoms is assumed. The reader is referred to appropriate sections of this textbook for more information on assessment and diagnosis of these problems.

PALLIATIVE MANAGEMENT OF PAIN

According to the International Association for the Study of Pain (1979), pain is identified as a subjective experience and is described as "an unpleasant sensory or emotional experience related to actual or potential tissue damage." Pain is a subjective symptom; there is no test to measure pain. The patient should be actively involved in establishing the goals of pain management, and family members should be involved, when possible. Table 20.2 presents a review of the various types of pain.

The American Society for Pain Management Nursing (2013) issued a position paper on pain management in palliative care. They noted that pain at the end of life *continues to be a substantial concern* and has been estimated

Table 20.2 Types of Pain

Pain may be described as an unpleasant sensory and/or emotional experience related to actual or potential tissue damage. The perception of pain is the result of tissue injury leading to the origination and conduction of pain signals by the central nervous system. Peripheral stimulation occurs when free nerve endings, or nociceptors, found in various parts of the body (e.g., skin, blood vessels, viscera, muscles) are stimulated, which in turn stimulates action potentials to be transmitted along afferent nerve fibers to the spinal cord.

When thinking of a person with pain, it is useful to think about whether the pain is acute or chronic. Sometimes the person may have chronic pain with a new acute pain added.

Acute Pain

- Well-defined temporal pattern of onset.
- Transient, may be associated with hyperactivity of the autonomic nervous system.
- Increased blood pressure, pulse rate, respiratory rate, and perspiration.
- Patients may look like they are in pain and may cry or moan.

Chronic Pain

- Syndrome that is defined by a pattern of pain that persists beyond healing of the acute lesion or recurs over periods of months, or is associated with a lesion not expected to improve.
- Patients experience a decrease in observable signs of pain.
- Blood pressure and pulse rate are normal.
- Sleep disturbance, decreased appetite, depression, and lassitude may be present.

Because of therapeutic implications, it can be helpful to clinicians to determine whether an individual's pain is classified as nociceptive, neuropathic, or both.

Nociceptive Pain

Nociceptive (organic) pain results from activation and sensitization of nociceptors, or pain receptors, located throughout the body. Nociceptive pain may be further subdivided into somatic and visceral pain

1. Somatic pain
   - May be constant, aching, throbbing.
   - Examples include bone metastases, postsurgical incisional pain, musculoskeletal inflammation, or spasm.
2. Visceral pain
   - Results from inflammation, compression, distention, or stretching of thoracic or abdominal viscera (e.g., intra-abdominal metastases, liver metastases).
   - May be diffuse, gnawing, or cramping.

Neuropathic Pain

Neuropathic pain refers to syndromes that may be related to damaged peripheral or central neural structures as a result of tumor progression or infiltration or from chemical injury to the peripheral nerve or spinal cord from surgery, irradiation, or chemotherapy.

- May be continuous or lancinating.
- May be burning, shooting, electric shock–like, squeezing, vise-like.

to still occur in 46% of patients in the last month of life. Concerns about shortening life continue to worry clinicians who use the double-effect argument, although studies demonstrate that adequate pain control may actually extend and prolong life in some cases. To address this concern, they make the following recommendations:

- Enhance evidence-based education for providers in this area.
- Promote accountability for all health professionals to support patient preferences.
- Foster the concept that pain management is a core health care right.
- Recognize that all pain should be treated.
- Improve public understanding of barriers, harmful effects of pain, and need for appropriate treatment.
- Improve accessibility to effective pharmacological, nonpharmacological, and advanced technological treatment modalities.
- Decrease legal, regulatory, and reimbursement obstacles (American Society for Pain Management Nursing, 2013).

The findings of the IOM's report, *Dying in America* (2014), confirms that there is a long way to go to begin to implement and meet these recommendations.

Assessment

Pain management begins with accurate assessment of the patient's pain. This assessment should be incorporated across practice settings into all routine bedside and ambulatory visits, as well as when there is a report of worsening

pain or new pain. Inadequate pain assessment was identified as one of the most frequently mentioned barriers hindering adequate cancer pain management (Oldenmenger et al, 2009). Adequate assessment should enable the healthcare provider to determine the cause of the pain, assist in determining treatment, and evaluate the effectiveness of therapeutic interventions and their impact on the quality of life. Assessment of pain is subjective and relies heavily on the patient's report. The use of a multidimensional assessment tool can facilitate understanding and assist in determining treatment efficacy. Validated assessment tools include the Brief Pain Inventory (Daut et al, 1983) and the McGill Pain Questionnaire (Graham et al, 1980). However, it is sometimes difficult to utilize these tools when evaluating a fragile, medically ill person at the end of his or her life. A 10-point (0–10) scale is commonly used to measure pain intensity. If the patient cannot use a numerical scale, a categorical scale of none, mild, moderate, and severe is recommended. Pain assessment should include a detailed history of the pain (including intensity, quality, temporal factors, aggravating and relieving factors, and its effect on activity, mood, and ability to eat) and characteristics, a comprehensive physical examination, a psychosocial evaluation, and a thorough diagnostic work-up to determine the underlying cause of the pain. Table 20.3 outlines the basic principles of pain assessment.

Table 20.3 Basic Principles of Pain Assessment

- Believe the patient's complaint of pain. The patient is the expert in determining the level of pain he or she is experiencing.
- Take a careful history of the pain complaint and incorporate into the overall plan and goals of care.
- If the patient has difficulty communicating because of cognitive or physical impairments, obtain a history from the family or caregiver.
- Observe for nonverbal cues (e.g., crying, grimacing).
- Assess for other symptoms (e.g., agitation, delirium, dyspnea) that may cloud the pain assessment.
- Assess for onset, timing, temporal characteristics, pattern of referral, and aggravating and relieving factors.
- Assess for breakthrough or incident-related pain.
- Examine the site of pain on every patient encounter.
- Facilitate work-up that clarifies the etiology of the pain and extent of disease.
- Evaluate the psychological state of the patient and assess for depression, anxiety, delirium, or suicidal ideation.
- Determine appropriate opioid and route of administration. Consider the cost of medications and economic burden on the patient and family. Consider use of adjuvant analgesics, especially for neuropathic pain.
- Assess and reassess response to treatment and monitor for presence of side effects.
- Treat side effects aggressively.

Management

Palliative management of the patient in pain includes pharmacotherapy, interventional techniques, and nonpharmacological pain management interventions.

Pharmacotherapy

In 2005, the American Pain Society (APS) published guidelines for the management of cancer pain in adults and children; these guidelines promote a systematic and comprehensive approach to cancer pain management. The recommendations are based on a review of the literature rating each one on the strength and consistency of evidence. In its approach to pharmacotherapy, APS recommends that the initial treatment of cancer pain be based on the severity of the pain reported by the individual patient and follows the WHO Three-Step Analgesic Ladder (WHO, 2009). (See Fig. 20.1.) Despite the fact that the WHO treatment principles are widely accepted as the main prescribing guide in cancer pain management, there is insufficient information regarding their level of implementation (Hakonsen et al, 2008). Since 1990, the WHO Three-Step Analgesic Ladder advocates use of analgesics corresponding to three levels of pain intensity and utilizing nonopioid analgesics (NSAIDs and acetaminophen), opioids, and adjuvant analgesics as follows. These recommendations have remained relatively consistent in principle.

Step 1. Pain Persisting or Increasing Patients with mild to moderate pain should be treated with a nonopioid analgesic and, if indicated, an adjuvant drug. Examples of nonopioid analgesics are acetaminophen and the NSAIDs such as aspirin, ibuprofen, indomethacin, and naproxen. Examples of adjuvant drugs include tricyclic antidepressants (TCAs) such as amitriptyline or imipramine and anticonvulsants such as gabapentin, pregabalin, and lamotrigine.

Step 2. Pain Persisting or Increasing Patients who are opioid naive and present with mild to moderate pain or who fail to have adequate analgesia from a nonopioid should be treated with a mild opioid (previously called "weak opioids") and a nonopioid, as well as an adjuvant drug as appropriate. Examples of opioids that can be utilized at this level are codeine, hydrocodone, and oxycodone, with or without acetaminophen. Additionally, adjuvant therapy may be added for fear and anxiety.

Step 3. Freedom From Cancer Pain Patients who present with moderate to severe pain or who fail to have adequate analgesia from the second level of intervention should receive an opioid (previously called "strong opioids") and a nonopioid and/or an adjuvant medication as appropriate. As with mild pain, adjuvant medications are selected on the basis of the underlying pain etiology of an individual patient. Examples of opioids appropriate for moderate to severe pain include morphine, hydromorphone, fentanyl, oxymorphone, levorphanol, and methadone. Opioids are frequently used in combination with a nonopioid if not contraindicated by an

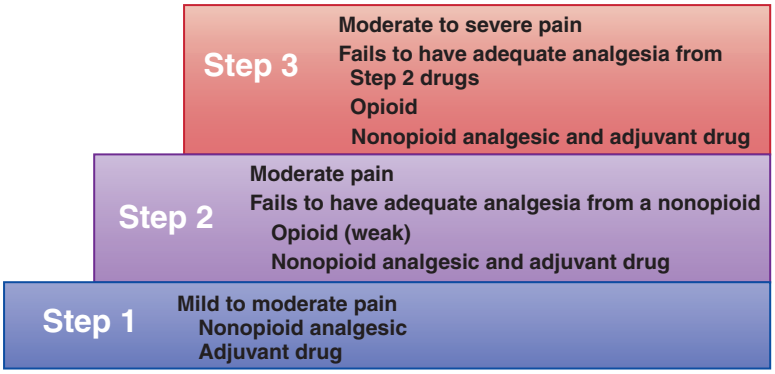

Figure 20.1 Three-step analgesic ladder.

individual's clinical situation. Additionally, adjuvant therapy may need to be added for fear and anxiety.

Health-care providers are advised to place patients receiving opioid therapy on bowel regimens to prevent opioid-induced constipation (Dy et al, 2008). Important considerations when providing pharmacotherapy for an individual's pain management include previous opioid experiences, determining the appropriate opioid (including the route of administration and dosage schedule), and calculating an equianalgesic dose if switching to another opioid (American Pain Society, 2005). Of practical concern is whether a particular medication is covered by an individual's drug plan. Documentation of dose-limiting side effects or treatment failures can help when advocating for prior authorizations for formulary exceptions.

Selecting the Appropriate Opioid When given properly, opioids are among the safest medications available, because adverse effects are predictable and generally controllable. The potency of opioids varies, but they are generally interchangeable with appropriate dose and dosing interval adjustments (Knotkova et al, 2009).

Numerous factors, both patient and drug related, must be considered in the selection of an appropriate opioid. The opioid should be compatible with the patient's age, pain severity, dosing needs, and route of administration requirements. Often financial considerations need to be taken into account, especially when the patient is receiving multiple drugs and the cost of medications needs to be limited. This is another example of the skills and knowledge that advanced practice nurses bring to this endeavor. They are skilled at seeing the *whole* of the iceberg—the concrete manifestations "above the waterline," so to speak, but also informed and sensitive awareness to things unsaid, concerns "below the surface," including psychosocial, economic, spiritual, and concrete issues. At the end of life, certain routes of administration may be preferable owing to patient comfort, ease of administration, ability to swallow, pain severity, and need to titrate rapidly (American Pain Society, 2005). The *Circle of Caring* approach to care supports the multifaceted responses to the patient and family.

When evaluating an opioid for chronic use, renal and liver function should be assessed before initiation of the opioid. Opioids with long half-lives may not be tolerated in many elderly patients because of clearance or metabolism issues. Renal function declines in older adults. It is also helpful to remember that in elderly patients, normal serum creatinine concentrations do not exclude renal impairment. If patients have underlying renal or liver insufficiency, they should be monitored for signs of toxicity.

For patients with moderate to severe pain who have limited prior treatment with opioids, begin with a short half-life agonist (such as morphine, hydromorphone, or oxycodone). Morphine is the preferred drug because it is widely available, is relatively low in cost, can be administered via a variety of routes, and comes in a variety of formulations including controlled- or sustained-release products that allow for tablets at 8- to 12-hour dosing intervals. Morphine should be used judiciously in patients with renal impairment because of the accumulation of morphine-3-glucuronide and morphine-6-glucuronide. It is easier for clinicians to initiate and titrate an opioid with a shorter half-life than one with a longer half-life (such as levorphanol or methadone). Meperidine is not recommended for the management of chronic cancer pain because of its potential for central nervous system excitability, with possible tremors, myoclonus, and seizures due to the accumulation of the metabolite normeperidine from repeated administration. This effect is pronounced when administered orally (Andersen et al, 2003).

Selecting an Appropriate Route of Administration Both the National Comprehensive Cancer Network (NCCN) cancer pain guidelines for adults (2014) and pediatric patients (2013) and the Clinical Practice Guidelines for the Management of Cancer Pain Panel (Jacox et al, 1994) advocate that the clinician begin with the most available, least invasive route. The oral route is generally preferred. In general, when drugs are administered orally, they have a slower onset of action, a delayed peak time, and a longer duration of effect than drugs administered parenterally. Drugs administered parenterally have a rapid onset of action but a shorter duration of action. This route can be an advantage when dealing with severe incidental pain or rapidly escalating pain.

If the oral route is unavailable, the rectal, sublingual, transdermal, or parenteral route may be used. Rectal suppositories containing morphine, hydromorphone, and oxymorphone are available, and controlled-release morphine sulfate may be administered rectally.

The transdermal fentanyl patch is useful for patients who cannot tolerate oral drugs or for patients for whom compliance with an around-the-clock schedule is difficult to maintain. The fentanyl patch is contraindicated in the management of acute pain. Because analgesic effects are often not appreciated by a patient until 12 to 24 hours after initiation of therapy, an initial titration should not occur before 3 days of fentanyl patch initiation. It is difficult to rapidly titrate using this delivery system. A hospitalized patient may be more safely and efficiently titrated using a fentanyl patient-controlled analgesia (PCA) pump to determine fentanyl requirements. When the fentanyl patch is removed, serum concentrations fall slowly. The fentanyl patch is not recommended for use in patients who have varying levels of pain or who have severe effects such as sedation or confusion from opioids, because these effects may persist for long periods after the patch is removed. A short-acting opioid for breakthrough pain should be prescribed for patients using the fentanyl patch.

Parenteral routes of administration should be considered for patients who require rapid onset of analgesia or high doses of opioids that cannot be administered orally. Parenteral routes include intermittent IV, intramuscular (IM), or subcutaneous (SC) injections and continuous SC or IV infusions. Intermittent SC injections may be administered with the placement of an indwelling 27-gauge butterfly needle, which will eliminate the need for painful intermittent injections. Studies suggest that SC administration is equipotent to the IV dose. Continuous SC or IV infusion devices may also provide patient-controlled rescue doses as an adjunct to the continuous, or basal, rate.

As its name implies, in patient-controlled analgesia, the patient is the only one who should push the prn dose button. This helps to ensure patient safety and prevent overdose situations. However, for patients at the end of life, it may not be possible because of debilitated state, cognitive ability, or neuromuscular impairment for the patient to activate the rescue dose feature (Anghelescu et al, 2005). In this situation, the American Society for Pain Management Nursing (ASPMN, 2006) advocates for the use of authorized agent–controlled analgesia (AACA). AACA is defined as "a method of pain control in which a consistently available and competent individual is authorized by a prescriber and properly educated to activate the dosing button of an analgesic infusion pump when the patient is unable, in response to that patient's pain" (Wuhrman et al, 2007). The authorized agent may be the nurse who is responsible for that particular patient. In that case, AACA could be nurse-controlled analgesia (NCA). Or, in another situation, the authorized agent could be a nonprofessional person such as a parent or significant other, and the method could be referred to as caregiver-controlled analgesia (CCA). The proper use of CCA by a designated proxy can allow for patients to die comfortably at home, without the need to transfer to another setting. The expression "PCA by proxy" is not encouraged because it implies that a potentially unsafe, uneducated, unauthorized individual is activating an individual's PCA pump. The population suitable for AACA (either NCA or CCA) is usually opioid tolerant. Both the ASPMN and the literature propose AACA as a means of safe, effective pain control when a designated proxy is carefully chosen and educated about appropriate use of a PCA for an individual patient (Anghelsescu et al, 2005; Czarnecki et al, 2008; Kenagy & Turner, 2007; Wuhrman et al, 2007). It is important to establish policies and procedures for organizations utilizing AACA in their populations to determine criteria for proxy selection, patient monitoring, and education of proxy and health-care team members. Any organization or institution setting up AACA is referred to the recommendations of the ASPMN along with Kenagy and Turner (2007).

Selecting a Dosing Schedule Patients with continuous or frequent pain generally benefit from around-the-clock dosing, which prevents the pain from recurring. Indeed, in order to achieve freedom from pain, WHO advocates giving drugs around the clock at regular intervals and maintains that this stepped therapy is 80% to 90% effective. Continuous-release formulations of opioids utilize either tablets or transdermal delivery systems such as fentanyl, which may improve patient adherence to opioid regimens. A "rescue" or prn dose provides a means to treat pain that breaks through the fixed analgesic schedule or pain that occurs with specific activities such as changing position or ambulating. The drug used for breakthrough pain is usually the same drug in a shorter-acting, immediate-release formulation than the continuous- or sustained-release opioid that is administered on a regular schedule (American Pain Society, 2005). When using transdermal fentanyl, a short half-life opioid is recommended for breakthrough pain (Hanks et al, 2004). Continuous- or sustained-release formulations should not be used as rescue doses or to rapidly titrate the opioid for patients with severe pain (see Table 20.4). In these settings, short-acting opioids should be used. Often a parenteral formulation allows for rapid onset of analgesic action for patients in pain crisis. After analgesia is obtained and a stable dose has been determined, conversion to a continuous-release formulation can be made.

Switching to Another Opioid Patients with suboptimally controlled pain who develop unmanageable side effects that limit upward dose titration on one opioid can benefit from a switch or rotation to another opioid (de Stoutz et al, 1995; Knotkova et al, 2009). If a switch to another opioid is required, the equianalgesic dose table should be used as a guide to determine a reasonably effective and safe starting dose. Because of the existence of incomplete cross-tolerance between drugs, it is necessary to reduce the equianalgesic dose of the new, alternative

Table 20.4 Rescue Dose and Dose Titration

Rescue Dose

The rescue dose is an additional dose of the opioid that is administered on an as-needed basis to treat breakthrough pain; a short-acting, immediate-release opioid should be used. Oral rescue doses are usually administered on an every-1-to-2-hour schedule as needed. The dose of the oral rescue should be equivalent to approximately 10%–20% of the total 24-hour dose. The dose of the parenteral rescue opioid should be 50% of the hourly infusion rate for patients receiving continuous infusion, administered on a 15- to 30-minute as-needed schedule. It is generally recommended that patients who require four to six rescue doses in a 24-hour period should have an escalation of the baseline dose.

Dose Titration

All patients with chronic cancer pain should be assessed regularly for pain intensity and relief and for the presence of adverse effects. A stepwise escalation of the opioid dose should be done until adequate analgesia or intolerable adverse effects develop. Generally, it is safe to titrate opioids 25%–50% every 24–48 hours. The severity of the pain should determine the rate of dose titration. Doses can become extremely large as a result of titration. It is important to remember that there is no ceiling to opioid doses and titration needs to be based on pain intensity and relief. Caution should be employed when titrating opioids with long half-lives, such as levorphanol or methadone, because accumulation of drug can occur with subsequent toxicity.

opioid by one-half to two-thirds for patients on higher doses of the initial opioid. If switching to an opioid with a long half-life, such as methadone, accumulation of the drug can occur, and the methadone dose should be decreased by 90%. (Table 20.5 presents an equianalgesic dose table, Table 20.6 gives an example of switching routes using the same opioid, and Table 20.7 shows an example of switching from one opioid to another.) Clinicians need to be aware that the science underlying

Table 20.6 Example of Switching From One Route of Administration to Another (Same Drug)

The following example illustrates how to switch from one route of administration to another using the same drug. A 42-year-old woman with metastatic ovarian cancer is receiving morphine sulfate 15 mg/hr IV. She is going to be discharged in 2 days and would prefer to go home with an oral medication. Her parenteral morphine dosage needs to be converted to an oral morphine dosage, e.g., morphine sulfate 15 mg/hr IV to MS Contin PO.

1. Calculate the 24-hour dose of the opioid (including around-the-clock [ATC] and prn rescue doses).
   - Morphine sulfate 15 mg/hr IV = 15 mg × 24 hr = 360 mg IV/24 hr
2. Convert the 24-hour dose of the drug (at prior route of administration) to 24-hour dose of drug (at new route of administration) using the equianalgesic table.
   - Morphine sulfate 10 mg IV = 30 mg PO or 1:3
   - 360 mg IV × 3 = 1,080 mg PO
3. Determine the dosing interval of the new drug. Using sustained-release morphine given q8–12hr, the patient needs 1080 mg PO over 24 hours; therefore, 500 mg every 12 hours.
4. Calculate the prn rescue dose as 5%–15% of the total 24-hour mg dose of the drug. (It may be necessary to adjust the dose because it is commercially available.)
   - 5% of 1,080 mg = 54 mg
   - Therefore, the decision was made to give 60 mg PO q2hr prn as a rescue dose.

Table 20.5 Equianalgesics

Drug	IV/IM/SC	PO	IV:PO	Half-life	Duration
Morphine sulfate	10 mg	30 mg	1:3	2–3 hours	2–4 hours
Codeine	130 mg	200 mg	—	2–3 hours	2–4 hours
Hydromorphone	1.5 mg	7.5 mg	1:5	2–3 hours	2–4 hours
Levorphanol	2 mg	4 mg	1:2	12–15 hours	4–6 hours
Meperidine	75 mg	300 mg	1:4	3–4 hours	2–4 hours
Methadone	10 mg	20 mg	1:2	12–15 hours	4–8 hours
Oxycodone	—	20 mg	—	2–3 hours	2–4 hours
Oxymorphone	1-mg or 5-mg suppository	—	—	2–3 hours	2–4 hours
Fentanyl	100-mcg patch/IV	4-mg morphine sulfate IV/hr			

Adapted from American Pain Society. *Principles of analgesic use in the treatment of acute pain and cancer pain*, ed 6. American Pain Society, Glenview, IL, 2008.

Table 20.7 Example of Switching From One Oral Opioid to Another

A 65-year-old man with metastatic prostate cancer to bone is receiving sustained-release oral morphine 60 mg PO q12hr and is experiencing severe uncontrollable nausea and vomiting. The decision is made to switch him to oral hydromorphone.

Calculate the 24-hour dose of the prior opioid (including ATC and prn rescue doses).

- Sustained-release morphine 60 mg PO q12hr = 120 mg PO/24 hr

1. Convert the 24-hour dose of the prior drug to the 24-hour dose of the new drug using the equianalgesic table.
   - Hydromorphone 7.5 mg PO = Morphine sulfate 30 mg PO
   - Hydromorphone 7.5 mg/X = Morphine sulfate 30 mg/120 mg
   - Cross multiply to get 30X = 900 mg
   - Divide both sides by 30 to get X = 30 mg hydromorphone PO/24 hr
2. Calculate the adjusted total 24-hour dose of the new drug.
   - Adjust the dose of new drug as follows:
     a. Reduce the total 24-hour dose of new drug by 25%–50% to account for incomplete cross tolerance. 50% of hydromorphone 30 mg PO q24hr = 15 mg hydromorphone PO q24hr.
     b. If the patient has inadequate analgesia and no side effects from the prior drug, it may not be necessary to reduce the dose of the new drug.
     c. Reduce the drug more if the patient had significant side effects from the prior drug.
     d. If the patient is frail, reduce the dose of the new drug more (75%).
     e. Reduce the dose of the new drug more if the dose of the prior drug was high (>75 mg IM morphine equivalent/day).
     f. If the new drug is methadone, reduce the total 24-hour dose by 90%.
   - Determine the dosing interval of the new drug.
   - Hydromorphone 15 mg PO/24 hr = 2.5 mg PO q4hr. (It may be necessary to adjust the dose because it is commercially available. Hydromorphone 2 mg PO q4hr.)
3. Calculate the prn rescue dose as 5%–15% of the total 24-hour mg dose of the drug being switched. 15% of hydromorphone 15 mg PO q24hr = 2.25 mg hydromorphone PO q24hr. (It may be necessary to adjust the dose because it is commercially available. Rescue dose = hydromorphone 2 mg PO q2h prn.)

relative potency continues to evolve (Knotkova et al, 2009).

Table 20.8 outlines common adjuvants for specific types of pain (e.g., neuropathic and bone pain). A 2009 study that reviewed the prospective database of 1,038 patients with bone metastasis who were referred to a rapid response radiotherapy program found that a significant proportion of patients were undermedicated for pain each year from 1999 to 2006 (Kirou-Mauro et al, 2009). Individuals with an anticipated life expectancy of more than 4 months; a Karnofsky Performance Status of greater than 60; an adequate bone marrow reserve; and no pending or actual pathological fracture, hypercalcemia, or spinal cord compression were identified as suitable candidates for radiopharmaceuticals. Individuals with more limited bone involvement could be referred for possible focal or wide-field (hemibody) external beam radiation. Dy et al (2008), in their evidenced-based standards for cancer pain management, proposed that individuals with metastatic bone pain be offered single-fraction radiotherapy as a treatment option.

The recommendations for the treatment of neuropathic pain are evolving. In 2007, the Fourth International Conference on the Mechanisms and Treatment of Neuropathic Pain (an independent expert panel) and the International Association for the Study of Pain (a multidisciplinary medical specialty society) developed comprehensive evidence-based guidelines for the pharmacological management of neuropathic pain (Dworkin et al, 2007). After a diagnosis of neuropathic pain is established, it is recommended to initiate therapy of the disease that may be causing the neuropathic pain (if possible) and to start first-line symptom treatment with either a secondary amine TCA (e.g., nortriptyline or desipramine) or a selective serotonin and norepinephrine reuptake inhibitor (SSNRI; e.g., venlafaxine or duloxetine). Another option would be to initiate either gabapentin or pregabalin (calcium channel alpha-2-sigma ligand). In addition, patients with a localized peripheral neuropathic pain could use a topical lidocaine alone on the painful area or use it in combination with a TCA, SSNRI, or calcium channel alpha-2-sigma ligand agent. Opioid analgesics and tramadol have been shown to have analgesic efficacy in multiple randomized controlled trials (RCTs) in patients with neuropathic pain and can be utilized for those with severe pain or to assist with pain relief during titration of the first-line medications. Opioid analgesics and tramadol should also be considered for first-line treatment when there is acute neuropathic pain or for treatment of neuropathic cancer pain. If a patient experiences only partial pain relief on one agent and does not experience intolerable side effects, another first-line agent can be added to the original agent. If, however, the pain relief on the original first-line agent is inadequate after an adequate titration trial, the patient should be switched to an alternative first-line agent. Patients with neuropathic pain need

Table 20.8 Adjuvant Drugs for Specific Types of Pain

Neuropathic Pain

Tricyclic antidepressants
- amitriptyline
- desipramine
- imipramine
- nortriptyline

Antiepileptics
- gabapentin (Neurontin)
- carbamazepine (Tegretol)
- oxcarbazepine (Trileptal)
- topiramate (Topamax)
- levetiracetam (Keppra)
- sodium valproate (Depacon)
- tiagabine (Gabitril)
- lamotrigine (Lamictal)
- zonisamide (Zonegran)

Local anesthetics
- EMLA (topical eutectic mixture of local anesthetics lidocaine and prilocaine)
- Epidural and IV lidocaine
- Oral local anesthetics: mexiletine (Mexitil), tocainide (Tonocard)
- Topical lidocaine 5% patches (Lidoderm)

Glucocorticoids

Alpha-2-adrenergic agonists
- tizanidine (Zanaflex)
- clonidine

NMDA receptor antagonists
- ketamine
- dextromethorphan
- amantadine

GABA agonists
- baclofen

Bone Pain

Glucocorticoids

Bisphosphonates
- pamidronate disodium (Aredia)
- zoledronate (Zometa)

Other osteoclast inhibitor
- calcitonin

Radiopharmaceuticals
- Strontium-89
- Strontium-153

Other

Skeletal muscle relaxants
- tizanidine (Zanaflex)
- Benzodiazepines: diazepam benzodiazepines: diazepam (Valium), clonazepam (Klonopin), lorazepam (Ativan)
- Antihistamines
- Antispasmodics: baclofen

Topical agents
- Capsaicin cream
- Lidocaine 5% patch (Lidoderm)
- EMLA cream

to be continually reassessed for pain relief and quality-of-life issues. Those who fail the first-line agents or who did not meet criteria initially can try opioid analgesics or tramadol as a second-line agent. Third-line agents to be considered include certain antiseizure medications (such as carbamazepine, lamotrigine, oxcarbazepine, topiramate, and valproic acid); antidepressants (such as bupropion, citalopram, paroxetine); mexiletine; *N*-methyl-D-aspartate (NMDA) receptor antagonist; or topical capsaicin. These medications have shown inconsistent results. A referral to a multidisciplinary pain center or a pain specialist is recommended if an individual does not obtain relief from second- or third-line medications (Dworkin et al, 2007). In general, clinicians need to be aware that long-term studies comparing one medication to another, head to head, and those comparing combination regimens still need to be done and must be a priority for research in the treatment of chronic neuropathic pain (O'Connor and Dworkin, 2009). As noted in the 2014 IOM report, pain control continues to be an ongoing area of challenge.

Guidelines that evaluate the clinical practice of using gabapentin and TCAs in the treatment of neuropathic pain in cancer patients found that there is little evidence to demonstrate the superiority of either TCAs or gabapentin over one another in the treatment of neuropathic pain. Both can be effective and are recommended for use in this population. Within the class of TCAs, amitriptyline may have some beneficial effectiveness but may not be as well tolerated in some individuals (Librach et al, 2006).

The Quality Standards Subcommittee of the American Academy of Neurology in 2004 reviewed the literature and made recommendations for another specific neuropathic pain population—those with pain from postherpetic neuralgia. They found TCAs, gabapentin, pregabalin, topical lidocaine patches, and opioids to be effective in the treatment of postherpetic neuralgia pain. They also found epidural morphine, epidural methylprednisolone, acupuncture, benzydamine cream, lorazepam, vitamin E, dextromethorphan, iontophoresis of vincristine, lorazepam, or indomethacin to be of benefit. They noted that at present there is insufficient evidence to make recommendations regarding the long-term effects of the treatments evaluated (Dubinsky et al, 2004). Two updates were added to these guidelines from the National Guideline Clearing House. First, as of December 16, 2008, the U.S. Food and Drug Administration (FDA) is requiring that all manufacturers of antiepileptic drugs include a warning in the labeling of these drugs advising patients prescribed these drugs that there is an increased risk of suicidality. Second, on January 16, 2009, the FDA issued a public health advisory reminding both health-care professionals and patients and their families about the potentially serious hazards of using topical anesthetics. Their concern is that when applied to large areas of skin, or when the area of application is covered, there is a potential for these products to produce an irregular heartbeat, breathing difficulties, seizure, coma, or even death. Their advisory group made recommendations for the safe use of these products (Dubinsky et al, 2004).

Invasive Interventional Pain Management Techniques

There is a small subgroup of patients with pain who may benefit from invasive pain management techniques. Specifically, this group includes individuals who have pain that is localized to one or two areas that is expected to persist. These anesthetic and neurosurgical approaches are indicated when conservative measures utilizing opioids and adjuvant analgesics have failed to provide adequate analgesia or when the patient is experiencing intolerable, unmanageable side effects. These procedures include regional analgesia (spinal, intraventricular, and intrapleural opioids), sympathetic blockade and neurolytic procedures (celiac plexus block, lumbar sympathetic block, cervicothoracic [stellate ganglion] block), or pathway ablation procedure (chemical or surgical rhizotomy or cordotomy). In evaluating patients for these invasive approaches, it is important to ascertain that all other conservative measures have been adequately tried and have failed. Other factors to consider include presence of infection, coagulopathy or use of anticoagulant drugs, functional state, prognosis, coexisting medical conditions, spinal cord disease, and the possibility of rapid progression of disease outside of site that is going to be blocked or ablated (Cherny et al, 1996). Availability of experienced, local health-care providers who can monitor and manage the intervention is essential. A procedure performed by an inexperienced surgeon or anesthesiologist on a medically ill patient may have a suboptimal or an unpredictable outcome (Hassenbach & Cherny, 2004). Readers are directed to other references for a more detailed discussion of interventional pain management techniques (Layman-Goldstein & Coyle, 2010).

To summarize, the APRN should treat according to evidence-based guidelines, which includes keeping abreast of the latest literature in these areas, as well as the limitations of that literature. A good beginning is to treat according to the NCCN guidelines for adult cancer pain (2014). If the patient is thought to be weeks or days from expected death, do not reduce opioid dosage related to a falling blood pressure, respirations, or level of consciousness, and titrate for optimal comfort. This is the goal in palliative care. The clinician should be able to recognize and treat opioid-induced neurotoxicity such as myoclonus and hyperalgesia. If the opioid must be reduced, it should be reduced gradually by 50% within a 24-hour period to prevent acute withdrawal or pain crisis. Patient preference regarding analgesia versus decreased level of consciousness must be a priority. Routes of administration should be modified as needed, applying equianalgesic dose conversions. Specialist consultation may be necessary for management of refractory pain.

Nonpharmacological Pain Management Techniques

Nondrug or nonpharmacological pain management interventions are used to address aspects of an individual's pain that have not responded to other pain management techniques. Selection of a particular nondrug intervention is based on the underlying etiology of the pain and can complement the pharmacological interventions. Nondrug techniques are not to be used as a substitute for pharmacological interventions. Although nondrug interventions cover a broad spectrum of approaches, the three main approaches to nondrug pain management are (1) psychological interventions, (2) physiatric and neurostimulatory interventions, and (3) complementary/integrative interventions. Some interventions may fall into more than one approach. At present, the evidence for the use of nondrug pain management techniques is limited by the lack of large, well-designed, rigorous studies. It is encouraging to see that the evidence-based literature supporting use of these techniques continues to grow (Deng et al, 2004, 2007; Lorenz et al, 2008; Wiffen & Eccleston, 2009).

Psychological interventions for pain management can include patient and family education, distraction, self-statements, relaxation techniques, guided imagery and hypnosis, patient pain diaries, and cognitive-behavioral therapy. Cognitive and behavioral interventions are helpful in reducing emotional distress, improving coping, and offering the patient and family a sense of control. A meta-analysis by Devine (2003) reviewing the effects on pain of nonpharmacological interventions (such as educational, psychosocial, and cognitive-behavioral interventions) in adults with cancer supported the use of these interventions as an adjuvant to analgesic therapy. The Clinical Practice Guidelines for the Management of Cancer Pain Panel (Jacox et al, 1994) and the National Comprehensive Cancer Network (NCCN) cancer pain guidelines for both adults (2014) and pediatric patients (2013) encourage the use of psychosocial interventions for pain management early in the course of disease, as part of a multimodal approach. Clinicians may find that an individual with a life-threatening illness is well versed in using specific psychological approaches and is open to using these techniques to aid in coping with pain and other symptoms. On the other hand, the person may be too weak, debilitated, and cognitively impaired to be taught or even to use a simple, previously utilized, relaxation technique. Assessment is key to developing a realistic plan. The intervention must match the specific problem with an appreciation for the patient's and caregiver's abilities and motivations. Also, nurse practitioners need to be aware of which experts are available in their practice community to facilitate referrals.

Education about pain and its management is an important component of any pain management plan. Oldenmenger et al (2009) found that in 5 out of 11 RCTs patient education decreased pain intensity in a statistically significant way. However, pain control may not be enhanced by additional education without a systematic approach that addresses other barriers, such as inadequate analgesic titration or untreated side effects. The PRO-SELF pain control program "uses education along

with repeated reinforcement, skill building, and ongoing nursing support to improve self-care pain management in patients with cancer and their family caregivers" (West et al, 2003). It has been successful in improving the management of cancer pain (American Pain Society, 2005).

In 1996, the National Institutes of Health (NIH) Technology Panel evaluated the effects of relaxation on pain and sleep. This review provided strong evidence for the use of relaxation techniques to reduce pain. The panel divided relaxation techniques into brief and deep methods. In general, the brief methods take less time to acquire or practice. Very often brief methods are abbreviated forms of a corresponding deep method. The brief methods include deep breathing, focused breathing, paced respiration, and self-control. Deep methods include such techniques as progressive muscle relaxation (PMR), autogenic training, and meditation. To use autogenic training, the patient is taught to imagine a peaceful environment and to focus on a "heaviness in the limbs, warmth in the limbs, cardiac regulation, centering on breathing, warmth in the upper abdomen, and coolness in the forehead" (NIH Technology Assessment Panel, 1996, p. 314). The use of PMR involves the tensing and then relaxing in sequence of each of the 15 major muscle groups.

In 2003, Devine performed a meta-analysis on the effect of nondrug interventions such as educational, psychosocial, and cognitive-behavioral interventions on adults with cancer-related pain by reviewing 25 interventional studies published from 1978 through 2001. Six of these studies tested the effect of education. A homogeneous small-to-moderate statistically significant beneficial effect on pain was found. In her discussion Devine pointed out that with the widely accepted strong mandate to educate patients about their pain and its management, there may not be much of a difference between experimental and control content (Devine, 2003).

Physiatric and neurostimulatory modalities include cutaneous stimulation, exercise, immobilization, acupuncture, and transcutaneous electrical nerve stimulation. Referral to a professional who specializes in these modalities may be indicated as appropriate.

Some of the nondrug approaches to pain management that have been discussed are considered mainstream, traditional Western medicine. Other nonconventional therapies fall under the heading of complementary or alternative. Although complementary and alternative therapies are often grouped together under the heading of complementary and alternative medicine (CAM), they are very different. Complementary therapies are used *in addition to* conventional therapies and in some settings are labeled "integrative." Alternative therapies are used *in place of* traditional, mainstream treatment and are not encouraged in the setting of utilizing evidence-based interventions (Berenson, 2005; Cassileth & Gubili, 2009). *Integrative interventions* is becoming the preferred term for these approaches that complement or augment traditional approaches. The National Center for Complementary and Alternative Medicine (NCCAM) groups the CAM modalities into five main areas:

- Alternative medical systems
- Mind–body interventions
- Biologically based therapies
- Manipulative and body-based therapies
- Energy-based therapies

The nondrug interventions that are discussed in this chapter, either traditional or complementary/integrative, are considered a part of the overall pain management plan. Acupuncture, mind-body therapy, and massage therapy are shown in studies to have the strongest evidence for their clinical use in pain control (Deng et al, 2004).

In Traditional Chinese Medicine (TCM), it is thought that good health depends on the balance of energy in the body. Energy—called *chi* or *qi*—is thought to be constantly circulating in the body. Acupuncture attempts to promote circulation of this vital energy. *Acupuncture,* a holistic, energy-based treatment from TCM, has been shown to effectively treat health problems including pain, depression, and nausea (Deng et al, 2004, 2007; NIH Consensus Conference, 1998). Despite building evidence in the literature supporting the use of acupuncture, it still is underutilized in end-of-life palliative care (Standish et al, 2008). In this approach, thin, disposable needles, usually stainless steel, are placed in precise anatomical points (365 specific locations) to balance energy movement along the body's 12 meridians (Berenson, 2005; Decker, 2000). *Acupressure* is the application of finger pressure to the acupuncture points. *Moxibustion* is the stimulation of an acupuncture point by heat. This is done by burning a special compressed combustible substance near the acupuncture point. Other variations in acupuncture stimulation of sites include the use of electrical stimulators or lasers. The NIH Consensus Conference (1998) found that the data in support of acupuncture are as strong as those for many accepted Western medicine–based therapies, and the incidence of adverse effects from acupuncture is substantially lower than for many standard medical procedures or medications used for the same conditions. Adverse effects from acupuncture can include an occasional drop of blood or bruise at the needle insertion site, mild discomfort at site, infection, or, depending on insertion site, pneumothorax. The latter two effects are rare and depend on the experience and training of the acupuncturist (Berenson, 2005).

Based on high-quality evidence, the Integrative Oncology Practice Guidelines recommend acupuncture as "a complementary therapy when pain is poorly controlled" (Deng et al, 2007). Some studies indicate that it may be helpful as an adjunct treatment in painful situations such as headache, menstrual cramps, fibromyalgia, myofascial pain, osteoarthritis, and low back pain. Its effectiveness in relieving musculoskeletal pain remains controversial (Deng et al, 2004). Controlled studies using

acupuncture in palliative care patients are in the process of development. Ideally, as more research is done and acupuncture is further incorporated into the mainstream health-care system, more informed decisions regarding the appropriateness of acupuncture for patients in varying situations will be made (NIH Consensus Conference, 1998). As health-care professionals, it is important to guide patients from a perspective of evidence, not marketing. A more detailed discussion of acupressure and acupuncture is beyond the scope of this text. At this time, most insurance policies do not cover acupuncture or other integrative approaches, and most patients and families have to pay out of pocket for these interventions.

Music, a mind–body technique, has been shown to be an effective intervention for pain control through a variety of physiological and psychological effects. Affective, cognitive, and sensory processes can be engaged, activated, and altered by music. In palliative care, music therapy "strives to promote well-being and quality of life for patients and caregivers" (Magill, 2009). This is done by processes such as use of prior skills, alteration of mood, distraction, relaxation, and improved sense of control. Physical effects include increasing or decreasing pulse and blood pressure (Magill-Levreault, 1993; Tuls Hallstead & Tuls Roscoe, 2002). Music therapy, as defined by Spross and Wolff Burk (1995), is "the scientific and systematic use of music to effect beneficial changes in physiological and psychological processes that influence experiences of pain and illness" (p. 175). The use of music therapy in the medically ill can reduce mood disturbance (Cassileth et al, 2003) and affect the suffering and total pain that a sick individual experiences. Tuls Halstead and Tuls Roscoe (2002) offer many concrete examples of how to use music to assist patients as listeners and performers.

Music should not be considered the first-line treatment for pain relief. Fifty-one RCTs of adults or children met criteria to look at the effect of music on acute, chronic, or cancer pain. There was a small but positive finding that music reduced pain and reduced requirements for morphine-like analgesics. The types of pain included in the studies (acute postoperative, chronic, labor, procedural, or experimental pain with the majority involving procedural or postoperative pain) may not readily generalize to pain in individuals at the end of life. More rigorous, well-designed studies looking at the use of music as part of a pain management plan for individuals at the end of life are needed.

Cognitive interventions such as relaxation, guided imagery, and hypnosis discussed earlier fall under the NCCAM category of mind–body methods that may also be helpful in the management of chronic pain.

Reiki, a form of energy therapy, is a Japanese term for universal life energy. Current studies are underway to evaluate its role in symptom management, including that of pain. *Reiki* is defined as a vibrational or subtle energy most commonly facilitated by light touch, the use of which is thought to balance the biofield and strengthen the body's ability to heal itself. Reiki practitioners gently place their hands on a fully clothed individual's head, back, front, and the site of discomfort (if the person desires) to promote relaxation and decrease pain (Berenson, 2005; Vitale, 2007). A phase 2 study of Reiki in the management of pain in individuals with advanced cancer showed improved pain control and improved quality of life using this noninvasive intervention but no overall reduction in opioid use (Olson et al, 2003).

A Cochrane Database review of touch therapies for pain relief in adults looked at the effectiveness of Reiki, Therapeutic Touch, and Healing Touch (So et al, 2008). Of the studies evaluated for this review, only three studies met criteria for inclusion for Reiki, five for Healing Touch, and seventeen for Therapeutic Touch. The review found that these touch therapies may have a modest effect on pain relief. Of interest, it found that studies that utilized more experienced practitioners had greater reduction of pain. It concluded that more studies, especially those looking at the effect of touch therapies in children, are needed to provide sufficient evidence to promote the use of these interventions for pain relief.

Patients often initiate nondrug interventions, such as application of heat or use of vibration, and frequently choose a technique based on previous use of a particular intervention or on their personal knowledge of home remedies. The technique chosen may or may not be an optimal method to relieve a particular type of pain. In 2002, the National Center for Complementary and Alternative Medicine (NCCAM) released a study that showed that six of the top nine reasons that people use complementary medicine are pain related (Gray et al, 2002). Although pharmacological interventions are usually a well-thought-out part of a pain-management plan, the use of nondrug interventions often is not. There may be little input from an individual's doctor or nurse in initiating an intervention (Rhiner et al, 1993). Many insurance plans do not currently cover nondrug methods, even when prescribed by a licensed provider as part of a well-thought-out pain management plan. The literature continues to evolve as to which specific nondrug interventions will be most effective in helping to control pain at end of life.

Evidence-based standards promoting high-quality management of cancer pain call for screening for the presence of pain and subsequent assessment if pain is identified (Dy et al, 2008). Successful pain management is based on ongoing assessment and reassessment of the patient. It is important to evaluate the individual carefully and apply what is appropriate for that individual in a particular situation, bearing in mind the individual's goals of care. After the initiation of systemic analgesic therapy (based on the WHO analgesic ladder approach) and treatment of underlying disease (if appropriate), the next step would be to consider the addition of psychological,

physiatric and neurostimulatory, or integrative techniques to improve pain control and possibly improve the balance between analgesia and side effects (American Pain Society, 2005; Cherny & Portenoy, 1994; Dy et al, 2008; Rhiner et al, 1993). If these measures are ineffective, the consideration of the use of invasive techniques is appropriate (Hassenbach & Cherny, 2004; Miguel, 2000). Finally, if it is impossible to balance pain relief and side effects, sedation at the end of life must be considered.

PALLIATIVE MANAGEMENT OF DYSPNEA

Dyspnea may be one of the most frightening and difficult symptoms a patient can experience and can be more difficult to treat than pain. Dyspnea is a subjective feeling of breathlessness, the sensation of labored or difficult breathing, which contributes to severe disability and impaired quality of life. It occurs before death in an estimated 20% to 70% of patients with advanced cancer (Bruera et al, 2000; Ripamonti, 1999; Solano et al, 2006). Patients often describe feelings of suffocation, tightness, congestion, air hunger, choking, or heavy breathing. A review of the literature on management of dyspnea at the end of life reinforces the growing recognition that dyspnea and fear of dyspnea produce profound suffering for patients who are dying and their families. The causes of dyspnea are numerous and related to pulmonary disease, cardiac disease, cancer, metabolic abnormalities, radiation therapy, and surgery. Anxiety is always a component. Higginson and McCarthy (1989) reported that dyspnea prevalence increases in terminally ill patients and is the major uncontrollable symptom. The American Thoracic Society strongly endorses the concept that palliative care for dyspnea be available to patients in all stages of illness and should be individualized based on the needs and preferences of the patient and his or her family (Lanken et al, 2008). It further supports the use of invasive or noninvasive home ventilators and other equipment; the use of oxygen, when appropriate; noninvasive positive pressure ventilation for hypercapnic adults; use of a fan; and opioids and anxiolytics in the management of dyspnea at the end of life.

The 2013 NCCN Guidelines Version 2 includes two new algorithms for palliative management of dyspnea. They stress the importance of prioritizing patient preferences and educating and supporting the family and friends who may be in attendance. These guidelines note that ongoing emotional and spiritual support may be needed for both patient and family to manage this most distressing symptom.

Assessment

Dyspnea is a multidimensional symptom, having both physical and psychological components. For most patients with organic disease, the respiratory distress gets worse with progression of disease. It is highly distressing for families and caregivers, who often feel helpless.

Various tools to measure dyspnea have been documented in the literature and include use of a visual analog scale, structured interviews, self-report questionnaires, and numerical rating scales. Clinical assessment of dyspnea should include a complete history of the symptom, its onset and duration, and precipitating and relieving factors; associated symptoms; and response to medications, oxygen, and behavioral interventions. In cancer patients, data suggest that the frequency and severity of dyspnea increase with progression of disease and, when death is approaching, may be seen as a poor prognostic sign (Booth, 2006). In patients with COPD, intractable breathlessness develops late in the course of the disease, gradually progressing over years.

Etiology and Management of Dyspnea in the Patient With Advanced Cancer

The possible causes of dyspnea in the patient with advanced cancer are multiple and detailed in Table 20.9. Often the etiology is multifactorial, and more than one etiology may be present, especially at the end of life. Relief of dyspnea is aimed at treatment of the underlying disease process, whether malignant or nonmalignant in origin. Symptomatic interventions are used when the process is not reversible.

A variety of sources advocate the use of morphine to manage intractable dyspnea. Jennings et al (2002) completed a systematic review of the use of opioids in breathlessness. They reviewed 18 studies, and the meta-analysis showed a statistically significant positive effect of opioids on the sensation of breathlessness. In another systematic

Table 20.9 Common Causes of Dyspnea in the Advanced Cancer Patient

- Anemia
- Infection
- Pneumonia
- Congestive heart disease
- COPD
- Obstruction of airway by tumor
- Lymphangitic tumor spread in lung
- Pleural effusion
- Asthma
- Pulmonary emboli
- Superior vena cava syndrome
- Fluid overload

- Radiation fibrosis
- Rib, bone fractures
- Anxiety
- Hepatomegaly
- Ascites
- Excess secretions

review of randomized controlled trials assessing all pharmacological and nonpharmacological interventions for dyspnea in cancer patients, Ben-Aharon et al (2008) analyzed the results of 18 trials. Fourteen evaluated pharmacological interventions included opioids, oxygen, helium-enriched air, and furosemide. Four trials evaluated nonpharmacological interventions. The administration of subcutaneous morphine resulted in a significant reduction of dyspnea using a Visual Analog Scale compared with placebo. No difference was observed in dyspnea when nebulized morphine was compared with subcutaneous morphine. The addition of benzodiazepines to morphine was significantly more effective than when morphine was administered alone, without additional adverse effects. Table 20.10 outlines the opioid trials and describes the effect of interventions.

The use of oxygen to relieve dyspnea has been examined. Oxygen was not superior to room air for alleviating dyspnea except for patients with hypoxemia. Oxygen has shown no benefit in alleviating dyspnea in patients without hypoxemia (Ahmedzai et al, 2004; Bruera et al, 2003; Bruera, de Stoutz, et al, 1993; Philip et al, 2006). Hypoxemic patients may not be dyspneic, and if they are, reversing the hypoxemia does not always lessen dyspnea. Patients who are dyspneic should be taught how to use a fan before using inhaled oxygen or air (Booth

Table 20.10 Interventions for Dyspnea

Interventions	Comments
Oxygen	3–5 L/min via nasal cannula In addition to supplemental oxygen, temporary supplemental support such as CPAP or BiPAP may be considered for severe, acute dyspneic episode that is considered reversible
Pharmacotherapy	
Morphine sulfate	SC: 50% higher than regularly scheduled dose SC: 5 mg bolus or 2.5 times regular dose every 4 hours SC: 10 mg every 4 hours IV: 1–5 mg/hr
Bronchodilators	Nebulized: Adrenergic and anticholinergic agents 4 times/day (ipratropium bromide [Atrovent], albuterol [Proventil], isoproterenol HCl [Isuprel], or metaproterenol sulfate [Alupent]) PO or IV: aminophylline PO: theophylline (Theo-Dur) 400 mg daily
Corticosteroids	Inhaler: beclomethasone (Vanceril) 1–2 inhalations 3–4 times/day PO or IV: dexamethasone (Decadron) 8–12 mg daily, then taper PO: prednisone 10–30 mg daily
Anxiolytics	PO: lorazepam (Ativan) 0.5–2 mg every 4–6 hours PO: diazepam (Valium) 2–10 mg 2–4 times daily PO: chlorpromazine (Thorazine) 25–50 mg 3–4 times daily PO: haloperidol (Haldol) 0.5–2 mg 2–4 times daily
Diuretics	PO: furosemide (Lasix) 20–40 mg daily
Anticholinergics to reduce secretions	Scopolamine, atropine, hyoscyamine, and glycopyrrolate (does not cross blood–brain barrier; less likely to cause delirium); scopolamine—transdermal and/or SC
Nonpharmacological Therapies	
Cognitive-behavioral	Relaxation therapy Guided imagery Music Distraction Stress management
Physical measures	Cooler room Fans Physical comfort measures
Support	Ongoing emotional and spiritual support for both patient and family is needed to manage this most distressing symptom

et al, 2008). Helium-enriched air resulted in dyspnea improvement compared with room air or oxygen-enriched air, but this has been evaluated in only one trial (Ahmedzai et al, 2004).

The Oncology Nursing Society, in its Evidence-Based Interventions for Cancer-Related Dyspnea, recommends the use of oral immediate-release and parenteral morphine in treating dyspnea (DiSalvo et al, 2008). It also supports the use of supplemental oxygen in patients with proven hypoxemia.

Nonpharmacological Interventions

Acupuncture, psychological support, breathing control, and coping strategies for dyspnea have been evaluated. In one study of acupuncture followed by acupressure versus placebo acupuncture followed by placebo acupressure, acupuncture was not beneficial for dyspnea relief in cancer patients (Vickers et al, 2005). Nursing intervention studies showed that support, breathing control, and coping strategies have significantly improved breathlessness (Bredin et al, 1999; Corner et al, 1996; Moore et al, 2002). The Cochrane Database review by Bausewein et al (2008) assessed randomized controlled and controlled clinical trials assessing the effects of nonpharmacological and noninvasive interventions to relieve breathlessness due to advanced stages of cancer, COPD, interstitial lung disease, chronic heart failure, or motor neuron disease. They reviewed 47 studies that were categorized to include single interventions such as walking aids, music, chest wall vibration, acupuncture/acupressure, relaxation, neuroelectrical muscle stimulation, and fan. Cooler temperatures, electric fans, stress management techniques, and a variety of physical comfort measures individualized to that patient may help. Multicomponent interventions included counseling and support, breathing training, counseling and support with relaxation, case management, and psychotherapy. They concluded that breathing training, walking aids, neuroelectrical muscle stimulation, and chest wall vibrations appear to be effective in relieving breathlessness in advanced stages of disease. Additionally, there is emerging evidence that in addition to supplemental O_2, temporary ventilator support such as continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP) may be helpful for a severe dyspneic episode that is deemed to be reversible. Management of dyspnea is based on the cause and includes pharmacotherapy (e.g., bronchodilators, steroids, diuretics, vasodilators, antibiotics, opioids, and sedatives), oxygen, nonpharmacological therapies (e.g., relaxation and breathing exercises), and other appropriate therapies (e.g., transfusion, thoracentesis, and radiation therapy). For most dying patients, the pharmacological use of benzodiazepines, opioids, and corticosteroids remains the primary treatment (Dudgeon, Kristjanson, et al, 2001; Dudgeon, Lertzman, et al, 2001). There may be much resistance among primary-care providers to the use of opioids and sedatives because of unfamiliarity with these drugs, lack of experience in treating dyspnea in dying patients, low priority given to this symptom, and fear that these drugs may hasten death. If symptoms are difficult to manage, a consultation with a palliative care expert is recommended, and sedation may be appropriate at the end of life.

Table 20.10 presents interventions commonly used for the management of dyspnea. All interventions should be based on the goals of care, with patient and family included in all decision making.

Based on clinical practice, the use of the mnemonic BREATHES (adapted from Kuebler, 1996) may assist the health-care provider in the symptomatic management of dyspnea:

B: Bronchospasm/persistent cough. Consider nebulized albuterol and/or steroids.

R: Rales/crackles, excess secretions. If present, consider reducing fluid intake. If the patient is receiving IV hydration, reduce the fluid rate or discontinue. Consider gentle diuresis with furosemide 20 to 40 mg PO and spironolactone 100 mg PO daily. If secretions are copious, consider scopolamine patch every 72 hours, atropine 0.3 to 0.5 mg subcutaneous or sublingual every 4 hours prn, or glycopyrrolate (Robinul) 0.1 to 0.4 mg IV/IM/SC every 4 to 12 hours prn.

E: Effusion. Consider thoracentesis or a chest tube, if appropriate and depending on the goals of care. Consider intermittent pleural drainage with an indwelling thoracentesis tube.

A: Anxiety. Manage anxiety with low-dose benzodiazepine such as lorazepam (Ativan) 0.5 to 2 mg every 4 hours prn.

T: Tachypnea and breathlessness. Opioids reduce respiratory rate and feelings of breathlessness and anxiety. If patient is opioid naive, begin with morphine sulfate 10 to 15 mg PO every 4 hours and titrate 25% to 50% daily/every other day as needed. Administer nasal oxygen and/or use of a fan. Coadministration of a benzodiazepine such as lorazepam is useful.

H: Hemoglobin low/anemia. Consider a blood transfusion if anemia is contributing to dyspnea and fatigue. If no improvement, do not continue to transfuse.

E: Educate and empathize. Provide teaching and support to the patient and family during this highly stressful period.

S: Sedate. If dyspnea is intractable despite routine, standard efforts, and the patient is actively dying, consider palliative sedation at the end of life.

In the cancer population, two of the more common causes of dyspnea are airway obstruction from extrinsic compression or endobronchial tumor and malignant pleural effusion. Other options include therapeutic bronchoscopy with stent placement and the use of indwelling catheters for intermittent drainage of pleural effusions.

Case Study 20.1 presents an example of the palliative management of a patient with dyspnea.

CASE STUDY 20.1 Dyspnea

Mr. Rather, a 70-year-old man with lung cancer that has metastasized to bone, has persistent dyspnea. He has received radiation therapy to the mediastinum and completed his last course of chemotherapy 4 months ago. He is still at home receiving morphine sulfate 30 mg PO every 4 hours around the clock for bone pain, which has been very effective. He is also receiving prednisone 30 mg PO two times daily for bronchospasm and has an albuterol inhaler, which he rarely uses. He complains of feeling breathless and anxious. He is also very fatigued and cannot sleep at night. He refuses to go to the hospital and says he wants to die in his own bed. He refuses further aggressive intervention and has signed a home do-not-resuscitate (DNR) order. On physical exam, his breath sounds are decreased bilaterally, with occasional rhonchi and no crackles. He has no distended neck veins, gallop, or peripheral edema. His respiratory rate is 24 per minute at rest.

ASSESSMENT AND INTERVENTION

1. Determine the etiology of dyspnea. In the terminally ill patient, dyspnea often has multiple causes. A thorough history and physical examination should be performed and will assist in determining specific interventions. If excessive fatigue is present, consider obtaining a complete blood count to determine if anemia is contributing to dyspnea. Rule out infection and congestive heart failure as contributing causes. Excessive secretions may be treated with agents such as scopolamine, atropine, hyoscyamine, and glycopyrrolate. If appropriate, use pulse oximetry to determine benefits of oxygen therapy, or try O_2 via nasal cannula at 3 L/min prn.

   Mr. Rather is presently receiving morphine sulfate for pain. Increasing the opioids by 50% to a dose of 45 mg PO every 4 hours should assist with tachypnea and anxiety. He will require assessments daily, and the opioids should be titrated daily or every other day by 25% to 50%. Consider increasing his prednisone dose to treat the bronchospasm and adding a trial of nebulized morphine 2.5 to 5.0 mg every 4 hours prn. Encourage use of an albuterol inhaler three or four times daily for bronchospasm.
2. Consider the benefit versus burden of additional interventions that are employed. Mr. Rather has stated that no further aggressive interventions are to be used. As the goals of care have been identified by the patient, it is important that his family members understand them as well.
3. Assess functional status and reduce the need for physical exertion. Provide for assistance with daily activities, positioning techniques, and frequent rest periods. Use of a fan may reduce feelings of breathlessness.
4. Address anxiety and provide support and reassurance. Determine level of support from family and significant others and from spiritual and religious beliefs. Reassure Mr. Rather that symptoms can be controlled. Provide an anxiolytic.
5. Provide for nonpharmacological interventions (e.g., progressive relaxation, guided imagery) if appropriate to reduce anxiety, handheld fans, and a cool room.

PALLIATIVE MANAGEMENT OF DELIRIUM

Delirium is one of the most common neurological complications at the end of life. The probability of developing delirium is determined by factors that both predispose patients to developing delirium and increase their vulnerability. Delirium, according to the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-V) (American Psychiatric Association, 2013), is characterized as follows:

- Disturbances in attention (reduced ability to direct, focus, sustain, and shift attention and awareness)
- Changes in cognition (e.g., memory deficit, disorientation, language disturbance, perceptual disturbance) that is not better accounted for by a preexisting, established, or evolving dementia
- The disturbance develops over a short period (usually hours to days) and tends to fluctuate during the course of the day
- There is evidence from the history, physical exam, or lab findings that the disturbance is caused by a direct physiological consequence of a general medical condition, an intoxicating substance, medication use, or more than one cause

Table 20.11 outlines DSM-V criteria for the diagnosis of delirium.

Estimates of the prevalence of delirium range from 25% to 40% for patients with cancer at some point during their disease; in the terminal phases of disease, the incidence increases to 90% (Breitbart et al, 2002). The cause of delirium in the medically compromised and dying patient is often multifactorial and often nonspecific.

Table 20.11 DSM-V Criteria for Diagnosing Delirium

1. Disturbance in attention (i.e., reduced ability to direct, focus, sustain, and shift attention and awareness).
2. A change in cognition (e.g., memory deficit, disorientation, and language disturbance or perception disturbances) not better explained by a preexisting established or evolving dementia.
3. The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.
4. There is evidence from the history, physical exam, or lab findings that the disturbance is caused by the direct physiological consequences of a general medical condition, an intoxicating substance, medication use, or more than one cause.

Source: American Psychiatric Association. *Diagnostic and statistical manual of mental disorders, fifth edition.* American Psychiatric Association, Washington, DC, 2013.

Assessment

Because of the complexity of delirium in palliative care settings, it is often underrecognized and undertreated. Behavioral manifestations of delirium include a variety of symptoms that may be interpreted as depression, psychosis, or dementia and may include physiological manifestations such as dysphagia, dysarthria, tremor, or asterixis in patients with comorbid hepatic encephalopathy or uremia. Multiple factors that need to be assessed in the patient include fluid status, electrolyte balance, infection, and polypharmacy. Symptoms include disordered cognition and alteration in arousal (attention), disturbance in consciousness and impaired attention, cognitive changes (memory deficit, disorientation, language disturbance, perceptual disturbance), nightmares, anxiety, restlessness and agitation, irritability, insomnia and daytime somnolence, hallucinations, delusions, and difficulty concentrating. Other symptoms that are often associated with impairment of consciousness, cognitive failure, and psychotic symptoms include disorders of the sleep–wake cycle, vivid dreams, abnormal thoughts, motor abnormalities, and mood changes (Caraceni & Simonetti, 2009). From a behavioral perspective, delirium can be further categorized as hypoactive or hyperactive, depending on level of motor activity and agitation. Patients with hypoactivity are often not diagnosed or receive late diagnosis, owing to the belief that hyperactivity alone is the hallmark of delirium. In reality, hypoactive delirium is the most common type found in the palliative care setting (Breitbart & Alici, 2008) and is often confused with depression. It is characterized by lethargy, sedation, and decreased level of awareness and is associated with a higher rate of mortality. Other assessment measures include the Delirium Symptom Interview (DSI) and the Intensive Care Delirium Screening Checklist (IDS). (Table 20.12 outlines the symptoms and signs of delirium.)

Delirium is often undertreated for several reasons, including lack of assessment tools, inadequate knowledge of early signs of confusion, and inadequate time spent with the patient to determine cognitive function. Mental status questionnaires, such as the Mini–Mental State Exam (Folstein et al, 1983), the Confusion Assessment Method (CAM) (Inouye et al, 1990), and the Memorial Delirium Assessment Scale (MDAS) (Breitbart et al, 1997), are tools that are relatively easy to administer. A review by Hjermstad et al (2004) concluded that the Structured Clinical Interview for DSM-III-R (Spitzer et al, 1990), the Delirium Symptom Interview (Albert et al, 1992), and the CAM are most relevant to palliative care. The CAM is used as a screening tool but has not been validated for use in palliative care. Diagnostic tests that may uncover physiological changes in the patient that correlate with decreased cognitive function include electroencephalography and brain imaging studies such as computed tomography and magnetic resonance imaging.

Management

Treatment of delirium usually includes identification of the underlying cause, correction of the precipitating factors, and symptom management. Multiple underlying causes may include infection, organ failure, medication adverse effects, dehydration, and metabolic abnormalities (Breitbart & Alici, 2008). Medications commonly associated with delirium are opioids, corticosteroids, benzodiazepines, and anticholinergics. In the very ill or dying patient, however, there may be multiple, often irreversible, causes. The goal of palliative care of delirium

Table 20.12 Common Signs and Symptoms of Delirium

1. Level of alertness/wakefulness/arousal:
   - Hypoalert (hypovigilant)—*most common type found in the palliative care setting; often confused with depression*—characterized by lethargy, sedation, decreased level of awareness and is associated with a higher mortality rate
   - Hyperalert (hypervigilant)
   - Mixed—features of both hypovigilant and hypervigilant with fluctuations during the course of the day
2. Impaired attention
3. Altered sleep–wake cycle
4. Motor changes—hypoactive or hyperactive
5. Affective changes
6. Hallucinations (auditory, visual, or mixed)
7. Delusions
8. Cognitive deficits on mental status testing
9. Dysphagia, dysarthria, tremor, or asterixis in patient with comorbid condition such as hepatic encephalopathy or uremia

is the promotion of comfort and relief of suffering. Whenever possible, cognitive function should be maintained. In one study of hospitalized cancer patients, the presence of delusions was the most significant predictor of patient distress (Breitbart et al, 2002); distress occurred for patients with either hyperactive or hypoactive delirium.

Interventions that may be helpful include restoration of fluid and electrolyte balance, environmental changes, and supportive techniques such as elimination of unnecessary stimuli, provision of a safe environment, and measures that reduce anxiety. Reorientation to the environment by staff and family members by placing familiar objects such as pictures and a large clock and calendar may be helpful. Careful nutrition and bowel and bladder monitoring may avoid dehydration and agitation caused by discomfort. Pain should be assessed for regularly and treated appropriately. Maintaining good sleep hygiene measures by a quiet area with minimal interventions may prevent alteration in the sleep–wake cycle. Relaxation techniques such as massage, soothing music, and warm drinks are also indicated. If the cause of delirium is pharmacological, nonessential and central nervous system depressant drugs should be discontinued. Pharmacotherapy, using sedatives and neuroleptics, however, may be used to manage delirium.

Breitbart et al (1996) conducted a double-blind three-drug analysis of the effectiveness of chlorpromazine, haloperidol, and lorazepam in 30 hospitalized AIDS patients. The analysis indicated that both chlorpromazine and haloperidol were effective; the lorazepam arm of the study was stopped because of early adverse effects, namely cognitive impairment.

The American College of Critical Care Medicine has stated that haloperidol should be considered the preferred drug for treatment of delirium in critically ill adults (Shapiro et al, 1995). Haloperidol is considered the drug of choice in the treatment of delirium at the end of life by a number of reviews and case reports (Breitbart et al, 1996; Caraceni & Simonetti, 2009; de Stoutz et al, 1995; Fainsinger et al, 1993; Massie & Holland, 1992; Mazzocato et al, 2000; Roth & Breitbart, 1996).

An intervention review by Lonergan et al (2009) compared the efficacy and incidence of adverse effects of haloperidol with risperidone, olanzapine, and quetiapine in the treatment of delirium. A decrease in delirium scores was not significantly different comparing the effect of low-dose haloperidol (less than 3.0 mg per day) with that of the atypical antipsychotics olanzapine and risperidone (Han & Kim, 2004;). Low-dose haloperidol did not have a higher incidence of adverse effects than the atypical antipsychotics. High-dose haloperidol (greater than 4.5 mg per day) in one study was associated with an increased incidence of extrapyramidal effects (Hu et al, 2004).

One study compared haloperidol and placebo in the prevention of postoperative delirium (Kalisvaart et al, 2005). The study showed no difference between haloperidol and placebo in the incidence of postoperative delirium, but the severity of delirium was significantly higher in placebo patients than in haloperidol patients; the duration of delirium was significantly less for haloperidol patients than for placebo patients. These results show a clear benefit for surgical patients who are at risk for delirium who are treated preventively with haloperidol.

Table 20.13 lists drugs commonly used to manage delirium. Table 20.14 gives an overview of the key points in the assessment and management of the patient with delirium.

Table 20.13 Drugs Used to Manage Delirium

Drug	Dosage	Route
haloperidol (Haldol)	0.5–2 mg every 2–12 hours For mild delirium, begin with 0.5 mg 2 times daily; for more severe symptoms begin with 1 mg 2–3 times daily	PO, IV, SC, IM
thioridazine (Mellaril)	10–75 mg every 4–8 hours	PO
chlorpromazine (Thorazine)	12.5–50 mg every 4–12 hours	PO, IV, IM
lorazepam (Ativan)	0.5–2 mg every 1–4 hours	PO, IV May worsen delirium and should not be used as monotherapy, always in addition to a neuroleptic when sedation is required
midazolam (Versed)	30–100 mg/24 hr	IV, SC
risperidone	0.5–2 mg every 2–12 hours	PO
olanzapine (Zyprexa)	2.5–5 mg every 12–24 hours	PO Use if sedation is needed to manage an agitated delirium

Table 20.14 At a Glance: Assessment and Management of Delirium

1. Determine the etiology of delirium including common predisposing factors (fever, infection, tumor, altered metabolism of drugs, alcohol, comorbid conditions, urinary/bowel retention). Cause is most often multifactorial in dying patients.
2. Medications commonly associated with delirium are opioids, corticosteroids, benzodiazepines, and anticholinergics.
3. Obtain a careful history of onset and duration of symptoms. Severity of symptoms should be determined. A Mini–Mental State Exam should be performed at intervals during hospitalization. Other assessment measures include the Delirium Symptom Inventory (DSI) and the Intensive Care Delirium Screening Checklist (ICDSC).
4. Treat the underlying cause if possible.
5. Review the goals of care with the patient and family and document in the medical record.
6. Identify advance directives with the patient and family and document in the medical record.
7. Pharmacological management should always include administration of a neuroleptic as a first-line treatment. Add a benzodiazepine if sedation is needed, but benzodiazepines should not be used as first-line therapy.
8. Incorporate nonpharmacological interventions when appropriate such as maintaining good sleep hygiene by maintenance of a quiet environment with minimal interventions.
9. Relaxation techniques such as massage, soothing music, warm drinks.

The European Association for Palliative Care and other palliative care experts advocate for the use of sedation to manage intractable symptoms at the end of life, including agitated delirium, that are refractory to aggressive measures. Symptoms that are refractory cannot be adequately controlled despite aggressive efforts to identify an acceptable therapy that does not compromise consciousness. When determining that a symptom is refractory, considerations include whether further interventions are incapable of providing adequate relief, are associated with excessive or intolerable morbidity, or are unlikely to provide relief in a timely manner. Inherent in this decision-making process is the informed consent of the patient, if possible, and the health-care proxy. Because loss of interactional function will most likely occur, it is important that the patient and family understand the outcomes of this decision. A pain and palliative care expert clinician should be involved in this process (Cherny et al, 2009).

Ethical and Legal Issues of a Caring-Based Practice

Chapter 21

ETHICAL ISSUES

The American Nurses Association (ANA) has designated 2015 as the Year of Ethics in conjunction with the 2014 Gallup Poll, once again citing nursing as being #1 on the list of professions with the highest ethical standards in their annual survey on honesty and ethics.

With economic, social, and legal constraints present in our everyday practice, it is no wonder that health-care providers face ethical dilemmas daily. This section begins with an overview of what ethics is, what constitutes an ethical dilemma, different theoretical approaches to analyzing dilemmas, and a description of ethical principles. Each of us lives by a moral code, whether or not we have taken the time to reflect on what this means. Some people live by the simple code of "an eye for an eye"; others use the "Golden Rule" that forms the core of major religions (see Table 21.1).

Table 21.1 Golden Rules

Whatsoever ye would that men should do to you, do ye even so to them.	*Christianity (Jesus)*
What is hateful to yourself, don't do to your fellow man.	*Judaism (Rabbi Hillel)*
What you don't want done to yourself; don't do to others.	*Confucius*
Hurt not other with that which pains thyself.	*Buddhism*
May I do to others as I would that they should do unto me.	*Plato*
Do naught to others which if done to thee would cause thee pain.	*Hinduism (Mahabharata)*
Hurt no one so that no one may hurt you.	*Islam (Muhammad)*

It is more and more difficult to practice ethically in health care today for many reasons, including dehumanizing procedures, technological advances that affect the quality of life, and the potential for unauthorized sharing of confidential information and violations of privacy because of easy access to data banks. Patients and providers must contend with these and many other problems. Historically, the "virtuous" man or woman who faithfully followed rules that were largely etiquette could be termed *ethical.* Even the early Code for Nurses of the American Nurses Association (ANA) in 1950 dealt with issues of etiquette as being synonymous with ethics. Today, in view of the questions posed by modern health-care practices, those rules seem simplistic.

Ethics

Ethics is a branch of philosophy that considers what is right and what one ought to do when confronted with moral choices. It is termed *bioethics* when those moral choices involve health care. Personal and professional values influence our daily professional lives. Many of these values are known and explicit; others are hidden and unknown. When involved in a professional practice, providers cannot escape the need to clarify their own values. Many excellent books on values clarification (see Resources) are available that can assist health-care providers in exploring their own values and in deciding what is meaningful or valued to them to facilitate self-understanding.

Ethics is integrally related to nursing because nursing is a practice with an inherent moral sense. Nursing ethics attempts to articulate that moral sense, to assess its fulfillment, to explore new possibilities for its fulfillment, and to appraise its adequacy. A classic saying is, "A patient doesn't care what a nurse knows until he knows a nurse cares." This could not be truer than in any situation with a health-care provider and a patient involving life and death choices. The patient wants to know that the provider is an advocate, a friend, and a trusted expert, not someone who is consumed with billing practices or always watching the clock. In addition, professional nursing is both "valued within U.S.

society and is uniquely accountable to that society" (ANA, 2010).

The Skill of Ethical Action

Ethics is the standards or principles governing one's actions in professional practice. It is what the professional "ought" to do. Ethical behavior serves to protect the rights of human beings; a code of ethics is characteristic of all professions. To apply ethics, there are three basic philosophical skills that clinicians need to foster or acquire. First, the clinician must develop an ability for in-depth questioning, not just taking information at face value. Next, the clinician must develop the ability to understand different points of view and make a reasonable, empathetic effort to understand another person's opposing viewpoint. Finally, the clinician must not be afraid to argue a point logically. A dialectic exchange occurs when both parties learn something; it is a win–win situation. It is similar to a formal debate in that those who do not know their opponents' arguments do not completely understand their own.

Professional Codes

The ANA has a Code of Ethics for Nurses; the American Medical Association (AMA) has a code of ethics titled the Principles of Medical Ethics; and the American Hospital Association has a Patient's Bill of Rights, which delineates the hospital's code of conduct owed to patients. There is also a Code of the International Council of Nurses (ICN). The ANA's Code of Ethics for Nurses (the Code) was first adopted in 1950. It helped to legitimize nursing as a profession because one of the components of a profession is having a code of conduct that governs its actions. The Code was formulated by nurses, for nurses, and was voted on at a national ANA convention that had delegates representing all ANA members. The Code serves as a contract between society and the nursing profession: It explicitly sets forth the values and ethical principles that guide the clinical decisions of all practicing nurses. The Code provides a framework within which nurses and advanced practice registered nurses (APRNs) can make ethical decisions and be held accountable to the public for those decisions. It also provides guidance for carrying out the professional role and aids in justifying differences between personal and professional values.

The primary purpose of the Code of Ethics is promotion of high-quality nursing care and protection of the public from incompetent or unethical nursing practice. The Code, revised in 2014, continues to indicate that the recipient of care is the primary consideration in any conflict of interest. The Code sets the ethical standards for nursing, whereas the Nursing Practice Act of each state establishes the legal standards. The requirements of the Code may often exceed, but are never less than, those of the law. To read about the Code of Ethics and the Interpretive Statements, go to www.nursingworld.org.

One of the provisions of the Code states that part of being a professional, and one who is ethical, is to advance the profession by being a member of the association that represents the professionals. For nurses, this is the ANA. Although there are many specialty nursing organizations, the ANA is the umbrella organization that speaks for all nurses. Yet only about 10% of nurses belong to the organization. Increasing membership, particularly among APRNs, is one of the challenges facing nurses who need to become active to effect legislative change. Involvement in the ANA is essential to assist nurses in participating in setting and monitoring national health objectives as in *Healthy People 2020,* including Health Literacy (see Table 21.2).

Ethical Dilemmas

Ethical dilemmas may stem from conflicts regarding what is "right" and other duties and obligations. These conflicts may be between two ethical principles one holds, between two possible actions that both seem right in some way, between the demand for action and the need for reflection, and between two unsatisfactory alternatives. Socrates said that we "must let reason determine our ethical decisions rather than emotion." This is why nursing students are taught to use ethical dilemma resolution guidelines to assist them in the process. Before we can resolve a dilemma, however, we must explore different theoretical approaches and discuss ethical principles.

Table 21.2 *Healthy People 2020*

Since 1979, *Healthy People* has set and monitored national health objectives that meet a broad range of health needs, encourage collaboration across geographical locations, guide individuals toward choosing informed healthy decisions, and measure the impact of preventive actions. *Healthy People 2010* led the way to achieve increased quality and years of healthy life and the elimination of health disparities.

Every 10 years, the U.S. Department of Health and Human Services uses scientific insights and lessons learned from the past decade, along with new knowledge of current data, trends, and innovations, to develop new guidelines. *Healthy People 2020* reflects assessments of major risks to health and wellness, changing public health priorities, and emerging issues related to the nation's health preparedness and prevention.

Regional public comment meetings across the nation were held to draft objectives and develop the framework for selecting the vision, mission, goals, focus areas, and criteria for prioritizing the objectives for the guidelines.

To keep abreast of the process and to see the guidelines, go to http://healthypeople.gov/HP2020.

Ethical Issues for Health-Care Providers

Although there are endless ethical issues for providers in the health-care arena, the most common ones facing practitioners today include the following:

- End-of-life issues: Do-not-resuscitate (DNR) orders, Allow Natural Death (AND) orders, advance directives, artificial nutrition and hydration
- Health-care reform issues
- Cost-containment issues
- Breaches of patient confidentiality
- Incompetent and/or unethical conduct of other health-care professionals
- Pain management and palliative care
- Informed consent
- Access to care
- Health literacy
- HIV and AIDS issues
- Issues surrounding genetics/genomics

Theoretical Approaches

There are many different ethical theories, from developmentalists such as Kohlberg with an ethic of justice, to a feminist perspective of Gilligan with her ethic of caring. Many studies have been done to examine the ethical reasoning of males and females. At least one study comparing the decision making regarding dilemmas between medical students (mostly male) and nursing students (mostly female) found no difference in reasoning abilities. We all face dilemmas with different value systems. Because each individual may use different ethical theories as a basis for his or her decision making, it is necessary to understand where someone else is coming from. These ethical theories suggest how to think and what to think about in dealing with conflicts that require choices. They do not solve dilemmas but rather suggest ways of structuring and clarifying the process.

Two of the most common approaches to analyzing ethical dilemmas are *deontology* and *teleology*.

Deontology

The term *deontology* literally means "from being." The concept involves the notion that there are specific duties we have as rational beings that cannot be broached without incurring moral evil. Immanuel Kant championed this moral perspective in his work.

- Principle of universalizability: Act the same in similar situations.
- Consider the nature of the act itself and the principles or rules involved.
- "Duties" are based on "rights."
- The means justify the ends.
- "Do unto others as you would have others do unto you."

Teleology

The term *teleology* literally means "the study of goals or ends." The concept here is that there are specific goals or ends that human life is intended to achieve, and the role of living well is to enable a person to achieve those goals or ends. Typically, a teleological approach will claim that a human being ought to achieve happiness. Happiness is defined in different ways. Then the ethicist will provide principles or rules of attaining that end. There are many different forms of teleological ethical positions. The most well known are Virtue ethics (Aristotle), Divine Command theory (Aquinas), and Utilitarianism (John Stuart Mill).

- Utilitarianism: The greatest amount of happiness or the least amount of harm for the greatest number
- Considers consequences; calculates benefits
- Theories that focus on goals or ends
- Ends justify the means
- Community-oriented theory; also thinks of future generations

The two approaches to analyzing dilemmas may be further explained by comparing the ways both could be applied in several situations. In the first situation, the same outcome may occur even though two different approaches are taken. Consider the patient who has just found out he is HIV-positive and does not want his partner to be told. A clinician using the deontological approach would act the same in any similar situation and would never tell a lie: The clinician would tell the partner that the patient was HIV-positive. A clinician using the teleological approach would focus on the ends justifying the means: The clinician would feel that the partner has a right to know because he could become infected. The clinician also would calculate the consequences of telling or not telling and would feel that it is best for everyone involved in this situation to know the truth about the patient's condition. In this situation, both the deontologist and the teleologist came to the same decision.

Another example of a situation in which these two different approaches are used, but with different outcomes, is a situation involving a terminally ill patient who is on life support. The deontologist would consider the nature of the act itself (the sanctity of life), the uniqueness of each individual, and the high sense of duty, and would keep the patient on the ventilator. The teleologist, on the other hand, would consider the consequences of maintaining the dying patient on life support, would recognize and consider the suffering of the patient and family, both now and after long-term ventilator treatment, and would support the family in withdrawing the life support. It is imperative that health-care providers look at both sides of ethical dilemmas and at both approaches to analyzing dilemmas so that they may effectively communicate with

someone who is approaching the situation from a different viewpoint. If the clinician is unable to "speak the language" of others involved in the dilemma, there is no communicating, and the dilemma may remain unsolved. Communication among all parties is essential.

Ethical Principles

Just as we use principles of physics, biochemistry, psychology, and body mechanics in our everyday functioning as clinicians, we must incorporate principles of ethics in our everyday reasoning (Table 21.3). In recognizing the relationship between principles in physics and those principles in ethics, one should keep in mind that the nature of the principles of physics govern the motion or properties of physical reality in such a way that explain why some object acts as it does. The principles in ethics usually contain the moral "ought." This is important, because unlike the principles of physics, the principles in ethics can be broken. We cannot violate the principle of gravity, but we can violate the principle of autonomy. In other words, when one thinks about the principles of ethics, these principles not only set a standard of behavior but also identify and explain why some actions fail to uphold the principle. These bioethical principles (relating to health care) help us respond to specific dilemmas despite the diversity of the moral traditions from which they are derived. Each ethical conflict that a clinician faces may call for the application of different principles. A dilemma may occur that requires one principle to be sacrificed in favor of another, depending on the situation. Just because the clinician may be clinically competent does not necessarily mean that he or she has expertise in dealing with ethical dilemmas. Reasoning at a principled level is a skill that each individual must practice in order to become morally competent.

Autonomy

The first ethical principle is *autonomy,* which deals with personal liberty of action and self-determination, along with respect for all persons as individuals. It is one of the most frequently mentioned moral principles in contemporary biomedical ethics. Autonomy, sometimes defined as "free will," is a principle deeply rooted in the liberal Western tradition emphasizing the importance of individual freedom and choice. *Autonomy* means "the ability to act or choose without outside interference." For example, if someone were persuaded to invest his or her life savings in a shady business venture, there is some real sense that that person acted freely. However, if you were asked to hold your hand over some button that, if pushed, would launch some terrible weapon, then your hand was forced down, it would not be reasonable to say that you acted freely. The main difference here is that someone interfered with your ability to choose and act by forcing your hand. Mayeroff (1971) suggested that autonomy is living the meaning of one's life. A truly autonomous person freely chooses actions that are authentic and in concert with basic values. Clinicians, as well as patients, are autonomous. Professional autonomy includes control over the terms of practice, content of the discipline, and the regulation of standards.

This principle of autonomy in bioethical contexts is the basis for medical decisions and informed consent, along with access to health care. The principle of autonomy involves giving patients options and allowing them to choose their own course of action, thereby nurturing the wholeness of the person. Informed consent addresses the strong advocacy component of the health-care provider role and is a large component of autonomy (see Table 21.4). Lack of informed consent accounts for about 10% of all lawsuits against providers.

Situations requiring informed consent include invasive procedures; treatment with significant risks, such as chemotherapy; clinical trials; and research. Situations that do not require informed consent include those involving therapeutic privilege, in which the provider anticipates harm from the knowledge that would be shared during the consent process, in an emergency situation, or with the therapeutic use of

Table 21.3 Ethical Principles

Table 21.4 Elements of Informed Consent

Informed consent has two elements:

1. Informed: Information given to the patient about procedure or treatment
2. Consent: The patient's autonomous agreement

To be informed, the patient must receive, *in terms that he or she can understand,* all the information that would affect a reasonable person's decision to consent to or to refuse the procedure or treatment. The information should include all of the following:

1. Description of proposed procedure or treatment
2. Name and qualifications of person performing the procedure
3. Explanation of the potential for death or serious harm or for the discomforting side effects during or after the treatment
4. Alternative treatments available
5. The effects of not having treatment

placebos. Informed consent at its best helps to ensure that the patient takes an active role in dealing with the medical uncertainties and potential problems associated with any procedure to be performed.

A potential ethical behavior that restricts autonomy is paternalism. Health-care providers may assume that they know what's best for the patient and order what they deem to be appropriate, thus acting in a paternalistic manner toward patients, restricting their autonomy. The overall term is *parentalism,* that is, acting as a parent would toward a child and assuming that one knows what is best. An example of parentalism is the clinician who orders a medication for a patient without obtaining his or her consent and says, "Take this; it's essential." Although the treatment may be the correct one, to respect the patient as a person, we should involve him or her in the care and get the patient's approval for treatment. By giving the patient a vested interest in the outcome of care, he or she may be more likely to adhere to the prescribed regimen.

Parentalism involves both paternalism and maternalism. *Paternalism* is the way a father would act toward a child, a more stern approach. A clinician who says, "Cigarettes will kill you. If you're not going to stop smoking, I can't care for you anymore," is using a paternalistic approach. *Maternalism* is the way a mother would react to a child. The end result is the same as paternalism, but it usually involves gentle coercion. A clinician addressing the same patient in a maternalistic manner might say, in effect, "Please don't smoke; it hurts my feelings when you don't follow my recommendations. I don't want to go to your funeral." The best way a clinician can respect a patient's autonomy is to give him or her all the facts, and let the patient choose.

Parentalistic behavior, regardless of benevolent motives or the magnitude of the benefit to be secured or the harm to be avoided, overrides the right of each adult to be treated as a person. To respect another as a person and to maintain his or her autonomy is to take full account of the patient's values. To disregard these values and act paternalistic toward a patient shows contempt for the individual as a person. It regards the person as a mere object rather than one's equal as a person, even if the provider is trying to do something to benefit the patient or protect the patient from harm.

It is within this principle of autonomy that the patient's competence and capacity are considered when dealing with patients who exhibit mental status changes. *Competence* is a legal status; all adults older than age 18 years are assumed to be competent unless a judge specifically declares otherwise. *Capacity* is judged clinically and has to do with whether or not the patient is capable of understanding the options presented. *Substituted judgment* is a different approach to maintaining someone's autonomy because the patient's own value system is used in making a decision: One seeks to decide what the patient would have decided if the patient had been able to do so.

There are some instances in which the principle of autonomy may be overridden by the state. These situations include an emergency procedure that is necessary to protect a life, such as a blood transfusion for a child of a Jehovah's Witness or an intervention when the potential for suicide exists. A provider can legally treat a patient without getting his or her consent if the patient needs immediate treatment to save his or her life; to prevent loss of an organ, limb, or function; if the patient is unconscious; or, in the case of a minor, if the family cannot be reached. In such situations, the law assumes that if a patient could decide, he or she would choose to receive treatment. This exception is limited. It does not apply if the provider knows the patient had previously said he or she would refuse such treatment if and when offered, or if the provider can wait for consent to be obtained. In only two instances is it legal to have a consent form signed by someone other than the patient: (1) in the instance of a minor and (2) when the patient has been declared legally incompetent.

Another exception to the need for informed consent is when a patient waives the requirement to be informed. A patient may not want to know the details. Nonetheless, the provider still has two responsibilities. The provider must make sure the patient understands that risks and alternatives do exist, and then the provider must clearly document the patient's waiver of his or her right to receive information. Some facilities assume no responsibility for obtaining informed consent and supply no forms for doing so. Their premise is that even with detailed consent forms, it is impossible to provide all the relevant information and that completing the forms actually lessens the communication between the provider and the patient. The actual process of informed consent is what should be aimed for, rather than the completion of forms.

Beneficence

The second ethical principle is *beneficence,* which is mentioned in the Nightingale pledge. It is the provision of benefits and a balancing of harms and benefits and requires positive action. One must purposefully choose the right action, not merely by omission, and do what is in the best interest of the patient. Positive beneficence requires personal risk-taking. For example, clinicians who care for persons with AIDS are acting beneficently toward those patients by caring for them. Beneficence encompasses the principle of utility or proportionality when one weighs the probability of benefits and harms in order to produce the maximal net benefit (utility).

Nonmaleficence

The third ethical principle is *nonmaleficence,* the idea that a health-care provider should, above all, "do no harm,"

which is mentioned in the Hippocratic Oath. This principle, the foundation on which health care rests, forms the basis for most medical and nursing codes of ethics. It usually involves omissions and does not require taking positive action; the emphasis is on not taking the wrong action and doing something to harm the patient. Several moral rules, such as the prohibition of killing, are derived from nonmaleficence. It must be stressed, however, that it is almost always impossible to ensure someone's benefit without risking some harm. Consider the patient with cancer who is receiving chemotherapy. Chemotherapy may be considered a positive benefit, but the side effects are definitely deleterious. Paternalism is also deeply imbedded within this principle because it is extremely difficult to respect a patient's autonomy while wanting to resolve the conflicts between beneficence and nonmaleficence. Most clinicians want the patient to choose the "right" decision. Consider the situation in which we know a patient would benefit from chemotherapy, yet the patient refuses because of a bad experience that a relative had with similar therapy. The patient's autonomy overrides our beneficent wish in this situation.

Veracity

The fourth principle is *veracity,* or truth telling. Health-care providers may tell half-truths or may omit information because they feel that the patient cannot "handle" the news. Using the principle of autonomy, it is the right of the patient to know and to decide if he or she wants any further information or not. As practitioners, we cannot make that decision for our patients. Veracity is important for obtaining informed consent. The critical issue here is that the patient understands or comprehends what the procedure will do or will cost. One must not only tell the truth, but also tell it in a manner that is understandable by the listener.

Confidentiality

The fifth principle is *confidentiality,* which involves respecting privileged information. This is becoming more and more of a problem because computers can provide access to all kinds of personal information. Consider the situation of the patient who requests a breast cancer gene test to see if she is a candidate for prophylactic care, and the insurance company cancels her policy because she might develop breast cancer in the future. Confidentiality, as well as veracity, are extremely important components of the provider-patient relationship.

Health-care providers need to be aware of the Health Insurance Portability and Accountability Act (HIPAA), which has been fully implemented since 2003. All health-care providers are responsible for maintaining secure electronic files and for ensuring confidentiality when sharing information between health-care providers and third-party organizations. Mandated development of electronic health records (EHR) or electronic medical records (EMR) increase both the potential ethical dilemmas and the positive aspects of efficiency/communication issues.

Fidelity

The sixth ethical principle is *fidelity,* or keeping promises. How many times have we heard providers say that if treatment A does not work, they will try another drug, or treatment B? When the time comes, however, they change their minds because the referral is not indicated, or it would make a negative impact on the audit that the insurance company will do shortly, or the insurance company will not pay for it. We promise that we are going to do all we can to help a patient, and then, when care is futile, the type of care is changed to custodial caring rather than curative caring. Fidelity is critical also because it avoids setting up false expectations. If a health-care provider claims that he or she will do something but fails to follow through, the patient may later not request needed assistance because the patient is expecting the promise maker to once again fail to follow through. The result may be someone not receiving a needed treatment, not believing what others inform them, and so forth.

Justice

The principle of justice or fairness involves weighing individual rights. Justice is the most complex and difficult principle to apply to health care. We frequently must use this principle to allocate scarce resources. The concept of justice in play here is what philosophers call *distributive justice.* The notion involves the idea of how to be fair to everyone involved while recognizing that some resource is scarce. For example, consider the following ways in which a tax refund could be distributed. If the government receives more revenue than needed, there are several ways to distribute the excess: (1) Anyone who filed a tax form and overpaid could receive the same refund; (2) everyone who submitted a tax form and overpaid would receive back what that person overpaid; or (3) everyone who submitted a tax form and was born on a Sunday would receive the same share, but no one else would receive a share. All three of these possible distribution patterns of tax refunds are possible, but no one would think (unless that person was born on Sunday) that the third pattern was fair. The real debate is between the first and the second pattern of distribution. Typically, distribution patterns that are considered fair are ones in which proportionality of the scarce resource is balanced by the need or the immediacy of receiving the resource. There may be only four hearts available for transplant. Eight patients need these, but one patient may die within a few days without the transplant. The immediacy of the need would weigh into how these resources were distributed if the distribution were just. The decision must be based on principles rather than emotion; to be fair to patients, like cases should be

treated alike. For example, if there are only so many patient-controlled analgesia pumps available and several candidates need one, who will get the last one? Who should get the liver transplant, and how many times should it be done before it is considered futile? One of the goals of *Healthy People 2010* was to eliminate health disparities. In *Healthy People 2020,* one of the goals is to identify nationwide health improvement priorities. The principle of justice employed in all situations will help achieve this goal.

If these ethical principles are applied deliberately and consistently in practice, fewer mistakes will be made, less harm will be done to patients, autonomy will be respected, and decisions will be based on ethics. Changes in the health-care system are a challenge to health-care providers. Do these changes present ethical dilemmas? Definitely so! An *ethical dilemma* is a situation in which there is no satisfactory answer, and, although many options are available, one seems to conflict with another. Nursing Situation 21.1 presents an ethical dilemma.

Resolution Guidelines

Although there is no blueprint for analyzing dilemmas, the mnemonic ETHICAL is a framework that can be used to provide a systematic method for acting consistently in ethical dilemmas, thus allowing reason rather than emotion to guide one's actions.

E Examine the data.
T Think about which person(s) should be making the decision.
H Humanize the options by constructing a decision tree.
I Incorporate the ethical principles, legal statutes, standards of care, and so on.
C Choose an option.
A Act.
L Look back and evaluate.

Consider the following situation and use **ETHICAL** as a framework to guide your actions:

Sylvia is an 86-year-old woman who presents with a massive suspicious breast lump and a new cough. She has not had a well-woman exam in years, nor has she done a monthly breast self-exam. The clinician explains that she wants Sylvia to get a mammogram. Sylvia refuses, stating that she does not want to know the results. What if the test is positive? Sylvia does not want surgery at her age. After a lengthy discussion, the clinician broaches the subject of advance directives. Sylvia states that, as a widow, she has nothing to live for, but she does not want to sign "a death sentence." She states, "When God wants me, he'll take me." This implies that she does not want extraordinary measures taken to keep her alive.

When applying the resolution guidelines in this situation, the first aspect to consider is **E**, examine the data. The clinician has detected a breast mass and recommended a mammogram as the next step in the diagnostic process. Sylvia has refused. In this step, all the information should be collected and the key participants identified. When interpreting the data, the conflicts presented in the situation should be identified. Are there conflicting rights and obligations? Is there a conflict between two unsatisfactory choices of action? The clinician should enter the world of the person involved and look at the situation from that perspective. The *Circle of Caring* model is definitely utilized in ethical

Nursing Situation 21.1 Ethical Dilemmas

Situation 1

Shelly has been an APRN for a number of years and has been frustrated with the change in the health-care system and the resultant care that patients receive. When Joseph Harms, one of her patients, was cut back to part-time hours at work, he and his wife lost their health insurance. Mrs. Harms has been treated by Shelly for several years now for type 2 diabetes mellitus and has been very erratic in glycemic control. The Harmses cannot afford to come in as frequently as they did in the past and now must pay the office and pharmacy bills out of their own pockets. Shelly gives them free samples whenever possible and feels like she is not giving the best quality care when they insist they cannot afford any blood work—only the Accu-Chek in the office. Each office visit costs $60. Shelly has no control over billing.

1. What may happen if a fasting blood sugar, glycohemoglobin (Hb A1C), and urinalysis are not routinely ordered?
2. What may happen if Mrs. Harms cannot afford to see the ophthalmologist and podiatrist this year?

Situation 2

Jessica is 16 years old and is on birth control pills. Her relationship with her mother is precarious. Jessica's mom accompanies her to the NP's office because of symptoms of bronchitis. Samantha, the NP, wants to order an antibiotic; but Jessica's birth control pills will not be effective during the course of antibiotics. Samantha is not sure if Jessica's mom knows her daughter is taking birth control pills. Jessica's mom won't leave the room.

1. Jessica's mom already stated she would not leave Jessica alone in the room. Should Samantha insist?
2. Even though Jessica's mother is present, should Samantha go ahead and tell Jessica about the interactions between antibiotics and birth control pills and the need to use another form of birth control when/if engaging in intercourse?
3. How far does the principle of confidentiality extend? Does the fact that Jessica is a minor play any part?

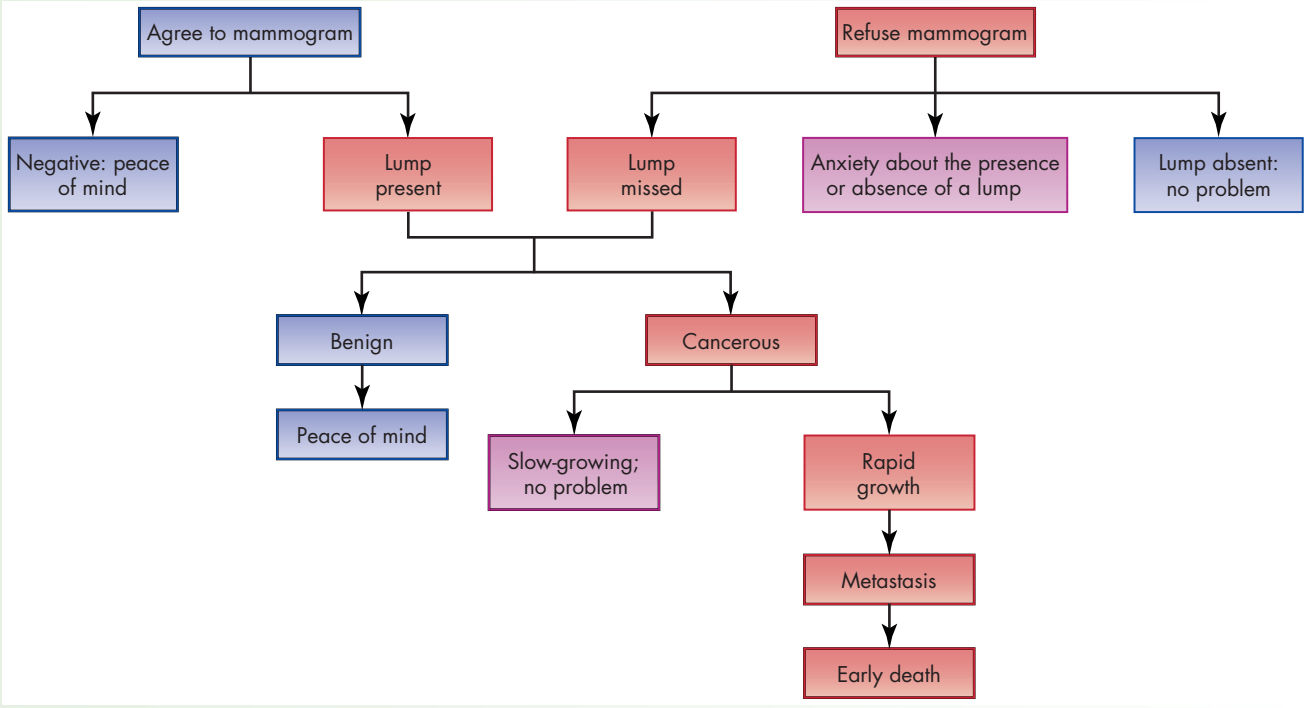
dilemmas. The clinician should delineate the scope of responsibility and authority of each person. Factors should be identified that could limit each person's ability to participate in the decision making, such as fear, coercion, and pain.

The second step, **T**, refers to thinking about and identifying the person(s) who should be making the decision. We do not know if other family members are involved in Sylvia's care, but because she is coming to the office by herself, the clinician assumes that she is independent, competent, and certainly capable of making her own decisions. Even if there were a daughter nearby, the decision would still be Sylvia's to make, although the clinician might ask Sylvia if he or she could discuss the situation with her daughter and share his or her perspective. In most instances, there are other persons or ethical agents involved in the decision making, such as the patient's family, physician, institution, clergy, social worker, and various therapists and consultants. The rights, duties, and responsibilities of each participant must be clarified and analyzed. In addition, because health-care ethics is a complex subject, there will always be difficult cases that will require consultation with people who have special training in relevant fields.

The third step, **H**, is to humanize the options by constructing a decision tree as shown in Table 21.5. This allows all the options to be considered along with all the consequences of those options. Visualizing the results in this fashion can help narrow down acceptable options.

The fourth step, **I**, stands for incorporating all the extraneous data that must be considered when making ethical and/or legal choices. Certainly the clinician is reflecting on his or her ethical principles. By allowing Sylvia the right to make her own choice, even though it is in disagreement with her own recommendation, the clinician is maintaining Sylvia's autonomy. If the clinician were to be beneficent in his or her actions, he or she might strongly urge (coerce) Sylvia to have the mammogram. But then what? Why pursue the mammogram if Sylvia has already stated that if it shows a problem, she will not consider any further action, for example, a biopsy, or more invasive surgery? Does Sylvia have the right to choose an option that might essentially be signing a "death warrant"? Yes, she does, as long as she is competent and has all the information presented to her. The decision tree allows Sylvia to see all the options and the resulting consequences. Although we cannot predict which branch of the tree this particular scenario will take, Sylvia has the right to consider all branches. In this step in the ethical inquiry, all the basic principles should be considered. How does each ethical principle relate to the decision? The Code of Ethics for Nurses should help guide the action. Although codes by definition are brief and general, when used in combination with exploring the relationship of all the ethical principles to the proposed decision, the outcome will be ethical. This step usually points to the most ethical course of action. The ultimate goal of laws is to protect individual rights without

Table 21.5 Resolution Guidelines: Constructing a Decision Tree



Each state defines the scope of practice within the state Nurse Practice Act. Every state has a Nurse Practice Act.

jeopardizing the welfare of the general population. Laws must be considered in directing action, seeking consultation, and requesting necessary assistance in selected patient-care situations.

The next step, **C**, involves choosing an action, and the following step **A** refers to actually acting on the decision. Sylvia has known all along what her choice would be—taking no action, which is actually choosing an action. The final step, **L**, stands for looking back or evaluating the situation, so that if the clinician were faced with a similar situation in the future, he or she might consider more choices and thus have more "branches" in the decision tree for consideration, or be aware of more legal precedence, and so forth. Especially when we are acting in the role of the primary moral agent, we need to keep abreast of the consequences of our own actions as well as those of others who are acting on behalf of the patient. Previous experience in similar situations can provide a frame of reference for comparisons and assist the clinician in making quality decisions. Although a decision tree is not meant to "lead" the patient to action, it does allow the patient and provider to consider more choices than may have been thought available. Brainstorming should be used; all choices proposed should be taken under consideration, even if they seem unrealistic at the time. Sometimes the first "irrational" choice ends up being the best choice for the patient and his or her family.

Institutional Ethics Committees

When health-care providers have difficult and unclear choices to make, the best course of action is to consult the local Institutional Ethics Committee (IEC). The Standards of The Joint Commission (TJC) state that "the organization has in place a mechanism for the consideration of ethical issues arising in the care of patients and to provide education to caregivers and patients on ethical issues in health care." Although this mandate may be applied loosely and does not mean that the organization will have an ethics committee in place, there is always some help available. A parish nurse may be available for consultation, a bioethicist may be available, or there may be an IEC in place. Some of the larger health-care institutions have ethics consultation services for ethical support to both patients/families and professional staff; the staff for these services may include ethicists who informally address nursing questions and concerns. The purposes of IECs are to serve as a forum for health-care professionals' ethical concerns, as well as for conflict resolution between any of the parties involved. IECs provide advice, education, and consultation to the staff and patients and possibly to the community on actual and potential questions of ethics. They also provide recommendations for and help in developing institutional policies, procedures, and guidelines in areas of bioethical concern; assist in developing formal policies and procedures for identifying, reporting, and resolving ethical questions and in conducting retrospective reviews of decisions on ethical questions; and offer recommendations for improving policies and procedures used to resolve ethical issues.

IECs are usually multidisciplinary in nature because of the varied amount and types of health-care workers involved in any patient situation. They are composed of physicians, nurses, social workers, clergy, administrative personnel, legal counsel, a patient representative, and someone from the community. The patient representative must actively advocate for the patient, and in doing so, subordinate his or her own needs, opinions, and moral positions to those of the patient or family member. The patient representative works to focus and refocus the committee on the welfare and rights of patients. The ANA and the AMA have developed many position statements (see the ANA Web site for position statements available), such as those on referrals to the most appropriate provider, sexual harassment, and so forth, to assist practitioners in drafting policies. Health-care providers should not hesitate to use their professional organizations as resources.

It is interesting to note that physicians and nurses reason very similarly when faced with ethical dilemmas. (See Nursing Research–Based Practice 21.1.)

Relationship Between Ethics and Law

Although clinicians strive to be ethical in all their actions, they must also think of legalities. Actions that are ethical are not always legal, whereas actions that are illegal are sometimes ethical (Table 21.6). APRNs should

Nursing Research–Based Practice 21.1

Winland-Brown, JE, and Dobrin, AL. A comparison of physicians' and nurses' responses to selected ethical dilemmas. *Forum on Public Policy Online*. Retrieved from http://forumonpublicpolicy.com/spring09papers/papers09spring.html

The purpose of this study was to explore the similarities and differences between physicians' and nurses' responses to four different ethical dilemmas. The dilemmas included surgical error, end-of-life care, possible physician or nurse drug use, and the medical repatriation of an illegal immigrant. Sixty-seven nurses and 26 physicians participated. This study found that physicians and nurses reason more alike than differently on ethical dilemmas. There was only one response to one dilemma where physicians and nurses reasoned significantly differently. Similarly, an equal number of physicians and nurses had experienced moral distress in the past. The variables of religion, gender, education, and ethnicity were significant for some of the responses to the dilemmas. Strategies were suggested to enhance moral reasoning and possibly lessen some moral distress.

Table 21.6 Relationship Between Ethical and Legal Issues*

	Legal	Illegal
Ethical	Assisting an older patient to complete an advance directive	Assisting in the death of a 99-year-old terminally ill patient
Unethical	Ordering emergency contraception in a Catholic Church–affiliated clinic	Billing for a treatment that was not done

*Although one may not agree with the choices of situations explaining ethical and legal issues, they are presented here for demonstration purposes—to explicate the intricacies of the ethical and legal relationship. Laws represent the minimum ethic governing behavior; compliance with them is mandated. Ethics operate at a higher level; they offer guidelines for resolving ethical dilemmas.

always strive to practice within the ANA Scope of Practice, their State Practice Act, and the Code of Ethics for Nurses, in addition to being cognizant of individual state laws on prescribing authority, signing death certificates, authorizing disabled parking permits, and so on. The circumscribed actions and duties that are allowable in the profession are termed the *scope of nursing practice,* which are defined and guided by each state in the Nurse Practice Act and by common law. Common-law principles govern many interactions affecting nursing and are based on a traditional justice perspective. The state Nurse Practice Act, however, is the single most important piece of legislation for nursing because it is the Practice Act that affects all facets of nursing practice. The Nurse Practice Act cannot grant exceptions, waive the Act's provisions, or expand practice outside the Act's specific provisions.

LEGAL ISSUES

Scope of Practice

The scope of practice defines the duties and responsibilities of the APRN and delineates the permissible boundaries of the professional practice. It is defined by statute, rule, or a combination of the two. A major legislative task for the future is for APRNs to define a separate scope of practice within each Practice Act that enables them to act autonomously without barriers to practice, such as limitations on prescriptive authority. Seventeen states allow independent practice as recommended by the Institute of Medicine (IOM) and national consensus statement. Twenty-one states require collaborative agreements with physicians, and 12 require physician supervision, delegation, or team management. Florida is the only state that does not authorize prescriptive authority for nurse practitioners (NPs) for schedule II drugs. With each legislative session, there is hope that all states will allow APRNs to practice to their fullest scope to benefit the American public.

A model for future APRNs was developed with the collaborative work of the APRN Consensus Work Group and the National Council of State Boards of Nursing APRN Committee. They established clear expectations for licensure, accreditation, certification, and education (known as LACE) for all APRNs, and ultimately these expectations will continue to shape future APRN practice. To download a copy of this report, go to www.aacn.nche.edu/Education/pdf/APRNReport.pdf.

Overview of Nurse Practitioners

There are over 171,000 NPs practicing in the United States today. Approximately 14,000 NPs completed their graduate programs in 2012. With increased demand, the number is estimated to be 244,000 by 2025. According to a 2012 survey from the American Association of Nurse Practitioners, the typical NP has the following characteristics:

- Is female (92%)
- Is white (90.3%)
- Is 48 years old
- Practices as a family NP (48.3%)
- Is actively practicing (89%)
- Has been in practice for 11 years as an NP
- Practices in a primary-care ambulatory setting
- Has an average full-time NP annual income of $98,760
- Sees three or four patients per hour (60%)
- Prescribes medications (97.2%) and writes 19 prescriptions/day
- Is satisfied with his or her practice

Licensure and Certification

Many nonnursing individuals assume that licensing and credentialing are synonymous. It is the responsibility of the clinician to educate other providers and consumers regarding what he or she can and cannot do. Legal authority for all nursing practice, including advanced practice nursing, rests with the individual Board that administers the legal statutes that define nursing practice in each state. Currently for APRNs, this oversight varies. In some states, the Board of Nursing administers and defines advanced nursing practice; in others, it is the Board of Medicine; and in a few states, it is the Board of Pharmacy. The American Association of Nurse Practitioners recommends that state boards of nursing regulate NP practice and prescriptive authority. Legal authority for professional practice was delegated to the states and territories by the U.S. Constitution and is not regulated by federal statutes.

An individual is permitted to practice basic or advanced practice nursing by licensure. *Licensure* protects the public from unsafe practitioners by ensuring a minimal standard for competency. Basic licensure as

a registered nurse (RN) is a legal status granted by each state's Board of Nursing. The National Council Licensure Exam that licenses RNs (NCLEX-RN) does not ensure high nursing standards. The NCLEX is designed to assess minimum competency to practice safely. The curriculum of a nursing program, although providing a foundation of nursing knowledge that will graduate a safe and competent practitioner, is not specifically geared to the NCLEX exam. Nursing programs retain autonomy over their own curricula.

Similarly, the NP curriculum is under the control of the graduate faculty and is geared to advancing nursing-based knowledge. On graduation, each prospective APRN applies to the appropriate state board for an advanced nursing license. In some states, the graduate must pass a national certification exam to be eligible for this license. Although the licensing statutes may spell out prescriptive privileges for APRNs, they do not necessarily do that, nor is that the primary purpose of professional licensure. Prescriptive authority for NPs varies from state to state. Some states mandate the filing of a protocol that documents physician oversight, but other states do not. (Table 21.7 shows a sample protocol.) Laws in most states do not mandate physician supervision of NPs. Protocols are similar to standing orders; they can be used as evidence to establish breach of the standard of care if they are not adhered to. The ability to prescribe controlled substances varies from state to state. Restrictions on prescriptive authority limit the ability of NPs to provide comprehensive health-care services.

Credentialing means that the practitioner has met certain criteria through licensure, education, and certification. Criteria for credentialing vary, depending on the credentialing body. A hospital, for example, may use credentialing to grant hospital privileges. Currently 43% of NPs hold hospital privileges, and 15% have long-term care privileges. This number is increasing daily. The

Table 21.7 Sample Advanced Practice Nursing Protocol

I. Requiring authority: Nurse Practice Act, Specific State—list Statutes, Chapters, Administrative Code. Administrative policies pertaining to certification of Advanced Practice Registered Nurses (APRN).

II. Advanced Practice Registered Nurse Certification: _____(name, home address, phone number) is certified as an APRN #_____ by the (list State) Board of Nursing.
Supervising Professional: Name, address, license number, and DEA number of physician.

III. General Area of Practice: _____ may manage the health care for those patients for which he or she has been educated. His or her master's degree is in _____.
List practice address, including primary and satellite sites.

IV. Specific Management Areas:

A. The following measures may be initiated by the APRN:
1. Conduct a history and physical on patients.
2. Take medication history, review medication profiles, and suggest necessary revisions.
3. Order and interpret diagnostic tests necessary to treat, including, but not limited to, lab work, x-ray exams, pulmonary function tests, electrocardiograms.
4. Diagnose and treat conditions within the scope of practice of a family nurse practitioner.
5. Instruct patient and families in treatment and medications.
6. Refer to other providers as appropriate.

B. The following medications may be prescribed, initiated, monitored, altered, or ordered by the nurse practitioner in accordance with education: antibiotics, antihistamines, antihypertensives, anti-inflammatory agents, antigout agents, anticonvulsants, antimicrobial agents, antifungals, antiarrhythmics, antiparasitic agents, antianginals, antidepressants, antianxiety agents, antipsychotics, beta blockers, calcium-channel blockers, cathartics, laxatives, contraceptives, diuretics, expectorants, muscle relaxants, NSAIDs, optical agents, otic agents, over-the-counter agents, steroids, stimulants, vasodilators, vaccines.
Controlled substances may be initiated by the APRN only within the facility in which he or she practices, after appropriate federal and state guidelines have been followed by the supervising physician. (Will vary according to state.)

C. Admit, initiate visits, and discharge patients in hospitals that have granted visiting privileges. Conduct histories and physicals, order diagnostic tests, treatments, and prescribe medications.

D. Any other measures within the scope of preparation and experience of the APRN.

V. All of the above functions may be performed under the general supervision of the physician.

granting of clinical privileges to practice in an institution is influenced by many factors. The primary factors governing the ability of an NP to obtain clinical privileges are the institutional policy, medical staff by-laws, state law, and TJC accreditation standards. Other factors include the desire of the collaborating physician and the NP's education, certification, and continuing education credits, along with his or her eligibility for third-party reimbursement and prescriptive privileges.

Certification is a voluntary process with no legal authority. The primary purpose of certification is to document excellence and specialization. Certification by a nongovernmental agency or association certifies that an individual has met certain predetermined standards for competency and specialization in a particular area. Although some states mandate that an NP pass a national certification exam before granting licensure to practice at an advanced level, not all states do. Currently 97% of all NPs hold national certification. National certification may be necessary to obtain third-party reimbursement; however, that is not the primary purpose of certification. Providing the public with information about the skills of the practitioners is not the primary purpose of certification, either. Other than the specialty organizations, there are two groups that certify APRNs in adult or family practice: the ANA through the American Nurses Credentialing Center (ANCC) and the American Association of Nurse Practitioners (AANP). Both organizations advocate that NPs be nationally certified and obtain annual continuing educational credits in pharmacology.

Prescriptive Authority

Since the mid-1970s, APRNs have had some type of prescriptive authority. Prescriptive authority is an integral component of advanced nursing practice and is regulated from state to state. It is important for APRNs to know the extent of the prescriptive authority they have in the state in which they are practicing and what restrictions, if any, there may be. Restrictions may range from collaborative or supervisory requirements to a need for countersignatures, formulary restrictions, specific protocols, and/or site restrictions. All states grant statutory independent prescribing authority to APRNs; however, three states exclude the authority to prescribe controlled substances. Some states require that APRNs have additional training to gain prescriptive privileges. State-specific regulations affecting prescribing authority severely limit the mobility of nurses who anticipate moving to another state. Both prescriptive authority and the mobility of the APRN's state license are legislative challenges facing APRNs today.

Unfortunately, medication errors accompany prescriptive privileges. At least 44,000 up to as many as 98,000 American deaths annually are due to preventable adverse events as a result of medication errors. Because most patients are taking three or more medications in a 24-hour period, drug–drug interactions are common. APRNs and anyone prescribing medications must ask each patient what medications he or she is taking before ordering a new one and must always consider the potential interactions. It is the clinician's responsibility to empower the patient with knowledge regarding any adverse effects of the medications. The clinician must educate the patient about signs and symptoms to watch for and should provide guidelines regarding when to notify the clinician if a problem arises. Of medical malpractice payments against NPs, 16.5% are a result of medication-related problems. Malpractice rates for NPs remain low, however, with only 2% of NPs named as primary defendants. One policy approach to the problem of medication errors is to implement mandatory reporting of all medical errors.

Reimbursement

Payment standards in the United States are driven by Medicare and Medicaid. APRNs have made great strides in this area and now receive third-party reimbursement in most settings. Payment by private insurance companies is contract specific and varies with each state's insurance commission. Reimbursement has long been a controversial issue. Should APRNs receive equal pay for the same work as physicians? In some areas, these practitioners are reimbursed at 80% of the physician rate. Does this mean they only did 80% of the work or did it only 80% as well as a physician would have? If one asks the recipient of care, the patient will most likely state that the APRN gave the same level of care provided by or expected from the physician. Reimbursement is a moot point, however, in managed care contracts, in which a fixed, predetermined rate is given to all providers, whether APRN or physician. Reimbursement issues are another legislative challenge facing these nurses. When reimbursement issues and practices are addressed, APRNs will be able to practice independently and truly autonomously.

Malpractice

Three components must all be present to establish malpractice: (1) The provider must have a duty to the patient, (2) the standard of care must be deviated from or breached, and (3) harm or damages must occur as a result of the duty and a breach of the standards of care. A plaintiff must prove duty, breach of the duty, damages or injuries, and causation. *Duty* means that a relationship has been established between the defendant and the plaintiff. *Breach of the duty* is the failure to do what the reasonable and prudent person would have done in the same or similar circumstances. *Damages or injuries* include medical expenses; pain and suffering, both physical and mental; lost wages and lost earning capacity; loss of companionship, society, affection, and sexual relations; hedonic damages; and punitive or exemplary damages. *Causation* means that the plaintiff must prove a direct

causal connection between the act of negligence and the alleged injuries.

Take the situation of Sally, a clinician caring for Mr. B., who is suffering from congestive heart failure. Sally increases his diuretic but makes no note of his potassium level and orders no replacement potassium. When Mr. B. returns a week later for routine lab testing, his potassium level is found to be low. Sally orders a potassium supplement to begin immediately and a follow-up potassium-level measurement. Is Sally guilty of malpractice? No. Although Sally did have a duty to Mr. B. and she did deviate from the standard of care (which would have been to order a potassium supplement at the beginning), no harm came to Mr. B. Because all the components were not met, malpractice was not established. If patients were aware of this, many false claims would not be filed. If Mr. B. had died from a fatal arrhythmia due to his low potassium level, however, then Sally could be held liable.

In the outpatient office setting, the most common reason for a malpractice suit for both physicians and APRNs is the failure to diagnose correctly. Approximately one-third of the malpractice cases brought against general practitioners involve cases of failure to diagnose in a timely manner. These cases usually involve cancer, particularly cancer of the breast. Failure to diagnose promptly accounts for the highest number of liability cases. Regarding NPs in particular, the most common reason for malpractice suits is related to failure to diagnose or delay in diagnosis. Diagnosing infections that lead to sepsis and diagnosing cancer were top liability issues. APRNs must carry liability insurance to protect themselves and their assets. Each APRN should have a lawyer who will represent him or her rather than the institution the APRN works for. However, nurses are often told that they should not carry their own insurance, and there are typically two reasons for this. The first is that a policy will encourage a lawsuit. There is no evidence to support this, and lack of coverage does not discourage a lawsuit, should there be a legitimate claim. The other reason is that nurses are told that their employer carries liability insurance that will also protect them. Although it is true that employers may provide insurance coverage for their employees, that coverage is subject to the provisions of the insurance agreement, and the employer is the client, not the nurse. Many physicians are "going bare," which means not carrying malpractice insurance. They must post a sign in their office to that effect. Some NPs are considering this as well. One must consider that a malpractice suit can destroy a life, both professionally and financially. As NPs would not consider being without health insurance, so they should not be without liability insurance.

Several different types of policies are available. One type, called the claims-made policy, covers only situations in which the incident occurred and the claim was made while the policy was in effect. Clinicians must review the policy to see if they are to be protected for past incidents, or they should purchase a tail policy that covers future claims. The best type of policy to get is an occurrence policy, which covers liability arising from all acts or omissions during the period the policy was in effect, no matter when the claim is brought. This is the ideal policy, because a claim can be made several years after an incident occurs.

Professional liability policies may be expensive, so the clinician may want to negotiate payment of the policy as part of the employment contract, if he or she is working in a group practice. Malpractice claims against NPs are on the rise, however slowly. The reasons can be attributed to three factors: changes in insurance markets due to fewer carriers, poor litigation laws that have arisen from current tort law practices, and the fact that the scope of practice for NPs has made them more autonomous. Excellent communication skills remain the number one reason why providers avoid a costly judgment or settlement. One study examined whether NPs used a patient-centered communication style or a provider-centered communication style in their patient encounters. Surprisingly, only a minority of NPs used patient-centered communication styles. As the rise in malpractice claims seems to be based on poor communication, NPs must be cognizant of this and consider the positive effects of patient-centered communication styles. (See Nursing Research–Based Practice 21.2.)

Collaboration

Collaboration is a form of interaction among and between providers during their delivery of care. The term implies that there are shared values and that the goal must be directed to what is in the patient's best interest. There is a constructive commitment to work toward that end. There is also mutual trust and understanding and respect of what each participant has to offer in this interdependent relationship. Both the nurse and physician must respect the boundaries of their disciplines and value what the other has to offer and bring to the relationship.

Nursing Research–Based Practice 21.2

Berry, JA. Nurse practitioner/patient communication styles in clinical practice. *J Nurse Pract* 5(7):508–514, 2009.

Nurse practitioners (NPs) spend more than two-thirds of patient-encounter clinical time in intrapersonal communication. The NP literature has little on NP/patient communication styles. The purpose of this study was to examine and document the most common verbal communication style used by NPs in patient interactions. Content analysis was used to analyze 53 NP/patient transcripts for communication style. Based on the transcript analysis, only a minority of NPs used a patient-centered communication style.

The IOM report *The Future of Nursing: Leading Change, Advancing Health* (2010) advocated for nurses to practice to the fullest extent of their education. The IOM emphasizes the importance of collaboration in the relationship of high-quality and safe patient care and suggests that five core competencies be incorporated in all health professionals' education:

- Provide patient-centered care.
- Work in interdisciplinary teams.
- Use evidence-based practice.
- Apply quality improvement.
- Use informatics.

The curricula of APRN programs have included these competencies; in addition, the *Circle of Caring* model emphasizes the essential nature of collaboration between APRNs and all physicians and health-care professionals with whom they work.

Additionally, APRNs must collaborate with physicians because there are many situations APRNs will encounter that are outside their scope of practice. The problem arises when the NP–physician relationship is one of supervision rather than collaboration. Different state boards of nursing delineate the NP's role in different ways. Some states require that physicians supervise or sponsor APRNs, which limits the nurse's scope of practice. Other states require that there be a collaborative relationship. A major challenge for the APRN is to assert his or her autonomy and maintain a professional, collegial, and collaborative relationship with physicians.

The IOM stresses the need for interprofessional education, and many universities and communities are creating opportunities for this to happen among nurses, physicians, social workers, and others. Nursing Research–Based Practice 21.3 illustrates the importance of learning interprofessional skills as a student.

In 1997, when the Oxford Health Plan allowed members to choose NPs as their primary-care providers and paid them the same rate as physicians for the same care, APRNs were finally recognized as independent practitioners who could provide quality care. In a situation such as this, collaboration is key because APRNs are the first to recognize that they are not expert in all areas.

Before being hired, it may be difficult to foresee whether a practice will be truly collaborative or not. There are tools available to assist a new NP in learning the skills of contract negotiation. One such comprehensive tool used to evaluate one's needs and desires in an employment or contractual arrangement is published by the American Academy of Nurse Practitioners, titled "Contract Negotiation for Nurse Practitioners."

Health-Care Reform

The United States is the only industrialized nation in the world without a national health insurance plan in place. The debate over health care reform has centered on the following questions:

- Is there a fundamental right to health care?
- Who should have access to health care and under what circumstances?

Nursing Research–Based Practice 21.3

Machin, AI, and Jones, D. Interprofessional service improvement learning and patient safety: A content analysis of preregistration students' assessments. *Nurse Educ Today* S0260–S0269, 2013.

A culture of continuous service improvement underpins safe, efficient, and cost-effective health and social care. This paper reports a qualitative research study of assessment material from one cohort of final year preregistration health and social care students' interprofessional service improvement learning experience. Initially introduced to the theory of service improvement, students were linked with an interprofessional buddy group and subsequently planned and implemented, if possible, a small-scale service improvement project within a practice placement setting. Assessment was by oral project presentation and written reflection on learning. Summative assessment materials from 150 students were subjected to content analysis to identify the following: service user triggers for service improvement, ideas to address the identified area for improvement, and perceptions of service improvement learning. Triggers for service improvements included service user disempowerment, poor communication, gaps in service provision, poor transitions, lack of information, lack of role clarity and role duplication, and differed between professions. Ideas for improvement included both the implementation of evidence-based best practice protocols in a local context and also innovative approaches to problem solving. Students described both intrapersonal and interprofessional learning as a result of engaging with service improvement theory and practice. Service improvement learning in an interprofessional context has positive learning outcomes for health- and social-care students. Students can identify improvement opportunities that may otherwise go undetected. Engaging positively in interprofessional service improvement learning as a student is an important rehearsal for life as a qualified practitioner. It can help students to develop an ability to challenge unsafe practice elegantly, thereby acting as advocates for the people in their care. Universities can play a key support role by working collaboratively with service organizations; role modeling effective interprofessional working; and supporting research to measure the impact of education on practice.

- What quality is achieved for the high prices currently being spent?

The Patient Protection and Affordable Care Act of 2010

The Affordable Care Act (ACA) was signed into law on March 23, 2010, to reform health care in America. The new health-care law includes reforms to health insurance and the way the health-care industry is run in the United States. The ACA aims to greatly increase the number of Americans who have access to affordable health insurance. This is done by expanding Medicaid to America's poorest, providing tax credits to employers who cover their employees, providing tax credits to individuals who need help paying for insurance, reforming the health-care industry to rein in excess spending, taxing higher earners and the health-care industry, and opening up state-based, competitive, regulated, online health insurance exchanges (Marketplace) where individuals can buy insurance and receive cost assistance. The ACA makes health insurance coverage more secure and reliable for Americans who have it, makes coverage more affordable for families and small business owners, and brings down skyrocketing health-care costs that have put a strain on individuals, families, employers, and the federal budget. The ACA requires that all Americans have access to affordable health care (or pay a tax if they choose to opt out). *Affordable health care* is defined as costing 8% or less of annual income. The ACA also reforms Medicare and Medicaid, as well as the other aspects of the health-care system, including the rates that insurance companies and private health-care facilities receive and patients' rights to health care. (You can read the Affordable Care Act at www.CMS.gov.)

The Congressional Budget Office has determined that the ACA is fully paid for and will provide coverage to more than 94% of Americans while staying under the $900 billion limit that President Obama established. This will bend the health-care cost curve and reduce the health-care deficit over the next 10 years and beyond. The ACA contains nine titles, each addressing an essential component of reform (www.dpc.senate.gov/healthreformbill/healthbill04.pdf):

1. Quality, affordable health care for all Americans
2. The role of public programs
3. Improving the quality and efficiency of health care
4. Prevention of chronic disease and improving public health
5. Health care workforce
6. Transparency and program integrity
7. Improving access to innovative medical therapies
8. Community living assistance services and supports
9. Revenue provisions

The leading cause of personal bankruptcy in the United States has been medical debt. The ACA will provide health insurance coverage to the almost 46 million people, or the 15% of the U.S. population, without coverage. Many organizations, including the ANA, have examined the potential outcomes of the ACA. Oregon, as an example, is one state with a successful unified health-care program. They accomplished this by rank ordering the community values of persons in the state. Their number-one value is prevention, followed by quality of life. Because nurses are the advocates for patients and persons, our role is to continue to be involved in the development of public policy that will effect change in all aspects of health care. A study of a case involving medical repatriation addressed the issue of an undocumented worker who was not eligible for insurance and the outcome that ensued. This scenario illustrates the need for advocacy and changes in public policy to ensure quality of life for all residents. (See Nursing Research–Based Practice 21.4.)

As the ACA is implemented and APRNs adapt to the public's needs, attention will focus on the concepts of the Medical Home and expansion in both the number and practice of APRNs. See the ANA Web site at www.nursingworld.org.

All health-care providers have an ethical duty to actively engage in legislative efforts that will ensure the best

Nursing Research–Based Practice 21.4

Winland-Brown, JE, and Dobrin, AL. Medical repatriation: Physicians' and nurses' responses to a dilemma. *Southern Online Journal of Nursing Research* (SOJNR) 9(4), 2009.

Medical repatriation is an institutional dilemma that affects physicians and nurses. This study analyzed the responses of physicians and nurses to a hypothetical case study involving a young illegal immigrant involved in a truck accident who was deported back to Honduras for lack of medical resources. The only variable that was significant when considering deportation was ethnicity. There was no significant difference between the responses of either physicians or nurses whether the patient should be medically repatriated. When asked about solutions, respondents suggested involving the Hospital Ethics Committee, searching for additional resources to allow this patient to remain in the United States to receive rehabilitation services, and providing ethics training for physicians and nurses to enable them to resolve ethical dilemmas using principled thinking and to (it was hoped) decrease moral distress.

possible condition to optimize the health of the nation. As advocates, providers need to know their state legislators and governors. Information on how to contact each governor is located at the American Academy of Nurse Practitioner's Web site at www.aanp.org, which also includes links to Congressional Legislative Committees.

The ANA strongly believes that APRNs are one of the keys to solving America's health-care crisis. Their current efforts address the important role that APRNs must play in a reformed health-care system. See the ANA Web site for current information on health-care reform (www.nursingworld.org).

The Business of Advanced Practice

Marcella M. Rutherford, PhD, MBA, RN

Chapter 22

INTRODUCTION

Although there is a great deal of dialogue related to the state of the U.S. health-care system, the one thing that everyone agrees on is the need for reform. Too many people are not getting the health care they need—both in quantity and quality. The cost of health care for identical health services varies greatly from state to state. At this time, the path to reform is found in the Patient Protection and Affordable Care Act (PPACA), commonly referred to as the Affordable Care Act (ACA) or "Obamacare," signed into law by President Obama on March 23, 2010. This legislation is focused on expanding coverage, controlling health-care spending, and improving health-care delivery. As health care is being reformed, advanced practice registered nurses (APRNs) have a unique opportunity to be part of the restructuring of the U.S. health-care system. In a system that is looking at cost and quality, APRNs are well positioned to be integral in lowering costs and improving the quality of care. APRNs' costs of care are approximately half of those of the internist and a quarter of costs related to a specialty physician (Porter & Lee, 2013).

To be effective leaders in health care, APRNs need to be knowledgeable about all aspects of the business of health care. APRNs will need the ability to communicate their unique value to the community, to other members of the health-care team, and to the payers. Health care is moving from fee-for-service and toward a performance-based/value-based reimbursement model. In this change-driven environment, providers will need a value agenda that focuses on maximizing the health of their patients.

APRNs have a unique opportunity in this evolving health-care environment. APRNs work in both rural and urban areas and are trained to provide care in various settings, including community health-care centers, public health departments, hospitals and hospital clinics, school/college student health clinics, employee health settings, physician offices, independent medical offices, insurance organizations, rehabilitation and skilled nursing facilities, hospices, home health agencies, the armed forces, Veterans Administration facilities, and schools of nursing. Health-care change has shifted health-care services to the outpatient setting when possible and is moving the primary focus from sick care to wellness care. This shift fits well with the holistic, social justice focus that is at the heart of all four APRN roles—nurse anesthetist, clinical nurse specialist, nurse midwife, and nurse practitioner. This chapter will focus primarily on the business factors in health-care delivery that affect the role of the nurse practitioner (NP). The PPACA will increase the role NPs play in Accountable Care Organizations and in the medical home. With the growing shortage of primary-care physicians and the rising number of previously uninsured people gaining coverage (15 million through 2014 and increasing to 35 million by 2016), the United States will need more practitioners (Iglehart, 2013).

To be effective advocates for health-care reform and to be successful as industry decision-makers, NPs need business skills. This chapter offers an overview of the current U.S. health-care environment, a review of third-party payers, the basics of PPACA, essentials of business practices, current reimbursement rules, tips for measuring and communicating value, and information for managing a health-care practice. In addition, NP business skills, NP professional choices, and the need for strategic planning are covered. Each section will provide key elements that affect the ability of a practitioner to thrive and achieve professional goals.

OVERVIEW OF TODAY'S U.S. HEALTH-CARE ENVIRONMENT

Today's health-care practitioner faces a health-care system in flux. The only sure thing in health-care reform is that it will be reformed. The cost of health care continued to increase despite several decades of aggressive incremental reimbursement policy change initiatives. Both political parties agreed that a new strategy was needed. According to the Kaiser Family Foundation (2012), the health-care portion of the U.S. economy increased from 7.2% in 1970 to 17.9% in 2010. Policy experts attribute a significant portion of the spending to medical technology. In the fall of 2013, there was good news from the government's actuaries, finding total national health spending was growing at the lowest rate ever seen. In August 2013, employer insurance premium increases were averaging just 4% for family policies, whereas in previous years costs commonly increased by 10% to 15% (Altman, 2013). Some of this slowdown in health-care costs can be attributed to the

2008 recession (patients not seeking health services as readily), but some of the slowdown is arguably attributable to the PPACA. In 2010, this bill was signed into law and included "new limits on how much insurance companies can charge for administration and profits (with rebates to consumers if they charge too much), and state review of rates proposed by insurance companies" (Altman, 2013, paragraph 3).

Whether the PPACA is harming or helping the U.S. health-care system is being debated. It is important, however, for all providers to know the main features of the bill that include the following:

- New federal insurance market rules that establish essential standard benefit packages included in all plans
- New health insurance exchanges that will lower administrative costs, pool risk, and offer individuals and small businesses a choice of affordable plans
- A shared responsibility for health care by preserving employer-sponsored insurance and offering tax credits to small businesses
- Improvement of Medicare prescription drug benefits by slowly eliminating the "donut-hole" gap by 2020
- A long-term financing program to support the disabled
- Investment in a stronger primary care foundation by increasing Centers for Medicare and Medicaid Services (CMS) payment for primary care, encouraging patient-centered medical homes, investing in primary-care training, and expanding community health centers
- An innovation center within CMS using payment methods to reward for quality versus volume of services; this innovation also encourages payment based on patient outcomes and provides incentives for productivity
- The creation of an Independent Payment Advisory Board that will make recommendations to reduce cost growth and improve quality
- Investment in the infrastructure that will offer publicly reported information on the quality, costs, and performance of providers; use of information technology in medical care and health insurance carriers; and policies on disease prevention, public health, quality, safety, and the health-care workforce (Goldsteen & Goldsteen, 2013, p. 260)

NPs are poised to gain a prominent role in the implementation of PPACA. Practitioners will be needed in primary care, pediatrics, and obstetrics to offer services to the large numbers of individuals who will gain coverage for health-care services.

THIRD-PARTY PAYER RULES

Whether NPs are employed by a hospital or a medical practice or are self-employed, the reimbursement policies that pay their wages will be determined by a third-party payer. Third-party payers fall into seven general categories:

- Medicare
- Medicaid
- Indemnity insurance companies
- Managed care organizations (MCOs)
- Workers' compensation (WC)
- Veterans Administration (VA)
- Auto liability

In addition to these third-party payers, those patients without health insurance are considered private pay.

Each payer has its own policies and fee schedules. All utilize Medicare guidelines as their foundation and make adjustments based on their plan goals. The Centers for Medicare and Medicaid Services (CMS) is the federal agency that administers and provides oversight of both agencies. In 1977, CMS policy gave billing approval for nonphysician practitioners, including NPs. Some payers credential NPs and reimburse them similar to physician billing. Other carriers may either pay NPs based on unique billing rules or may have no specialty for NP billing, instructing NPs to bill under the physician's provider number.

Medicare

Health-care providers wishing to bill the Medicare program can join the program by filling out an application on the Internet-based Provider Enrollment Chain and Ownership System (PECOS) or a using the traditional paper form (CMS-855). Each Medicare provider is assigned a provider number and a unique physician identifying number (UPIN) for billing. As a Medicare provider, the NP agrees to perform services for payment according to the current Medicare physician fee and guidelines. The NP's scope of practice, prescriptive authority, and requirement of physician collaboration are designated by the state legislation. The state gives authority for the nurse licensing board to regulate APRNs.

CMS policy payment is based on yearly published physician and nonphysician provider fee schedules (Medicare Physician Fee Schedule [MPFS]) (CMS, 2013g). For physicians, CMS identifies what services will cost (100% of the physician MPFS) and then stipulates that 80% of the allowed rate will be paid by CMS and 20% is the responsibility of the patient. NPs are reimbursed by CMS at 85% of the physician's fee, with the patient still paying a 20% share. Most patients on the traditional Medicare plan also acquire a secondary insurance plan to cover the 20% patient out-of-pocket expense. In addition to the 20% patient responsibility, Medicare has a yearly deductible. In 2014, the Medicare Part A (hospital services) deductible is $1,216 for each benefit period and the Medicare B (physician/provider, outpatient service) deductible is $147 per year. Information on Medicare beneficiary out-of-pocket expenses can be found at www.medicare.gov/your-medicare-costs/costs-at-a-glance/costs-at-glance.html (CMS, 2013d).

Patient responsibility payment (co-pay and deductible) should be collected in the beginning of the calendar year. These fees, if not precollected, will remain the patient's payment responsibility. Patient billing increases the expense to the practice because of the cost and time involved in collecting funds at a later date. Patients with a Medicare health maintenance organization (Medicare Advantage) plan follow the rules of the commercial carrier. Providers are required by Medicare to make an effort to collect the patient responsibility for services.

Medicare Advantage Plans

Medicare Advantage plans (an umbrella plan under an MCO) must be approved by CMS to become an alternative carrier for Medicare beneficiaries. These plans offer all of the benefits of Medicare and usually offer additional benefits and lower co-payments. Medicare Advantage carriers are paid subsidies by CMS for services rendered by the plan per member. These carriers market their ability to offer traditional CMS service in addition to added health services at a lower cost due to business strategies and economic efficiencies based on their volume of commercial business relationships. Problems have been noted when these plans have not been able to deliver services with greater efficiency than Medicare. Because of the high medical utilization and costs associated in the care of these patients, it became less financially desirable for commercial carriers to offer Medicare Advantage plans. If the plan's payout exceeds the fixed CMS payment, the Medicare Advantage plan incurs a loss.

"Opting Out" Providers

All providers have the option to elect to be a "nonparticipating" provider or to "opt out" of the Medicare program. As a nonparticipating physician, the practitioner can set his or her charge rate at 115% of the Medicare rate but can collect only 95% of the Medicare fee (CMS, 2013f). The Medicare program will pay 75% of the MPFS and the patient must pay the remaining 20% of the allowed (fee) amount, resulting in a 95% payment of the standard CMS fee to the opting-out provider. These physicians, however, are not subject to all of the billing restrictions set by CMS. The physician can elect to be in the Medicare program only one time per year and must provide notice to patients and referring physicians if he or she elects to become nonparticipating.

Patients also must be informed of the physician's status before services are rendered. "Opting out" of the Medicare program limits the ability of participating physicians to utilize referral services. No participating Medicare physicians can refer to physicians who have opted out of the Medicare program. The "opting-out" physician must keep a minimum of $250,000 available at all times to cover any malpractice claims that may arise from health services. An NP working for an "opting-out" physician will not be able to bill for Medicare services. NPs that are employed by or leased by an "opting-out" physician are at a higher risk for being named in a malpractice case.

Medicaid

Medicaid offers medical assistance for individuals and families with low incomes and resources. Unlike Medicare, it was designed to be jointly funded by both federal and state governments. The federal government assists states in providing medical care to people who meet the program's financial eligibility criteria. Medicaid payments are made directly to the participating providers, who in turn must accept the Medicaid (lower) payment as payment-in-full. Two exceptions are (1) disproportionate share hospital payments (hospitals taking care of a high, disproportionate share of Medicaid-eligible patients) and (2) hospice care.

Under Medicaid, states may impose nominal coinsurance and deductible rates. Emergency and family planning services must be exempt from the co-payment responsibility. The federal contribution matches the individual states' contribution as mandated by law. Reimbursement rates must remain sufficient to enlist enough providers willing to perform services and ensure that medical care is available to the general population in the region.

Guidelines for the Medicaid plan are available at the Medicaid Web site (http://medicaid.gov). Benefits for Medicaid were expanded and enhanced by PPACA and are outlined at http://medicaid.gov/AffordableCareAct/affordable-Care-Act.html (CMS, 2013). There are limitations and criteria for APRN reimbursable services outlined in each state's guidelines that can be located by selecting each state on the Web site.

Other Insurance Plans

Auto liability, workers' compensation, and CHAMPVA (see www.va.gov/hac/forbeneficiaries/champva/champva.asp) are additional health plans. It is important that these plan responsibilities are identified at the time of service (e.g., auto accident injury, injury sustained while on the job, services provided to a veteran, etc.). All of these plans have provisions, billing criteria, and reporting criteria. For auto liability, it is important to identify whether the auto insurance or medical insurance should be billed. When a Medicare patient, for example, receives care that should be paid by his or her auto liability plan, payment will be denied for medical services billed to Medicare. Workers' compensation (WC) claims require notification to the person's employer, use of WC-contracted providers for care, and specific documentation for coverage that must be submitted to the plan. Traditionally these plans limit use of NPs for care delivery, but this should not deter a practitioner from seeking provider status.

Cash/Private Pay

Even with PPACA, there will still remain approximately 20 million people in America who are without health insurance, and many of these individuals will not be

U.S. citizens. Patients who delay seeking health care often enter the health-care system in acute need of care and require higher cost treatment. Despite the fact that the United States invests more than twice the resources in health care as other industrialized nations, it ranks 37th based on health-care outcomes (infant mortality, life expectancy, etc.) compared with the other nations (Roehr, 2008). The nation's return on investment for health care would cause any banker to look for alternative projects!

PPACA

At the core of PPACA are provisions to enhance the outcomes and value of the U.S. health-care system. PPACA legislation is changing the way clinicians are organized and how health care is delivered; it is also focused on reducing cost while improving the quality of services. Because of this law, approximately 60% of the uninsured will gain access to health care. Through PPACA, health-care delivery teams, comprised of both clinicians and nonclinicians, communicate and work together toward the goal of returning the patient to optimum health.

PPACA provisions are detailed at www.HealthCare.gov, a federal Web site managed by the U.S. Department of Health and Human Services. Highlights of the consumer benefits in the bill include the following:

- Consumer assistance programs
- Preventive care
- Children's preexisting conditions coverage
- Preexisting condition cannot affect coverage
- Young adult coverage (under age 26 years can get coverage on parent's plan)
- Affordable insurance exchange plan options
- Small business employees able to purchase insurance from consumer operated and oriented plans (CO-OP).
- Lifetime limits on health plans banned
- Insurance rate increases limited to 10% per year, unless justified
- Provisions for adults aged 65 years or older—preventable care offered with no cost sharing
- Medicare drug discounts—eliminating the "donut hole" by 2020 and offering cost relief starting in 2010

Physician and public support for this legislation remains mixed, with about 50% of the public questioning the benefits of the system. In the autumn of 2013, citizens who had high co-pay and high-deductible plans began getting notices that either their plan premium cost would increase dramatically (plan benefits did not meet the essential standard benefits) or that their plan was being eliminated. These events caused a nationwide negative reaction. In addition, the Web site designed to assist community members to shop for plans on the exchange functioned poorly throughout the month of November 2013. By December, however, the Web site was functioning adequately, and the sign-up period was extended to March 31, 2014.

In addition to the initial problems with enrolling, there are concerns that younger individuals will opt out of health plan coverage. Should this healthy low-risk group decide not to enroll through the exchange or not to sign up for an employer's plan, the financial foundation of this legislation may not be sustainable. For PPACA to work, the younger insured must financially support the older members of society.

PPACA is anticipated to create a surge in patient demand for access to health care. Finding a practitioner will become challenging. The limited number of primary care providers is causing many states to reexamine the scope of practice laws for NPs. NPs are educated to provide primary-care services, but the American Medical Association (AMA) has supported laws that limit NP scope-of-practice, citing concerns for patient safety (Iglehart, 2013). Currently, NPs provide essential primary care; offer disease management; and enhance coordination of care, increase patient care access, and offer high-quality oversight of health care at lower costs. Not only is the MPFS payment for NPs 15% lower than the medical physician's payment, but (as of 2011) the family practitioner's yearly income was approximately $100,000 higher than the average family NP's annual salary (Medical Group Management Association, 2012).

NPs are the largest group of APRNs and function under various degrees of physician supervision depending on the licensing state. Research demonstrates that NPs' primary-care outcomes are equal to or better than physicians' and that NPs gain equal or higher patient satisfaction ratings (National Governors Association, 2012; Newhouse, et al., 2012). The various House and Senate committees involved in implementing PPACA have included NPs as primary providers and acknowledge the shortage of primary-care physicians. In many rural communities and for hospice patients, NPs offer the only access to health care and are critical for reducing health-care costs and meeting the needs of the current underserved citizens. In addition, the Institute of Medicine (IOM) has recommended that nurses be allowed to function to the full scope of their practice. Congress is set to address this issue, but patient demand and need are causing each state to look at this issue as well. Only a few states have fully adopted the APRN Consensus Model, a uniform model supported by the American Nurses Credentialing Center to align licensure, accreditation, and certification in practice. This model must be adopted by all state boards of nursing for implementation planned in 2015. So far, fewer than 20 states allow NPs to practice independently of a physician, based on their training (National Governors Association, 2012).

The PPACA was designed to allow the greatest number of U.S. citizens under age 65 years with employer insurance plans to continue to get insurance coverage as a benefit in their employer benefit package. Employers of more than 50 full-time (working 30 hours or more per week) employees are required to offer the standard

MCO plans. For small businesses (fewer than 50 employees), for employees who work less than 30 hours weekly, and for those not on employer plans, individual plans are available for purchase through state exchanges. The exchange allows citizens to select a plan that meets their financial and health needs. Tax incentives and penalties will be utilized to encourage enrollment. Medicaid eligibility has also been expanded through the Medicaid plan.

The PPACA's goal is to eventually enroll approximately 35 million of the over 50 million U.S. citizens currently without health-care coverage. PPACA legislation eliminates the high deductible, low co-insurance, limited hospital coverage plans of the past. Pharmaceutical costs will be reduced to more affordable rates on PPACA payment formularies. This legislation has changed the health-care game, requiring all MCOs to offer preventive services with no additional cost to beneficiaries. All health plans must now offer the designated minimal benefits, and the beneficiaries can select from a variety of approved plans. Information on the quality of and costs related to the various plans is being disseminated on the Internet. Competition for lower-cost and higher-quality providers and plans will shape health-care reform.

Future reforms for PPACA include the use of telemedicine and other strategies that will offer a competitive advantage for providers. Hospitals and providers are joining Accountable Care Organizations (ACOs) and developing communication networks that will expand their abilities to create efficient teams to treat the full range of patients' health needs. These efficient and effective ACOs will gain higher reimbursements and stimulate carrier and patient demand. Providers who are early adopters will seek out the most talented colleagues to join their ACOs. As a team, this group will focus on offering high-quality, low-cost health care, and the group will financially benefit from this effort. Data reporting and transparency of outcomes will drive health service choices, and those providers who consistently produce desired outcomes at competitive costs will be rewarded.

The use of technology will also offer providers a competitive advantage. Electronic medical records (EMRs) are required and will enhance business practices. EMR utilization will allow improved care communication and care coordination between providers, aligning care offered to patients across the inpatient and outpatient spectrum. NPs' strengths include their holistic approach to patient care, and this technology will enhance their effectiveness in overseeing care delivery.

BUSINESS ESSENTIALS

Without adequate funding, providers will be limited in the services and resources they can utilize to support their practice. NPs should understand the importance of maintaining adequate cash flow, obtaining payment for services, overseeing outstanding accounts receivables, implementing a collection policy, controlling overhead costs, utilizing the financial statements, and planning for success by creating and using a realistic operating budget.

Maintaining Cash Flow

Maintaining optimum cash flow is a fundamental goal in all businesses. Without adequate liquid capital, a business will not grow or survive. Today, most health-related services are on a fee schedule determined by a carrier contract. Providers are required to follow the carrier's billing guidelines. A continuous flow of funds is needed to pay for expenses generated in each business cycle.

In today's health-care industry, providers are challenged by payment disbursement interruptions; carrier and patient payments are not guaranteed solely because the service was delivered. Services can be medically indicated and result in healthy outcomes, but if documentation and medical coding do not match approved services' billing guidelines, payment may be initially denied. The number of claims that result in slow payment (greater than 30–45 days) can range between 30% and 50%, and this delay negatively affects provider cash flow.

The profit margin in health care today is very slim. Medicare payment is designed to cover provider costs, and Medicaid payment ranges 15% to 20% lower than Medicare. Net profits for most providers are achieved from the MCOs.

As with any major change in business, PPACA has created a feeling of concern in many providers. Physicians struggle to understand how health-care reform's bundled payment (payment to all providers involved in the complete episode of care) will affect provider cash flow. Bundled payment is designed to cover the services of independent provider units, covering "the full care cycle for acute medical conditions, the overall care for chronic conditions for a defined period of time (usually a year), or primary and preventative care for a defined patient population (healthy children for instance)" (Porter & Lee, 2013, p. 60). Unlike fee-for-service or global capitation, this method aligns payment to care delivery and outcomes under the control of the provider team.

Health-care reform is aimed at bending the cost curve downward; therefore, further cost cutting is predicted and causes concern. Efficiency and quality outcomes will be rewarded in higher reimbursements. Payment models need to include severity adjustments, regional demographic differences, and unavoidable patient complications based on frailty, as well as provisions for unforeseeable high-cost medical events.

Obtaining Payment for Services

All third-party payments are based on the MPFS, referred to as the carriers' "allowed amount" or plan fee schedule. As health-care costs continued to rise, all health-care plans looked for ways to keep insurance payment fees from increasing. Insurance plans implemented higher patient

out-of-pocket responsibilities by increasing the deductible and co-payment amounts. In addition, benefits became more limited. Patient out-of-pocket expenses became a larger portion, reducing or not increasing the percent of the medical bill paid by insurance. PPACA has changed this process by eliminating the high deductible, high co-payment plans and stipulating a ceiling of profit that MCOs can realize from unspent premiums. Starting in 2013, overpayments are being refunded annually back to their beneficiaries.

The patient's out-of-pocket responsibility is deducted from the insurance plan's contracted service rate and is reflected on both the insurance plan's statement and the provider's billing; both are provided to the patient beneficiary. For the provider, collecting the patient responsibility for services is a significant portion of accounts receivable. Provider profit margins have also been reducing over the last 10 years. A provider's billing process starts when the patient's demographics are first collected (preadmission or at the time of admission) and continues until the bill is collected. Patients' benefit packages change yearly, and the change in the level of patient responsibility needs to be adjusted by the provider. Because employers change carriers frequently, it is essential that the provider require proof of insurance eligibility at each patient visit. Obtaining patient financial responsibilities creates a collection burden for the provider. Expenses of the practice/organization (accounts payable) are incurred before billing, so if payments are not collected in a timely manner, cash resources to cover payables will become a problem. Slow collection of cash/payment also results in less money to support practice enhancements/resources needed for services. Issues in claims processing that affect cash flow include the following:

- "Unclean" claims—Claims with missing patient demographics, medical coding, and required data elements
- Slow processing of billing records or posting of carrier payment
- Delay or failure to address bill denials and carriers' requests for additional documentation
- Failure to identify underpayments from plan carrier—lower than contract rate
- Changes in software data fields and software interfaces implemented by providers and/or carriers
- Failure to collect patients' responsibility before services

Electronic billing and EMR use reduce labor hours needed for the billing process at both the provider practice and the payer. Reporting tools in the current office software can make billing follow-up more efficient. Providers who ensure that claims are complete, are accurate, and comply with the carrier's guidelines will benefit by timely payment (within 30 days) for the services they provided.

Overseeing Outstanding Accounts Receivables

Accounts receivable (AR) represent the money billed for services rendered to patients that remains unpaid. It is critical that accounts receivable are monitored by financial managers, ensuring that outstanding bills are collected or that changes in payment resulting from new billing requirements and regulations are identified in a timely manner. **The longer money goes uncollected, the less likely it will be collected.** When money goes uncollected beyond 120 days, it is very difficult to obtain payment. Uncollected expected payments (with good practices this remains around 10% of the expected amount) should be kept at the lowest percentage possible.

Accounts more than 30 days old should be reviewed, identifying why the payment has not been received. Hiring knowledgeable coders and offering continuous education to medical billers will be supported by a lower AR. Current and compatible claims software for claim tracking is required, but it is important to select software that enhances provider processes.

Loss of experienced billing employees is a common reason for unanticipated cash-flow delays. Providers need to have a basic understanding of claims-management processes to be able to assist and troubleshoot cash-flow issues and to oversee the training of new billing managers.

Collection Policy

All patients require education as to their payment responsibilities when accessing health-care services. Many patients do not understand their insurance policy benefits and payment responsibility. Patients often feel that they already pay a substantial sum of money in their monthly health premiums and that this should entitle them coverage for needed health services. Co-payments and deductibles are seen as excessive. Explanations of benefits that come after rendered service can cause the patient to become distrustful. In addition, many patients in today's economy are unable to pay the co-payment or deductible portion. Many patients did not pay close attention to the plan benefits when they signed up for the plan. Dedicating employee time to verify and explain eligibility and carrier benefits before treatment is worth the expense. Ensuring patient understanding of payment before services protects the patient–provider relationship.

Controlling Overhead Costs

Increasing practice efficiencies and controlling day-to-day costs enhance a practice's profitability. Implementing cost reduction measures, however, requires careful economic analysis of the impact on the quality of care and on the medical outcomes to patients. If the outcome choices are considered equal, the least costly service should be chosen. Health-care outcomes, however, are often difficult to measure; and, until recently, little

emphasis was placed on measuring the cost-effectiveness of care outcomes. Economic analysis should evaluate both the cost benefits and cost-effectiveness of services.

Cost analysis involves understanding the resources/costs needed to provide a service. Direct cost—labor time, supplies, and minor equipment—are easy to identify and should always be evaluated before adding a new service. Indirect costs—administrative, cleaning, electricity, human resources costs, and the like—may be harder to allocate to each service but should be included in the analysis for a valid assessment. In addition, some costs are fixed whereas others are variable—fluctuating with the volume of activity. The office rent or mortgage payment, for example, is a fixed cost; supply expenses (printer paper, record documents, etc.) are variable. To make a profit, payment dollars must cover both direct and indirect expenses related to the services—covering associated variable costs and contributing to fixed expenses.

To maximize financial gain, practitioners and office managers tend to feel that cost shortfalls can be made up with increasing the volume of patients treated. The normal established-patient visit is commonly scheduled as a 15-minute block of time. New patients, however, require more time to gather the patient's history. Established-patient visits are more predictable. Managing scheduling offers some efficiencies to the office; strategies that intermingle established-patient visits between new-patient visits could prevent patient bottlenecks. An appropriate mix of new and established patients is important to ensure a profitable office day.

A nurse practitioner's fee, according to Medicare, is set at 85% of the MPFS. Physician overhead costs commonly hover around 50% of net revenue (CMS, 2013f). An NP's *value* can be linked to the resulting revenue (billed charges) and net revenue (collected payment less expenses associated with the services) generated by the NP. Tables 22.1 and 22.2 provide an example of how to calculate the break-even analysis to demonstrate an NP's impact on practice revenue. Hospital visits, procedures, and other services would need to be added to an estimate. Factors such as the number of new patients, the number of MCO patients (contracted fee rate ranges from 70%–120% of Medicare fees), the length of the visit, the number of private-pay patients, and so forth can affect the profitability of a provider's services. NPs should evaluate their individual patient care practice habits and the impact of these on the overall financial health of the practice.

Utilizing Financial Statements

Financial statements offer a business the ability to monitor the impact of monthly transactions taking place in the practice. The performance of a business can be reviewed using the following accounting reports:

- *Balance Sheet*—Quantify the net worth of the business at a set time (monthly, quarterly, or yearly).
- *Operating or Income Statement*—Compares revenue to expenses in a period of time.
- *Cash-Flow Statement*—Details the movement of cash in and out of the business.
- *Net Income Statement*—Demonstrates whether assets grew as a result of the year's business activities.

An NP should review these documents in order to monitor the health of the company. For example, if the

Table 22.1 Profit/Loss Estimation

CPT	Vol	% vs	Fee	85%	Overhead	Acct. Receiv.	Collections
99201	69	5%	$43.89	$37.31	$21.95	$1,514.21	$1,362.78

Collection %	90%	

revenue of the company increases dramatically but the costs also increase significantly, the company may not realize additional net profit. These financial statements provide an overview of the company assets, as well as the corresponding liability or debt.

Planning for Success: Using the Operating Budget

Success in business does not just happen; it is a result of research, planning, financial knowledge, and hard work. The rate of rise in health-care costs can be controlled by "developing cost-effective technologies, delivering care in the most cost-effective settings, and using the most cost-effective practice available" (Emanuel, 2008). The APRN role fits well into this prescription for tomorrow's health-care system.

All businesses need direction and boundaries within which sound financial decisions can be made. Budgeting has several very important purposes for those managing a business. Budgets help planning, improve communication, facilitate coordination, improve motivation, help control expenses, and contribute to assessing performance. Budget preparation should involve all members of the business. Gathering all of the anticipated practice needs (expenses) for an upcoming year from all stakeholders will minimize variances to the budget. A successful practitioner sets goals and plans resource needs. The budget projects an estimate of the upcoming year's anticipated revenue and expenses based on obtaining the best information available from all care providers.

REIMBURSEMENT RULES

The provider plays an important role in ensuring the success of the business by clearly identifying the diagnosis and service codes that are appropriate for each patient's visit. As a strong business partner, each practitioner who possesses reimbursement knowledge can optimize the billing payment. Specific documentation of key components of care can make a significant difference in the allowed reimbursement.

CPT® Coding (Unlisted Procedures)

Current procedural terminology (CPT®) offers the official procedural coding rules and guidelines required when reporting medical services and procedures performed by physicians and nonphysician practitioners (AMA, 2013). This reference text should be purchased yearly and should be readily available to each practicing provider. Two vendors that publish CPT manuals and other coding references are found on the following Web sites: www.ama-assn.org/ama/pub/category/3113.html and www.ingenix.com. CPT® coding lists and guides are available electronically and can assist in the coding process with algorithms that assist those coding.

In 1977, the Health Care Financing Administration (HCFA) was developed within the Department of Health and Human Services (HHS) to rein in the spiraling costs of health care related to the Medicare program. Originally in 1965, Medicare was the responsibility of the Social Security Administration (SSA). Federal assistance to the Medicaid program was administered by the Social and Rehabilitation Service (SRS). The Department of Health, Education, and Welfare (HEW) oversaw the SSA and SRS. HCFA was created to coordinate Medicare and Medicaid. HCFA was challenged with controlling costs, monitoring services, and updating code references used to uniformly document current care. These codes facilitated assigning descriptors to service delivery as well as assigning reimbursement rates for each service code. HCFA (later to be overseen by CMS) selected CPT® codes developed by the Editorial Board of the American Medical Association. Medicare utilized these codes at an increasing rate in the 1980s. By the early 1990s, commercial insurance carriers (MCOs) were using these codes in their contracts and billing records as well. The Resource-Based Relative-Value Scale (RBRVS) was authorized by Congress to be used to set reimbursement rates (Hsiao, 1987). Today the federal agency is referred to as CMS. This RBRVS scale is discussed later in the chapter.

CPT® Coding Rules

Beginning in the 1990s, physicians were paid for office or surgical procedures based on calculated resource costs, which are designed to reflect the costs needed to provide services. These costs were calculated based on three components:

- The physician's work or medical expertise—makes up approximately 54% of relative value unit (RVU).
- The practice overhead expenses—making up approximately 41% of the RVU.
- Professional liability and malpractice expenses—derived from a formula.

This RVU is multiplied by a conversion factor, which is a monetary value determined yearly by HCFA/CMS and is adjusted for the cost of living/market-basket rates in the geographical region. RVUs are assigned by CMS based on recommendations from the Relative-Value Update Committee of the AMA. Each specialty society in AMA presents detail work and practice expenses to CMS when new CPT® codes or fee rates are requested to be changed. These details are published in the Federal Register before finalization, allowing provider and user comments.

According to the AMA, the purpose of CPT® is to provide a uniform language that describes medical, surgical, and diagnostic services, providing an effective means for reliable nationwide data collection and communications among all stakeholders. In 2000, the CPT® Code Set was designated by the HHS as the national coding standard for physician and other health-care professional services and procedures under the Health Insurance Portability and Accountability Act (HIPAA). Having a common nomenclature allows uniformity in management reporting, medical review, education, outcome measurement, and medical research. CPT® is the accepted nomenclature utilized by all health-care facilities, providers, and vendors. Each service or procedure is represented by a five-digit code. CPT® code inclusion or exclusion does not indicate an endorsement by AMA of the procedure, nor does it indicate that payment will be made.

As of 2005, all CMS billing was required to be sent electronically, unless certain exceptions were granted. The CPT® code set was mandated for all billing records. To improve cash flow and minimize claim denials based on untimely submission, most providers benefit from electronic billing to insurance carriers.

The CPT® manual and Medicare Physician Fee Schedule (MPFS) are published once a year. There are three levels of CPT® codes:

1. Category I—Codes used in contemporary medical practice
2. Category II—Tracking codes used for new or performance measurement
3. Category III—Temporary coding used for new procedures, technology, and services

Yearly code updates are made available in October and implemented in January. Codes without an associated payment fee are commonly related to patient education and nursing services. Transition periods are often extended with reimbursement change.

The CPT® manual Category I codes are presented in six sections:

1. Evaluation and Management
2. Anesthesiology
3. Surgery
4. Radiology
5. Pathology
6. Medicine

CPT® Unlisted Codes

Practitioners should select the code that provides the most specific and accurate match to the services performed. If no code exists that accurately identifies the provided services, an "unlisted" service code is provided in each of the six sections of CPT®. Unlisted codes are discussed later in this chapter.

CPT® Modifiers and Add-on Codes

Specific guidelines for CPT coding are presented at the beginning of each section in the text and should be reviewed before selecting a code. "*Add-on codes*" are at times indicated and should accompany a primary procedure code. Examples of add-on codes for CPTs include "prolonged service" codes that indicate additional time spent with the patient. These codes should never be used alone and must be used with the appropriate primary or level of evaluation and management (E&M) code. A *modifier* provides a means to report that a service or procedure has been altered by the circumstances of its use. It is important that modifiers be used appropriately because proper use may be associated with additional reimbursement. Modifiers are the only means for the practitioner to adjust standard payment rules. Box 22.1 provides an example of the use of modifiers to document services in order to receive the full payment of the proper use of modifiers.

The CPT® and payment fee values are applicable only to CMS services and are regulated and paid by the regional CMS carriers. MCOs can independently determine whether to utilize certain CPT® code rules and/or the reimbursement values for the payment year.

New CPT® Requests

It is important that practitioners participate in and provide CPT® information directly or submit feedback through professional organizations. The CPT® manual

Box 22.1 Modifier Use for Payment

Separately Identifiable Service on the Same Day as an E&M: Modifier 25

A previously treated patient is referred to a gynecological specialist's office following abnormal Pap test results. The patient's pathology is reviewed, and a vaginal exam is performed. From the examination, it is determined that a colposcopy procedure is warranted. The colposcopy procedure is performed on the same day as the evaluation and management (E&M) examination by the same physician. The practitioner will bill a 99213 for an established-patient visit of expanded focused complexity and add a -25 modifier to the CPT code in the bill record. The colposcopy is also billed on the same day of service and was ordered as a result of the E&M findings. Without the -25 modifier on the CPT code, the E&M visit would not be paid.

provides instructions on requesting updates to the CPT® nomenclature. The effectiveness and accuracy of CPT® relies on its ability to reflect actual practice; therefore, practitioners should communicate changes in practice and request coding changes that match provided services. As profit margins shrink, accurate coding becomes essential to maximizing the viability of the business. When requesting a new code, the practitioner should provide supportive information from research articles and medical journals, specific cost information related to the uniqueness of the code, and a specific recommendation concerning the new or existing codes. Suggestions should be submitted to the CPT® Editorial Research and Development of the American Medical Association. Code changes can also be submitted online at the AMA/CPT Web site: www.ama-assn.org/ama/pub/physician-resources/solutions-managing-your-practice/coding-billing-insurance/cpt.page under the area "Applying for CPT® codes."

"Incident To"

"Incident to a physician's professional service" is a billing phrase related to services furnished under the direct supervision of a physician. This does not mean that the physician needs to be in the room, but he or she must be in the same suite or office. The services are related to the course of treatment resulting from an initial visit with the physician and administered by a nonphysician. The nonphysician (often a registered nurses or NP) must be an employee of, or leased by, or performing as an independent contractor of the physician. In this situation, services may be billed under the physician's provider number, obtaining 100% of the physician fee (CMS, 2013f). RNs can provide service "incident to" a physician, but this service is billed under the physician's provider number and is paid at 100% of the contract rate.

NPs may also deliver services "incident to" and generate billing and payment at 100% of the contract rate using the physician's UPIN provider number. CMS provider rules offer guidance under "incident to" billing for services provided under the following circumstances:

- Considered physicians' services when furnished by an allopathic or osteopathic physician
- Performed by a person who meets the definition of an NP
- Not otherwise excluded from coverage by law
- Performed in collaboration with a physician
- State law allows NPs to perform the services

NPs may bill and be reimbursed using their own UPIN when a physician is not on site or in the office. These services, in comparison, are reimbursed at 85% of the MPFS.

Collaboration

Federal law defines the term *collaboration* to mean the following:

> A process in which a nurse practitioner works with a physician to deliver health-care services within the scope of the practitioner's professional expertise, with medical direction and appropriate supervision as provided for in jointly developed guidelines or other mechanisms as defined by the law of the State in which the services are performed. 42 U.S.C.S. § 1395x(aa)(6) (Buppert, 2012, p. 154).

The Balanced Budget Act of 1997 approved reimbursement to APRNs for Medicare patients, but it did not alter the language in the law. Some states do not require collaboration whereas others do, and when the term *collaboration* is used, the definition above applies. Regulations vary by state, and collaboration requirements (no collaboration, collaborative relationship, or collaboration with a submitted written protocol) should be verified annually. With PPACA and the IOM report, states are being pressured to allow nurses to practice at their full scope of knowledge.

CPT® Level II Codes

Each year, CMS releases its Healthcare Common Procedure Coding System (HCPCS) code set in the HCPCS Annual Update. The 2014 code set is available on the following Web site: www.cms.gov/Medicare/Coding/HCPCSReleaseCodeSets/Alpha-Numeric-HCPCS.html. HCPCS codes are established by CMS's Alpha-Numeric Editorial Panel and represent primarily items and supplies and nonphysician services not covered by CPT® Level I coding. Drug administration, pharmaceuticals, and durable medical equipment supplies are located in this file. As stated in the previous section, new CPT® codes are often assigned an HCPCS II code and are tracked for a year before a permanent CPT® level code is identified. Demonstration codes used for data collection are also assigned an alphanumeric code. Payment may or may not be associated with these codes, but they are important for data tracking.

ICD-9-CM Codes

CMS and the National Center for Health Statistics (NCHS), two departments within the federal government, provide guidelines for coding and reporting using the International Classification of Diseases, 9th Revision, Clinical Modification (ICD-9-CM), which can be located at www.cdc.gov/nchs/icd/icd9cm.htm or through the vendor Ingenix (Ingenix, 2013). These guidelines have been approved by the AHA, the American Health Information Management Association (AHIMA), CMS, and NCHS. These guidelines are required under HIPAA for all health-care settings. Volumes 1 and 2 are used by all providers, and Volume 3 codes are used exclusively by hospitals for procedural reporting. These codes communicate the diagnosis of the patient's visit or care episode. These codes ensure that consistent and required documentation related to the reasons for care is noted in the medical record. ICD-9-CM coding is used by all insurance carriers to support the services provided in the encounter.

The health-care practitioner is legally accountable for indicating the patient's diagnosis. CMS and many commercial carriers have implemented medical policies that allow computer editing that verifies that the CPT and ICD-9-CM code match. For example, a chest x-ray exam will not be paid as a preoperative screening test unless the patient has a diagnosis indicating respiratory symptoms.

ICD-10-CM

The federal agency NCHS is responsible for and has been challenged with the implementation of a revised ICD-10-CM that will replace ICD-9-CM Volumes 1 and 2. This version was originally presented for a comment period in December 1997. After 60 days, this version of the ICD-10-CM was removed from the NCHS homepage. A new draft version has been available for public viewing since 2003, and the AHA and the AHIMA are conducting joint testing. After this extended testing period, ICD-10-CM has a planned implementation date of October 2014. Many countries have already been using these code sets for several years. This new coding set will extend the number of available codes from 13,600 to over 69,000, adding detail and specificity to current billing and data coding. This change in diagnosis code options will make a significant practice and documentation change for all practitioners. A free Web reference available to providers on this coding can be found at www.icd10data.com. Educational tools and manuals can also be accessed at the CMS Web site: www.cms.gov/Medicare/coding/ICD10/downloads/pcs_refman.pdf.

Providers need to prepare their billing, practice management, and electronic health record vendor for this change and must be sure to verify when all contracted payers are prepared to accept these new codes. In addition, providers and staff will need to be trained on this new coding. Practices should anticipate additional costs associated with the transition to this new data documentation, as well as an initial reduction in productivity.

Medicare Physician and Nonphysician Practitioner Fee Schedule

Each year CMS publishes the *Physician and Non-Physician Practitioner Fee Schedule,* and more information can be accessed at www.cms.gov/apps/physician-fee-schedule/overview.aspx (CMS, 2013b). An MPFS search tool is available at this site.

Electronic billing and automated electronic filing sets have made the implementation of timely transitions to the new MPFS rate possible. This schedule provides a payment rate based on a state local base rate multiplied by the RBRVS, explained earlier in this chapter. The MPFS is the payment rate for all Medicare services provided for that year. When procedures occur that have no CPT, the new code will be paid as a percentage of charge (managed care plans) or at a rate similar to the most similar CPT code. Unlisted codes are provided in every CPT section; but payment for these nonspecific codes may be delayed, requiring the provider to send medical documentation to detail the services provided. Manual billing, with the supporting documentation to substantiate services, delays payment beyond 45 to 60 days.

MCO plans negotiate contracts with providers based on payment at a percentage of charge or at a percentage of the Medicare fee. Carriers may pay some specialists higher than Medicare does but also can offer fees lower than Medicare rates. In many states, primary-care physicians and internists are paid at a percentage lower than Medicare. General practitioners' and internists' practice volume, or payer mix, is composed of a high percentage of MCO-insured patients. To maintain their patient volume, internists are often financially pressured to sign contracts at rates lower than the MPFS or risk losing a large number of clients. This atmosphere has created an environment where providers are competing for well clients covered by better-paying carriers.

Accountable Care Organizations

Collusion—secretly and collectively sharing rates for the purpose of monopolizing or maintaining a higher payment rate—is prohibited by physician specialties. In addition, MCOs market their plans to employers and clients by demonstrating the large network availability. Periodic trends have surfaced with providers joining various ownership arrangements in order to facilitate fee negotiations, offering MCOs a large number of providers that have a substantial patient base. These large practice groups are often successful in negotiating higher commercial fee schedules. After PPACA became law, this large provider group business model has been rejuvenated in the form of Accountable Care Organizations (ACOs).

ACOs are groups of providers—providers, hospitals, outpatient-care facilities—that come together to coordinate the care of patients. The concept was developed by CMS, and additional information can be found at www.cms.gov/Medicare/Medicare-Fee-for-Service-Payment/ACO/index.html (CMS, 2013e). ACOs are an important part of PPACA success and support the CMS focus of providing care to patients based at both the lowest cost and the highest quality. ACO members work together as a team, and all benefit from the efficiencies and quality of care they can collectively achieve. These low-cost, high-quality provider groups will receiver higher bundled reimbursement shared by the ACO. ACO participation is optional for any provider.

In a geographical area where provider networks are not robust, the MCO provider fee schedule may be higher than the MPFS in an effort to attract specialists in the geographical area. MCOs often bundle CPT® services (e.g., multiple CPT® codes billed on the same day may result in only one CPT® fee paid), so contract rates can be misleading and should be analyzed closely. MCO denials and contract language such as "claims will

be paid according to the company's claim processing guidelines" forewarn the provider and allow the carrier to adjust its payment fee. MCO fee schedules should be reviewed yearly to evaluate if the payment fees are updated to the current MPFS (the basis for the MCO's fee rate).

Evaluation and Management Documentation

The encounter form or record is the tool that prompts the clinician to provide proper documentation needed to support billing. Coding not only supports billing but also provides invaluable data, identifies patient trends, and offers data that can help a provider plan for future community needs. These CPT® evaluation and management (E&M) codes require providers to document the extent and complexity of the patient's history, physical exam, and medical decision making. E&M codes relate to the recorded facts, findings, and provider observations and offer a consistent data record for each patient by the carrier.

The level of E&M coding (99201–99205 for new patients and 99211–99215 for established patients) is based on the documentation in the medical record. This documentation provides the following data:

- Reason for consultation
- History of the present illness
- Review of body systems (number of systems involved)
- Physical examination
- Recommendation(s) for testing and treatment

E&M codes differ based on the care setting: hospital inpatient, hospital observation day, hospital outpatient, physician office, and so on. The intensity of care needed in these various settings is provided in the documentation for these E&M codes. The practitioner may also bill using consultation codes. When performing a consultation, the provider is required to document and communicate findings to the referring physician. A consulting provider offers a medical opinion based on the patient findings. Documentation is often requested by the carrier to justify the level of care provided and billed. All practitioners should develop documentation forms/software records that contain the key elements of information for medical record documentation. Table 22.3 offers a chart audit tool that can be used to review the correct assignment of the level codes.

Electronic Medical Record

Electronic medical records (EMRs) are required by all providers in 2014, and penalties will be assessed in 2015 to late adopters. The American Recovery and Reinvestment Act legislation was designed to create a means to store patient medical records and make "meaningful use" of these data. Funding and incentives were made available for providers for several years before the 2014 deadline. In 2015, penalties ranging from 1% to 5% will be levied (Athenahealth, 2012). The importance of all providers using EMRs is based on the principles of securing patient information and reducing administrative health-care costs. Standardizing EMRs and billing data will also improve provider cash flow, allowing carriers to process claims more efficiently and reduce health-care costs.

EMRs offer the following benefits:

1. Providing a record that can be networked across secure provider systems, providing a longitudinal account of patient care.
2. Developing an information system that allows tracking of care from the acute-care setting to nursing home, retirement home, or clients' private residences.
3. Moving away from an emphasis on episodes of care and toward measurement of care across all settings.
4. Facilitating patient identification that allows providers to track the patient throughout the care delivery system, offering information in a need-to-know environment.

The EMR can offer a system that would store complete documentation across the continuum of providers, collect accurate health data, provide practitioner alerts and reminders, communicate up-to-date resources, link evidence-based bodies of knowledge used for clinical decision support, present real-time cost-effective options, enhance timely reimbursement through interconnectivity to payers offering patient eligibility and authorization requirements, provide accurate identification of patient-to-medication match, present a clean and accurate electronic bill, and electronically transmit payment to providers.

VALUE MEASUREMENT

Practitioners should review common policies implemented to control and support practice decision making that falls under fraud and abuse/compliance plans, HIPAA, risk management, and performance improvement. In addition, all providers will benefit from data collection that allows them to demonstrate the value and quality of their performance. A plethora of data and quality indicators are now being generated from health-care delivery practices. To be useful, these data require careful review and analysis. Strategies related to information management, in which nurses are crucial participants, include integration of the electronic health record into all care settings; developing rapid online access to patient records, including information from other clinicians in alternate settings; participating in the creation of a repository of health information and nurse quality indicators; interacting and utilizing online information services, including telemedicine; and use of various technology for health planning and scheduling. In addition, being good stewards of health-care technology should stimulate providers to use the least costly, less invasive technology, if it produces comparable diagnosis and treatment.

Table 22.3 E&M Chart Audit Tool

CPT	Focus	Elements		
New	*Visits*	*History*	*Exam*	*Medical Decision*
99201	New Patient, Level 1	HPI 1—3 Elements ROS: N/A PFSH: N/A	Single-system: 1–5 Multisystem: 1–5	Straightforward
99202	New Patient, Level 2	HPI: 1–3 Elements ROS: 1 PFSH: N/A	Single-system: 6+ Multisystem: 6+	Straightforward
99203	New Patient, Level 3	HPI: 4+ Elements ROS: 2–9 PFSH: 1	Single-system: 12 Multisystem: 12/2+ organ or 2 from 6 systems	Low complexity
99204	New Patient, Level 4	HPI: 4+ Elements ROS: 10 PFSH: – 3	Single-system: all +1 from each system Multisystem: 2+ organs from 9 systems	Moderate complexity
99205	New Patient, Level 5	HPI: 4+ Elements ROS: 10 PFSH: – 3	Single-system: all +1 from each system Multisystem: 2 from 9 systems	High complexity
Established Visits				
99211	Established Patient, Level 1	Minimal/RN visit	Minimal exam	None
99212	Established Patient, Level 2	HPI: 1–3 Elements ROS: N/A PFSH: N/A	Single system: 1–5 Multisystem: 1–5	Straightforward
99213	Established Patient, Level 3	HPI: 1–3 Elements ROS: 1 PFSH: N/A	Single system: 6+ Multisystem: 6+	Low complexity
99214	Established Patient, Level 4	HPI: 4+ Elements ROS: 2–9 PFSH: 1	Single system: 12	Moderate complexity
99215	Established Patient, Level 5	HPI: 4+ Elements ROS: 10 PFSH: 3	Multisystem: 12/2+ organ or 2 from 9 systems Single system: all +1 from each system Multisystem: 2 elements from 9 systems	High complexity

Note: NEW PATIENTS need all 3 criteria: History, Exam, and Medical Decision, whereas ESTABLISHED PATIENTS require 2 out of 3 criteria (History, Exam, and Medical Decision).

Abbreviations: HPI, history of present illness; ROS, review of systems; PFSH, past, family, and social history.

Fraud and Abuse/Compliance Plans

As health care has evolved and become more sophisticated, the area of health-care ethics has grown. Ethical conflicts arise when providers balance competing pressures affected by professional values, changes in delivery systems, and financial regulations. An example of this is the investigations that the U.S. Department of Justice has pursued when dealing with Medicare fraud allegations. U.S. health-care fraud is estimated to cost $80 billion annually and has caused the federal government to levy high fines and determine the need for whistleblower protection.

The health-care industry has not always been honest about its billing practices, and in response Medicare requires audits of a certain percentage of charts or medical records to prove that the charges are accurate and the proper diagnosis and procedure codes were used. Examples of health-care fraud include up-coding reimbursement claims, billing for medically unnecessary therapy, and billing Medicare and insurance carriers for physician

services provided by the nurse practitioner. As of 1996, to willfully and knowingly utilize deceptive billing is a legal violation. The False Claims Act was updated in 2006. Reckless disregard for the rules is auditable and subject to corrective audits and fines. Fines and damages can be levied up to three times the claim amount, with mandatory penalties of $5,000 to $10,000 per claim (CMS, 2009). Tables 22.1 and 22.2 show typical audit forms.

Compliance Plan

All health-care businesses should develop a compliance plan. A compliance officer should be identified and can assist in developing and maintaining an established plan that includes practice safeguards, preventing episodes of fraud and abuse. Antikickback efforts, conflict of interest disclosure, and identification of questionable business practices should be fostered. Adhering to a compliance plan is the responsibility of all employees to ensure that business practices discourage fraud and abuse. One area that needs oversight is the correct assignment of E&M level codes based on history taking, examination, and medical decision making.

HIPAA

HIPAA can mean different policy concerns to different people. The act was separated into two parts, Title I and Title II:

- Title I of the Health Insurance Portability and Accountability Act of 1996 (HIPAA) protects health insurance coverage for workers and their families when they change or lose their jobs.
- Title II addresses administrative simplification and requires the U.S. Department of Health and Human Services to establish national standards for electronic health-care transactions and national identifiers for providers, health plans, and employers. It also addresses the security and privacy of health data. These standards were implemented to improve the efficiency and effectiveness of the nation's health-care system by encouraging the widespread use of electronic data interchange in health care (CMS, 2005).

HIPAA legislation is important to the daily management of the practitioner practice setting. This legislation focuses on password management, workstation security, e-mail and Internet use, and facility/physical security. Password protection is emphasized to ensure the privacy of patients' health-care information. With increased mandatory submission of electronic billing files and EMRs, a provider must take added precautions to protect the patient's electronic personal information.

Risk Management

Risk management is an extension of performance improvement. This program should be organization-wide, with a focus on identifying risks, controlling occurrences, preventing damage, and controlling legal liability. The goal of risk management is to prevent any undesirable event from happening and to minimize the impact of financial loss due to a malpractice claim. There are eight areas of responsibility for risk management programs:

1. Risk identification
2. Loss prevention and reduction, including incident reports and investigations
3. Insurance claims management
4. Administration of workers' compensation and handling of medical/legal issues
5. Liability assessment of contracts
6. Risk management education
7. Handling product recall and Safe Medical Device Act issues
8. Ensuring compliance with accreditation standards and state and federal laws

Practitioners can be involved with any of the aforementioned areas of risk management. With the rising number and cost of malpractice claims, risk management becomes a powerful tool to demonstrate that prudent care is monitored to ensure appropriate health-care practices.

HEDIS Reporting

Providers should be aware of performance reporting that is required by CMS. The Health-Plan Employer Data and Information Set (HEDIS) is a set of standardized performance measures identified as indicators for consumers so that they can evaluate the quality and cost aspects of the care delivery. Indicators are selected based on current health issues such as cancer, diabetes, asthma, heart disease, and so on, monitoring such indicators as immunization age, mammography frequency, urinary tract infection occurrence, cervical cancer screening, and the like. HEDIS is supported and overseen by the National Committee of Quality Assurance.

Safety and Performance Improvement

Performance improvement initiatives should be part of the day-to-day routine of the medical practice. In some medical offices, the NP is the only professional nursing caregiver. The practitioner should take the lead to encourage office personnel to undertake processes that focus on ongoing improvement. Data analysis of quality monitoring requires the ability to derive trends from statistical data. Once a negative trend is identified, a corrective action plan to address the trend is imperative, demonstrating and monitoring a successful turnaround and improvement.

Both medical and financial errors are not rare, occurring at a rate greater than acceptable to the public and medical community. According to the IOM (2000) study, *To Err Is Human,* a high number of medical errors were identified in the U.S. medical environment, but it took almost 7 years for comprehensive safety and quality

outcome changes to be noted throughout the health-care system. Today's health-care leaders are being challenged to decrease errors. The task of reviewing existing medical practices using a systems approach is daunting; however, the benefits are worthwhile.

Other issues that affect the quality of a health-care practice involve actions where the patient feels depersonalized, perceptions of shorter care delivery time, unwarranted denial of coverage, health-care choice restrictions, and overprescribing of unwarranted testing. Many health plans' policy regulations and benefit restrictions have been linked to an increase in malpractice liability claims. Maintaining and fostering a trusted relationship between the provider and the patient has a significant impact on patient participation in care, satisfaction with outcome, timely payment of bill responsibility, and limiting exposure to litigation.

APRNs play a valuable role in diligently overseeing health-care outcome improvement efforts, demonstrating accountability in practice. Clinicians are highly valued for their ability to recognize familiar patterns and to use their gut instincts in times of complexity, identifying options for interventions (Kerfoot, 2004). A practitioner must not only think through a diagnostic clinical problem, but also provide input on the economic impact of the care delivered in this clinical episode, offering valuable analysis of the outcome data that are collected from the patients.

Pay for Performance

Stimulated by quality initiatives and the desire to ensure public accountability and public disclosure, the Bush administration through the Deficit Reduction Act of 2005 required a quality adjustment in the Medicare diagnosis-related group payment for certain hospital-acquired conditions. In 2006, CMS identified 19 quality indicators that providers were financially incentivized to track and document. These conditions were identified as resulting in high-volume, high-cost areas of medical care. In 2007, CMS announced a new program called "Hospital-Acquired Conditions (Present on Admission Indicators Reporting) (HACs not POA)" (CMS, 2013b). This new CMS policy was a dramatic payment rule change for Medicare. In 2013, 11 HACs not POA were identified as high-volume preventable patient occurrences and were tracked in all hospitals. The 11 conditions are available at www.cms.gov/Medicare/Medicare-Fee-for-Service-Payment/HospitalAcqCond/Hospital-Acquired_Conditions.html (CMS, 2013b). These HACs not POA result in a decrease in reimbursement from CMS; payment does not cover the costs related to the HAC. Hospitals across the nation have implemented care criteria—often called bundles—aimed at ensuring that these HACs would not occur. CMS undertook this effort because its responsibility required it to safeguard the Medicare Trust Fund by not paying federal monies for preventable medical errors.

Section 3025 of the Affordable Care Act added Section 1886(q) to the Social Security Act establishing the Hospital Readmissions Reduction Program, which requires CMS to reduce payments to Inpatient Prospective Payment System (IPPS) hospitals with excess readmissions, effective for discharges beginning on October 1, 2012 (CMS, 2013e). Currently, the policy does the following:

1. Defines *readmissions* as admissions within 30 days to the same or other hospital
2. Includes readmission diagnoses of acute myocardial infarction, heart failure, and pneumonia
3. Establishes a method to calculate the excessive readmission ratio for each condition and compares it to the ratio of the national hospital data set; uses this to determine the adjustment to the reimbursement rate
4. Establishes a risk adjustment methodology for each diagnosis using National Quality Forum (NQF) data, comparing each facility's readmission ratio to other similar facilities in the United States and adjusting the ratio for clinically relevant factors (demographics, patient frailty, etc.)

Provider Comparison Web Sites

Many states have created Web sites for citizens to query data regarding these identified health outcomes, allowing citizens to compare individual providers and hospitals using common quality indicators. Transparency is being fostered, and providers and payers are being evaluated based on malpractice claims and health outcomes. Financial reward, therefore, is granted to medical providers with quality results. PPACA's legislation includes initiatives to educate the public on both the costs and the quality of their health-care needs and choices. These comparison reporting sources are designed to create competition, but they also offer providers an opportunity to recapture the trust of the community.

Value-Based Purchasing

The term *value-based purchasing* (VBP) was emphasized as an important initiative of CMS (2013c). This initiative has grown with PPACA. Data collection efforts are pervasive in both the medical and nursing professions. Over 1,000 nursing quality measures are used in hospitals, and many of the quality indicators are directly related to nursing care. Provider quality measures are also focused on indicating value outcomes related to a health-care experience. On August 1, 2013, CMS announced the display of the fiscal year (FY) 2014 IPPS Final Rule, which included a number of policies related to the Hospital VBP Program. In FY 2014, the second year for VBP provider incentives, CMS finalized payment and operational details. CMS also finalized new policies for FY 2016 that included (1) new VBP measures, (2) performance periods, (3) performance standards, and (4) domain weighting.

The final rule also included policies related to certain measures for FY 2017 through FY 2019, including

performance periods and performance standards for those program years, as well as a new domain structure for FY 2017 based on the National Quality Strategy and its priorities of better patient outcomes, quality, safety, and lower cost for Medicare payments (CMS, 2013d).

National Committee for Quality Assurance

The National Committee for Quality Assurance (NCQA) is a nonprofit organization focused on improving the quality of health care by working with providers to foster identifying, measuring, analyzing, and promoting health-care quality. The NCQA seal displayed by a health care facility is a well-known symbol, displayed proudly by a facility and identifying it as well managed and delivering quality health services. NCQA providers must undergo a rigorous review process and submit data annually to maintain the NCQA status (NCQA, 2013). NCQA has developed over 60 standards and requires practices to measure and report annually on over 40 of them.

Medicare's Physician Quality Reporting System

Medicare's Physician Quality Reporting System (PQRS) is a CMS payment incentive program based on reporting provider performance data. Eligible Medicare providers (EP) are identified from their claims and the data provided on quality measures. Beginning in 2015, data will be extracted from EP claims.

MANAGING A HEALTH-CARE BUSINESS

The information highway is changing practitioner–client relationships (Bowman-Hayes, 2009). NPs' strengths have always resided primarily in their clinical expertise and their holistic approach to patient care; as a patient advocate, an NP encourages patient independence and offers needed health-care diagnostic and treatment services and self-care teaching. Today's practitioner is also challenged to assist patients as they navigate the Web, coordinate care between networks of providers, and explain information retrieved from a variety of sources. More and more patients are using Internet resources for guidance once medical symptoms arise. NPs need to support patients who do not have access to a computer. Soon those patients will be experiencing knowledge deficits, as well as health-care access deficits.

NP Business Choices

Selecting a business arrangement that offers a practice environment beneficial for NP goals has the greatest prospect for professional success. Business arrangements and clinical expectations should be clearly communicated by all partners and the team of practitioners. Negotiations should include a frank discussion of salary, benefits, hospital privileges, and on-call expectations. In addition, the NP should understand the inherent malpractice risks with the selected specialty and what arrangements are in place to mitigate these risks.

Negotiating Salaries and Benefits

Before signing an agreement with a practice site, the NP should draft a practice agreement as required by the state in which he or she wishes to practice. Each state has detailed criteria defining the level of collaboration that is required between the NP and an oversight physician, if required. Prescriptive authority, still an issue between the AMA and nursing, may require process changes that should be discussed.

The practice specialty, colleague(s) personality, practice environment, patient population, and the current style in the practice setting should be reviewed. Dialogue should be initiated on the degree of autonomy and role of the NP and the other practitioners. Topics to cover during a formal interview with the practitioner include the following:

- Are there any current or pending malpractice claims against the business?
- What is the practice's Medicare and Medicaid status?
- Will I have hospital privileges?
- What number and type of managed care contracts does the practice have? How do these carriers contract and reimburse NP services?
- What is the number of nurses (registered nurses [RNs] and licensed practical nurses [LPNs]/licensed vocational nurses [LVNs]) and support staff available to assist the NP?
- What expectations are there for my net revenue generation?
- What is the expected number of patient visits per day?
- How will I be compensated for services?

There are four base methods by which an NP can negotiate payment:

1. Straight salary
2. Salary based on percentage of payments
3. Salary plus a percentage (bonus) based on payments
4. Hourly rate

There are positives and negatives to each method.

Straight salary is the easiest method of payment. The practitioner is paid a set amount weekly, biweekly, or monthly; the income stream is easily calculated. If the hours or work increase dramatically, however—that is, on-call time, rounds, discharge summaries, dictation, and so forth—there is no additional compensation.

Salary based on a *percentage of payments* is based on an inconsistent dollar amount used to predict and calculate income. A practitioner's salary is calculated on the percentage of payments collected the prior month. Many factors can affect net payment, and the payments collected are often not within the practitioner's control. For example, the type of computer system, number of billing

staff, content of managed care contracts, changes in referral sources, and so forth can all create dramatic changes in the cash flow. This payment method has the largest possibility for error and fluctuation.

The *salary plus percentage (bonus)* based on payments allows the practitioner to profit from a higher volume of patients encountered and longer work hours needed to provide service for patients seeking care. This method, however, must be set at a predetermined rate that is achievable. In this method, the practitioner would be paid a set amount weekly, biweekly, or monthly; and, when the payments generated by the practitioner reach a predetermined milestone, additional bonus payments would be provided. In this payment method, the NP should make sure the base salary is adequate to meet the NP's financial commitments.

The last method of payment—*hourly payment*—is a well-understood payment method, and it is similar to how hospital employees and nurses have historically been paid. In this method the practitioner provides time records with the hours worked for payroll payment. This method allows for fluctuations in patient flow and changes in job responsibilities. It also requires the nurse to essentially punch a time card or report hours worked, reducing the level of autonomy the practitioner has in the business.

Employment Benefits

When interviewing for a position, the practitioner should make a list of benefits that are necessary and those that are desired. The benefits that fall into the must-have category usually include health, dental, short-term disability, malpractice, and life insurance; paid vacation time; a retirement plan or 401K; and paid sick time. On-call pay may be seen as a benefit if this allows NPs to enhance their salary based on their availability. Desirable benefits include long-term disability insurance, education allowance, car/parking allowance, investment options, professional meetings reimbursement, and so forth. Each practitioner should survey other NPs to verify the standard benefits packages noted in the area. The NP should fully research all aspects of the practice and communicate needs and wants in writing. Negotiating requested salary and benefits can be supported by the revenue an NP can estimate generating for the practice.

Obtaining Hospital Privileges

All hospitals have credentialing approval processes that require the practitioner to submit and validate his or her educational preparation, licensing, certifications, and clinical competencies. Credentialing usually falls under the allied health validation process established by The Joint Commission and the medical staff hospital bylaws. Practitioners can obtain a copy of the hospital's rules and regulations and familiarize themselves with these regulations, ensuring all guidelines of the facility are achievable.

Practice Insurance

Insurance policies are critical for every business, allowing each business to meet the state's requirements for incorporation. The practitioner should be aware of the insurances needed for all businesses. Some insurance plans are required to obtain the tax identification number (TIN or EIN), and these must be obtained in order to apply for a city, state, and county business license. Table 22.4 provides an overview of optional and mandatory insurance plans selected to protect businesses.

Practice liability insurance provides risk protection for an employer and practitioner against unforeseen events. As an owner, practitioner, or administrative employee of the business, liability value of the practice (capital equipment and resources in the business) should be reviewed annually. As the practice grows and changes, these policies must remain current and reflect the worth of the current equipment and property owned by the practice. For example, significant growth in computers and software in the practice should be added to the practice liability policy, because these resources significantly increase the value of the practice.

A business expense that requires additional consideration includes workers' compensation (WC) insurance. WC insurance coverage has become very expensive over the last decade. With one or two employee claims in the fiscal year, WC coverage and available premiums may become limited and very costly. High-risk businesses may be forced to seek plans through the Joint Underwriting Association, often described as the state's providers of last resort. WC premiums may be high enough to affect the financial health of a business. All practitioners should be aware of the practice policies and make sure employee

Table 22.4 Corporation Insurance Plans

Type of Plan	Coverage
Workers' compensation	Medical expenses resulting from on-the-job injury, illness, and death
Unemployment insurance	State and federal coverage; provides payment for loss of employment
Liability insurance insurance	Covers structure, furniture, equipment in the event of a disaster
Business interruption	Covers loss of payments/income in the event of a disaster
Employee fidelity bonds	Verifies employee honesty and deters theft
Life insurance	Many types and should be investigated; covers practitioners
Disability insurance	Risk of disability greater than death and creates financial hardship
Malpractice insurance	Protects practitioner in the event of lawsuit

screenings (protective measures against practice risk) are included in policy, such as drug screening, background verification, and employment screening. Yearly employee education is essential and should include workplace safety processes. Employee actions that deviate from these processes or safety directions should receive documented counseling to protect the practice from avoidable claims.

Malpractice insurance has become a concern and a hotly discussed medical practice expense. Malpractice premiums have doubled and tripled for physicians and NPs over the last few years. The numbers of frivolous lawsuits are increasing, and practitioners are at risk, working in an environment that appears to encourage patients to seek litigation when care outcomes are not as expected or to their liking. Certain physician specialties are more highly litigated, and these specialties have the alternative to "go bare." This option requires the practitioners to declare they will meet the minimum patient compensation payment requirements of the state and to demonstrate an ability to meet liability claims up to a payment limit. Practitioners without malpractice coverage create a concern that the risk will be borne by all those providers required to maintain malpractice insurance—that is, hospitals, hospital-based practitioners, and practitioners who have not opted to "go bare." NPs need to be aware of this business practice, ensuring that they do not end up as the sole insured provider of the business.

If the provider desires to carry insurance protection, he or she should purchase the highest amount of coverage affordable. The ideal coverage is an occurrence policy for $1 million per claim and $3 million in aggregate coverage. Because failure to have proper coverage can be catastrophic, or at least very expensive, it makes good sense to understand the product being purchased and the exposures that are not covered. Several states require that practitioners carry malpractice insurance or post a bond. When investigating choices in malpractice insurance plans, the practitioner should review and compare several different carriers for limits of coverage, whether the policy covers the business and employees, extent of coverage for legal costs, how long the insurance company has been in existence, and the differences between claims-made policies and occurrence policies. The rates can vary greatly, and the stability of each carrier should be examined. It is important to calculate the price of tail coverage when shopping policies and understand the definition of disability for automatic tail provisions. *Tail coverage* is an insurance policy that insures the healthcare providers for malpractice claims reported after a claims-made policy lapses. The status of the malpractice crisis for practitioners will affect how practitioners practice in the future.

Business Planning and Strategies

To compete in the business of health care, practitioners must plan and develop business strategies. Creating a business plan that fits the practice will guide, maintain, develop, and manage the company. This information should be used to market the efforts of the company to future patients.

A business strategic plan helps the business get organized and provides a roadmap for measureable success. This plan should be developed to guide current and future growth of the business. The business plan will support the needs for funding and will allow lenders to assess the risk involved in investing. It is important that the practitioner review the practice's financial statements. Strategies for business success should be identified, and data sources that will allow the plan to measure success at meeting these goals should be identified. Table 22.5 provides items to include in the business plan.

Table 22.5 Business Plan

Inclusions	Description
Company objectives	Summary of company key ideas
Executive summary	Company leadership and objectives
History of the company	Idea that started the company
Company goals	Short- and long-term goals, as well as identifying the customer • Strengths • Opportunities for growth
Management team	Background and responsibilities of the managers
Vision/mission statement	Unique aspects of your service
Capital and operating expenses	Costs of doing business
Value indicators	Quality measures
Marketing strategy	Convincing lenders and contributors of potential for the business • Analysis of competitors • Demand • Access • Advertisement and promotion
Research and practice evidence	Processes for submission, collection, and reporting
Financial projections	Balance sheet, income statements, cash flow, and units of service
Business risk	Risk management initiatives and monitoring
Change strategy	Benchmarks used to indicate success and failure

Marketing Plan

PPACA will affect the demand for NPs. NPs, however, are traditionally poor at marketing their services to the public and media. Nurse practitioners tend to share their successes and inroads with those within the profession using nursing journals, conferences, and word of mouth communication between colleagues. Consumers, the media, and the general public have been largely overlooked as targets of the NP marketing message.

NPs should identify marketing strategies and then measure the impact of these efforts. First, practitioners can explore opportunities that will inform patients and the public on the role and value of the NP. Print material distributed to patients can offer clarification and differences in roles, as well as highlight educational and practice experiences. Second, practitioners may reach out to the media. Practitioners can seek out local news and broadcasting media that specialize in health. Third, practitioners should share the news regarding faculty, new offices, public health issues, and so forth. This important health outcome data regarding their practice outcomes should be shared with local media via press releases. Fourth, practitioners can make themselves available to news media for commentary and interviews. Fifth, all practitioners should be able to articulate the cost savings they bring to health care. With the health-care industry's increasing need to reduce the costs of health delivery, NPs have an opportunity to establish their role as a leader in the health-care team. Table 22.6 provides a listing of common policies and procedures that guide business managers and employees.

Table 22.6 Common Policies and Procedures

- Hours of practice
- Utilization of space and resources
- Forms and collection of patient information
- Collect co-payments and deductibles at the time of the visit
- Verify eligibility and patient coverage before treatment, on carrier Web site
- Implement frequent billing cycle (e.g., every 15 days)
- Accept credit cards for co-payments and deductible
- Establish payment plans for patients not able to pay in full
- Collecting money, posting money, and depositing money should be handled by different employees
- Verify that billers make daily bank deposits and that receipts are matched daily to the posted payments of that day
- Protect the confidentiality and storage of patient records
- Hazardous waste
- Credentialing of all providers
- Hiring and firing of employees is in accordance with state laws
- Risk management education
- Occupational Safety and Health Administration (OSHA) compliance and HIPAA documentation
- External regulator reporting requirements
- Pharmaceuticals and resources needed for practice
- Quality assurance and effectiveness monitoring
- Compliance forms and yearly verification
- Emergency plans
- Employee education plan
- Equipment monitoring
- Provide general liability for the practice
- Develop a plan for malpractice coverage for all providers
- Business and facility security
- Volunteer policy
- Advertisement and marketing

CONCLUSION

With the 2014 expansion of health coverage through PPACA legislation, one question looms on the minds of all stakeholders: How will the nation cope with the surge of new patients and their demand for health services? There is already a shortage of primary-care physicians, creating a workforce issue. In addition, the population is growing, as is the percentage of individuals over 65 years of age. Health-care reform will be implemented over the next decade across the United States and will face many challenges. NPs have an opportunity to move past historical limitations and to restructure the delivery system, innovating and taking on tasks that allow them to practice according to their training and to lead this period of change.

NPs who develop a professional vision, articulate their value to the community, demonstrate flexibility, and provide innovative means to create a successful business are needed in today's and tomorrow's health-care system. Knowledge of the financial aspects of health care will be required for NPs to participate in health-care policy decisions. Today's practitioners will need knowledge that enhances their ability to analyze and report data that show the quality of their services, that highlight efficiencies related to costs, and that demonstrate their role in increasing access to care for all patients. Clinical and economic expertise will enhance the value-drivers for the profession. Basic business skills will support planning, innovation, and implementation of process changes. NPs are ideally trained to deliver low-cost health care while ensuring that the highest quality is not sacrificed for efficiency. As stakeholders, NPs should play an essential role in overseeing health-care change and ensuring the viability of the health-care system.

The 15-Minute Hour: Practical Psychotherapy for Primary Care

Brandi Parker Cotton, PMHNP-BC, MSN • Eliezer Schnall, PhD • Marian Stuart, PhD

Chapter 23

Contemporary advanced nursing practice presents many challenges, not the least of which is being on the frontlines of health management. Patients present for short office visits with complicated chief complaints, often seeking immediate relief from both physical and mental discomfort. In real-world clinical practice, the distinction between psychiatric and medical illness is often blurry, because mental and physical health interconnect. Specifically, psychological problems are often expressed as physical symptoms, and medical problems frequently precipitate psychological distress. Just as medical illness is usually best treated when detected in an early stage, early intervention is critical for psychological problems. Additionally, the emphasis on behavioral health, self-care, and prevention calls for the inclusion of a behavioral health specialist on primary-care teams.

The majority of psychiatric symptomatology will be managed within the primary-care setting. For example, a study by the World Health Organization sampled 1,500 patients around the world, in cities such as Ankara, Athens, Rio de Janeiro, Shanghai, Bangalore, Seattle, Berlin, and Manchester (Üstün & Sartorius, 1995), and found that 25% of patients met criteria for a psychiatric disorder. A more recent study by Smith et al (2014) indicates the need to modify educational curricula for medical students and residents with increased attention to psychiatric diagnoses and treatment. Noting that 25% of patients in outpatient clinics meet criteria for a *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) diagnosis (more common than hypertension and diabetes combined), the authors argue for improved diagnostics and management of psychiatric symptomatology (Smith et al, 2014).

Considering these statistics, it is unsurprising that patients present for primary-care visits reporting psychological concerns. Besieged by psychosocial stressors, patients seek relief for troubled relationships, stressful life events, recent losses, and economic strain. Although most providers agree that a thorough assessment of these contextual influences is important, the pressures of time-sensitive patient encounters create barriers to comprehensive and person-centered care. Given the significant impact of psychosocial factors on the prognosis of disease, building psychotherapeutic skills is critical for primary-care providers. Techniques such as reflective listening, validating emotions, and encouraging patient empowerment are easily utilizable within short office visits. This chapter highlights the various modalities by which providers can assess and address acute stress and maladaptive responses that predict poorer prognosis of disease states; several therapeutic techniques are suggested for routine implementation during brief patient encounters.

STRESS

Stress is the physical and mental response that results from having to adapt to demands from the external and internal environments. When under stress, people generally cope less effectively than when they feel comfortable or pleasantly challenged. Distress is experienced when people's resources are overwhelmed by the constant challenges of life, leading to feelings of loss of control. Our understanding of the relationships among stress, coping, and health has been enhanced by the classic, long-term prospective studies of Vaillant (1979), whose findings suggest the following:

- Overwhelmed people regress functionally.
- Poor adaptation is associated with ill health, because risk of disease increases in those with anxiety, depression, and inadequate stress management.
- Offering support to those under stress may facilitate their return to adaptive function and health.

Given this understanding, health promotion and disease prevention require teaching constructive ways of coping with stress. When people become overwhelmed by the circumstances of their lives, whether due to a cataclysmic event, daily hassles, or even personality characteristics, they often become sick and may visit their primary-care provider. It is thus important to screen effectively for stressors and adopt techniques for providing support.

SOCIAL SUPPORT

Social support is a key element in stress management. When one's perception of control over life circumstances decreases, subjective feelings of stress increase dramatically. However, as social support increases, the stress level decreases. Not surprisingly, it has been shown that poor social support is deleterious to health. Health-care providers are in a position to convey essential social support, by providing positive feedback to the patient or by suggesting strategies for handling a particular problem. When people are psychologically stressed or medically ill, they may be particularly vulnerable to negative feelings, namely inadequacy and isolation. A key benefit of social support is that it augments a person's sense of competence and of connection. By reminding patients about their basic strengths, clinicians enhance patients' abilities to function in a healthy way.

COMMONALITIES AMONG PSYCHOTHERAPEUTIC TECHNIQUES

Practitioners by virtue of professional training and commitment to wellness are uniquely positioned to assist their patients in coping, regardless of the specific nature of the problem. Skillfully employed, this professional therapeutic persona alone can decrease stress and enable patients to cope more effectively. After discussions with a health-care provider about their concerns, patients often feel better and may even be able to solve formerly intractable problems. Many providers feel more comfortable calling this "counseling," but such interactions are essentially psychotherapy. Among the elements common to all major schools of psychotherapy noted by Goldfried and Padawer (1982) are (1) patient expectation of receiving help, (2) participation in a therapeutic relationship, (3) obtaining an external perspective, (4) encouraging corrective experience, and (5) repeated reality testing.

TECHNIQUE: "BATHEING" THE PATIENT

Incorporating appropriate questions and responses regarding a patient's psychosocial situation is an acquired skill. The BATHE technique was developed by Stuart, a psychologist, and Lieberman, a medical doctor, in their work with medical students. The technique has been a staple in Rakel's *Textbook of Family Medicine* since the 1990s and published in book form as *The Fifteen Minute Hour* (Stuart & Leiberman, 2008). It is both a quick screening test and an intervention for psychiatric problems, especially appropriate for new patients and those presenting with acute problems and mental distress. It has become an established method of identifying and addressing psychosocial aspects of patients' problems during a brief office visit. It should be utilized early in the interview, usually after elicitation of the chief complaint and the history of the present illness. BATHE has become a standard of primary care. The acronym, intended to complement the "SOAP" method of medical documentation (see Chapter 4 of this volume, pp. 58–59), stands for Background, Affect, Trouble, Handling, and Empathy. Focus on History 23.1 presents the BATHE technique. Although BATHE is not the only technique a clinician can employ, it brings order and efficiency to what may otherwise become a muddled and time-consuming attempt at psychosocial assessment. In the process, it helps tie the biomedical model to the psychosocial in a way that is meaningful for both practitioner and patient. By asking pointed, focused questions that lend themselves to brief but comprehensive answers, the clinician is able to incorporate this very necessary form of assessment into a format that enhances rapport and also helps the patient express feelings, gain insight into the meaning of the situation, and become empowered. Most significantly, it satisfies all the aforementioned elements of psychotherapy: BATHE provides the expectation of help, a therapeutic relationship, an external perspective, the encouragement of new behavior, and the ongoing opportunity to test reality. The clinician must exercise discipline, however, and refrain from a lengthy exploration of the patient's life. BATHE's therapeutic effect derives simply from its focus on the patient's feelings, the subjective meaning of the situation, assessment of how things are being handled, and empathic demonstration of support.

Focus on History 23.1 The BATHE Technique

- **B**ackground The simple question "What is going on in your life?" determines the context of the patient's visit.
- **A**ffect Questions such as "How does that make you feel?" encourage patients to identify and report their emotional reactions to the circumstances described.
- **T**rouble The question "What troubles you most about this?" helps both practitioner and patient focus on the situation's subjective meaning. Even when the patient's affect is positive, a modified version of this question should be asked: "Is there anything about it that troubles you?"
- **H**andling The answer to "How are you handling that?" helps the practitioner assess the patient's level of functioning, helps the patient connect mind and behavior, and communicates the thought that the patient has indeed taken steps toward handling the situation.
- **E**mpathy The statement "That must be very difficult" legitimizes the patient's reaction. Even when the patient is functioning suboptimally, it is important to reflect back the content of the circumstances and support the patient's attempts at resolution.

The BATHE technique has empirical evidence to support its use in increasing patient satisfaction. In 2008, Leiblum published a study exploring the use of the BATHE technique within the primary-care setting. Four experienced family medicine physicians working in a large urban outpatient office, who were trained in the BATHE technique, took part in a study that explored outcomes relating to patient satisfaction with this brief therapeutic intervention. BATHEd patients were more likely satisfied with the information the physician provided and their perception of physician concern for them and were more likely to recommend their physician to others. More recently in 2011, a study explored the use of the BATHE technique within the perioperative setting at Mount Sinai Medical Center in New York. One hundred surgical patients were randomly enrolled in the BATHE group or the control group. The use of the BATHE technique within this setting suggests that it is both clinically effective and practical: Findings suggest that use of the BATHE method increased patient satisfaction but did not increase the length of the physician evaluation (DeMaria et al, 2011).

Ownership

The BATHE technique helps the provider more fully assess the patient's situation and make therapeutic suggestions so the patient can deal with his or her problem more effectively. This is true whether the problem seems predominantly biomedical or psychosocial, because elements of each are invariably involved in the patient's overall situation. Nonetheless, it is crucial that the provider not assume responsibility for resolution of the patient's situation. The patient continues to "own" his or her problem; however, a more comprehensive understanding of the situation and its effect on the patient allows the provider to assist more effectively. Further, as the patient gains confidence that the provider is supportive and able to help, the element of trust in the therapeutic relationship is enhanced.

Applying the BATHE Technique

Practitioners may worry that application of the BATHE technique may uncover unanticipated issues that cannot be adequately addressed within the allotted time. However, BATHE's evaluative component is a *screening tool,* and the clinician must use judgment as to when and how extensively to explore what has surfaced. Sometimes it is important to say, "I am glad you brought this up. Let me examine you to see if there is some physical problem that we need to be concerned about, and afterward we can talk some more." In most cases, BATHEing the patient will take less than a minute and can help prevent the unexpected and time-consuming patient revelations sometimes held until the end of the visit. The essence of psychotherapy consists of making the patient feel competent and connected, and there are numerous additional and complementary techniques that can help accomplish this. Many such strategies and examples can be found in Stuart and Lieberman's *The Fifteen Minute Hour* (2008). In most cases, however, just "BATHEing" the patient helps to clarify the situation. Once this is complete, patients should have their feelings validated and be supported in expressing those feelings. They should be provided brief information about the effects of stress along with specific suggestions for stress management and relevant problem-solving. If necessary, the patient should be invited to return and explore the situation further. As always, serious problems necessitate referral to a mental health professional, but the practitioner's role in uncovering important issues is invaluable.

THE POSITIVE BATHE

The last decade has seen the emergence of a new mental health subfield called positive psychology. Researchers such as Martin Seligman, Edward Diener, and Christopher Peterson are encouraging psychologists to focus on human virtues, character strengths, and the benefits of happiness and personal growth, rather than the traditional exclusive concentration on the study and treatment of mental illness and disturbance. This is very consistent with nursing's emphasis on health promotion and supporting patients' strengths. An impressive and growing literature links positive affect with health and longevity. Positive thought and emotion is believed to bolster the immune system and has even been associated with better health behaviors. One specific area that has garnered attention is gratitude, a trait associated with a sense of well-being and positive feeling. In fact, investigators have shown empirically that related interventions, such as asking subjects to write gratitude letters or keep gratitude journals, lead to decreased physical and mental health symptoms (Peterson, 2006; Stuart & Lieberman, 2008). In keeping with these themes, a new "Positive BATHE" intervention has been developed to help patients focus on autonomy and personal accomplishment, thankfulness, and general positive affect. Practically, learning this additional BATHE repertoire also allows the provider a second form of intervention, especially useful when interacting with the chronically ill or others who may return frequently for follow-up appointments. In this new version, BATHE is an acronym for **B**est, **A**ccount, **T**hankfulness, **H**appen, and **E**mpowerment. Focus on History 23.2 presents the "Positive BATHE" technique.

MOTIVATIONAL INTERVIEWING

Motivational Interviewing (MI) is a therapeutic technique supported by a large volume of research. Employed within a wide array of clinical settings, MI is an empirically validated strategy for assisting patients with behavioral change. Developed by Robert Miller, PhD, as a target therapy for substance abuse, the tenets of MI extend to a wide range of clinical audiences. MI asserts that ambivalence is a normal, nonpathological

Focus on History 23.2 The Positive BATHE Technique

- **B**est Asking patients "What's the best thing that has happened to you lately?" encourages recall of positive events, which likely leads to positive affect.
- **A**ccount When patients reflect on the causes of positive events, they discover what they should do to promote recurrence of these events. Questions such as "How do you account for that?" advance this form of contemplation.
- **T**hankfulness The question "What are you most thankful for?" is aimed at triggering gratitude related to the events mentioned and thereby positive feelings and good health.
- **H**appen Asking "How can you make things like that happen again?" suggests that the patient be proactive in attaining positive experiences. It also challenges patients to put character strengths and adaptive traits to use in their day-to-day interactions.
- **E**mpowerment Enthusiastic and empathic practitioner responses, such as "It sounds like you have a fantastic idea!" and "I am sure you can do it!" empower the patient to take the steps necessary for further success and achievement.

component of the change process. Clinicians assist patients in addressing ambivalence by exploring intrinsic motivation, values, and goals. The basic principles of MI promote respect for individual autonomy and belief that the patient is an expert on his or her own behavior. This is a consistent way of supporting the patient's self-care behaviors and taking responsibility for the patient's own health. MI involves empathetic listening and establishing a nonjudgmental, nonconfrontational patient approach. Collaboration and joint decision making encourage "change talk." Techniques of MI include asking open-ended questions, offering affirmative and supportive statements, reflectively listening, and summarizing the patient's situation. MI also encourages clinicians to request permission before offering advice or interventions. Unsolicited advice is likely to promote resistance. If a patient is not yet ready to change a behavior (e.g., beginning a diet, monitoring glucose, adopting an exercise routine, decreasing substance use), it is unlikely that clinicians' advice will be well received (Miller & Rollnick, 2012, pp. 62–72).

The Four Principles of Motivational Interviewing use the acronym RULE (Rollnick et al, 2007, pp. 7–10):

Resist the righting reflex.
Understand your patient's motivation.
Listen to your patient.
Empower your patient.

An important tenet of MI is the use of reflective listening, a key component in helping patients explore ambivalence and resistance to change. Reflective listening ranges from simple to complex: repeating, rephrasing, paraphrasing, and reflecting feeling. Dialogue is strategic; clinicians guide the conversation with reflective statements, not questions, accepting the patient regardless of her or his readiness for change (Rollnick et al, 2007, pp. 7–10).

Consider the following clinical scenarios.

CASE STUDY 23.1

Martin is a 33-year-old man with a history of heavy alcohol use. He presents to his provider and reports a recent job loss due to excessive tardiness. He reports concern that his family faces eviction for failure to pay rent. Martin then discloses that much of his tardiness was a result of hangovers from heavy drinking. He has voiced concerns in the past, specifically reporting: "My wife nags me about spending too much time with my drinking buddies." He expresses concern that an intensive substance abuse program will be too time-consuming but reports several unsuccessful efforts to remain sober when using the 12-step program Alcoholics Anonymous (AA).

Patient: "I know I can really drink a lot after work. It relaxes me, you know. The job thing is tough—my wife has been pressuring me to get treatment or something. I tried AA but it didn't work. A friend of mine did some intensive thing, but I don't have time for that. How am I supposed to spend eight hours at some treatment facility when I need to be out looking for a job?"

The acronym OARS highlights four important components of MI (Miller & Rollnick, 2012):

Open-ended response:
- "What's this been like for you?"
- "What's most important to you at this point?"

Affirming patient:
- "It can be incredibly difficult to acknowledge these things. The fact that you are here today and talking with me about it shows a commitment to making things better."

Reflecting listening:
- "So the drinking is causing strain. It's also a way for you to relax."
- "You want to find a program that is right for you."

Summarizing for patient:
- "From our last few visits, I know you've been thinking about cutting back on the drinking. It seems like today, after the job loss, you are more concerned than you were at our previous visits. You are thinking about treatment options, but it's really important to you to find a program that is going to fit your lifestyle."

Last, providers should **ASK** permission:
- "Do you want any information about alternative treatments in the area?"

CASE STUDY 23.2

Anna is a 43-year-old woman with a body mass index of 35. She is the mother of two and works as a secretary. Anna is diagnosed with hypercholesterolemia and type 2 diabetes. She consumes a high-calorie diet and maintains a sedentary lifestyle.

Patient: "I know I need to lose weight. I keep planning on walking, but it's so cold now."

Open-ended response:
- "Tell me a little more about your goals in this area."

Affirming patient:
- "Implementing an exercise routine can be really difficult. The fact that you are considering how to make it work for you and your lifestyle is an important step."

Reflecting listening:
- "Sounds like you want to exercise, but outdoor exercise isn't realistic in this weather."

Summarizing for patient:
- "You've been monitoring your weight over the past several months, and it seems like you're feeling discouraged with the results. Winter weather makes it even more challenging for you to meet your goals. You want a plan that's going to work for you."

ASK permission:
- "Several of my patients have had a lot of success with a new program—would you like to hear about it?"

The previous clinical examples illustrate how techniques of MI differ from the traditional approach of encouraging behavioral change. MI is rooted in empathic listening and collaborative decision making. Empiric data support these techniques as an effective strategy for increasing adherence to antivirals in HIV-positive patients, decreasing high-risk behaviors, promoting weight loss, treating eating disorders, increasing physical activity, and addressing domestic violence. The diverse application of MI principles suggests its promising role in promoting positive behavioral changes within a broad range of clinical settings (Miller & Rollnick, 2012).

SUMMARY

Patients' beliefs, values, perspectives, and health behaviors are situated within a broad social and environmental context. Understanding this context is essential to building and establishing rapport between patient and provider and providing holistic, person-centered care. In spite of considerable time constraints, practitioners adopt therapeutic tools to assist patients in changing maladaptive responses and unhealthful behaviors. Utilizing brief psychotherapeutic modalities, such as BATHE, Positive BATHE, and Motivational Interviewing, can improve both patient satisfaction and health outcomes. The 15-Minute Hour indeed lends itself to positive and meaningful interactions.

Putting Caring into Practice: Caring for Self

Mary Lavin, DNP, FNP-BC • Rebecca Carley, DNP, ANP-BC

Chapter 24

The importance of self-care for the clinician cannot be overstated. As advanced practice registered nurse (APRN) students confront the demands of graduate school and, later, beginning practice, they realize the necessity of maintaining balance; work and professional responsibilities, family and home life, coursework and clinical practicums—all demand attention. Self-care and health promotion are major components of caring for patients; it is imperative that nurse practitioners care for themselves as well.

A review of the processes introduced in the *Circle of Caring* model provides a valuable starting point for the discussion of self-care of the APRN and indeed any health-care provider. Caring for others makes it incumbent on us all to care for "self." The goal is to actualize the model by directing health-supporting activities toward oneself first, enabling the practitioner to experience and integrate the value gained from self-care, and to use this strength as a source of replenishment in helping others. This chapter provides an introduction to self-care definitions, enumerates some of the challenges to self-care, and makes suggestions for self-assessment and for practical application of healing strategies in advanced practice nursing and primary-care practice in general.

BACKGROUND: CARING AND SELF-CARE

Caring has long been considered the domain of nursing, although many other health-care providers care in their own ways. The *Circle of Caring* model presented in Chapter 1 and developed throughout this textbook helps us to deepen our conceptualization of the ways nursing contributes to the process of healing. This model provides for conceptualization instead of simply skills and techniques, and it expands the traditional medical model. The caring processes include patience, courage, advocacy, authentic presence, commitment, and knowing. Caring is central to the profession of nursing and is at the core of many, if not all, nursing theories.

Caring for others has been the usual focus of nursing, but the need to retain nurses within the profession has fostered a new emphasis on self-care of the nurse. Defining *self-care* is a difficult endeavor because there is no single definition that is broadly accepted in the literature. Godfrey et al (2011) conducted an extensive evaluation of the concept of self-care by examining in detail the definition of self-care through content analysis of 139 definitions that spanned a time period from 1970 through 2009. Seven components of the definition of self-care were identified. These components were stated as aspects related to the following: health, illness and disability, general outcomes, performer of the self-care, action of the self-care, health-care professionals, and the health-care system. Self-care historically has been represented as a low-quality and ineffectual behavior, but the 2000s brought about a broadening of the term and a new appreciation of the importance of self-care.

Some commonly used definitions illuminate these components.

- The World Health Organization defines self-care as "a deliberate action that individuals, family members, and the community should engage in to maintain good health ... Self-care includes all health decisions people make for themselves and their family to become and remain physically and mentally fit such as eating healthy foods, exercising regularly, practicing good hygiene, and avoiding health hazards. People in good health, those who are ill or with disability can engage in self-care ... Self-care is the ability of individuals, families, and communities to promote health, prevent disease, and maintain health and to cope with illness and disability with or without the support of a health-care provider" (cited in Godfrey et al, 2011, p. 16).
- Wilkinson and Whitehead defined *self-care* as "not involving a health professional ... and the individual independently attains and preserves [his or her] desired level of health. Self-care could be understood as people being responsible for their own health and well-being through staying fit and healthy: physically, mentally, and where desired, spiritually" (2009, p. 1,145).
- The American Holistic Nurses Association (AHNA) Standards of Holistic Practice requires the integration of self-care and personal development activities into one's life. Holistic nurses engage in self-assessment, self-care, and personal development and are aware of being instruments of healing. Holistic nurses value themselves and mobilize the necessary resources to care for themselves. They strive to achieve harmony

and balance in their own lives and to assist others to do the same. The AHNA describes self-care practices as self-assessment, meditation, yoga, good nutrition, energy therapies, movement or dance, journaling, and creative expression (art, music).
- Orem defines self-care as comprising those activities performed independently by an individual to promote and maintain well-being throughout life (AHNA, 2014).

Regardless of the definition, many helping disciplines are beginning to focus on the issue of self-care for their members. A keyword search will provide an overabundance of literature around this topic across disciplines such as the following: psychology, social work, medicine, education, and emergency medical services. The impact of stress and trauma on optimal functioning and retention of providers is of growing concern amid the changing health-care environment. Many professional associations have developed and incorporated self-care resources that are available on each association's Web site. For example, the American Nurses Association has recently implemented the Healthy Nurse initiative to address self-care issues among nursing professionals (www.ana.org).

Nurse practitioners care for patients with a wide variety of lifestyles, health-care choices, acute-care illnesses, and chronic health-care conditions. To help their patients maintain optimal health, nurse practitioners frequently discuss and advocate for self-care programs with individuals and families. Modeling healthy lifestyle behaviors is an important aspect of patient support and teaching. By caring for himself or herself effectively, the nurse practitioner will promote self-care in patients.

CHALLENGES TO SELF-CARE INHERENT IN ADVANCED PRACTICE NURSING

Self-care is an important strategy for nurse practitioners (NPs) for many reasons. There is a great deal of stress inherent in the NP role in primary care. Recent changes in health care in the United States will also greatly affect the role and increase the consequent stress of the nurse practitioner. *The Future of Nursing* (Institute of Medicine [IOM], 2010) suggests that the future of health care will be greatly influenced by nursing and that nurses and nurse practitioners should be allowed to work to the full extent of their education. The Affordable Care Act of 2010 will increase patient access to care and, therefore, increase demand for primary-care practitioners. The Quality and Safety Education for Nurses competencies also demand that nurse practitioners maintain patient safety standards, utilize evidence-based practice strategies, and implement continuous quality improvement. These are all excellent standards of care and will help to provide and maintain comprehensive care for all individuals. However, the demands of new roles combined with the increasing patient population in primary-care practices will continue to stress primary-care providers.

Additional challenges to nurse practitioners include compliance with insurance regulations and maintenance of certifications, the technology explosion, and societal changes. Insurance regulators have a major impact on the time management of, the reimbursement of, and, consequently, the demand for nurse practitioners, as well as other health-care professionals. Reimbursement rates for nurse practitioners' services are often less than the rates for physician providers who are providing the same care. Primary-care practices provide many services that are not covered by insurance carriers such as the completion of prior authorizations for medications and diagnostic tests, as well as forms required for schools and camps.

The introduction and integration of the electronic health record (EHR) during the past decade has created a challenge for all health-care providers to maintain effective communication with patients during office visits. Although the EHR has major benefits for documentation and continuity of care, there is also an increased time demand for documentation during patient visits. Increased time demands are also generated through the adoption of other technology, such as automated appointment scheduling, Web portals for accessing lab results, and texting patient reminders or encouragement for self-care. Although many of these technologies can enhance patient care, new systems must be implemented for the adoption of these practices. In addition, patients frequently search the Internet for answers to health-care questions. Sometimes this patient-conducted research allows for more informed questions for health-care providers, but it often also contributes to patients' anxiety regarding their symptoms.

Social issues such as joblessness, poverty, immigration of undocumented persons, high costs for medications and other treatments, and the aging population all can adversely affect the health care and self-care of patients. Nurse practitioners in primary care are involved in the management of acutely ill and chronically ill patients whose care needs may be challenging and difficult to deal with emotionally. To further complicate matters, APRNs must also deal with confusion about professional boundaries, particularly in light of the emerging doctorate of nursing practice (DNP) and changes in legislation and reimbursement.

There has also been an increasing demand by the IOM and other organizations for the development of interdisciplinary education and health-care teams. This is an overall positive initiative, but it does bring its own stressors. Other health-care professionals are responding to many of these demands, and there is blurring of some roles as different professionals attempt to remain viable and to expand their roles in health care. The roles and responsibilities of the APRN are also changing to reflect these demands. Some of these transitions in scope of care will need legislative action or changes in rules and regulations within licensing/credentialing bodies.

The changing face of health care dictates the need for flexibility as we approach a new era in health care. APRNs have more opportunity to work independently, yet they experience increased risk of legal action. In addition, APRNs may feel squeezed between the conflicting values and roles of being both nurse and primary-care provider, constantly having to negotiate unique interprofessional relationships with other health-care providers. Nurses want to advocate for their patients in a system that does not always appreciate or, at times, even allow them to do their job appropriately and effectively.

Providing excellent care day in and day out can lead to compassion fatigue and/or burnout for individual nurse practitioners. Several authors describe compassion fatigue and burnout as related but separate concepts (Valent, 2002; Lombardo & Eyre, 2011). *Compassion fatigue* occurs when one cannot rescue or save an individual from harm, and this leads to feelings of guilt and distress. Compassion fatigue appears suddenly and resolves quickly. *Burnout* occurs when one cannot achieve his or her goals and results in "frustration, a sense of loss of control, increased willful efforts, and diminishing morale" (Valent, 2002, p. 27). Burnout arises and declines more slowly, but both burnout and compassion fatigue can have negative consequences for both the provider and the client (Sabo, 2006).

THE REASON FOR SELF-CARE MANAGEMENT

All nurses experience varying degrees of stress, compassion fatigue, or burnout at some point in their career. Nurse practitioners are easily able to identify problems within others, but frequently avoid dealing with issues that might affect their own well-being. The most important strategy for nurse practitioners is to identify their stressors before they can affect their well-being and that of their clients. Very often nurse practitioners know that something is wrong but avoid taking the time needed to address the concerns in the middle of a highly packed day.

Focusing on personal and professional shortcomings does not lead to optimal health. Nurse practitioners are often able to understand and accept the deficiencies of others, yet they hold themselves to unattainable standards. Self-compassion is the ability to be compassionate to oneself. Emotional intelligence is the ability of the person to recognize emotions, understand the meaning of the emotions, and realize how the emotions affect other people. Characteristics of emotional intelligence include self-awareness, self-regulation, motivation, empathy, and social skills. You can assess your current level of emotional intelligence at www.mindtools.com. Heffernan et al (2010) found a positive correlation between self-compassion and emotional intelligence among nurses. Two overarching principles of a self-care management plan are resilience and positive intentionality. These concepts are interrelated and can enhance the success of self-care practices.

Resilience has been defined by many authors as the ability to keep functioning in the face of continued stress, difficult work conditions, or trauma. Resilience can be seen as a strategy for responding to difficult or adverse situations by positively adjusting to stressors. Resilience can be associated with hope, positivity, and self-efficacy (Sullivan et al, 2012). Some research studies suggest that resilience can actually be strengthened in nurses through the use of different strategies. A review of the literature regarding resilience in health professionals by McCann et al (2013) suggests that laughter/humor, self-reflection, beliefs/spirituality, and professional identity are all related to the characteristic of resilience. Developing positive relationships and encouraging positive attitudes and emotional insight will reinforce resilience.

Positive intentionality is a form of focused consciousness and energy according to Jean Watson. Holding thoughts of caring, loving, kindness, and open receptivity rather than having manipulative intent or seeking power over others leads to healing (Watson, 2002). Focusing on positive intentionality in thoughts and actions enhances caring energy, which leads to healing and improved health.

THE PROCESS OF SELF-CARE MANAGEMENT

Self-Assessment

Practicing nurses and experienced nurse practitioners are skilled at assessing a patient's readiness for change and developing plans to improve self-care, but these professionals may not take time to apply a similar process to themselves. The principles discussed in Chapter 3 and the alternative therapies discussed throughout this text can be applied to self-care of the nursing professional. Self-assessment of the provider's current status includes reflection on strengths and identification of areas that need support. This might include time for reflection and appropriate self-evaluation of performance. It might also include identification of strategies that are suggested and validated for stress management. A variety of self-assessment tools are available to assist in the identification of concerns with links to or suggestions for appropriate strategies to make changes. Many organizations have identified professional quality-of-life assessment tools, such as ProQol (http://www.proqol.org).

This self-care assessment can be used to examine the type of self-care strategies that the nurse practitioner is using and identify other areas that might be important for self-care management. Some nurse practitioners will be able to identify stressors and concerns independently. Any method is acceptable as long as it leads to engagement in self-care behaviors.

Goal Setting

Each nurse practitioner can identify individual areas to work on, setting goals depending on his or her perception

of balance in life. Specific strategies such as increased exercise and adequate sleep may be important for one person, whereas another may need to focus on prayer or meditation. It is important for the nurse practitioner to evaluate all aspects of the person—physical, psychological, spiritual, and professional and work domains—so that appropriate interventions are utilized to optimize well-being. The APRN engages in self-evaluation concerning clinical practice to monitor and ensure the quality of health-care practice. This is consistent with the National Organization of Nurse Practitioner Faculties (NONPF) core competency for nurse practitioner practice.

Strategies

Strategies for self-care can be divided into categories for all components of well-being of the individual. These include physical aspects, as well as psychosocial and spiritual components. It is important that each professional examine his or her practice to determine whether there are realistic expectations for performance in the clinical area. In addition, other life stressors such as family needs, chronic illnesses, holidays, vacations, and relationships can compound professional stressors.

Physical signs and symptoms of increased stressors such as insomnia, loss of appetite, overeating, and weight gain or loss can require interventions to ensure optimal well-being for the provider. Interventions suggested by personal health-care providers should be followed for optimal physical care. This might include weight loss programs, exercise programs, and strategies for sleep. Occasionally, a practitioner may benefit from some extra personal time for reflection and meditation. Access to and self-referral to treatment programs can be helpful in sustaining interventions.

Professionally, it seems important for nurse practitioners to develop their own "inner circle," a trusted peer group composed of people with similar beliefs, who can mentor them in individual needs. In the literature, the role is referred to as a "coaching" function for professionals (Marshall & Zolnierek, 2012). Discussion of stressors, alternative choices for managing stressors, and debriefing after difficult situations can help to promote self-confidence and self-efficacy. Peers can also be helpful during transition times. Positive, nurturing relationships are imperative for the development of resilience. The focus on positivity is an important strategy because positive feelings increase energy and help one feel more optimistic about challenging situations. Developing emotional insight and balance in life can also augment a person's resilience. The characteristic of resilience is associated with confidence and self-efficacy. These self-care strategies will help to prevent adverse effects of stress.

Many professionals are involved in various other self-care strategies. Because so many lay publications are devoted to self-care and self-help, there is a plethora of strategies that can be utilized for self-care. Many of these strategies are well researched and validated for effectiveness. But perhaps the most important consideration is that each professional must identify the most appropriate strategies for his or her own self-care. Many professionals participate in exercise programs, yoga, walking and running programs, or weight management programs; many use music, massage, and/or meditation to reduce stress.

Some newer modalities and older Eastern medicine modalities for self-care have also been researched and validated. The Centers for Disease Control and Prevention (CDC) provides ongoing research findings on alternative therapies and serves as an excellent resource of information. Two interesting modalities that are well researched are mindfulness-based stress reduction and energy field strategies.

- **Mindfulness-based stress reduction** is one strategy that has been shown to reduce stress, anxiety, and chronic depression and is recently being utilized for management of other lifestyle problems (see www.umassmed.edu.cfm/index.aspx).
- **Energy field therapies**. *Therapeutic Touch* (TT) is a nursing strategy developed by Dora Kunz and Dolores Krieger. Krieger was a former student of Martha Rogers at New York University, who applied the principles of energy-field interactions, creating a sequential process whereby nurses and caregivers direct their intentionality toward the patient's well-being. Research studies have shown that TT is useful in reducing pain, improving wound healing, aiding relaxation, and easing the dying process (see www.therapeutictouch.org).

Reiki is a form of complementary energy therapy that helps to rebalance the energy field around the person to help restore him or her to a balanced, positive state of energy flow. This therapy helps the individual to feel relaxed and peaceful and has been utilized in a variety of settings to manage stress (Cuneo et al., 2010; Natale, 2010).

CASE STUDY 24.1

Jane R. has been a nurse practitioner for 10 years working in family primary care. Her current salaried position is in an urban community health center that provides care to a multicultural population. During an 8-hour workday, Jane will see 24 to 26 patients. She is the newest provider in the practice and is still building up her case load, so during most days she will see 4 to 6 new patients. Jane admits that most days she completes her EHR documentation at home, spending 2 to 3 hours most workdays and occasionally 1 day on the weekend reviewing and following up on labs and responding to patient e-mails or

CASE STUDY 24.1—cont'd

telephone calls. Jane is constantly worrying about what she is behind on or what she may have missed. Her children are grown and out of the house, but she finds little time to socialize or engage in activities she used to enjoy. She feels guilty that she is not spending more time with her husband. Her husband is concerned about her workload and the constraints work has put on her life.

Jane decided to discuss this issue with the NP who oriented her to this job. She was comforted to find out that her mentor was working as much as she was, but they both wondered if the other providers were having similar experiences. At the next monthly staff meeting, they raised the issue, and Jane was surprised to find that most of the providers were taking work home at night. The group decided to bring this issue to administration as an unacceptable situation. The issue is now being discussed and strategies for improving the situation are being considered. As a result of Jane's contemplation about work stressors, she realized that over time she has stopped exercising, eating well, or having restorative sleep. A colleague suggested that she make an appointment with a nurse who practices Therapeutic Touch. After undergoing several treatments, Jane notes that she is sleeping better, has energy to exercise, and feels less anxious.

CASE DISCUSSION

Jane R. experienced many of the work stressors discussed in this chapter. These stressors compromised her quality of life and her ability to participate in self-care. Reaching out to a colleague and eventually the other providers at her workplace helped Jane to realize that she was not alone. The cooperation and collaboration of her work group provided strength in approaching the administration of the health center. Through this process she realized that she has not been participating in self-care. She was able to seek support from colleagues and to improve her ability to function and participate in self-care.

SUMMARY

In the role of health-care providers in primary care, nurse practitioners are exposed to many stressors and challenges that can lead to frustration and self-criticism, as well as compassion fatigue and burnout. Nurse practitioners are well aware of the importance of self-care strategies and health promotion when caring for patients. It is imperative that nurse practitioner students and APRNs internalize these same concepts of self-care, resilience, and positivity, as well as maintain their sense of intentionality, in order to attain and preserve well-being and professional excellence.

The nurse practitioner must remain open to new strategies and modalities for self-care in the quest to balance personal and professional life. Many professional and other groups advertise conferences, lectures, and webinars on self-care strategies. These strategies, when first utilized by nurse practitioners, can also be taught as self-care strategies for patients.

Nursing is the art and science of human caring. Self-care for practitioners and patients requires continual efforts and openness to new strategies and modalities for health promotion, health education, and patient advocacy. The resilience and positivity developed through self-care strategies will allow APRNs to direct their skill and intentionality toward creating a peaceful, harmonious environment and to share and model excellent care for patients.

Physiological Influences of the Aging Process

appendix A

Age-Related Change	Appearance or Functional Change	Implication
Integumentary System		
Loss of dermal and epidermal thickness	Paper-thin skin	Prone to skin breakdown and injury
Flattening of papillae	Shearing and friction force more readily peels off the epidermis Diminished cell-mediated immunity in the skin	
Atrophy of the sweat glands	Decreased sweating	Frequent pruritus
Decreased vascularity	Slower recruitment of sweat glands by thermal stimulation Decreased body odor Decreased heat loss Dryness	Alteration in thermoregularity response Fluid requirements may change seasonally Loss of skin water Increased risk of heat stroke
Collagen cross-linking	Increased wrinkling	Potential effect on one's morale and feeling of self-worth
Elastin regression	Laxity of skin	
Loss of subcutaneous fat Decreased elasticity	Intraosseous atrophy, especially to back of hands and face	Loss of fat tissue on soles of feet—trauma of walking increases foot problems
Loss of subcutaneous tissue	Purpuric patches after minor surgery	Reduced insulation against cold temperatures; *prone to hypothermia* Check why injury is occurring; be alert—potential abuse or falls
Decreased number of melanocytes	Loss of pigment Pigment plaque appears	Teach importance of using sun block creams; refer to dermatologist as needed
Decline in fibroblast proliferation	Decreased epidermal growth rate Slower re-epithelialization Decreased vitamin D production and synthesis	Decreased tissue repair response
Decreased hair follicle density	Loss of body hair	
Decreased growth phase of individual fibers	Thin, short villus hairs predominate Slower hair growth	
Loss of melanocytes from the hair bulb	Graying of the hair	Potential effect on self-esteem

Continued

Age-Related Change	Appearance or Functional Change	Implication
Alternating hyperplasia and hypoplasia of nail matrix	Longitudinal ridges	Nails prone to splitting
	Thinner nails of the fingers	Advise patient to wear gloves, keep nails short, avoid nail polish remover (cause dryness); refer to podiatrist
	Thickened, curled toenails	May cause discomfort
Respiratory System		
Decreased lung tissue elasticity	Decreased vital capacity	Reduced overall efficiency of ventilatory exchange
	Increased residual volume Decreased maximum breath capacity	
Thoracic wall calcification	Increased anteroposterior diameter of chest Displacement of apical impulse	Obscuration of heart and lung sounds
Cilia atrophy	Change in mucociliary transport	Increased susceptibility to infection
Decreased respiratory muscle strength	Reduced ability to handle secretions and reduced effectiveness against noxious foreign particles Partial inflation of lungs at rest	Prone to atelectasis
Cardiovascular System		
Heart valves fibrose and thicken	Reduced stroke volume, cardiac output; may be altered	Decreased responsiveness to stress
	Slight left ventricular hypertrophy	Increased incidence of murmurs, *particularly aortic stenosis and mitral regurgitation*
Mucoid degeneration of mitral valve	S_4 commonly heard	
	Valve less dense; mitral leaflet stretches with intrathoracic pressure	
Fibroelastic thickening of the sinoatrial node; decreased number of pacemaker cells	Slower heart rate	Increased prevalence of arrhythmias
	Irregular heart rate	
Increased subpericardial fat Collagen accumulation around heart muscle		
Elongation of tortuosity and calcification of arteries	Increased rigidity of arterial wall	Aneurysms may form
Elastin and collagen cause progressive thickening and loss of arterial wall resiliency	Increased peripheral vascular resistance	Decreased blood flow to body organs
		Altered distribution of blood flow
Loss of elasticity of the aorta dilation		Increased systolic blood pressure, contributing to coronary artery disease
Increased lipid content in artery wall	Lipid deposits form	Increased incidence of atherosclerotic events, such as *angina pectoris*, stroke, gangrene
Decreased baroreceptor sensitivity (stretch receptors)	Decreased sensitivity to change in blood pressure	Prone to loss of balance—potential for falls
	Decreased baroreceptor mediation to straining	Valsalva maneuver may cause sudden drop in blood pressure

Age-Related Change	Appearance or Functional Change	Implication
Gastrointestinal System		
Liver becomes smaller	Decreased storage capacity	
Less efficient cholesterol stabilization absorption	Increased evidence of gallstones	
Dental enamel thins	Staining of tooth surface occurs	Tooth and gum decay; tooth loss
Gums recede	Teeth deprived of nutrients	
Fibrosis and atrophy of salivary glands	Prone to dry mucous membranes	Shift to mouth breathing is common
	Decreased salivary ptyalin	Membrane more susceptible to injury and infection May interfere with breakdown of starches
Atrophy and decrease in number of taste buds	Decreased taste sensation	Altered ability to taste sweet, sour, and bitter Change in nutritional intake Excessive seasoning of foods
Delay in esophageal emptying	Decline in esophageal peristalsis	Occasional discomfort as food stays in esophagus longer
	Esophagus slightly dilated	
Decreased hydrochloric acid secretion	Reduction in amount of iron and vitamin B_{12} that can be absorbed	Possible delay in vitamin and drug absorption, *especially calcium* and *iron*
Decrease in gastric acid secretion		Altered drug effect Fewer cases of gastric ulcers
Decreased muscle tone	Altered motility	Prone to constipation, functional bowel syndrome, esophageal spasm, diverticular disease
	Decreased colonic peristalsis	
Atrophy of mucosal lining	Decreased hunger sensations and emptying time	
Decreased proportion of dietary calcium absorbed	Altered bone formation, muscle contractility, hormone activity, enzyme activation, clotting time, immune response	Symptoms more marked in women than in men
Decreased basal metabolic rate (rate at which fuel is converted into energy)		May need fewer calories
		Possible effect on life span
Genitourinary and Reproductive Systems		
Reduced renal mass	Decreased sodium-conserving ability	Administration and dosage of drugs may need to be modified
Loss of glomeruli	Decreased glomerular filtration rate Decreased creatinine clearance Increased blood urea nitrogen concentration	

Continued

Age-Related Change	Appearance or Functional Change	Implication
Histological changes in small vessel walls	Decreased renal blood flow	
Sclerosis of supportive circulatory system		
Decline in number of functioning nephrons	Decreased ability to dilute urine concentrate	Altered response to reduced fluid load or increased fluid volume
Reduced bladder muscular tone	Decreased bladder capacity or increased residual urine	Sensation of urge to urinate may not occur until bladder is full
Atrophy and fibrosis of cervical and uterine walls	Menopause; decline in fertility	Urination at night may increase
Reduced number and viability of oocytes in the aging ovary	Narrowing of cervical canal	
Decreased vaginal wall elasticity	Vaginal lining thin, pale, friable Narrowing of vaginal canal	Potential for discomfort in sexual intercourse
Decreased levels of circulating hormones	Reduced lubrication during arousal state	Increased frequency of sexual dysfunction
Degeneration of seminiferous tubules	Decreased seminal fluid volume Decreased force of ejaculation Reduced elevation of testes	
Proliferation of stromal and glandular tissue	Prostatic hypertrophy	Potentially compromised genitourinary function; *urinary frequency; increased risk of malignancy*
Involution of mammary gland tissue	Connective tissue replaced by adipose tissue	Easier to assess breast lesions
Neuromuscular System		
Decreased muscle mass	Decreased muscle strength Tendons shrink and sclerose	Decreased tendon jerks Increased muscle cramping
Decreased myosin adenosine triphosphatase activity	Prolonged contraction time, latency period, relaxation period	Decreased motor function and overall strength
Deterioration of joint cartilage	Bone makes contact with bone	Potential for pain, crepitation, and limitation of movement
Loss of water from the cartilage	Narrowing of joint spaces	Loss of height
Decreased bone mass	Decreased bone formation and increased bone resorption, leading to osteoporosis	More rapid and earlier changes in women
Decreased osteoblastic activity		Greater risk of fractures
Osteoclasts resorb bone	Hormonal changes	Gait and posture accommodate to changes
Increased proportion of body fat	Centripetal distribution of fat and invasion of fat in large muscle groups	Anthropometric measurements required
Regional changes in fat distribution		Increased relative adiposity

Age-Related Change	Appearance or Functional Change	Implication
Thickened leptomeninges in spinal cord	Loss of anterior horn cells in the lumbosacral area	Leg weakness may be correlated
Accumulation of lipofuscin	Altered RNA function and resultant cell death	
Loss of neurons and nerve fibers	Decreased processing speed and vibration sense	Increased time to perform and learn
	Altered pain response	Possible postural hypotension
	Decreased deep tendon, Achilles tendon	
		Safety hazard
Decreased conduction of nerve fibers	Decreased psychomotor performance	Alteration in pain response
Few neuritic plaques		Possible cognitive and memory changes
Neurofibrillary tangles in hippocampal neurons		Heavy tangle formation and neuritic plaques in cortex of patients with Alzheimer's disease
Neuromuscular System		
Changes in sleep–wake cycle	Decreased stage 4, stage 3, and rapid eye movement phases	Increased or decreased time spent sleeping
	Deterioration of circadian organization	Increased nighttime awakenings
		Changed hormonal activity
Slower stimulus identification and registration	Delayed reaction time	Prone to falls
Decreased brain weight and volume		May be present in absence of mental impairments
Sensory System		
Morphological changes in choroid, epithelium, retina	Decreased visual acuity	Corrective lenses required
	Visual field narrows	Increased possibility of disorientation and social isolation
Decreased rod and cone function		Slower light and dark adaptation
Pigment accumulation		
Decreased speed of eye movements	Difficulty in gazing upward and maintaining convergence	
Sclerosis of pupil sphincter	Difficulty in adapting to lighting changes	Glare may pose an environmental hazard
	Increased threshold for light perception	Dark rooms may be hazardous
Increased intraocular pressure	Increased incidence of glaucoma	
Distorted depth perception		Incorrect assessment of height of curbs and steps; potential for falls
Ciliary muscle atrophy	Altered refractive powers	Corrective lenses often required
Nuclear sclerosis *(lens)*	Presbyopia	Near work and reading may become difficult
Reduced accommodation	Hyperopia	
Increased lens size	Myopia	
Accumulation of lens fibers		

Continued

Age-Related Change	Appearance or Functional Change	Implication
Lens yellows	Color vision may be impaired	Less able to differentiate lower color tones: blues, greens, violets
Diminished tear secretion	Dullness and dryness of the eyes	Irritation and discomfort may result Intactness of corneal surface jeopardized
Loss of auditory neurons	Decreased tone discrimination and voice localization High-frequency sounds lost first	Suspiciousness may be increased because of paranoid dimensions secondary to hearing loss Social isolation
Angiosclerosis calcification of inner ear membrane	Progressive hearing loss, especially at high frequency Presbycusis	Difficulty hearing, particularly under certain conditions such as *background noise, rapid speech, poor acoustics*
Decreased number of olfactory nerve fibers	Decreased sensitivity to odors	May not detect harmful odors Potential safety hazard
Alteration in taste sensation		Possible changes in food preferences and eating patterns
Reduced tactile sensation	Decreased ability to sense pressure, pain, temperature	Misperceptions of environment and safety risk
Endocrine System		
Decline in secretion of testosterone, growth hormone, insulin, adrenal androgens, aldosterone, thyroid hormone	Decreased hormone clearance rates	Increased mortality associated with certain stresses (burns, surgery)
Defects in thermoregulation	Shivering less intense	Susceptibility to temperature extremes *(hypothermia/hyperthermia)*
Reduction of febrile responses	Poor perceptions of changes in ambient temperature Reduced sweating; increased threshold for the onset of sweating Fever not always present with infectious process	Unrecognized infectious process operative
Alteration in tissue sensitivity to hormones	Decreased insulin response, glucose tolerance, and sensitivity of renal tubules to antidiuretic hormone	
Enhanced sympathetic responsivity		
Increased nodularity and fibrosis of thyroid		Increased frequency of thyroid disease
Decreased basal metabolic rate	Alteration in carbohydrate tolerance	Increased incidence of obesity
Hematological System		
Decreased percentage of marrow space occupied by hematopoietic tissue	Ineffective erythropoiesis	Risky for patient who loses blood

Age-Related Change	Appearance or Functional Change	Implication
Immune System		
Thymic involution and decreased serum thymic hormone activity	Decreased number of T cells	Less vigorous and/or delayed hypersensitivity reactions
	Production of anti-self reactive T cells	
Decreased T-cell function	Impairment in cell-mediated immune responses	Increased risk of mortality
Appearance of autoantibodies	Decreased cyclic adenosine monophosphate and glucose monophosphate	Increased incidence of infection
		Reactivation of latent infectious diseases
	Decreased ability to reject foreign tissue	
		Increased prevalence of autoimmune disorders
	Increased laboratory autoimmune parameters	
Redistribution of lymphocytes	Impaired immune reactivity	
Changes in serum immunoglobulin	Increased immunoglobulin A levels Decreased immunoglobulin G levels	Increased prevalence of infection

appendix
B

Laboratory Values in the Older Adult

Laboratory Test	Normal Values	Changes With Age	Comments
Urinalysis			
Protein	0–5 mg/100 mL	Rises slightly	May be due to kidney changes with age, urinary tract infection, renal pathology
Glucose	0–15 mg/100 mL	Declines slightly	Glycosuria appears after high plasma level; unreliable
Specific gravity	1.005–1.020	Lower maximum in elderly 1.016–1.022	Decline in nephrons impairs ability to concentrate urine
Hematology			
Erythrocyte sedimentation rate	Men: 0–20 Women: 0–30	Significant increase	Neither sensitive nor specific in aged
Iron Iron binding	50–160 mcg/dL 230–410 mcg/dL	Slight decrease Decrease	
Hemoglobin	Men: 13–18 g/100 mL Women: 12–16 g/100 mL	Men: 10–17 g/mL Women: none noted	Anemia common in the elderly
Hematocrit	Men: 45%–52% Women: 37%–48%	Slight decrease speculated	Decline in hematopoiesis
Leukocytes	4,300–10,800/mm^3	Drop to 3,100–9,000/mm^3	Decrease may be due to drugs or sepsis and should not be attributed immediately to age
Lymphocytes	500–2,400 T cells/mm^3 50–200 B cells/mm^3	T-cell and B-cell levels fall	Infection risk higher; immunization encouraged
Platelets	150,000–350,000/mm^3	No change in number	
Blood Chemistry			
Albumin	3.5–5.0/100 mL	Decline	Related to decrease in liver size and enzymes; protein-energy malnutrition common
Globulin	2.3–3.5 g/100 mL	Slight increase	
Total serum protein	6.0–8.4 g/100 mL	No change	Decreases may indicate malnutrition, infection, liver disease
Blood urea nitrogen	Men: 10–25 mg/100 mL Women: 8–20 mg/100 mL	Increases significantly up to 69 mg/100 mL	Decline in glomerular filtration rate; decreased cardiac output
Creatinine	0.6–1.5 mg/100 mL	Increases to 1.9 mg/100 mL seen	Related to lean body mass decrease
Creatinine clearance	104–124 mL/min	Decreases 10%/decade after age 40 years	Used for prescribing medications for drugs excreted by kidney
Glucose tolerance	62–110 mg/dL after fasting; <120 mg/dL after 2 hours postprandial	Slight increase of 10 mg/dL/decade after 30 years of age	Diabetes increasingly prevalent; drugs may cause glucose intolerance

Laboratory Test	Normal Values	Changes With Age	Comments
Triglycerides	40–150 mg/100 mL	20–200 mg/100 mL	
Cholesterol	120–220 mg/100 mL	Men: increase to 50 mg/100 mL, then decrease Women: increase postmenopausally	Risk of cardiovascular disease
Thyroxine	4.5–13.5 mcg/100 mL	No change	Changes suggest thyroid disease; may be seen in euthyroid patients with acute or chronic illness or caloric deficiencies
Triiodothyronine	90–220 ng/100 mL	Decrease 25%	
Thyroid-stimulating hormone	0.5–5.0 mcg/mL	Slight increase	Sensitive indicator for diagnosing thyroid disease
Alkaline phosphatase	13–39 IU/L	Increase by 8–10 IU/L	Elevations >20% usually due to disease; elevations may be found with bone abnormalities, drugs (e.g., narcotics), and eating a fatty meal

Source: Kennedy-Malone, L, et al. *Advanced practice nursing in the care of older adults.* FA Davis, Philadelphia, 2014, pp 651–652.

appendix
C

Common Tests and Their Associations With Diseases and Conditions

Laboratory Test	Increase	Decrease
Acid phosphatase, prostatic	Prostate cancer, prostatic massage, benign prostatic hypertrophy, prostatitis, metastatic bone disease, liver disease, lysosomal storage diseases, sickle cell crisis, thrombocytosis	—
Alanine aminotransferase	Hepatitis, cirrhosis, fatty liver, liver metastases, biliary tract obstruction, infectious mononucleosis, hepatic congestion, pancreatitis, muscular dystrophy, myocardial infarction, renal disease, chronic alcohol abuse	Pyridoxine (vitamin B_6) deficiency
Albumin	Dehydration, diabetes insipidus	Overhydration, malnutrition, malabsorption, nephrosis, hepatic failure, burns, multiple myeloma, metastatic carcinomas, acute illness, rheumatic diseases, thyroid disease
Alkaline phosphatase	Bone growth, bone metastases, Paget's disease, osteomalacia, osteoporosis, hyperparathyroidism, hepatic disease, biliary obstruction; cancer of the liver, breast, colon, gallbladder, lung, or pancreas; pulmonary infarction, myocardial infarction, heart failure	Anemia, pernicious anemia, hypothyroidism, hypophosphatasia, hypervitaminosis D, zinc deficiency, magnesium deficiency
Alpha-fetoprotein (in nonpregnant women and men)	Cirrhosis, liver cancer, hepatitis	—
Amylase	Pancreatitis, gastrointestinal obstruction, mesenteric thrombosis and infarction, biliary obstruction, macroamylasemia, parotitis, renal disease, lung carcinoma, acute alcohol ingestion, after abdominal surgery	Severe liver disease, pancreatectomy, pancreatic insufficiency
Aspartate aminotransferase	Myocardial infarction, heart failure, myocarditis, pericarditis, myositis, trauma, hepatic disease, biliary tract obstruction, pancreatitis, infectious mononucleosis, renal infarction, neoplasia, cerebral damage, seizures, hemolysis, alcohol abuse, post–cardiac catheterization, angioplasty or surgery	Pyridoxine (vitamin B_6) deficiency, advanced stages of liver disease, uremia, hemodialysis

Laboratory Test	Increase	Decrease
Bilirubin	Hepatic disease, biliary obstruction, hemolytic anemia, pulmonary infarction, Gilbert's syndrome, Dubin-Johnson syndrome, hypothyroidism	—
Calcium	Hyperparathyroidism, acidosis, dehydration, bone cancer, lymphoma, myeloma, sarcoidosis, hyperthyroidism, hypervitaminosis D, milk-alkali syndrome, thyrotoxicosis	Hypoparathyroidism, renal failure, malabsorption, alkalosis, pancreatitis, cirrhosis, hypoalbuminemia, hyperphosphatemia, vitamin D deficiency, overhydration
Cholesterol	High-fat diet, alcoholism, hyperlipoproteinemia, hypothyroidism, biliary obstruction, nephrosis, poorly controlled diabetes mellitus, pancreatitis	Hyperthyroidism, infection, malnutrition, heart failure, malignancies, severe liver disease, chronic obstructive pulmonary disease
High-density lipoprotein cholesterol	Exercise, familial hyperlipoproteinemia, increased clearance of triglyceride, alcohol ingestion, exogenous intake of insulin or estrogens	Malnutrition, obesity, cigarette smoking, diabetes mellitus, hypothyroidism, hypertriglyceridemia, liver disease, renal failure, nephrosis, uremia
Creatine kinase	Myocardial infarction, muscle disease or injury, collagen-vascular disease, meningitis, brain infarction, hyperthermia, after surgery	Sedentary lifestyle
Creatinine	Renal disease, renal calculi, dehydration, muscle disease	Decreased muscle mass, hyperthyroidism, hypopituitarism, liver disease
Glucose	Diabetes mellitus, pheochromocytoma, hyperthyroidism, Cushing's syndrome, acromegaly, brain damage, hepatic disease, renal disease, hemochromatosis, stress (e.g., from emotion, burns, shock, anesthesia), acute or chronic pancreatitis, Wernicke's encephalopathy (vitamin B_1 deficiency), chronic hypervitaminosis A	Excess exogenous insulin, insulinoma, Addison's disease, myxedema, hepatic failure, malabsorption, pancreatitis, glucagon deficiency, extrapancreatic tumors, early diabetes mellitus, postgastrectomy, autonomic nervous system disorders, malnutrition, acute alcohol ingestion
Lactate dehydrogenase	Myocardial infarction, pulmonary infarction, hemolytic anemia, pernicious anemia, megaloblastic anemia, leukemia, lymphoma, hepatic and biliary disease, renal disease, musculoskeletal disease, pancreatitis	—
Lipase	Pancreatic and biliary disease	—
Magnesium	Addison's disease, adrenocortical insufficiency, massive hemolysis, antacid overuse, renal insufficiency	Severe loss of body fluids, malabsorption, renal disease, hyperaldosteronism, hyperparathyroidism, hypercalcemia, uncontrolled diabetes, dietary deficit, hemodialysis, inappropriate secretion of antidiuretic hormone
Phosphorus	Renal failure, hypoparathyroidism, diabetic ketoacidosis, lactic acidosis, respiratory acidosis, acromegaly, hypocalcemia, high phosphate intake (intravenous or oral), vitamin D intoxication, leukemia	Hyperparathyroidism, hypercalcemia, osteomalacia, hypokalemia, disorders that increase renal excretion or decrease renal absorption, vitamin D deficiency, salicylate poisoning, alkalosis, dietary deficit, ingestion of P-binding antacid, alcohol withdrawal, acute gout, hemodialysis

Continued

Laboratory Test	Increase	Decrease
Potassium	Acidosis, hypoadrenalism, hereditary hyperkalemia, hemolysis, acute renal failure, hemodialysis, hypoaldosteronism, thrombocytosis, dehydration, burns, intake of potassium-retaining diuretic, angiotensin-converting enzyme inhibitors, or excessive use of salt substitutes	Malnutrition, vomiting, metabolic alkalosis, diarrhea, nephrosis, hyperaldosteronism, hypomagnesemia, ectopic adrenocorticotropic hormone excess, beta-hydroxylase deficiency, thyrotoxicosis, administration of diuretics, excessive intake of licorice, laxative abuse, excessive sweating
Prostate-specific antigen	Prostate cancer, benign prostatic hyperplasia, prostatic massage, prostatic abscess, prostatitis, cystoscopy	Administration of finasteride
Sodium	Dehydration, vomiting, diabetes insipidus, excessive salt ingestion, diabetes mellitus with diuresis, diuretic phase of acute tubular necrosis, hypercalcemic nephropathy with diuresis, essential hypernatremia due to hypothalamic lesions, hyperaldosteronism, lactic acidosis	Excess exogenous antidiuretic hormone, nephrosis, hypoadrenalism, myxedema, heart failure, diarrhea, vomiting, diabetic acidosis, adrenocortical insufficiency, hyperlipidemia, hyperglycemia, hyperproteinemia
Total protein	Multiple myeloma, myxedema, lupus, sarcoidosis, diabetes insipidus, dehydration, collagen-vascular disease	Burns, cirrhosis, malnutrition, nephrosis, malabsorption, overhydration, gastrointestinal protein loss
Triglyceride	Nephrosis, cholestasis, pancreatitis, cirrhosis, diabetes mellitus, hepatitis, familial hyperlipoproteinemia, alcoholism, glycogen storage diseases, hypothyroidism, metabolic syndrome, nephrotic syndrome, pancreatitis	Malnutrition, hyperthyroidism, hypolipoproteinemia, a-beta lipoproteinemia
Troponin	Myocardial damage	
Urea nitrogen	Renal disease, dehydration, gastrointestinal bleeding, leukemia, heart failure, shock, postrenal azotemia, obstruction of urinary tract, acute myocardial infarction, muscle wasting	Hepatic failure, overhydration, acromegaly, dietary protein insufficiency, prolonged intravenous feedings
Uric acid	Gout, renal failure, diuretic therapy, leukemia, lymphoma, polycythemia, acidosis, psoriasis, hypothyroidism, multiple myeloma, pernicious anemia, tissue necrosis, inflammation, cancer chemotherapy, hemolytic anemia, high-protein weight-reduction diet, lead poisoning, polycystic kidneys, parathyroid hormone imbalance, sarcoidosis, type III hyperlipidemia	Administration of uricosuric drugs, allopurinol, or large doses of vitamin C; Wilson's disease, severe hepatic disease, low-purine diet
